Annual surface air temperature and precipitation have *very likely* increased and maximum snow depth has *likely* increased over most of North Asia since the mid-1970s. The highest warming has been found in spring in ESB and RFE, strengthening from south to north with linear trends of 0.8°C–1.2°C per decade over the 1976–2014 period (*high confidence*). A temperature decrease was identified just in winter in the southern part of WSB and ESB as a result of natural variability, but halved from –0.6°C per decade in 1976–2012 to –0.3°C per decade for the longer 1976–2018 period due to recent warmer winters (*high confidence*). Over North Asia annual precipitation increases with estimated trends of 5–15 mm per decade in the 1976–2014 period have been recorded with an exception over the Kamchatka and the Chukchi peninsulas, where decreases of up to –20 mm per decade in the same period have been found (*medium confidence*). Snow cover duration has *very likely* decreased over Siberia and increases in maximum snow depths of 1.8 cm, 1.1 cm and 4.6 cm per decade have been observed for WSB, ESB and RFE respectively from 1976 to 2016 (*limited evidence*).

Most of the CMIP5 and some CMIP6 GCMs overestimate the annual mean air temperature and precipitation over the North Asia region (*medium confidence*). GCMs generally represent the observed decadal temperature trend (*medium confidence*) and biases primarily come from the winter (DJF) season (*high confidence*). Results of a very limited number of RCMs applied over the whole region show that they have warmer biases for maximum and colder biases for minimum temperatures (*limited evidence, medium agreement*). Sparsity of observational data particularly in the northern part of ESB and the whole of the RFE results in *low confidence* in the assessments of model performance in North Asia.

Surface air temperature and precipitation in North Asia are projected to increase further (*high confidence*) with warming higher than the global average and around 6°C at the 4°C GWL. Temperature change in 2080–2099 relative to 1981–2000 is *likely* in the range of 3°C in summer to 4.9°C in winter under the RCP4.5 scenario, and 5.6°C in summer to 9.7°C in winter under the RCP8.5 scenario. Precipitation is projected to increase with ensemble-mean changes of 9% in summer under both RCP4.5 and RCP8.5, and of 22% and 56% in winter respectively.

Atlas.5.3 South Asia

Atlas.5.3.1 Key Features of the Regional Climate and Findings from IPCC Previous Assessments

Atlas.5.3.1.1 Key Features of the Regional Climate

The countries in this region are mostly semi-arid to arid and therefore depend heavily on the summer monsoon (June–September, JJAS) which is when most of the precipitation falls over the South Asia region (SAS; Figure Atlas.17). The topographic mechanical effect of the Tibetan Plateau (TIB) promotes moisture convergence downstream which triggers the early summer monsoon onset particularly over the Bay of Bengal and south China. In winter, westerly disturbances (WD) originating over the Atlantic Ocean bring moisture. The interaction between the WD and the Himalayas causes precipitation over northern and western parts of South Asia that is crucial to maintain the glacier mass balance. The observed teleconnection patterns over SAS for temperature show cooling effects during NAM and warming effects when in positive phase with ENSO, IOB, AMM and AMV (Annex IV). IOD also influences South Asian precipitation (Annex IV).

Atlas.5.3.1.2 Findings From Previous IPCC Assessments

Recent IPCC reports assessed that it is *very likely* that the mean annual temperature over South Asia has increased during the past century (Figure 2.21 in Hartmann et al., 2013, Figure 24-2 in Hijioka et al., 2014), and the frequency of cold (warm) days and nights have decreased (increased) across most of Asia since about 1950 (Figure 2.32 in Hartmann et al., 2013). The AR5 assessed that there is *high confidence* that the large-scale patterns of surface temperature are generally well simulated by the CMIP5 models though with problems in some regions, particularly at higher elevations over the Himalayas (Flato et al., 2013). CMIP5 models projected for the 21st century a significant increase in temperature over South Asia (*high confidence from robust evidence*) and in projections of increased summer monsoon precipitation (*medium confidence*) (Collins et al., 2013). The AR5 assessed there is *high confidence* that high-resolution regional downscaling, which generate results complementary to those from global climate models, adds value to the simulation of spatial variations in climate in regions with highly variable topography (e.g., distinct orography, coastlines), and for mesoscale phenomena and extremes (Flato et al., 2013).

Inconsistent evidence was found on the declining trends in mean precipitation and increasing droughts from 1950 onwards considering

1960–1990 as the baseline period. Similarly, SREX (Table 3-3 in Seneviratne et al., 2012) reported *low confidence* (due to lack of literature) in trends in climate indices related to extreme precipitation events. The Indian summer monsoon circulation was found to have weakened, but this was compensated by increased local atmospheric moisture content leading to more rainfall (*medium confidence*). It is *likely* that the occurrence of snowfall events is decreasing in South Asia along with other regions due to an increase in winter temperatures (Hock et al., 2019b). Based on satellite- and surface-based remote sensing it is *very likely* that aerosol optical depth has increased over southern Asia since 2000.

Atlas.5.3.2 Assessment and Synthesis of Observations, Trends and Attribution

Recent studies show that annual mean land temperatures over India warmed at a rate of around 0.6°C per century during 1901–2018, which was primarily contributed by a significant increase in annual maximum temperature of 1.0°C per century, while the annual minimum temperature showed a lesser increasing trend of 0.18°C per century during this period, with a significant rise only in the recent few decades (1981–2010) at a rate of 0.17°C per decade (Srivastava et al., 2017, 2019). The annual average of daily maximum and minimum temperatures has increased over almost all Pakistan with a faster increasing trend in the south (*high confidence*). Minimum temperatures have increased faster (0.17°C–0.37°C per decade) than maximum temperatures (0.17°C–0.29°C per decade) with the diurnal temperature range reduced (–0.15°C to –0.08°C per decade) in some regions (Khan et al., 2019).

There has been a noticeable declining trend in rainfall with monsoon deficits occurring with higher frequency in different regions in South Asia (see also Section 8.3.2.4 on the South Asian monsoon). Concurrently, the frequency of heavy precipitation events has increased over India, while the frequency of moderate rain events has decreased since 1950 (*high confidence*) (Goswami et al., 2006; Dash et al., 2009; Christensen et al., 2013; Krishnan et al., 2016; Kulkarni et al., 2017; Roxy et al., 2017). There is a considerable spread in the seasonal and annual mean precipitation climatology and interannual variability among the different observed precipitation datasets over India (Collins et al., 2013; Prakash et al., 2014; Kim et al., 2018; Ramarao et al., 2019). Yet, the regions of agreement among datasets lend *high confidence* that there has been a decrease in mean rainfall over most parts of the eastern and central north regions of India (Singh et al., 2014; Roxy et al., 2015; Juneng et al., 2016; Krishnan et al., 2016; Guhathakurta and Revadekar, 2017; Jin and Wang, 2017; Latif et al., 2017). A global modelling study with high resolution over South Asia (Sabin et al., 2013) indicated that a juxtaposition of regional land-use changes, anthropogenic-aerosol forcing and the rapid warming signal of the Equatorial Indian Ocean was crucial to simulate the observed Indian summer monsoon weakening in recent decades (*medium confidence*).

A dipole-like structure in summer monsoon rainfall trends is observed over the northern Indo-Pakistan area with significant increases over Pakistan and decreases over central north India resulting from strengthening (weakening) of vertically integrated

meridional moisture transport over the Arabian Sea (Bay of Bengal) (*low confidence*) (Latif et al., 2017). Positive annual precipitation trends are observed in global and regional datasets (Figure Atlas.11 and the Interactive Atlas) during 1961–2015 and over arid provinces of Pakistan (for rabi and kharif cropping seasons) during 1951–2015 of 2.8–34.8 mm per decade (Khan et al., 2020) imply *high confidence* for increased precipitation in Pakistan. Observations located in the monsoon-dominated strip in Pakistan indicate that the mean monsoon onset became earlier during 1971–2010 (Ali et al., 2020).

Snow and glaciers are major water resources of all countries in South Asia. Glacier melting is mainly controlled by natural phenomena but anthropogenic emissions of black carbon (BC) are now making a significant contributing to total glacial melting in the Hindu Kush Himalaya (HKH) region (Menon, 2002; Ramanathan et al., 2007; Ramanathan and Carmichael, 2008). BC concentration is seven to 10 times higher in mid-altitudes (1000–4000 metres above sea level) than at high altitudes (>4000 metres above sea level). The concentration of BC sampled from the surface of snow/ice samples as well as ice-core records shows decreasing ice albedo and an acceleration in glacier melting (Cross-Chapter Box 10.4; Wester et al., 2019). Karakoram and western HKH snow cover is increasing, a phenomena known as the ‘Karakoram anomaly’, and partially attributed to an increase in the strength of westerly disturbances (Wester et al., 2019).

Significant glacier retreat has been observed since 1960 in TIB with lower rates in the interior of the region (Yao et al., 2007). A large inter-decadal variation in snow cover is also observed from 1960 to 2010. Observations and model simulations showed that the increasing temperature of frozen grounds is leading to thawing and reduced depth of permafrost, with further significant reductions projected under future global warming scenarios (*medium confidence*) (Yang et al., 2019).

Atlas.5.3.3 Assessment of Model Performance

Whilst simulations of Indian summer monsoon rainfall (ISMR) have improved in CMIP5 compared to CMIP3 in terms of northward propagation, time for peak monsoon and withdrawal (Sperber et al., 2013), they fail to simulate the trends in monsoon rainfall and the post-1950 weakening of monsoon circulation (Saha et al., 2014). This is partially attributed to the failure of coarse-resolution CMIP5 models to simulate fine-resolution processes such as orographic effects or land surface feedback, and problems in cloud parametrization result in an overestimation of convective precipitation fraction (M.S. Singh et al., 2017). In CMIP6, a significant improvement is found in capturing the monsoon spatio-temporal patterns over India, particularly in the Western Ghats and north-eastern Himalayan foothills (Gusain et al., 2020). Over Pakistan the CMIP6 models simulate surface temperature better in JJA than DJF (Karim et al., 2020). The CMIP6 ensemble underestimates annual mean temperature over all of South Asian with mixed results for precipitation (Almazroui et al., 2020b). The CMIP6 GCMs have a large cold bias in both mean annual maximum and minimum temperatures in the complex Karakorum and Himalayan mountain ranges but exhibit warm biases in mean annual minimum temperature in most of the rest of South Asia.

Regional climate model (RCM) downscaling of CMIP5 models as part of CORDEX South Asia uses higher resolution (50 km) and improved surface fields such as topography and coastlines to resolve better the complexities of the monsoon and other hydrological processes (Giorgi et al., 2009). The added value of their simulations, relative to the driving GCMs, presents a complex picture. CORDEX RCMs better represent spatial patterns of temperature (Sanjay et al., 2017), the spatial features of precipitation distribution associated with the Indian summer monsoon (Choudhary and Dimri, 2018), and the simulation of monsoon active- and break-phase composite precipitation (Karmacharya et al., 2017b). The RCMs follow the driving GCMs in underestimating seasonal mean surface air temperature and overestimating spatial variability in precipitation. They amplify CMIP5 cold biases over almost the entire region, including over the HKH region, Afghanistan and south-west Pakistan during winter (Iqbal et al., 2017), and substantial cold biases of 6°C–10°C are found over the Himalayan watersheds of the Indus basin (Nengker et al., 2018; Hasson et al., 2019). Neither RCMs nor their driving CMIP5 GCMs reproduce well the region's precipitation climatology (Mishra, 2015). In addition, important characteristics of ISMR such as northward and eastward propagation, onset, seasonal rainfall patterns, intra-seasonal oscillations and patterns of extremes did not show consistent improvement (S. Singh et al., 2017). Also, these RCM simulations have not demonstrated added value in capturing the observed changes in ISMR characteristics over recent decades, though RegCM4 simulations at 25 km showed high accuracy in capturing monsoon precipitation characteristics and atmospheric dynamics in historical simulations (Ashfaq et al., 2021).

Evaluation of four global reanalysis products (ERA5 and ERA-Interim, JRA-55 and MERRA-2; Atlas.1.4.2) for snow depth and snow cover over TIB was performed against 33 in situ station observations, Interactive Multisensor Snow and Ice Mapping System (IMS) snow cover and a satellite microwave snow-depth dataset (Orsolini et al., 2019). Most of the reanalyses showed a systematic overestimation. Only ERA-Interim assimilated IMS snow cover at high altitudes, whereas ERA5 did not and the excessive snowfall, snow depth and snow cover in ERA5 was attributed to this difference. The analysis of annual maximum consecutive snow-covered days for the period 1980–2018 over TIB using JRA-55 and passive microwave satellite observations showed a decreasing trend in all time periods and in recent snow seasons for MERRA-2 (Bian et al., 2020). The uncertainty assessment of model physics in snow modelling over TIB using ground-based observations and high-resolution snow cover satellite products from the Moderate Resolution Imaging Spectroradiometer (MODIS) and FengYun-3B suggests that errors can be overcome by optimizing parametrizations of the snow cover fraction rather than optimizing physics-scheme options (Y. Jiang et al., 2020).

Atlas.5.3.4 Assessment and Synthesis of Projections

CMIP5 and CMIP6 surface temperature projections for South Asia are consistent across the range of GWLs with increases greater than the global average, more so over TIB (Figure Atlas.17). CMIP6 models show higher sensitivity to greenhouse gas emissions, projecting higher warming for a given emissions scenario. The north-western parts of South Asia, mainly covering the Karakorum and Himalayan mountain

ranges, are projected to warm more (over 6°C under SSP5-8.5, with higher warming in winters than in summer; Interactive Atlas) and this will accelerate glacier melting in the region. The warming pattern of maximum and minimum temperatures are projected to intensify in higher latitudes compared with mid-latitudes of South Asia in CMIP5 simulations for all RCP scenarios (Ullah et al., 2020).

Seasonal precipitation projections show increased winter precipitation over the western Himalayas and decreased precipitation over the eastern Himalayas. On the other hand, summer precipitation projections show a robust increase over most of South Asia, with the largest over the arid region of southern Pakistan and in adjacent areas of India, under SSP5-8.5 (Almazroui et al., 2020b). Daily bias-adjusted projections from 13 CMIP6 GCMs using all emissions scenarios project a warmer (3°C–5°C) and wetter (13–30%) climate in South Asia in the 21st century (Mishra et al., 2020).

With continued global warming and anticipated reductions in anthropogenic aerosol emissions in the future, CMIP5 models project an increase in the mean and variability of summer monsoon precipitation over India by the end of the 21st century, together with substantial increases in daily precipitation extremes (*medium confidence*) (Krishnan et al., 2020), see also Section 8.4.2.4 on changes in the South Asian monsoon. The CMIP5 GCMs consistently project an increase in moisture transport over the Arabian Sea and Bay of Bengal towards the end of the 21st century, an increase in moisture convergence and consequent increases in monsoon rainfall over the Indo-Pakistan region which are higher under RCP8.5 than RCP4.5 (Srivastava and Delsole, 2014; Mei et al., 2015; Latif et al., 2018). Out of 20 CMIP5 GCMs, four showed an increase in magnitude and lengthening of the summer monsoon across India under RCP8.5. The intensity of both strong and weak monsoons is projected to increase during the period 2051–2099 (Srivastava and Delsole, 2014).

Summer precipitation changes in South Asia are consistent between CMIP3 and CMIP5 projections, but the model spread is large for winter precipitation changes. Changes in summer monsoon rainfall will dominate annual changes over South Asia (Woo et al., 2019). CMIP3 GCMs project a gradual increase in annual precipitation over monsoon-dominated areas of Pakistan throughout the 21st Century and increases in humid and semi-arid climate areas (Saeed and Athar, 2018).

Warming of 2.5°C–5°C is projected over northern Pakistan and India (Syed et al., 2014). CORDEX-South Asia projections over north-east India under RCP4.5 for the period 2011–2060, show increasing trends for both seasonal maximum and minimum temperature over north-east India (Interactive Atlas). The future projections of South Asian monsoon from the CORDEX-CORE exhibit a spatially robust delay in the monsoon onset, an increase in seasonality, and a reduction in the rainy season length over parts of South Asia at higher levels of radiative forcing (Ashfaq et al., 2021).

With TIB continuing to warm, snow cover and snow water equivalent are projected to decrease but with regional differences due to synoptic influences (Cross-Chapter Box 10.4; Wester et al., 2019). There is *limited evidence* on whether the 'Karakoram Anomaly' will persist in coming decades, but its long-term persistence is *unlikely* with

continued projected warming (*high confidence*) (Section 9.5.1.1). It is projected that peak river flow at higher altitudes will commence earlier, due to warming influences on snow cover area and snow/glacier melt rates and with more precipitation falling as rain rather than snow, and the magnitude and seasonality of flow will change over South Asia (Charles et al., 2016).

Atlas.5.3.5 Summary

Mean, minimum and maximum daily temperatures in South Asia are increasing and winters are getting warmer faster than summers (*high confidence*). The South Asian monsoon has shown contrasting behaviour over India and Pakistan. There is *high confidence* that there has been a decrease in mean rainfall over most parts of the eastern and central north regions of India and an increase in precipitation in Pakistan.

Global model performance over the region has improved from CMIP3 to CMIP5 to CMIP6 in the multi-model ensemble-mean simulation of the amplitude and phase of the seasonal cycles of temperature and precipitation. However, there was no appreciable improvement in regions with steep orography, and there has remained substantial inter-model spread in seasonal and annual mean temperatures over South Asia with generally cold biases which are largest in the complex Karakorum and Himalayan mountain ranges. CMIP6 GCMs also show a dry bias (15–20%) in mean annual precipitation in the majority of the South Asia region with a wet bias in Nepal, Pakistan and northern India.

It is *likely* that surface temperatures over South Asia will increase more than the global average and more so over TIB, with projected increases of 4.6°C (3.4°C–6.0°C) during 2081–2100 compared with 1995–2014 under SSP5-8.5 and 1.3°C (0.7°C–2.0°C) under SSP1-2.6 (Interactive Atlas). Summer monsoon precipitation in South Asia is *likely* to increase by the end of the 21st century while winter monsoons are projected to be drier. Over the same time periods CMIP6 models project an increase in annual precipitation in the range 14–36% under SSP5-8.5 and 0.4–16% under SSP1-2.6 (*medium confidence*).

With continued warming, TIB snow cover and snow water equivalent are *likely* to decrease and with more precipitation falling as rain rather than snow in SAS. It is projected that the peak river flow at higher altitudes will commence earlier due to the effect of warming on snow cover and snow/glacier melt rates, causing changes in magnitude and seasonality of flow.

Atlas.5.4 South East Asia

Atlas.5.4.1 Key Features of the Regional Climate and Findings from Previous IPCC Assessments

Atlas.5.4.1.1 Key Features of the Regional Climate

The South East Asia region is composed of countries that are part of Indochina (or mainland South East Asia) and countries that are very archipelagic in nature and have strong land-ocean-atmosphere

interactions, including those that are part of the Maritime Continent and the Philippines. Its climate is mainly tropical (i.e., hot and humid with abundant rainfall). Rainfall seasonal variability in the region is mainly affected by the synoptic-scale monsoon systems, the north–south migration of the Inter-tropical Convergence Zone (ITCZ) and tropical cyclones (mainly for the Philippines and Indochina), while intra-seasonal variability can be influenced by the MJO (Annex IV). Temperature and especially rainfall are also interannually affected by ENSO and Indian Ocean basin and Dipole (IOB/IOD) modes (Annex IV and Table Atlas.1).

Atlas.5.4.1.2 Findings From Previous IPCC Assessments

The AR5 WGI showed that the mean annual temperature of South East Asia has been increasing at a rate of 0.14°C–0.20°C per decade since the 1960s, along with an increasing number of warm days and nights, and a decreasing number of cold days and nights (Christensen et al., 2013). The AR5 also reported the lack of sufficient observational records to allow for a full understanding of past precipitation trends in most of the Asian region, including South East Asia, and that precipitation trends that were available differed considerably across the region and between seasons (Christensen et al., 2013).

On projected changes, findings from AR5 showed that warming is *very likely* to continue with substantial sub-regional variations over South East Asia (Christensen et al., 2013). The median increase in temperature over land projected by the CMIP5 ensemble mean ranges from 0.8°C in RCP2.6 to 3.2°C in RCP8.5 by the end of the 21st century. Moderate future increases in precipitation are *very likely*, with projected ensemble mean increases of 1% in RCP2.6 to 8% in RCP8.5 by 2100. In SR1.5, there is a projected increase in flooding and runoff over South East Asia for a 1.5°C to 2°C global warming, and these will increase even more for a greater than 2°C level of warming (Hoegh-Guldberg et al., 2018).

Atlas.5.4.2 Assessment and Synthesis of Observations, Trends and Attribution

Within the last decade, there has been an increasing number of studies on climatic trends over South East Asia, carried out on a regional basis (Thirumalai et al., 2017; Cheong et al., 2018) or focused on specific countries (Cinco et al., 2014; Villafuerte et al., 2014; Mayowa et al., 2015; Villafuerte and Matsumoto, 2015; Guo et al., 2017a; Supari et al., 2017; Sa'adi et al., 2019; Tan et al., 2021). They document *virtually certain* significant increases in mean as well as extreme temperature. The minimum temperature extremes *very likely* warmed faster compared to the maximum temperature. Temperatures, including extremes, are strongly influenced by ENSO in the region (Cinco et al., 2014; Thirumalai et al., 2017; Cheong et al., 2018). Over much of the region, extreme high temperatures occurred mostly in April and almost all April extreme temperatures occur in El Niño years (Thirumalai et al., 2017). In most of South East Asia (except for the north-eastern areas), there was *likely* an increase in the number of warm nights with El Niño episodes within the period 1972–2010 (Cheong et al., 2018).

Changes in mean precipitation are less spatially coherent over South East Asia. Over Thailand, the average number of rain days has

decreased by 1.3 to 5.9 days per decade while average daily rainfall intensity has increased by 0.24–0.73 mm day⁻¹ per decade (Limsakul and Singhruck, 2016). Precipitation is also affected by ENSO events (Tangang et al., 2017; Supari et al., 2018). Over South East Asia, there has been a significant increase in the amount of precipitation and its extremes with La Niña episodes in the past decades, especially during the winter monsoon period (*high confidence*) (Villafuerte and Matsumoto, 2015; Limsakul and Singhruck, 2016; Cheong et al., 2018).

Figure Atlas.11 shows trends in mean temperature and precipitation during 1961–2015 for two global datasets, indicating a significant overall warming over South East Asia (*high confidence*), with higher rates of warming in Malaysia, Indonesia, and the southern areas of mainland South East Asia (*low confidence*). Annual mean precipitation trends (Atlas.1.4.1 and the Interactive Atlas, which includes the regional dataset Aphrodite) over the region are mostly not significant except for increases over parts of Malaysia, Vietnam and the southern Philippines (*medium confidence*).

It is important to note that the availability, quality, and temporal and spatial density of observation data may lead to uncertainties and varying results in South East Asia (Juneng et al., 2016). Some efforts have been made to produce better observationally-based gridded datasets for the region (e.g., Nguyen-Xuan et al., 2016; van den Besselaar et al., 2017; Yatagai et al., 2020).

Atlas.5.4.3 Assessment of Model Performance

Performance in simulating rainfall over South East Asia varies among CMIP5 GCMs (*high confidence*). Only some are capable of reasonably simulating the rainfall seasonal cycle and spatial pattern (Siew et al., 2013; Raghavan et al., 2018). Over mainland South East Asia, the performance of CMIP5 GCMs in simulating rainfall during the wet season was superior to that for annual and dry-season precipitation (J. Li et al., 2019).

RCMs have been intensively used over the region in recent years in a series of single or multi-model experiments and there is *medium confidence* that they reproduce reasonably well seasonal climate patterns of temperature, precipitation and large-scale circulation over the different sub-regions of South East Asia with added values compared to their host GCMs (Kwan et al., 2014; Ngo-Duc et al., 2014, 2017; Van Khiem et al., 2014; Juneng et al., 2016; Katzfey et al., 2016; Loh et al., 2016; Raghavan et al., 2016; Cruz et al., 2017; Ratna et al., 2017; Trinh-Tuan et al., 2018; Nguyen-Thuy et al., 2021). RCM ensemble means tend to outperform the individual models in representing the climatological mean state (Ngo-Duc et al., 2014; Trinh-Tuan et al., 2018; Nguyen-Thi et al., 2021). There is relatively high consistency among the simulations of historical climate over mainland South East Asia compared to those over the Maritime Continent for both seasonal and interannual variability (Ngo-Duc et al., 2017). The consistency in rainfall simulations was lower than for temperature simulations.

Some RCMs showed a systematic cold bias (Manomaiphiboon et al., 2013; Kwan et al., 2014; Ngo-Duc et al., 2014; Loh et al., 2016; Cruz and Sasaki, 2017; Cruz et al., 2017) that was mainly due to model

physics (Manomaiphiboon et al., 2013; Kwan et al., 2014) and/or the biases in the SST forcing (Ngo-Duc et al., 2014). A few simulations revealed a warm bias over some areas such as in the Maritime Continent (Cruz et al., 2017) or Vietnam (Van Khiem et al., 2014). The biases for rainfall in GCMs and RCMs over South East Asia were found to be less systematic with wet or dry biases depending on the sub-regions (Manomaiphiboon et al., 2013; Kwan et al., 2014; Van Khiem et al., 2014; Juneng et al., 2016; Supari et al., 2020; Tangang et al., 2020; Nguyen-Thi et al., 2021), although wet biases were more pronounced in RCMs (Kwan et al., 2014; Van Khiem et al., 2014; Kirono et al., 2015; Juneng et al., 2016; Supari et al., 2020; Tangang et al., 2020). Some RCMs overestimated rainfall interannual variability (Juneng et al., 2016) while some others underestimated it (Kirono et al., 2015). Simulated rainfall amount is sensitive to the choice of convective scheme (Juneng et al., 2016; Ngo-Duc et al., 2017) and the choice of land surface scheme (Chung et al., 2018). Rainfall biases in current climate simulations can be greatly reduced if a bias adjustment method such as quantile mapping is applied (Trinh-Tuan et al., 2018). The pattern of tropical cyclone numbers in the region were reasonable represented by RCM outputs (Van Khiem et al., 2014; Kieu-Thi et al., 2016; Herrmann et al., 2020).

Atlas.5.4.4 Assessment and Synthesis of Projections

Mean temperature in South East Asia is projected to continue to rise through the 21st century (*virtually certain, very high confidence*). Projections by multi-model regional climate simulations of CORDEX-SEA showed a temperature increment over land under RCP8.5 to range from 3°C–5°C by the end of the 21st century relative to the pre-1986–2005 period (Tangang et al., 2018). For the same periods, the average mean temperature increase over land projected by CMIP5 (CMIP6) varies, with 10th–90th percentile ranges, from 0.7°C to 1.3°C (0.7°C to 1.8°C) under RCP2.6 (SSP1-2.6) to 2.8°C to 4.4°C (2.6°C to 4.8°C) under RCP8.5 (SSP5-8.5) (Interactive Atlas). For all GWLs the land region is projected to warm by a slightly smaller amount than the global average, with 10th–90th percentile ranges for CMIP5 (CMIP6) of 1.2°C–1.6°C (1.2°C–1.5°C) for the 1.5°C GWL and of 3.3°C–4.0°C (3.3°C–3.9°C) for the 4°C GWL relative to the 1850–1900 baseline (calculated from RCP8.5 (SSP5-8.5) projections). Changes for other warming levels, periods and emissions pathways are shown in Figure Atlas.17 and can be explored in the Interactive Atlas.

Projections of future rainfall changes are highly variable among sub-regions of South East Asia and among the models (*high confidence*). The CMIP5 and CMIP6 ensembles showed an increase in annual mean precipitation over most land areas by the mid- and late 21st century, although only with a strong model agreement for higher warming levels (Figure Atlas.17 and the Interactive Atlas), while CORDEX produces a general decrease in projected precipitation (Figure Atlas.17). Based on CORDEX South East Asia multi-model simulations, significant and robust increases of mean rainfall over Indochina and the Philippines were projected while there is a drying tendency over the Maritime Continent during DJF for the early, mid and end of the 21st century periods under both RCP4.5 and RCP8.5 (Figure Atlas.19; Tangang et al., 2020). At the end of the 21st century during DJF and under RCP8.5, an increase of 20% in mean rainfall is projected over Myanmar, northern central Thailand and northern

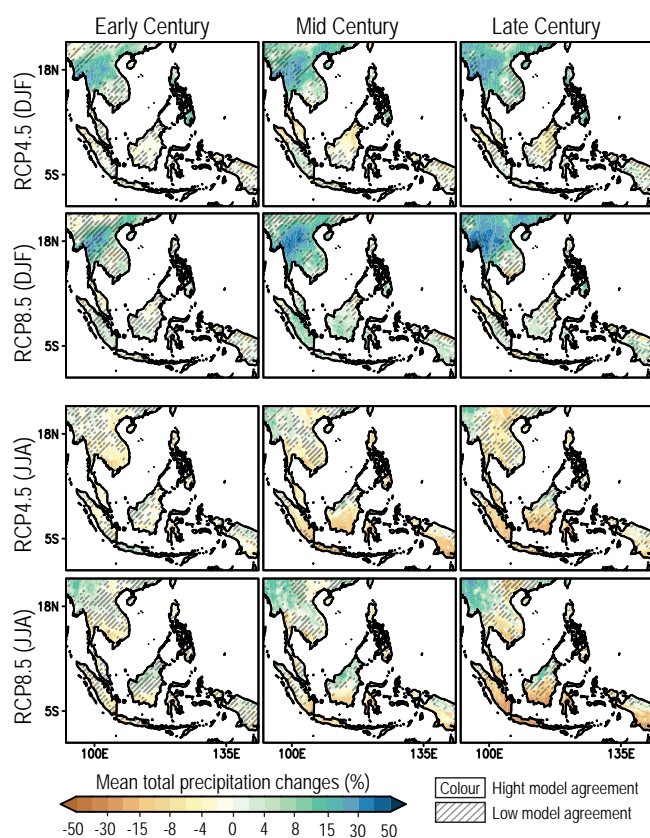

Figure Atlas.19 | The RCM-projected changes in mean precipitation between the early (2011–2040), mid- (2041–2070) and late (2071–2099) 21st century and the historical period 1976–2005. Data are obtained from the CORDEX-SEA downscaling simulations. Diagonal lines indicate areas with low model agreement (less than 80%). Figure adapted from Tangang et al. (2020).

Laos, and of 5–10% over the eastern Philippines and northern Vietnam. During JJA, significantly drier conditions are projected over almost the entire South East Asia region except over Myanmar and northern Borneo. Over the Indonesian region, especially Java, Sumatra and Kalimantan, as much as a 20–30% decrease in mean rainfall is projected during JJA by the end of the 21st century. The projected drier condition over Indonesia from CORDEX is consistent with that of Kusunoki (2017), Giorgi et al. (2019), Kang et al. (2019) and Supari et al. (2020) and is associated with enhanced subsidence over the region (Kang et al., 2019; Tangang et al., 2020).

Atlas.5.4.5 Summary

It is *virtually certain* that annual mean temperature has been increasing in South East Asia in the past decades while changes in annual mean precipitation are less spatially coherent though with some increasing trends over parts of Malaysia, Vietnam and the southern Philippines (*medium confidence*).

Although various biases still exist, there is *high confidence* that the models can reproduce seasonal climate patterns well over the different sub-regions of South East Asia. There is *medium confidence* that the RCMs show added value compared to their host GCMs over the region.

Projections show continued warming over South East Asia, but *likely* by a slightly smaller amount than the global average. Projected changes in rainfall over South East Asia vary, depending on model, sub-region and season (*high confidence*), with consistent projections of increases in annual mean rainfall from CMIP5 and CMIP6 over most land areas (*medium confidence*) and decreases in summer rainfall from CORDEX projections over much of Indonesia (*medium confidence*).

Atlas.5.5 South West Asia

Atlas.5.5.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.5.5.1.1 Key Features of the Regional Climate

South West Asia includes the Arabian Peninsula (ARP) and West Central Asia (WCA) reference regions (Figure Atlas.17). ARP has a semi-arid or arid desert climate with very low annual mean precipitation and very high temperature. Its temperature is influenced by SST variations over the tropical ocean (e.g., ENSO) and the NAO and AO (see Annex IV for these and subsequent modes of variability; Attada et al., 2019). Rainfall is influenced by the IOD and ENSO, with more rainfall during El Niño (Kang et al., 2015; Kumar et al., 2015; Abid et al., 2018; Kamil et al., 2019) and less during La Niña (Atif et al., 2020). The wet season in ARP is mainly from November to April and the dry season is from June to August. Rainfall is confined mostly to the south-western part of the peninsula and contribution of extreme events to the total rainfall varies within 20–70% from region to region and season to season (Almazroui, 2020b; Almazroui and Saeed, 2020). WCA is separated from Eastern Europe by the Caucasus Mountains, is adjacent to ARP, with South Asia (SAS) to the south and West Siberia (WSB) to the north, and lies between the Mediterranean (MED), Tibetan Plateau (TIB) and East Central Asia (ECA) regions. WCA is heterogeneous in terrain with the Zagros Mountains and Iranian Plateau in the west and south-west, the Caspian Sea and lowland with deserts in the north and north-east. The regional climate of WCA is influenced by the NAO and ENSO and it is typically semi-arid or arid with a strong gradient in both precipitation and temperature from the mountains to the plains and from north to south.

Atlas.5.5.1.2 Findings From Previous IPCC Assessments

The IPCC AR5 established it is *very likely* that temperatures will continue to increase over WCA in all seasons whilst projections of decreased annual mean precipitation had *medium confidence* due to *medium agreement* resulting from model-dependent sub-regional and seasonal changes (Christensen et al., 2013). The AR5 also concluded that for a better understanding of the climate of the region, results of high-resolution regional climate models also need to be assessed and CMIP5 models generally had difficulties simulating the mean temperature and precipitation climatology for South West Asia. This is partly related to the poor spatial resolution of the models not resolving the complex mountainous terrain and the influence of different drivers of the European, Asian and African

climates. However, observational data scarcity and issues related to the comparison of observations with coarse-resolution models added to the uncertainty and remained poorly analysed in peer-reviewed literature on climate model performance (Christensen et al., 2013).

The SR1.5 stated that even for 1.5°C and 2°C of global warming, South West Asia is among the regions with the strongest projected increase in hot extremes with more urban populations exposed to severe droughts in West Asia, while an increase of heavy precipitation events is projected in mountainous regions of Central Asia (Hoegh-Guldberg et al., 2018; IPCC, 2018c). Higher temperatures with less precipitation will *likely* result in higher risks of desertification, wildfires and dust storms exacerbated by land-use and land-cover changes in the region with consequent effects on human health. Further drying of the Aral Sea in Central Asia will *likely* have negative effects on the regional microclimate, adding to the growing wind erosion in adjacent deltaic areas and deserts that is already resulting in a reduction of the vegetation productivity including croplands. There is also a projected increase of precipitation intensity in the Arabian Peninsula which is *likely* to lead to higher soil erosion particularly in winter and spring due to floods (Mirzabaev et al., 2019). WCA includes high mountains with enhanced warming above 500 m where, regardless of the emissions scenario, decreases in snow cover are projected due to increased winter snowmelt and more precipitation falling as rain (*high confidence*). A very strong interannual and decadal variability, as well as scarce in situ records for mountain snow cover, have prevented a quantification of recent trends in High Mountain Asia (Hock et al., 2019b).

Atlas.5.5.2 Assessment and Synthesis of Observations, Trends and Attribution

Since AR5, there has been an increasing number of studies on past climate change in South West Asia though meteorological stations are sparsely scattered in the region. They are mainly located in the plains below 2 km of altitude, very scarce in mountainous areas and have declined in number in WCA since the end of the Soviet Union in 1991. This increases the uncertainty in both temperature and precipitation trends, particularly for elevated areas (*high confidence*) (Christensen et al., 2013; Huang et al., 2014). So researchers use other sources of climate data in the region, particularly freely available gridded data (Annex I).

Globally, drylands showed an enhanced warming over the past century of 1.2°C–1.3°C, significantly higher than the warming over humid lands (0.8°C–1.0°C) (J. Huang et al., 2017). A strong increase in annual surface air temperature of 0.27°C–0.47°C per decade has been found over WCA between 1960 and 2013 (*very high confidence*) (Han and Yang, 2013; Li et al., 2013; Hu et al., 2014, 2017; Huang et al., 2014; Deng and Chen, 2017; Zhang et al., 2017, 2019a; H. Guo et al., 2018; Haag et al., 2019; Yu et al., 2019). Warming is most prominent in the spring based on the CRU dataset with rates *likely* ranging from 0.64°C–0.82°C per decade (Hu et al., 2014). Analysis of seasonal temperature trends based on high-resolution 1 km × 1 km downscaled dataset CHELSA and 20 stations in Uzbekistan has confirmed the maximum significant trend in temperature from 0.6°C up to 1°C per decade in spring from 1979 to 2013 and no significant

trend in winter (Khaydarov and Gerlitz, 2019). There is *very high confidence (robust evidence, high agreement)* that the shrinking of the Aral Sea has induced an increase in surface air temperature around the Aral Sea region in the range of 2°C–6°C (Baidya Roy et al., 2014; McDermid and Winter, 2017; Sharma et al., 2018). The plateau of Iran has experienced significant increases in the average monthly values of daily maximum and minimum temperatures with spatially varying rates of 0.1°C–0.3°C up to 0.3°C–0.4°C per decade and greater spatial variation in minimum temperatures (*high confidence*) (Mahmoudi et al., 2019; Fathian et al., 2020; Sharafi and Mir Karim, 2020).

Observed warming over northern ARP is higher than over the south, where minimum temperatures are increasing faster than maximum temperatures (Almazroui, 2020a). The rate of mean temperature increase is estimated at 0.10°C per decade over 1901–2010 (Attada et al., 2019), while it has reached 0.63°C (*likely* in the range of 0.24°C–0.81°C) per decade for the more recent period of 1978–2019 (Almazroui, 2020a).

An overall increasing trend of annual precipitation (0.66 mm per decade) was found over Central Asia based on GPCC v7 data for the period 1901–2013 (Hu et al., 2017), but annual trends were found not significant over the shorter period 1960–2013 (Figure Atlas.11 and Interactive Atlas). Winter precipitation saw a significant increase of 1.1 mm per decade (Song and Bai, 2016). These estimates have *low to medium confidence* since the satellite precipitation products have large systematic and random errors in mountainous regions. Moreover CMORPH and TRMM products fail to capture the precipitation events in the ice/snow covered regions in winter and show a substantial false-alarm percentage in summer, but the gauge-corrected GSMAP performs better than other products (Song and Bai, 2016; Guo et al., 2017b; Hu et al., 2017; S. Chen et al., 2019). Over the elevated part of eastern WCA precipitation increases in the range of 1.3–4.8 mm per decade during 1960–2013 were observed (*very high confidence*) (Han and Yang, 2013; Li et al., 2013; Hu et al., 2014, 2017; Huang et al., 2014; Deng and Chen, 2017; Zhang et al., 2017, 2019a; H. Guo et al., 2018; Haag et al., 2019; Yu et al., 2019). Reductions in spring precipitation and increases in winter have been reported for Uzbekistan over the period 1979–2013 based on station data but these are not significant (Khaydarov and Gerlitz, 2019). There is *very low confidence* of the impact of the Aral Sea shrinking on precipitation (Chen et al., 2011; Jin et al., 2017).

A decreasing trend of precipitation is reported for ARP with the mean value of –6.3 mm per decade (range of –30 mm–16 mm) for the period 1978–2019 (*low confidence*) with large interannual variability over Saudi Arabia, which covers 80% of the region (AlSarmi and Washington, 2011; Almazroui et al., 2012; Donat et al., 2014). The same decreasing trend in precipitation totals and an increasing trend in the number of consecutive dry days are found for most of the Iranian Plateau (*medium confidence*) (Rahimi and Fatemi, 2019; Fathian et al., 2020; Sharafi and Mir Karim, 2020). January-to-March mean snow cover and depth over mountainous areas decreased between 2000 and 2019 (*low to medium confidence* due to *limited evidence*) (Safarianzengir et al., 2020).

Atlas.5.5.3 Assessment of Model Performance

There is *limited evidence* about the performance of GCMs and RCMs in representing the current climate of South West Asia due to very few studies evaluating models over this region, but literature is now emerging particularly on CMIP5/CMIP6 and CORDEX simulations.

Over ARP, surface temperature biases for 18 of 30 CMIP5 models are within one standard deviation of the observed variability (Almazroui et al., 2017). A warm bias in summer and a cold bias for other months along with an underestimation of wet-season precipitation and an overestimation in the dry season have been reported in 26 CMIP5 models (Lelieveld et al., 2016). Thirty CMIP6 GCMs have limited skill in simulating annual precipitation patterns, annual cycle statistics and long-term precipitation trends over Central Asia partially due to considerable wet biases of up to 100% in the southern Xinjiang and Hexi Corridor regions (Guo et al., 2021). Also, CMIP6 models display a wide range of performance in reproducing ENSO teleconnections that influence the region (Barlow et al., 2021).

RCM simulations using the CORDEX-MENA domain reproduce the main features of the mean surface climatology over ARP with moderate biases (*high confidence*). RegCM4 driven by five GCMs (HadGEM2, GFDL, CNRM, CanESM2 and ECHAM6) showed an ensemble-mean cold bias of about -0.7°C and a dry bias of -13% over ARP (Almazroui, 2016) with a cold (warm) bias over western (south-eastern) areas (Syed et al., 2019). Temperature biases in 30-year historical simulations with WRF using three different radiation parametrizations were within $\pm 2^{\circ}\text{C}$ and mostly caused by surface long-wave radiation errors which affected nighttime minimum temperatures over 70% of the domain (Zittis and Hadjinicolaou, 2017). Mean absolute errors in COSMO-CLM driven by ERA-Interim were about 1.2°C for temperature, 15 mm per month for precipitation and 9% for total cloud cover, and with new parametrizations of albedo and aerosols optimized for the region the RCM simulated the main climate features of this very complex area (Bucchignani et al., 2016). RegCM4.4 also simulated the main features of the observed climatology (especially for dry regions) with temperature biases within $\pm 3.0^{\circ}\text{C}$. Annual precipitation was overestimated with winter and spring underestimated (Ozturk et al., 2018).

Four RCMs (REMO, RegCM4.3.5, ALARO-0, and COSMO-CLM5.0) driven by ERA-Interim, NCEP2 reanalyses and two different GCMs reproduced reasonably well the spatio-temporal patterns for temperature and precipitation though underestimated diurnal temperature range and had cold biases over mountainous and high plateau regions in all seasons. There is *low confidence* in this result because of low station density and a lack of high-elevation stations, and with biases dependent on the choice of the observational dataset. However, the performance of both GCMs and RCMs is better than reanalyses when compared to available observations (Mannig et al., 2013; Ozturk et al., 2017; Russo et al., 2019; Top et al., 2021).

Atlas.5.5.4 Assessment and Synthesis of Projections

Temperature and precipitation projections from CMIP5/CMIP6 and CORDEX for different GWLs, SSP and RCP scenarios, time periods

and baselines are shown in Figure Atlas.17 and further details can be explored in the Interactive Atlas.

In WCA, projections for different GWLs are consistent not only in annual and seasonal warming but in the ranges of the projections. Under RCP8.5, annual mean temperature will *likely* exceed 2°C by mid-century (compared with 1995–2014) and reach up to 4.8°C – 6°C by the end of the century (Yang et al., 2017), with faster warming projected by the CMIP6 ensemble under SSP5-8.5. In individual county-level studies on GCM future climate projections, temperatures increased by up to 7°C by the end of the century, depending on season and emissions scenario (Allaberdiyev, 2010; MENRPG, 2015; MNP, 2015; Gevorgyan et al., 2016; Osborn et al., 2016; Aalto et al., 2017; IDOE, 2017; Salman et al., 2017). Statistical downscaling of 18 CMIP5 GCMs projected an annual temperature increase of 0.37°C per decade (under RCP4.5) with the maximum in northern WCA and warming most conspicuous in summer (Luo et al., 2019). RCM downscaling of GCMs over Central Asia projected a larger increase of temperature under RCP8.5 for the 2071–2100 period, ranging from 5°C to 8°C (Ozturk et al., 2017).

In ARP, the projected change in ensemble mean annual temperature from 30 CMIP6 models is from 1.6°C (SSP1-2.6) to 5.3°C (SSP5-8.5) by 2070–2099 compared to 1981–2010 (Almazroui et al., 2020a). The projected warming is the highest in the north, reaching 5.9°C and lowest in the south (4.7°C). COSMO-CLM projections over the CORDEX-MENA domain show for ARP and WCA a strong warming with marked seasonality for the end of the 21st century, ranging from 2.5°C in winter under RCP4.5 to 8°C in summer under RCP8.5 and with large increases found over high-altitude areas in winter and spring (Bucchignani et al., 2018; Ozturk et al., 2018). The CMIP5 multi-model mean warming in boreal summer in 2070–2099, compared with 1951–1980, is projected to be about 2.5°C and 6.5°C at the 2°C and 4°C global warming levels respectively (Huang et al., 2014).

Future projections of precipitation in South West Asia have large uncertainties and thus *low confidence*. There are few significant changes, little consensus on the sign and with a tendency for reduction in CMIP5 being reversed in CMIP6 across all warming levels (Ozturk et al., 2018). Statistical downscaling of 18 CMIP5 GCMs under RCP4.5 projected an increase in precipitation of 4.6 mm per decade in South West Asia during 2021–2060 relative to 1965–2004 (Luo et al., 2019). CMIP5 simulations project a general decrease in precipitation over lowlands in Turkey, Iran, Afghanistan and Pakistan (Ozturk et al., 2017), and an increase over high-mountain regions (Aalto et al., 2017; Salman et al., 2018). At a 4°C global warming level, the multi-model mean annual precipitation for Turkmenistan and parts of Tajikistan and Uzbekistan is projected to decrease by 20%, with somewhat stronger relative decreases in summer (Reyer et al., 2017). Over northern WCA, the CMIP5 ensemble mean projects increases of over 3 mm per decade under RCP2.6 and over 6 mm per decade under RCP4.5 and RCP8.5 over the 21st century (Huang et al., 2014). Mean annual precipitation is projected to rise by 5.2% at the end of the 21st century (2070–2099) under RCP8.5, compared to 1976–2005, while mean annual snowfall is projected to decrease

by 26.5% in Central Asia (Yang et al., 2017). However, regardless of the sign of the precipitation change in the high-mountain regions of Central Asia, the influence of the warming on the snowpack will *very likely* cause important changes in the timing and amount of the spring melt (Differbaugh et al., 2013).

In ARP, the projected change in ensemble mean annual precipitation from 30 CMIP6 models ranges from 3.8% (–2.6 to 28.8%) to 31.8% (12.0–106.5%) under SSP1-2.6 and SSP5-8.5 emissions for the period 2080–2100 compared with 1995–2014 (Almazroui et al., 2020a). North-west ARP precipitation is projected to decrease between –6 to –27% per decade and in the south precipitation to increase by up to 8.6% per decade. CMIP6 projections are in line with those from CMIP3 and CMIP5, however they are less variable in the central area in CMIP6. The uncertainty associated with precipitation over ARP is large because of very low annual amounts and high variability.

Atlas.5.5.5 Summary

Increases in annual surface air temperature over South West Asia are *very likely* in the range of 0.24°C–0.81°C per decade over the last 50–60 years. Annual precipitation change over ARP since 1970 is estimated at –6.3 mm per decade (and in the range of –30 to 16 mm per decade) and over WCA is generally not significant except over the elevated part of eastern WCA where increases between 1.3 mm and 4.8 mm per decade during 1960–2013 have been observed (*very high confidence*). In mountainous areas, the scarcity and decline of the number of observation sites since the end of the former Soviet Union in 1991 increase the uncertainty of the long-term temperature and precipitation estimates (*high confidence*).

Mean temperature biases in RCMs are within $\pm 3^\circ\text{C}$ in South West Asia, and annual precipitation biases are positive in almost all parts of the region, except over the ARP where they are negative in the wet season (November to April) and over WCA in winter and spring (from December to May) (*medium confidence*). Since regional model evaluation literature has only recently emerged there is *medium evidence* about the performance of RCMs in South West Asia though with *medium to high agreement* on mean temperature and precipitation biases. RCMs simulate colder temperatures than observed over mountainous and high plateau regions (*limited evidence, high agreement*).

Further warming over South West Asia is projected in the 21st century to be greater than the global average, with rates varying from 0.25°C to 0.8°C per decade depending on the season and scenario, and the maximum rates found in the northern part of the region in summer (*high confidence*). The influence of the warming on the snowpack will *very likely* cause changes in the timing and amount of the spring melt. CMIP6 projected changes in annual precipitation totals are in the range of –3 to 29% (SSP1-2.6) and 12–107% (SSP5-8.5) in ARP (*medium confidence*). Strong spatio-temporal differences with overall precipitation decreases are projected in the central and northern parts of WCA in summer (JJA) with increases in winter (DJF) (*medium confidence*).

Atlas.6 Australasia

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Tables 11.10–12) and climatic impact-drivers in Chapter 12 (Table 12.5).

Atlas.6.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.6.1.1 Key Features of the Regional Climate

Australasia is divided into five regions for the Atlas (Figure Atlas.21), as follows: New Zealand (NZ), with a varied climate with diverse landscapes, mainly maritime temperate with four distinct seasons; Northern Australia (NAU), which is mainly tropical with monsoonal summer-dominated rainfall (monsoon season December to March, see Annex V), but with a hot, semi-arid climate in the south of the region; Central Australia (CAU) with a predominantly hot, dry desert climate; Eastern Australia (EAU) with a temperate oceanic climate at the coast to semi-arid inland; and Southern Australia (SAU), which ranges from Mediterranean and semi-arid in the west to mainly cool temperate maritime climate in the south-east. Various remote drivers have notable teleconnections to regions within Australasia, including an effect of the El Niño–Southern Oscillation (ENSO) and the Indian Ocean Dipole (Table Atlas.1 and Annex IV). Much of southern NZ and SAU are affected by systems within the westerly mid-latitude circulation, in turn affected by the Southern Annular Mode (SAM). The monsoon and the Madden–Julian Oscillation (MJO) affect rainfall variability in northern Australia.

Atlas.6.1.2 Findings From Previous IPCC Assessments

The AR5 WGI and WGII reports (IPCC, 2013c; Stocker et al., 2013; Reisinger et al., 2014) give *very high confidence* that air and sea temperatures in the region have warmed; cool extremes have become rarer in Australia and New Zealand since 1950, while hot extremes have become more frequent and intense (e.g., it is *very likely* that the number of warm days and nights have increased). The AR5 reported that it is *virtually certain* that mean air and sea temperatures will continue to increase, with *very high confidence* that the greatest increase will be experienced by inland Australia and the smallest increase by coastal areas and New Zealand. The AR5 reported a range of different precipitation trends within the region. For example, while annual rainfall has been significantly increasing in north-western Australia since the 1950s (*very high confidence*), it has been decreasing in the north-east of the South Island of New Zealand over 1950–2004 (*very high confidence*) and over the south-west of the state of Western Australia. In line with these trends, AR5 reported it is *likely* that drought has decreased in north-west Australia. Future projections for precipitation extremes indicate an increase in most of Australia and New Zealand, in terms of rare daily rainfall extremes (i.e., current 20-year return

period events) and of short duration (sub-daily) extremes (*medium confidence*). Likewise, however, there is a projected increase in the frequency of drought in southern Australia (*medium confidence*) and in many parts of New Zealand (*medium confidence*). Owing to hotter and drier conditions there is *high confidence* that the occurrence of fire weather will increase in most of southern Australia, and *medium confidence* that the fire danger index will increase in many parts of New Zealand.

The AR5 reported mean sea levels have also increased in Australia and New Zealand at average rates of relative sea level rise of $1.4 \pm 0.6 \text{ mm yr}^{-1}$ from 1900 to 2011, and $1.7 \pm 0.1 \text{ mm yr}^{-1}$ from 1900 to 2009, respectively (*very high confidence*). The assessment found that the volume of ice in New Zealand has declined by 36–61% from the mid- to late 1800s to the late 1900s (*high confidence*), while late-season significant snow depth has also declined in three out of four Snowy Mountain sites in Australia between 1957 and 2002 (*high confidence*). As mean sea level rise is projected to continue for at least several more centuries, there is *very high confidence* that this will lead to large increases in the frequency of extreme sea level events in Australia and New Zealand. On the other hand, the volume of winter snow and the number of days with low-elevation snow cover in New Zealand are projected to decrease in the future (*very high confidence*), while both snow depth and area are projected to decline in Australia (*very high confidence*).

The SROCC (Hock et al., 2019b) reports on the observed and projected decline in snow cover in Australasia, as well as the retreat of New Zealand glaciers following an advance in 1983–2008 due to enhanced snowfall. It also reports on the vulnerability of some Australian communities and ecosystems to sea level rise, increases in the intensity and duration of marine heatwaves driven by human influence (*high confidence*), the decrease in frequency of tropical cyclones' landfall on eastern Australia since the late 1800s (*low confidence* in an anthropogenic signal), and presents a case study on the multiple hazards, compound risk and cascading impacts from climate extremes in Tasmania in 2015–2016 (including an attributable human influence on some events). The SRCLL (Mirzabaev et al., 2019) found widespread vegetation 'greening' has occurred in parts of Australia, and an increase in the desertification and drought risk in future in southern Australia.

Atlas.6.2 Assessment and Synthesis of Observations, Trends and Attribution

Reliable station observations are available from around 1900 in Australasia, but in some regions the coverage was and remains poor. Australia and New Zealand have continued to warm, and many rainfall trends have continued since AR5. Changes and trends in temperature and precipitation from 1961 to 2015 from three different global datasets are displayed in Figure Atlas.11 and the Interactive Atlas, and show significant (at 0.1 significance level) warming trends over southern and eastern Australia. Most of the observed changes in precipitation over the region are not significant over this period. Although observed datasets (e.g., GPCC and GPCP) generally agree on a significant drying trend in the southern

regions of New Zealand during the shorter 1980–2015 period, this is in fact the reverse of the longer-term trends in 1961–2015 (Interactive Atlas).

For a longer-term perspective based on high-quality regional datasets, Figure Atlas.20 shows Australasia has warmed over the last century (*very high confidence*). Australian mean temperature has increased by $1.44^\circ\text{C} \pm 0.24^\circ\text{C}$ during the period 1910–2019 using the updated observed temperature dataset ACORN-SATv2.1, with 2019 Australia's hottest year on record and nine out of 10 of the warmest years on record occurring since 2005 (Trewin et al., 2020). Much of the warming has occurred since 1960, there is clear anthropogenic attribution of this change and emergence of the signal from the 1850–1900 climate (BOM and CSIRO, 2020; Hawkins et al., 2020). Warming has been more rapid than the national average in central and eastern Australia, with a warming minimum and non-significant trends since the 1960s in the north-west (CSIRO and BOM, 2015; BOM and CSIRO, 2020). The National Institute of Water and Atmospheric Research temperature record, NIWA NZ, shows a warming of $1.13^\circ\text{C} \pm 0.27^\circ\text{C}$ during the period 1909–2019, although several stations show non-significant trends since 1960 (Figure Atlas.20), including a warming minimum in the south-east at least partly due to a persistent shift in atmospheric circulation (Sturman and Quénol, 2013; MfE and Stats NZ, 2017, 2020).

Since 1960, precipitation has increased in much of mainland Australia in austral summer and decreased in many regions of southern and eastern Australia in austral winter (Figure Atlas.20). A detectable anthropogenic signal of increases in precipitation in Australia has been reported particularly for north central Australia and for a few regions along the south-central coast for the period 1901–2010 (Knutson and Zeng, 2018). Seasonally, there is a significant decline in winter rainfall in the south-west of the state of Western Australia (Figure Atlas.20), with an attributable human influence (*high confidence, robust evidence, medium agreement*) (Section 10.4 and references therein, e.g., Delworth and Zeng, 2014). Rainfall trends in the south-east are not significant since 1960 but have shown a notable reduction since the 1990s, and there is *limited evidence* for the attribution of this change to human influence (e.g., Rauniyar and Power, 2020). In New Zealand between 1960 and 2019 in both summer and winter, rainfall increased in some stations in the South Island and decreased at many stations in the North Island, however most station trends are not statistically significant (Figure Atlas.20; MfE and Stats NZ, 2020). In JJA, Milford Sound (increasing) and Whangaparaoa (decreasing) trends are significant.

In Australia, there has been a decrease in snow depth and area since the late 1950s, especially in spring (BOM and CSIRO, 2018). Based on a reconstructed snow cover record, the recent rapid decrease in the past five decades has been shown to be larger by more than an order of magnitude than the maximum loss for any five-decade period over the past 2000 years (McGowan et al., 2018). In New Zealand, from 1977 to 2018, glacier ice volume decreased from 26.6 km^3 to 17.9 km^3 (a loss of 33%; Salinger et al., 2019).

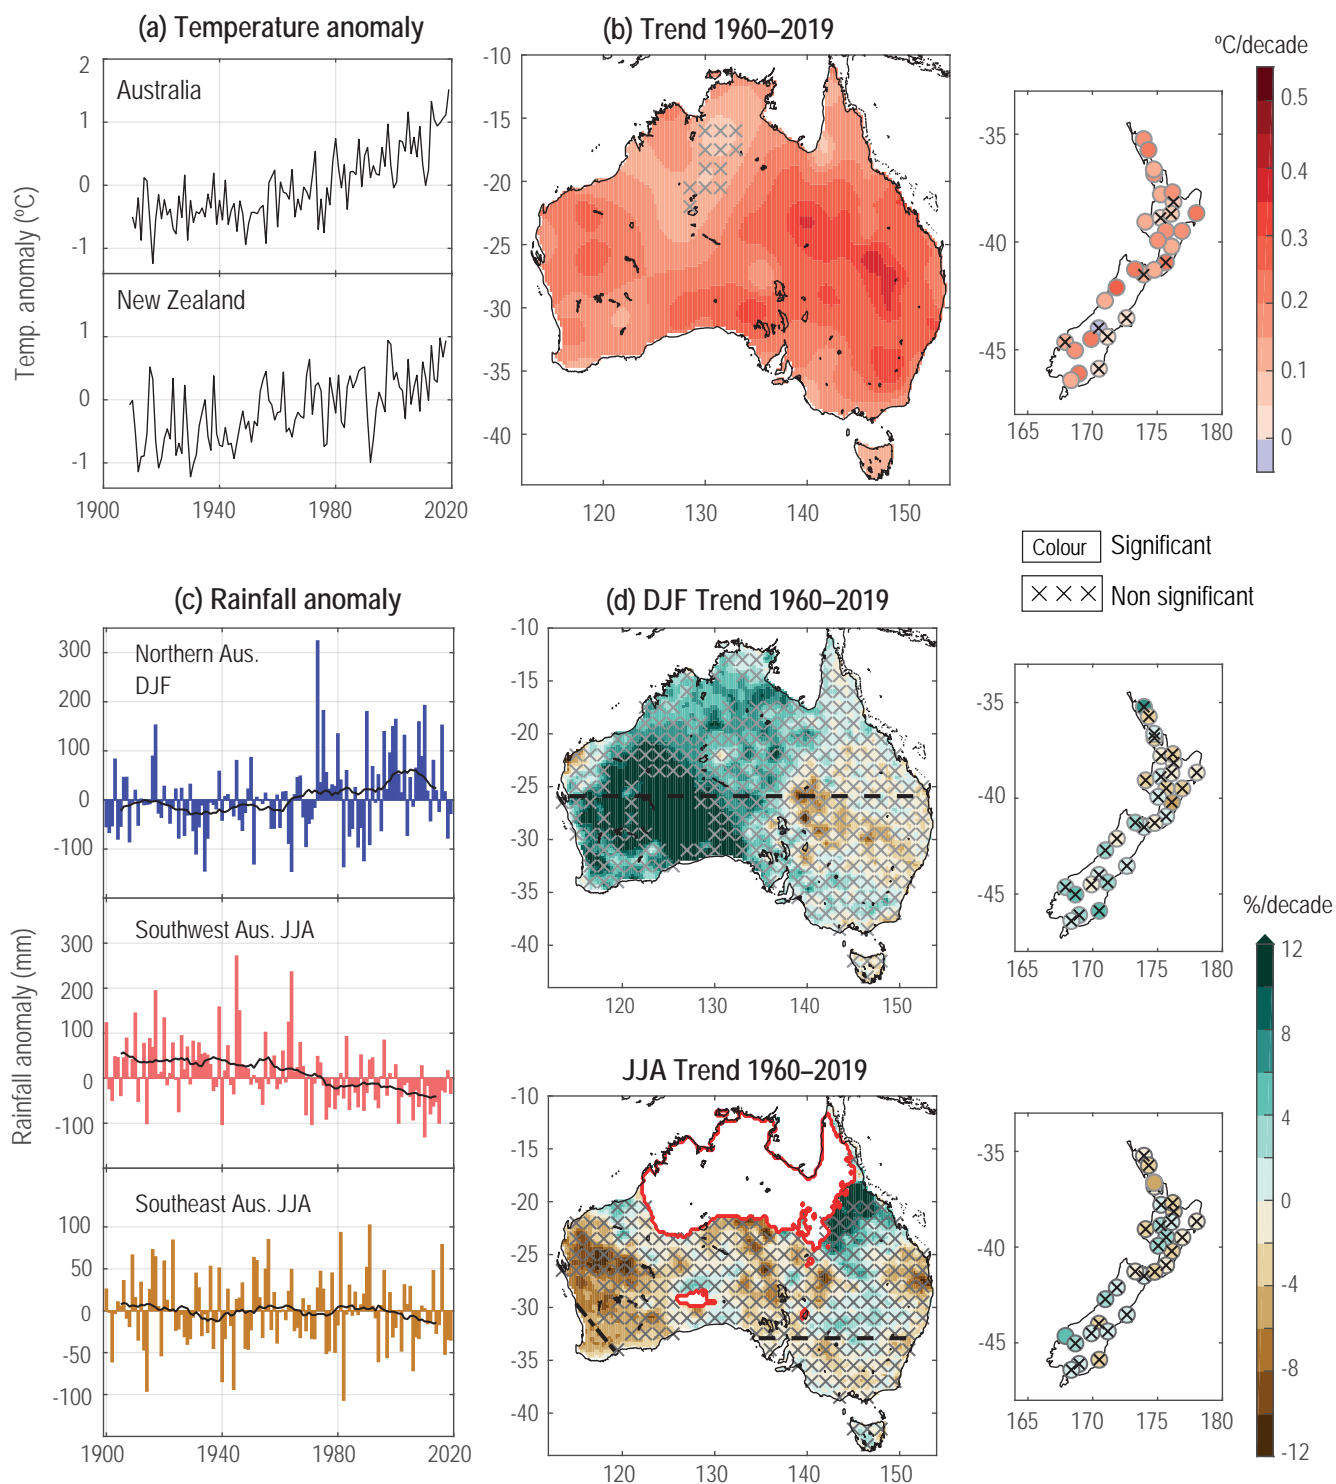

Figure Atlas.20 | Observed trends in mean annual temperature (a, b) and summer (December–January–February, DJF) and winter (June–July–August, JJA) precipitation (c, d) for Australia and New Zealand from high-quality regional datasets. Time series show anomalies from the 1961–1990 average and 10-year running mean; maps show annual linear trends for 1960–2019; rainfall trends are shown in % per decade, crosses show areas and stations with a lack of significant trend and regions of seasonally dry conditions (<0.25 mm day⁻¹) are masked and outlined in red. Datasets are Australian Climate Observation Reference Network – Surface Air Temperature version 2.1 (ACORN-SATv2.1) for Australian temperature, the Australian Gridded Climate Data (AGCD) for Australian rainfall (Evans et al., 2020), and the 30-station high-quality network for New Zealand temperature and rainfall. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Atlas.6.3 Assessment of Climate Model Performance

Most studies assessed in AR5 WGII were based on Coupled Model Intercomparison Project Phase 3 (CMIP3) models and Special Report on Emissions Scenarios (SRES) scenarios and CMIP5 models whenever available. The AR5 WGI reported that model biases in annual temperature and rainfall are similar to or lower than other continental regions outside the tropics, with temperature biases generally $<1^{\circ}\text{C}$ in the multi-model mean and $<2^{\circ}\text{C}$ in most models over Australia compared to reanalysis, and with a wet bias over the Australian inland region but a dry bias near coasts and mountain regions of both Australia and New Zealand.

Early results from CMIP6 suggest incremental improvements compared to CMIP5 in the simulation of the mean annual climatology of temperature and precipitation of the Indo-Pacific region surrounding Australasia, the teleconnection between ENSO and IOD and Australian rainfall and other relevant climate features (Grose et al., 2020). These assessments suggest that confidence in projections is similar to AR5 or incrementally improved. The CORDEX Australasia simulations are found to have cold biases in daily maximum temperature and an overestimation of precipitation but

overall showed added value in the simulation of the current climate (Di Virgilio et al., 2019; Evans et al., 2021).

Atlas.6.4 Assessment and Synthesis of Projections

Similar to the global average (Chapter 4), mean temperature in Australasia is projected to continue to rise through the 21st century at a magnitude proportional to the cumulative greenhouse gas emissions (*virtually certain, very high confidence, robust evidence*), CMIP5 and CMIP6 results are shown in Figure Atlas.21. A higher end to the range of temperature projections is found in CMIP6 compared to CMIP5 (Grose et al., 2020), produced by a group of models with high climate sensitivity (Forster et al., 2020), and this creates a higher multi-model-mean change. For example, projections for Australasia including ocean between 1995–2014 and 2081–2100 are 1.4°C (1.1°C – 1.8°C , 10th–90th percentile range) in CMIP5 under RCP4.5, but 1.8°C (1.3°C – 2.5°C) in CMIP6 under SSP2-4.5.

Using warming levels, the results can be directly compared, accounting for the different distribution of climate sensitivities in the two ensembles. In this framework, Australasia (land only) is projected

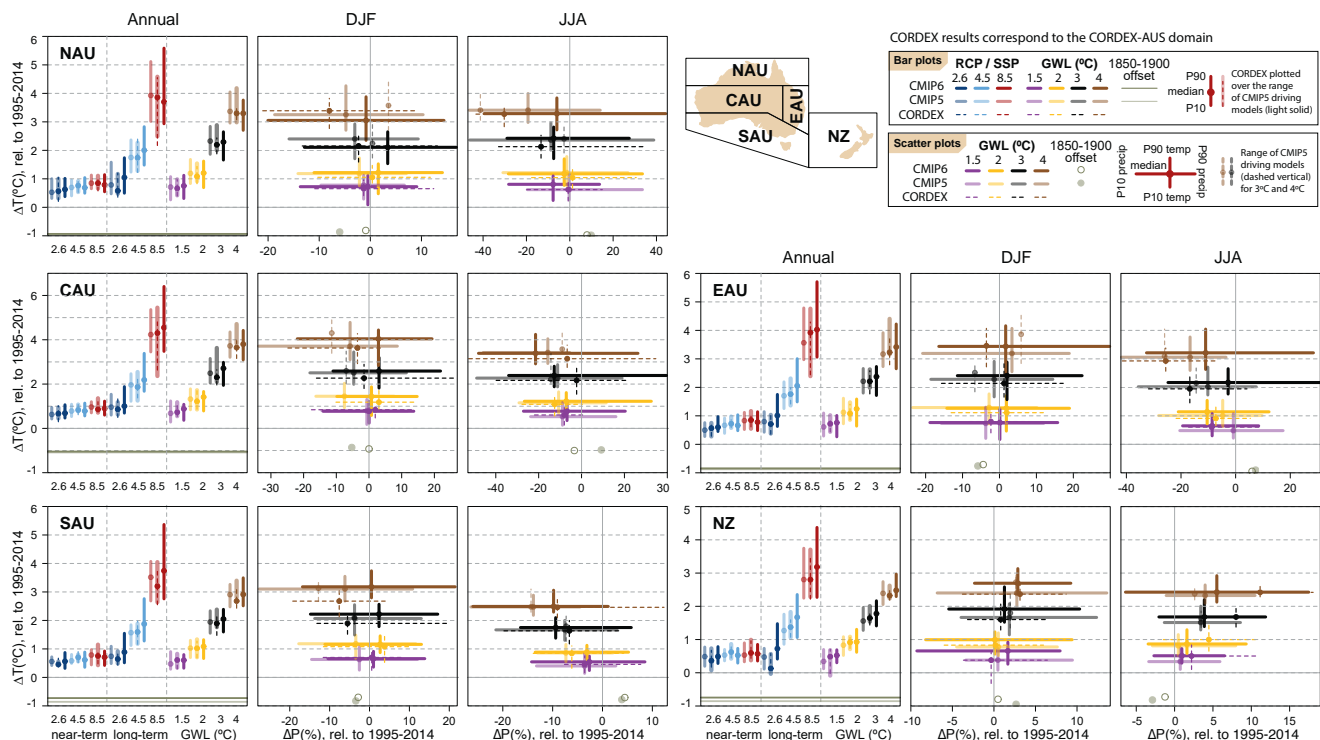

Figure Atlas.21 | Regional changes over land in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Australasia (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWs): 1.5°C , 2°C , 3°C and 4°C . The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWs. Changes are absolute for temperature (in $^{\circ}\text{C}$) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

to warm by a similar amount to the global average: 1.4°C–1.8°C for the 1.5°C warming level, through to 3.9°C–4.8°C for the 4°C warming level from the 1850–1900 baseline in CMIP6 using SSP5-8.5 (results using other SSPs and from CMIP5 are similar). Projected warming is greater over land than ocean, greater in Australia than in New Zealand, and greater over inland Australia than in coastal regions. Due to historical warming, projected temperature change from the AR6 baseline of 1995–2014 is lower: 0.3°C–1.0°C for the 1.5°C warming level, through to 2.9°C–4.0°C for the 4°C warming level. Changes for other warming levels, sub-regions and emissions pathways are shown in Figure Atlas.21 and can be explored in the Interactive Atlas. Regional modelling suggests projected temperature increase is higher in mountainous areas than surrounding low-elevation areas in New Zealand and Australia (Olson et al., 2016; MfE, 2018).

In line with recent trends, a significant reduction in annual mean rainfall in south-west Australia is projected, with the greatest reduction in winter and spring (*very likely, high confidence*). There is more than 80% model agreement for projected mean annual rainfall decrease in the south-west of the state of Western Australia for both the mid- (2041–2060) and far (2081–2100) future, and for all warming levels (Interactive Atlas). Rainfall decreases, mainly in winter and spring, are also projected for other regions within southern Australia with only *medium confidence* (*medium evidence, medium agreement*). Almost all models project continued drying in SAU in winter (JJA) and also in spring (SON), but a few models show little change. CMIP5 and CMIP6 results are similar or with a slightly narrower range in the latter (Figure Atlas.21). CORDEX produces a similar range of change in winter rainfall change for SAU as a whole. Circulation change is the dominant driver of these projected reductions, explaining the range of model results for southern Australia (CSIRO and BOM, 2015; Mindlin et al., 2020). Studies of winter rainfall change and circulation in southern Australia suggest the wettest changes in winter rainfall change may possibly be rejected (Grose et al., 2017, 2019a).

The model mean projection of northern Australian wet-season precipitation (a period including DJF) is for little change under all SSPs and warming levels, with *low confidence* in the direction of change as the projections include both large and significant decrease and increases (Figure Atlas.21 and Interactive Atlas). Evidence from warming patterns suggests a constraint on the dry end of projections (Brown et al., 2016), and the CMIP6 ensemble suggests that the projection follows the zonally averaged rainfall response in the Southern Hemisphere rather than changes in the western Pacific (Narsey et al., 2020). There is also evidence for a projected increase in rainfall variability in northern Australia in scales from days to decades (Brown et al., 2017). Liu et al. (2018) find that under 1.5°C warming, central and north-east Australia are projected to become wetter, however this projection has *low confidence*. There are similar projections from CMIP5 and CMIP6 (Figure Atlas.21).

Projections for EAU vary by season, with moderate model agreement on a decrease in rainfall in winter and spring, but with lower agreement in CMIP6 compared to CMIP5, and low model agreement on the direction of change in summer (Figure Atlas.21). CAU shows a similar range of change as EAU, with low model agreement on the direction of change in DJF, moderate agreement on direction

of change in JJA, but significant changes are projected by some models. Other seasonal and regional rainfall changes in Australia are reviewed in Dey et al. (2019).

For the NZ reference region, precipitation is projected to increase in winter and annual rainfall, with some differences in magnitude between CMIP5, CMIP6 and CORDEX (Figure Atlas.21). This projection of rainfall increase is a function of changes in the southern extent of the region, and notable regional differences are expected. Regional modelling suggests precipitation increases in the west and south of New Zealand and decreases in the north and east (MfE, 2018), with *medium confidence* and notable differences by season. Liu et al. (2018) project that the North Island will be drier, while the South Island will be wetter under both 1.5°C and 2°C warming levels. The projected increase in precipitation in the far future (2081–2100) for the southern regions of NZ has *high agreement* (Interactive Atlas). Other seasonal and regional rainfall changes in Australia can be explored in the Interactive Atlas.

The CORDEX Australasia simulations produce some regional detail in projected precipitation change associated with important features such as orography. Areas where there is coincident ‘added value’ in the simulation of the current climate and ‘potential added value’ as new information in the projected climate change signal (collectively termed ‘realized added value’) in Australia include the Australian Alps, Tasmania and parts of northern Australia (Di Virgilio et al., 2020). There have been several studies of regional climate change for New Zealand and states within Australia at fine resolution (5–12 km) that have produced important insights. One is enhanced drying in cool seasons on the windward slopes of the southern Australian Alps (decreases of 20–30% compared to 10–15% in the driving models), and conversely a chance of enhanced rainfall increase on the peaks of mountains in summer (Grose et al., 2019b), with the summer finding in line with those for the European Alps (Giorgi et al., 2016).

Under future warming, the snowpack in Australia is projected to decrease by approximately 15% and 60% by 2030 and 2070 respectively under the SRES A2 scenario (Di Luca et al., 2018), while in New Zealand the number of annual snow days is projected to decrease by 30 days or more by 2090 under RCP8.5 (MfE, 2018). New Zealand is also projected to lose up to 88 ± 5% of its glacier volume by the end of the 21st century (Chinn et al., 2012; Hock et al., 2019a).

Atlas.6.5 Summary

There is *very high confidence* that the climate of Australia warmed by around 1.4°C and New Zealand by around 1.1°C since reliable records began in 1910 and 1909 respectively, with human influence the dominant driver. Warming is *virtually certain* to continue, with a magnitude roughly equal to the global average temperature. A significant decrease in April to October rainfall in the south-west of the state of Western Australia observed from 1910 to 2019 is attributable to human influence with *high confidence* and is *very likely* to continue in future, noting consistent projections in CMIP5 and CMIP6. Other observed and projected rainfall trends are less significant or less certain. Model representation of the climatology

of Australasian temperature and rainfall has improved since AR5, through an incremental improvement between CMIP5 and CMIP6, and the development of coordinated regional modelling through CORDEX-Australasia. Snow cover is *likely* to decrease throughout the region at high altitudes in both Australia and New Zealand (*high confidence*).

Atlas.7 Central and South America

The assessment in this section focuses on changes in average surface temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Tables 11.13–15) and climatic impact-drivers in Chapter 12 (Table 12.6). It considers climate change over the regions shown in Figure Atlas.22, extending to all territories from Mexico to South America, including the Caribbean islands. This figure supports the assessment of regional mean changes over the region which, due to the high climatological and geographical heterogeneity, has been split into two sub-regions: Central America and the Caribbean, and South America.

Atlas.7.1 Central America and the Caribbean

Atlas.7.1.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.7.1.1.1 Key Features of the Regional Climate

The Central America and Caribbean region is assessed considering three reference regions Southern Central America (SCA), including the isthmus and the Yucatan Peninsula; Northern Central America (NCA), including Mexico (centre and north); and the Caribbean (CAR), including the Greater Antilles, the Lesser Antilles, the Bahamas and other small islands (see Figure Atlas.22); NCA is also covered in Section Atlas.9 North America.

Precipitation in most of SCA is characterized by two maxima in June and September, an extended dry season from November to May, and a shorter relatively dry season between July and August known as the midsummer drought (MSD; Chapter 10; Magaña et al., 1999; Perdigón-Morales et al., 2018). To some extent, precipitation seasonality is explained by the migration of the Inter-tropical Convergence Zone (ITCZ) (Taylor and Alfaro, 2005). The climate of NCA is temperate to the north of the Tropic of Cancer, with a marked difference between winter and summer, modulated by the North American Monsoon (NAmerM, Section 8.3.2.4.4). The CAR region has two main seasons, characterized by differences in temperature and precipitation. The wet or rainy season, with higher values of temperature and accumulated precipitation, occurs during the boreal summer and part of spring and autumn (Gouirand et al., 2020). The MSD is also present in the Greater Antilles and the Bahamas (Taylor and Alfaro, 2005), influenced by the oscillations of the North Atlantic Subtropical High (NASH), interacting with the Pacific and Atlantic branches of the ITCZ and modulated by the Atlantic Warm

Pool and the Caribbean low-level jet (CLLJ), while the Atlantic ITCZ is responsible for the unimodal rainfall cycle of the central and southern Lesser Antilles (Martinez et al., 2019). The CLLJ is a persistent climatological feature of the low-level circulation in the Central Caribbean, with a characteristic semi-annual cycle with maxima in the summer (main) and winter (secondary) (Amador, 1998; Magaña et al., 1999; Whyte et al., 2008). Temporal variability is influenced by several large-scale atmospheric modes (Annex IV and Table Atlas.1). A significant positive correlation between precipitation rates in CAR and the Atlantic Multi-decadal Variability (AMV) was found (Enfield et al., 2001). A similar result was found in southern Mexico (north of SCA) in the MSD region (see case-study discussion in Section 10.4.2.3; Méndez and Magaña, 2010; Cavazos et al., 2020). On the other hand, ENSO favours wet conditions in NCA, but its effect is modulated by Pacific Decadal Variability (PDV; Maldonado et al., 2016).

One of the most prominent features of the regional climate is the incidence of tropical cyclones (TCs), which represent an important hazard for almost all the countries of the region between June and November. A detailed assessment is given in Chapter 11.

Atlas.7.1.1.2 Findings From Previous IPCC Assessments

According to AR5 (Christensen et al., 2013), significant positive trends of temperature have been observed in Central America (*high confidence*), while significant precipitation trends are regionally dependent, especially during the summer. In addition, changes in climate variability and in extreme events have severely affected the region (*medium confidence*). A decrease in mean precipitation is projected in SCA and NCA. El Niño and La Niña teleconnections are projected to move eastwards in the future (*medium confidence*), while changes in their effects on other regions, including Central America and the Caribbean is uncertain (*medium confidence*). There is *medium confidence* in projections showing an increase in seasonal mean precipitation on the equatorial flank of the ITCZ affecting parts of Central America and the Caribbean.

In relation to the 1986–2005 baseline period, temperatures are *very likely* to increase by the end of the century, even for the RCP2.6 scenario, with changes of more than 5°C in some regions for the RCP8.5 scenario. Precipitation change is projected to vary between +10% and –25% (*medium confidence*) (Christensen et al., 2013). The SR1.5 (Hoegh-Guldberg et al., 2018) states there is a *high agreement* and *robust evidence* that at the 1.5°C global warming level the Caribbean region will experience a 0.5°C–1.5°C warming compared to the 1971–2000 baseline period, with greatest warming over larger land masses.

Atlas.7.1.2 Assessment and Synthesis of Observations, Trends and Attribution

Significant warming trends between 0.2°C and 0.3°C per decade have been observed in the three reference regions of Central America in the last 30 years (Planos Gutiérrez et al., 2012; P.D. Jones et al., 2016a; Hidalgo et al., 2017), with the largest increases in the North American Monsoon region (*high confidence*) (Figure Atlas.11 and the Interactive Atlas; Cavazos et al., 2020). There is *high confidence* of

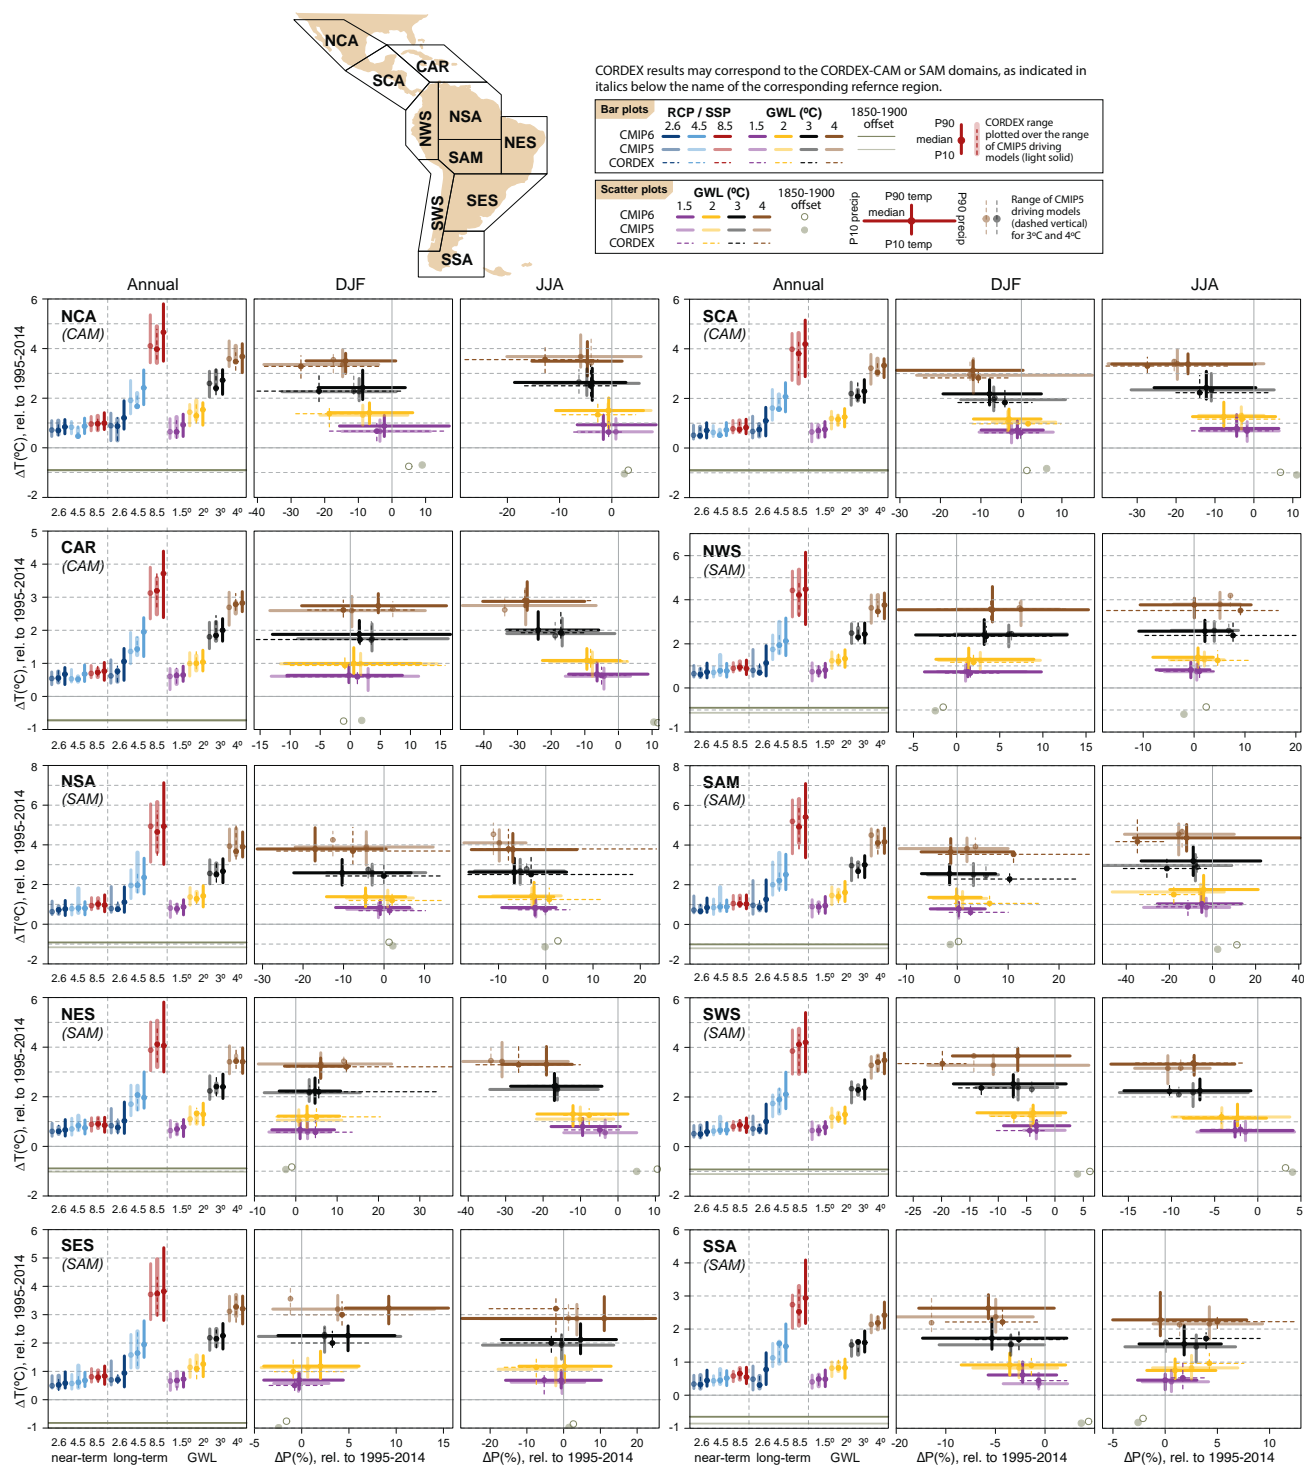

Figure Atlas.22 | Regional changes over land in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Central America, the Caribbean and South America (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2011–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

increasing temperature over parts of NCA, reaching 0.5°C per decade in Mexico and southern Baja California, with a lower rate (0.2°C per decade) in the Yucatan Peninsula and the Guatemala Pacific coastal region (Cueto et al., 2010; García Cueto et al., 2013; Martínez-Austria et al., 2016; Martínez-Austria and Bandala, 2017; Navarro-Estupiñan et al., 2018; Cavazos et al., 2020) and CAR (McLean et al., 2015) over the last 30 to 40 years. Cooling trends have been detected in limited areas of Honduras and northern Panama (Hidalgo et al., 2017).

Changes in mean precipitation rates are less consistent and long-term trends are generally weak. Different databases show significant differences depending mainly on the type and resolution of data (Centella-Artola et al., 2020). Small positive trends were observed in the total annual precipitation (Stephenson et al., 2014). In SCA and CAR, trends in annual precipitation are generally non-significant, with the exception of small significant positive trends for sub-regions or limited periods (Planos Gutiérrez et al., 2012; Hidalgo et al., 2017), and the 1970–1999 trends in precipitation in SCA are generally non-significant (J.M. Jones et al., 2016; Hidalgo et al., 2017). Positive trends in the duration of the MSD have been found in this region over the past four decades (*low confidence*) (Anderson et al., 2019). For CAR see also Atlas.10 Small Islands.

Atlas.7.1.3 Assessment of Model Performance

The ability of climate models to simulate the climate in this region has improved in many key aspects (Karmalkar et al., 2013; Fuentes-Franco et al., 2014, 2015, 2017; Vichot-Llano et al., 2014; Vichot-Llano and Martínez-Castro, 2017; Martínez-Castro et al., 2018). Particularly relevant for this region are increased model resolution and a better representation of the land surface processes (*high confidence*).

Regional climate models (RCMs) forced with reanalyses and atmosphere-only global climate models provide simulations with a reasonably good performance over the core North American Monsoon region, mostly in NCA (*high confidence*) (Bukovsky et al., 2013; Cerezo-Mota et al., 2016). RCMs also reproduce the seasonal spatial patterns of temperature and the bimodal rainfall characteristics of the NCA, SCA and CAR (*high confidence*) (Karmalkar et al., 2013; Centella-Artola et al., 2015; Martínez-Castro et al., 2018; Cavazos et al., 2020; Vichot-Llano et al., 2021b), though in some sub-regions specific models overestimate and shift the month of the maxima. RCM simulations in the region do not necessarily improve with the size of the domain, as important features of the regional circulation and key rainfall climate features, such as the CLLJ and MSD, are well represented for a variety of domains of different sizes (*high confidence*) (Centella-Artola et al., 2015; Martínez-Castro et al., 2018; Cabos et al., 2019; Cavazos et al., 2020; Vichot-Llano et al., 2021b).

Atlas.7.1.4 Assessment and Synthesis of Projections

Figure Atlas.22 and the Interactive Atlas synthesize regional mean changes in annual mean surface air temperature and precipitation for the Central American reference regions for CMIP6, CMIP5 and CORDEX for different warming levels and time periods. At the 1.5°C GWL, it is *very likely* that average annual temperature in Central America over land surpasses 1.3°C (CAR), 1.7°C (NCA) and

1.6°C (SCA). For the 3°C GWL, the corresponding projected ensemble mean regional warming values are 2.7°C (CAR), 3.5°C (NCA) and 3.1°C (SCA). CAR average annual warming is below the level of global warming, while the two continental reference regions are close to the global warming level with CMIP6 and CMIP5 showing very consistent results (Figure Atlas.22). However, when focusing on time slices instead of warming levels, the CMIP6 projections show systematically higher median values than CMIP5. CORDEX results are also consistent with the previous findings, though the subset of driving models spans a smaller range of uncertainty, particularly over CAR. Results have also been reported for this region based on CMIP5, CMIP6 and downscaled simulations over the CORDEX CAM domain or similar smaller domains (Taylor et al., 2013b; Nakaegawa et al., 2014; Imbach et al., 2018; Vichot-Llano et al., 2019; Almazroui et al., 2021). Statistical downscaling methods have been also applied to CMIP5 projections to obtain bias-adjusted regional projections (Colorado-Ruiz et al., 2018; Taylor et al., 2018; Vichot-Llano et al., 2019).

Global and regional models consistently project warming in the whole region for the end of the century, under RCP4.5 and RCP8.5 for CMIP5 projections with greater warming for continental compared to insular territories, *likely* reaching values between 2°C and 4°C (*high confidence*) (Campbell et al., 2011; Karmalkar et al., 2011; Cavazos and Arriaga-Ramírez, 2012; Cantet et al., 2014; Chou et al., 2014; Coppola et al., 2014; Hidalgo et al., 2017; Colorado-Ruiz et al., 2018; Imbach et al., 2018). The greatest warming of 5.8°C for the end of the century was projected for northern Mexico under RCP8.5 (Colorado-Ruiz et al., 2018), using an ensemble of CMIP5 GCMs (Interactive Atlas).

Regarding precipitation, it is *likely* that the annual average precipitation changes for the 1.5°C GWL will be in the ranges of –11 to 0% in CAR, from –12 to 0% in SCA, and from –10 to +3% in NCA (Interactive Atlas). For the 3°C GWL, the corresponding annual average precipitation changes will be from –17 to –2% in CAR, from –16 to +2% in NCA, and from –23 to 0% in SCA. A clear drying tendency is observed for the 3°C GWL relative to the 1.5°C GWL. Maloney et al. (2014) examined 21st-century climate projections of North American climate in CMIP5 models under RCP8.5, including Central America and the Caribbean. Summer drying was projected in CAR and SCA for most of the models, with good agreement. The strongest drying is projected to occur during July and August which are the months when the MSD occurs in many sub-regions (Figure Atlas.22 and the Interactive Atlas). Intensification of the MSD in SCA was also projected by using the Rossby Centre Regional Climate Model (RCA4; Corrales-Suastegui et al., 2020), but with a future decrease in area and frequency (Cross-Chapter Box Atlas.2). They also found a projected intensification of CLLJ and drying for the future time slice of 2071–2095, relative to their baseline of 1981–2005. Decreased precipitation was also projected for SCA (Imbach et al., 2018) with the 8-km resolution Eta RCM during the rainy season, including an intensification of the MSD, although no significant change was projected for the CLLJ.

Colorado-Ruiz et al. (2018) assessed an ensemble of 14 GCMs from CMIP5 for a 1971–2000 baseline period, projecting precipitation decreases of between 5% and 10% by the end of the century for the

RCP4.5 and RCP8.5 scenarios respectively. The greatest decrease in precipitation is projected during summer reaching 13%, especially in southern Mexico, Central America and the Caribbean. Dynamically downscaled simulations (Bukovsky et al., 2015) also projected a decrease of precipitation for the middle of the century (2041–2069) relative to 1971–1999 for the north of Mexico, though despite good agreement amongst the models, these results must be considered of *low confidence*, because of their poor simulation of important monsoon physical processes. Vichot-Llano et al. (2021a) used a multi-parameter ensemble of RegCM4, driven by the CMIP5 global model HagGEM2-ES projections to conclude that, relative to the 1975–2004 baseline, in the near (2020–2049) and more prominently in the far (2070–2099) future, drier conditions will prevail at over the eastern Caribbean. The projected future warming trend was statistically significant at the 95% confidence level over CAR and SCA. Almazroui et al. (2021) used an ensemble of 31 CMIP6 models to estimate climate change signals of temperature and precipitation in six reference regions in North and Central America and the Caribbean, finding a decrease in precipitation (10–30%) over Central America and the Caribbean under three scenarios with regional and seasonal variations.

There is *high agreement* and *high confidence* in the projected decrease of precipitation by the end of the century for most of the region, particularly for annual and summer precipitation, but there is *low confidence* on the magnitude of this decrease which varies between 5% and 50% for different projections and different sub-regions (see extended information in the Interactive Atlas).

The status of climate extreme trends and projections for the region has been assessed in Chapter 11 and the main findings are synthesized here. There is *high confidence* in the projections of significant heatwave events at the end of the century in SCA (Angeles-Malaspina et al., 2018) and an increase in warm days and warm nights over this region and CAR (Stennett-Brown et al., 2017). For CAR islands, using dynamically downscaled CMIP3 models, Karmalkar et al. (2013) projected an increase in drought severity at the end of the century, mainly due to a precipitation decrease during the early wet season. In SCA, projections suggest an increase in the MSD (Imbach et al., 2018) and an increase in consecutive dry days (Chou et al., 2014), consistent with the projections of Stennett-Brown et al. (2017).

Atlas.7.1.5 Summary

Significant warming trends between 0.2°C and 0.3°C per decade have been observed in the three reference regions of Central America in the last 30 years, with the largest increases in the North American Monsoon region (*high confidence*). Changes in mean precipitation rates are less consistent and long-term trends are generally weak. Small positive trends were observed in the total annual precipitation in part of the region.

Warming in the continental part of the region is projected to increase in the range of the mean global values for GWL of 1.5°C and 3°C, but in the Caribbean regional warming will be lower. Precipitation is projected to decrease with increasing GWLs, especially for CAR and SCA.

Projected change in mean annual precipitation shows a large spatial variability across Central America and the Caribbean. Under moderate future emissions overall negative but non-significant precipitation trends are projected for the 21st century (*low confidence*). Under higher-emissions scenarios and at higher GWLs, average precipitation is *likely* to decrease in most of the region, particularly in the north-western and central Caribbean and part of continental Central America, especially in SCA.

Atlas.7.2 South America

Atlas.7.2.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.7.2.1.1 Key Features of the Regional Climate

Regional synthesis of observed and modelled climate in South America is challenging due to the latitudinal extent of the continent, the Andes Mountains, and local-to-regional climatic features, which are influenced by multiple drivers. The main large-scale drivers include many modes of natural variability (Annex IV.2): the inter-decadal modes, Atlantic Multi-decadal Variability (AMV) and Pacific Decadal Variability (PDV); the interannual-to-annual modes, El Niño–Southern Oscillation (ENSO), the Indian Ocean Dipole (IOD), the Southern Annular Mode (SAM) and the North Atlantic Oscillation (NAO); seasonal variability driven by the meridional migration of the Inter-tropical Convergence Zone (ITCZ) and the timing and intensity of the South American Monsoon System (SAmM, Section 8.3.2.4.5), the Madden–Julian Oscillation sub-seasonal mode of natural variability (MJO) and the behaviour at finer scales of the tropical easterly waves.

The regional assessment in this section emphasizes the seven new South American reference regions (Figure Atlas.22; Iturbide et al., 2020) that have a largely consistent climate and response to climate change, and can be used for analysis and impact studies (Solman et al., 2008; Neukom et al., 2010; Barros et al., 2015; Nobre et al., 2016). At the sub-regional scale, several phenomena drive climate variability. Brazil's north-east (North-Eastern South America; NES) is the most densely populated dryland globally and recurrently affected by climatic extremes. The climate variability, particularly the precipitation, is marked by strong interannual variability related to ENSO, the ITCZ, and the North Tropical Atlantic Ocean SSTs (Marengo et al., 2018a). Northern (NSA) and North-Western South America (NWS) are part of the Amazonia region. Its most recognizable features are the high rainfall, high humidity and high temperatures that prevail in the region. Rainfall variability in these regions results from the interplay between regional atmospheric circulation, the SST variations in both the Pacific and Atlantic oceans, among other regional-to-local interactions (Marengo and Espinoza, 2016; Espinoza et al., 2020). The South American Monsoon (SAM) region has distinct wet (summer) and dry (winter) periods. Key drivers include the South Atlantic Convergence Zone (Marengo et al., 2012), the Bolivian High, the 40- to 60-day intra-seasonal oscillation, and the forcing of the high Andes Mountains to the west (Almeida et al., 2017). The geographic position of South-Western

South America (SWS) results in very specific climatic characteristics since SWS contains subtropical climates as well as sub-Antarctic and Antarctic climates. The climate of SWS is driven by seasonal changes in the position of subtropical high-pressure air masses in the South Atlantic and South Pacific oceans, the Southern Annular Mode, the dynamics of the cold Humboldt ocean current, and icy cold fronts and mid-latitude westerlies (Valdés-Pineda et al., 2016). The densely populated, highly productive sub-region of South-Eastern South America (SES) has cool winters and hot summers typical of the temperate zone, and climatic conditions are strongly tied to ENSO, whose influence is moderated by local air-sea thermodynamics in the South Atlantic (Barreiro, 2010). Lastly, the climate of the southern tip of South America (SSA) is cold and dry, and is influenced by the Southern Annular Mode, and the interaction between the wetter Pacific winds and the Andean Cordillera (Aceituno, 1988; Silvestri and Vera, 2009).

Atlas.7.2.1.2 Findings From Previous IPCC Assessments

According to AR5 WGII Chapter 27 (Magrin et al., 2014), during the last decades of the 20th century, observational studies identified significant trends in precipitation and temperature in South America (*high confidence*). Increasing trends in annual rainfall in South-Eastern South America contrast with decreasing trends in central southern Chile and some regions of Brazil. Warming has been detected throughout South America (near 0.7°C–1°C in the 40 years since the mid-1970s), except for a cooling off the Chilean coast of about –1°C over the same period.

The AR5 WGI (Flato et al., 2013) noted that climate simulations from CMIP3 and CMIP5 models were able to represent well the main climatological features, such as seasonal mean and annual cycle (*high confidence*), although some biases remained over the Andes, the Amazonian basin and for the South America Monsoon. On the other hand, climate models from CMIP5 showed better results when compared to CMIP3.

The SR1.5 (Hoegh-Guldberg et al., 2018) assessed that a further increase of 0.5°C or 1°C is likely to have detectable effects on mean temperature and precipitation in South America, particularly in tropical regions (NWS, NAS, SAM and NES), as well as in SES, given that changes in mean temperatures and precipitation have already been attributed in the last decades for global warming of less than 1°C.

Atlas.7.2.2 Assessment and Synthesis of Observations, Trends and Attribution

Studies on climatic trends in South America indicate that mean temperature and extremely warm maximum and minimum temperatures have shown an increasing trend (*high confidence*), particularly for a large region in Northern South America and the south-western Andes (NSA, SAM, NES, SWS and the north of SES; Skansi et al., 2013; de Barros Soares et al., 2017). Also, the trend of the difference between the annual mean of the daily maximum temperature and the annual mean of the daily minimum temperature was positive – up to 1°C per decade – over the extratropics with the

maximum temperature generally increasing faster than the minimum temperature, while a negative trend of up to –0.5°C per decade was observed over the tropics.

Regionally, analyses of temperatures point to an increased warming trend (*high confidence*) over Amazonia over the last 40 years, which reached approximately 0.6°C–0.7°C (Figure Atlas.11 and the Interactive Atlas) and with stronger warming during the dry season and over the south-east. The analyses also showed that 2016 was the warmest year since at least 1950 (Marengo et al., 2018b). Andean temperatures showed significant warming trends, especially at inland and higher-elevation sites, while trends are non-significant or negative at coastal sites (*high confidence*) (Vuille et al., 2015; Burger et al., 2018; Vicente-Serrano et al., 2018; Pabón-Caicedo et al., 2020). Over central Chile, positive trends are largely restricted to austral spring, summer and autumn seasons for mean, maximum and minimum temperatures (Burger et al., 2018; Vicente-Serrano et al., 2018). Over Peru, trends of maximum air temperature were mainly amplified during the austral summer, but trends of cold-season minimum air temperature showed an opposite pattern, with the strongest warming being recorded in the austral winter (Vicente-Serrano et al., 2018).

In general, the spatial patterns of observed trends in temperature are more consistent than for precipitation across the whole of South America (*medium confidence*) (Interactive Atlas; de Barros Soares et al., 2017). In south-east Brazil there is a region of highly significant decrease of rainfall in both wet and dry seasons recorded in the period 1979–2011 (Interactive Atlas; Rao et al., 2016). The most consistent evidence of positive rainfall trend occurs in the southern part of the La Plata basin (*high confidence*) (southern Brazil, Uruguay, and north-eastern Argentina; de Barros Soares et al., 2017). By contrast, there is *high confidence* that annual rainfall has decreased over north-east Brazil during the last decades (Carvalho et al., 2020). Contrary to temperature changes, trends in annual precipitation exhibit different signs across sectors in the Andes. For instance, annual precipitation trends in the north tropical (north of 8°S) and south tropical (8°S–27°S) Andes do not show a homogeneous pattern. Over the subtropical Andes, central Chile shows a robust signal of declining precipitation since 1970 (*high confidence*) (Pabón-Caicedo et al., 2020).

Observational studies show that the dry-season length over southern Amazonia has increased significantly since 1979 (*high confidence*) (Fu et al., 2013; Alves, 2016). In the Peruvian Amazon-Andes basin, there is no trend in mean rainfall during the period 1965–2007 (Lavado Casimiro et al., 2012) though statistically significant decreases in total annual rainfall in the central and southern Peruvian Andes from 1966 to 2010 were found (Heidinger et al., 2018). Despite that, recent analyses of Amazon hydrological and precipitation data suggest an intensification of the hydrological cycle over the past few decades (Gloor et al., 2015). In general, these changes are attributed mainly to decadal climate fluctuations (*high confidence*), ENSO, the Atlantic SST north–south gradient, feedbacks between fire and land-use change mainly across southern south-eastern Amazon, and changes in the frequency of organized deep convection (Fernandes et al., 2015; Sánchez et al., 2015; Tan et al., 2015).

Since AR5, there has been limited attribution literature in the South America. Recent publications based on observational and modelling evidence assessed that anthropogenic forcing in CMIP5 models explains the overall warming (*high confidence*) over the entire South American continent, including the increase in the frequency of extreme temperature events (Hannart et al., 2015). It has a detectable influence in explaining positive and negative precipitation trends observed in regions such as SES and the southern Andes (Vera and Díaz, 2015; de Barros Soares et al., 2017; Boisier et al., 2018; de Abreu et al., 2019). Despite that, there is *limited evidence* that human-induced greenhouse gas emissions had an influence on the 2014/2015 water shortage in south-east Brazil (Otto et al., 2015). Extreme event attribution on sub-continental scales is assessed in Chapter 11 and continental-scale attribution in Chapter 3.

In summary, analyses of historical temperature time series point strongly to an increased warming trend (*high confidence*) across many South American regions, except for a cooling off the Chilean coast. Annual rainfall has increased over South-Eastern South America and decreased in most tropical land regions, particularly in central Chile (*high confidence*). The number and strength of extreme events, such as extreme temperatures, droughts and floods, have already increased (*medium confidence*) (Table 11.7).

It is noted that the major barrier to the study of climate change in many regions of South America is still the absence or insufficiency of long time series of observational data (Carvalho, 2020; Condom et al., 2020). Most national datasets were created in the 1970s and 1980s, preventing a more comprehensive long-term trend analysis. To fulfil the users' demand for climatological and meteorological data products covering the whole region, several interpolation techniques have been used with reanalysis and gridded gauge-analysis products to add the necessary spatial detail to the climate analyses over land and for climate variability and trend studies, but these are subject to uncertainties (Skansi et al., 2013; Rozante et al., 2020).

Atlas.7.2.3 Assessment of Model Performance

Since AR5 the number of publications on climate model performance and their projections in South America has increased, particularly for regional climate modelling studies (Giorgi et al., 2009; Boulanger et al., 2016; Ambrizzi et al., 2019) and the understanding of their strengths and weaknesses (*high confidence*).

Most global and regional climate models can simulate reasonably well the current climatological features of South America, such as seasonal mean and annual cycles. However, significant biases persist mainly at regional scales (*high confidence*) (Blázquez and Nuñez, 2013b; Gulizia et al., 2013; Joetzjer et al., 2013; Jones and Carvalho, 2013; Torres and Marengo, 2013; Gulizia and Camilloni, 2015; Zazulie et al., 2017; Abadi et al., 2018; Barros and Doyle, 2018; Solman and Blázquez, 2019; Fan et al., 2020; Rivera and Arnould, 2020; Teichmann et al., 2021). During the dry season, precipitation is underestimated in most models over Amazonia (*medium evidence, high agreement*) (Torres and Marengo, 2013; Yin et al., 2013; Solman and Blázquez, 2019). Over regions with complex orography, such as

the tropical Andes of NWS, CMIP5 models tend to underestimate precipitation which is associated with the misrepresentation of the Pacific ITCZ and local low-level jets (Sierra et al., 2015, 2018), whereas over the subtropical central Andes in SWS, the models are found to overestimate both mean temperature and precipitation values (*limited evidence, high agreement*) (Zazulie et al., 2017; Rivera and Arnould, 2020; Díaz et al., 2021). Most models show a dry bias over SES (Díaz and Vera, 2017; Barros and Doyle, 2018; Solman and Blázquez, 2019; Díaz et al., 2021) associated with an underestimation of the northern flow that brings water vapour into the region (*medium confidence*) (Gulizia et al., 2013; Zazulie et al., 2017; Barros and Doyle, 2018). The biases in seasonal precipitation, annual precipitation and climate extremes over several regions of South America were reduced, including the Amazon, central South America, Bolivia, eastern Argentina and Uruguay, in the CMIP5 models when compared to those of CMIP3 (*medium confidence*) (Joetzjer et al., 2013; Gulizia and Camilloni, 2015; Díaz and Vera, 2017). The evidence is still insufficient to determine whether CMIP6 biases are reduced when compared with CMIP5 simulations regarding precipitation and its variability in South America. The temperature and precipitation patterns of anomalies associated with ENSO in tropical South America (NWS, NSA and NES) are better captured by GCMs in tropical South America (NWS, NSA and NES) than in extratropical South America (SES), particularly during austral summer and autumn (*limited evidence, high agreement*) (Tedeschi and Collins, 2016; Perry et al., 2020).

Based on regional simulations, studies showed that some RCMs improve the quality of the simulated climate when compared with the driving GCM (*medium evidence, high agreement*) (Llopart et al., 2014; Sánchez et al., 2015; Falco et al., 2019; Solman and Blázquez, 2019; Ciarlo et al., 2021; Teichmann et al., 2021). Regional climate model (RCM) simulations over South America can reproduce the main features of temperature and precipitation in terms of both spatial distributions (Solman et al., 2013; Falco et al., 2019) and seasonal cycles over the different climate regimes, including the main SAMerM features (*high confidence*) (Jacob et al., 2012; Solman, 2013; Llopart et al., 2014; Reboita et al., 2014; de Jesus et al., 2016; Lyra et al., 2018; Bozkurt et al., 2019; Ashfaq et al., 2021). However, RCMs showed systematic biases such as precipitation overestimations and temperature underestimations along the Andes throughout the year (*high confidence*), although these biases may be artificially amplified by the lack of a dense observational station network (Jacob et al., 2012; Solman et al., 2013; Bozkurt et al., 2019; Falco et al., 2019). RCMs tended to show dry biases over the Amazon and the northern part of the continent (SAM, NSA) during DJF and during the maximum precipitation associated with the ITCZ over NSA during JJA (*medium evidence, high agreement*) (Solman et al., 2013; Falco et al., 2019). Temperature overestimation and precipitation underestimation over La Plata basin (in SES) are also RCM common biases, with the warm bias amplified for austral summer and the dry bias amplified for the rainy season (*high confidence*) (Solman et al., 2013; Reboita et al., 2014; Solman, 2016; Falco et al., 2019). Despite their relevance, RCM simulations at very high resolution (less than 10 km) are still few in South America (*high confidence*) and are mainly designed for specific regions or purposes (Lyra et al., 2018; Bozkurt et al., 2019; Bettolli et al., 2021).

The evaluation of statistical downscaling models (ESD) in representing regional climate features in South America has increased since AR5, however there are still few ESD studies over the different sub-regions. Precipitation simulations based on ESD models are able to reproduce mean precipitation over tropical and subtropical South American regions, especially over maximum precipitation areas in western Colombia, south-eastern Peru, central Bolivia, Chile and the La Plata basin (*medium confidence*) (Souvigniet et al., 2010; Mendes et al., 2014; Palomino-Lemus et al., 2015, 2017, 2018; Soares dos Santos et al., 2016; Troin et al., 2016; Borges et al., 2017; Bettolli and Penalba, 2018; Araya-Osses et al., 2020; Bettolli et al., 2021). Temperature simulations are fewer but show added value to GCM simulations (*medium evidence, high agreement*) (Souvigniet et al., 2010; Borges et al., 2017; Bettolli and Penalba, 2018; Araya-Osses et al., 2020).

Overall, climate modelling has made some progress in the past decade but there is no model that performs well in simulating all aspects of the present climate over South America (*high confidence*). The performance of the models varies according to the region, time scale and variables analysed (Abadi et al., 2018). There is also a fairly narrow spread in the representation of temperature and precipitation over South America by the CMIP5 GCMs and also the RCMs, with biases that can be associated with the parametrizations and schemes of surface, boundary layer, microphysics and radiation used by the models. Finally, observational reference datasets, such as reanalysis products, used in the calibration and validation of climate models can also be quite uncertain and may explain part of the apparent biases present in climate models (*high confidence*).

Atlas.7.2.4 Assessment and Synthesis of Projections

It is *very likely* that annual mean temperature will increase over South America, with a wide range of projected changes of 1.0°C–6.0°C by the end of the 21st century (from RCP2.6/SSP1-2.6 to RCP8.5/SSP5-8.5 emissions, Figure Atlas.22). Overall, GCMs project higher temperature change than RCMs in austral summer and winter over all sub-regions and in winter mainly over the central part of the continent (Interactive Atlas; Coppola et al., 2014; Llopart et al., 2021; Teichmann et al., 2021). The largest warmings over the South American continent are projected for the Amazon basin (SAM and NSA) and the central Andes range (southern SAM, northern SWS and south-eastern NWS; Figure Atlas.22), especially during the dry and dry-to-wet transition seasons (austral winter and spring) (*high confidence*) (Blázquez and Nuñez, 2013a; Coppola et al., 2014; Pabón-Caicedo et al., 2020; Teichmann et al., 2021).

Using warming levels (Figure Atlas.22), the temperature is projected to increase at or above the level of global warming in all regions apart from SSA with additional warming (compared to a 1995–2014 baseline) of over 4°C for the 4°C warming level in NSA and SAM. Changes for other warming levels, sub-regions and emissions pathways are shown in Figure Atlas.22 and can be explored with the Interactive Atlas.

In general, models show a wide regional range in the direction and the magnitude of mean precipitation change in many South American regions, with large significant increases and decreases

(Figure Atlas.22 and the Interactive Atlas). In the medium and long term, under the high-emissions scenario, the CMIP5 multi-model ensemble projected an increase in precipitation (generally greater than 10%) in SES and NWS, and a decrease (less than 10%) in NSA across seasons (*high confidence, robust evidence*) (Solman, 2013; Chou et al., 2014; Coppola et al., 2014; Llopart et al., 2014, 2021; Reboita et al., 2014, 2021; Sánchez et al., 2015; Menéndez et al., 2016; Ruscica et al., 2016; Bozkurt et al., 2018a; Zaninelli et al., 2019). Also, in parts of SWS, annual precipitation is projected to decrease (up to 30%) by the late 21st century (Souvigniet et al., 2010; Palomino-Lemus et al., 2017, 2018; Bozkurt et al., 2018a). Under high RCPs, the CMIP5 ensemble projects that all Brazilian regions will experience more rainfall variability in the future, so drier dry periods and wetter wet periods on daily, weekly, monthly and seasonal time scales, despite the future changes in mean rainfall being currently uncertain (*medium confidence*) (Alves et al., 2021). Regarding the SAMerM, it is *very likely* that the monsoon will experience changes in its life cycle by the end of the 21st century for both RCP4.5 and RCP8.5 emissions and, in particular, delayed onset. However there is *low agreement* on the projected changes in terms of extreme and total precipitation of the monsoon season in South America (Llopart et al., 2014; Ashfaq et al., 2021). Changes in the SAMerM are assessed in Section 8.3.2.4.5.

Projected changes in seasonal precipitation and their uncertainties generally agree with the annual changes, particularly for the decreases in SWS (Figure Atlas.22). DJF precipitation changes in NSA and SAM are largely uncertain, with weak agreements in the projections, particularly for CMIP5 and CMIP6 ensembles, which project almost no change, and decreasing precipitation for NSA and a narrow range from slight increases to no change respectively for SAM.

Atlas.7.2.5 Summary

In summary, it is *virtually certain* that the climate of South America has warmed. Studies on climate trends in South America indicate that mean temperature and maximum and minimum temperatures have increased over the last 40 years. Long-term observed precipitation trends show an increase over South-Eastern South America and decreases in most tropical land regions (*high confidence*).

Evaluation of global and regional climate model simulations have increased over South America in the past decade and shown improved performance. However, the results reveal that no model performs well in simulating all aspects of the present climate (*very likely*). On the other hand, there is still a lack of high-quality and high-resolution observational data that may explain part of the important biases present in climate models (*high confidence*).

Climate model projections show a general increase in annual mean surface temperature over the coming century for all emissions scenarios (RCPs and SSPs) (*high confidence*), consistent with the observed warming, and with all regions except SSA warming faster than the global average. Unlike temperature, annual precipitation has patterns of decrease in North-Eastern South America (NES) and South-Western South America (SWS), and increase in Southern South America (SES) and North-Western South America (NWS)

(*high confidence*), with small changes projected under a low-emissions scenario. However, there is *low confidence* in the magnitude because of the large spread among models, both GCMs and RCMs.

Atlas.8 Europe

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Tables 11.16–11.18) and climatic impact-drivers in Chapter 12 (Table 12.7).

Atlas.8.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.8.1.1 Key Features of the Regional Climate

Westerly winds and the accompanying Atlantic storm track with cyclones and anticyclones travelling from the Atlantic towards inland Europe are the main climatic features that characterize daily to interannual variability in the European region. The Siberian High in winter determines cold weather in Eastern Europe and can affect other regions with cold outbreaks. Intra-seasonal and interannual variations are driven by modes of climate variability such as the North Atlantic Oscillation (NAO; Table Atlas.1 and Annex IV.2). Global warming can lead to systematic changes in regional climate variability via thermodynamic responses such as altered lapse rates (Kröner et al., 2017; Brogli et al., 2019) and land-atmosphere feedbacks (Zampieri and Lionello, 2011; Boé and Terray, 2014). Regional feedbacks involving the land-sea contrast, sea surface, land surface, clouds, aerosols, radiation and other processes modulate the regional response to enhanced warming.

Four climatic regions are defined for Europe (Figure Atlas.24). The Mediterranean region (MED) in the south is characterized by mild winters and hot and dry summers (Mediterranean climate; Section 10.6.4.2). It covers both Europe and Africa, and MED assessments in this section generally imply the entire MED domain unless stated otherwise. The Western and Central Europe region (WCE) has distinct summer and winter seasons with increasing continentality of climate eastwards. The Northern Europe region (NEU), close to the Atlantic Ocean, is characterized by high humidity and relatively mild winters, and strong exposure to the Atlantic storm track. Eastern Europe (EEU) covers the western part of Russia and neighbouring territories and has continental characteristics. Many regional datasets and model projections assessed here do not sufficiently cover the EEU region.

Atlas.8.1.2 Findings From Previous IPCC Assessments

The AR5 WGII (Kovats et al., 2014) reports with *high confidence* that observed climate trends show regionally varying changes in temperature and rainfall in Europe. The average temperature in Europe has continued to increase, with seasonally different rates of

warming being greatest in high latitudes in Northern Europe. Annual precipitation has increased in Northern Europe and decreased in parts of Southern Europe. The SROCC (Hock et al., 2019b) reports with *high confidence* that a reduction in snow cover at low elevation and glacier extent is observed in recent decades, with consequent changes in annual and seasonal runoff patterns. According to the SRCCL report (IPCC, 2019b) there is *high agreement* that observed vegetation greening and forestation in the last 30 years cools summer surface temperature and warms winter temperature due to decreased snow cover and increased snow shading in forested areas. It is *very likely* that aerosol column amounts have declined over Europe since the mid-1980s.

The AR5 (Collins et al., 2013) reports that the ability of models to simulate the climate in Europe has improved in many important aspects. Particularly relevant for this region are increased model resolution and a better representation of the land surface processes in many of the models that participated in CMIP5. The spread in climate model projections is still substantial, partly due to pronounced internal variability in this region (particularly NAO and AMO). In the winter half year, NEU and WCE are *likely* to have increased mean precipitation associated with increased atmospheric moisture and moisture convergence, and intensification in extratropical cyclone activity. No change or a moderate reduction is projected for MED. In the summer half year, it is *likely* that NEU and WCE mean precipitation will have only small changes with a notable reduction in MED. According to SR1.5 (Hoegh-Guldberg et al., 2018), these precipitation changes are more pronounced at 2°C than at 1.5°C of global warming. For a 2°C global warming level, an increase in runoff is projected for north-eastern Europe while decreases are projected in the Mediterranean region, where runoff differences between 1.5°C and 2°C global warming will be most prominent (*medium confidence*). According to SROCC (Hock et al., 2019b) the RCP8.5 projections lead to a loss of more than 80% of the ice mass from small glaciers by the end of century in Central Europe (*high confidence*). Snow cover and glaciers are projected to decrease throughout the 21st century.

Atlas.8.2 Assessment and Synthesis of Observations, Trends and Attribution

To support climatological analyses and model evaluation, national meteorological and hydrological services are increasingly making available high spatial and temporal resolution gridded and in situ homogenized and quality-checked datasets (Déqué and Somot, 2008; Vidal et al., 2010; Rauthe et al., 2013; Noël et al., 2015; Spinoni et al., 2015b; Ruti et al., 2016; Fantini et al., 2018; Lussana et al., 2018; Herrera et al., 2019; Skrynyk et al., 2020). The inclusion of additional station data and data rescue activities lead to a better representation of extreme precipitation statistics than the global- or continental-scale datasets (Atlas.1.4.1). Recent gridded products merging radar and station data allow higher spatial and temporal resolutions to be reached (Haiden et al., 2011; Tabary et al., 2012; Berg et al., 2016; Fumière et al., 2020). A number of regional reanalysis products has become available for the European region (Bollmeyer et al., 2015; Bach et al., 2016; Dahlgren et al., 2016; Landelius et al., 2016). A European ensemble of regional reanalyses from 1961 to 2019

is shown to add accuracy and reliability in comparison to global reanalysis products, but also introduces additional uncertainties, especially for threshold-based climate indices (Kaiser-Weiss et al., 2019). However, gridded European datasets are unreliable over data-sparse regions. Also, many datasets employ different approaches to interpolation and gridding, which adds to their uncertainty and complicates comparative evaluations (Fantini et al., 2018; Kotlarski et al., 2019; Berthou et al., 2020). For some sub-regions and performance metrics, differences between datasets have been shown to be of the same magnitude as errors in regional climate models (Prein et al., 2016; Prein and Gobiet, 2017; Fantini et al., 2018), but observational uncertainty is substantially reduced when datasets of similar nature and representativeness are used (Kotlarski et al., 2019).

In addition to the global display of observed temperature and precipitation trends in Figure Atlas.11, annual mean temperature and precipitation trends between 1980 and 2015 calculated from the gridded ensemble E-OBS dataset (Cornes et al., 2018) are shown in Figure Atlas.23, together with time series of temperature and precipitation anomalies relative to the 1980–2015 mean value from E-OBS, CRU, EWEMBI and Berkeley for temperature, and E-OBS, CRU, GPCC and GPCP for precipitation (see also Figure 2.11 for global mean values, and Atlas.1.4.1 for description of global datasets).

In NEU continued warming has been observed, particularly during spring. An annual mean temperature increase of 0.4°C per decade was reported between 1970 and 2008 (Rutgersson et al., 2015). In WCE temperature increases since the mid-20th century have been documented for Poland (Degirmendžić et al., 2004) and Ukraine (Boychenko et al., 2016; Balabukh and Malitskaya, 2017). Land-only observations indicate a rapid increase in summer (JJA) mean surface air temperature since the mid-1990s (Dong et al., 2017). In Eastern Europe no significant trend in winter mean air temperatures was found between 1881 and 2016 in Belarus (Loginov et al., 2018). In parts of the European area of the MED, spring and summer temperatures are reported to increase faster than in the other seasons (see the Mediterranean case study in Section 10.6.4 and Figure 10.18; Brunetti et al., 2006; Homar et al., 2009; Lionello et al., 2012; Philandras et al., 2015; Gonzalez-Hidalgo et al., 2016; Vicente-Serrano et al., 2017). Figure Atlas.23 shows that since 1980 in each European region all datasets show a consistent warming of annual mean temperature of $0.04^{\circ}\text{C yr}^{-1}$ to $0.05^{\circ}\text{C yr}^{-1}$. Trends in European land temperature cannot be explained without accounting for anthropogenic warming offset by anthropogenic aerosol emissions (Section 3.3.1.1 and Figure 3.9). It is *virtually certain* that annual mean temperature continues to increase in each European subdomain.

Multi-decadal trends in mean precipitation are generally small and non-significant. Apart from difficulties related to observational coverage (Prein and Gobiet, 2017), gauge undercatch (e.g., Murphy et al., 2020) and data inhomogeneity (e.g., Camuffo et al., 2013), strong interannual and multi-decadal variability is dominant over at least the last two centuries. However, significant precipitation trends have been recorded for recent periods, for example in south-western Europe between 1960 and 2000 (Peña-Angulo et al., 2020), and between 1961 and 2015 in NEU (Interactive Atlas). Also, some studies suggest that in the MED precipitation has declined and

more frequent and severe meteorological droughts have occurred between 1960 and 2000 (Spinoni et al., 2015a; Gudmundsson and Seneviratne, 2016), and in some regions cannot be explained without anthropogenic forcing (Section 10.4.1.2; Knutson and Zeng, 2018). Other studies suggest that this trend can be seen as an expression of multi-decadal internal variability driven mainly by the North Atlantic Oscillation (Table Atlas.1; Kelley et al., 2012; Zittis, 2018). Global dimming and brightening also are reported to affect precipitation trends in the Mediterranean region (Section 8.3.1.6 and Figure 8.7).

The large-scale spatial patterns of the E-OBS annual mean precipitation trend between 1980 and 2015 shown in Figure Atlas.23 is broadly consistent with trends derived from CRU, GPCC and GPCC (Figure Atlas.11) but with more explicit spatial detail. Trends calculated for regional averages are sensitive to the selection of the time window: for 1980–2015 annual mean precipitation averaged over the regions shows a positive trend (not significant at $p = 0.05$), while for CRU and GPCC the trend calculated over 1901–2015 is positive for NEU, EEU and WCE, and non-significant for MED. Precipitation trends in the MED are significant only in selected areas (Lionello et al., 2012; MedECC, 2020). Also the NEU trends show large spatial variability and are subject to decadal variability related to NAO (Heikkilä and Sorteberg, 2012), but are generally positive over the 20th century (Figure Atlas.23). There is *medium confidence* that annual mean precipitation in NEU, WCE and EEU has increased since the early 20th century. In the European Mediterranean, observed land precipitation trends show pronounced variability within the region, with magnitude and sign of trend in the past century depending on time period and exact study region (*medium confidence*).

Trends in snowfall and snowmelt are related to seasonal changes in both temperature and precipitation. In EEU, melt onset dates have advanced by one to two weeks in the 1979–2012 period (Mioduszewski et al., 2015). Over Eurasia, trends in spring and early summer snow cover extent increased over the 1971–2014 period (Hernández-Henríquez et al., 2015). Between 1966 and 2012, averaged over entire Eurasia, monthly mean snow depth decreased in autumn and increased in winter and spring (Zhong et al., 2018), while the snow cover extent was reported to have decreased during the past 40 years (Bulygina et al., 2011). In NEU late winter and early spring snow depth and snow cover decreases since the early 1960s are reported over Finland (Luomaranta et al., 2019) and Norway (Rizzi et al., 2018) with a dependence on altitude (Skaugen et al., 2012), while winter snow depth increased in northern Sweden (Kohler et al., 2006). It is *very likely* that since the early 1980s in snow-dominant areas in NEU and EEU the length of the snowfall season is reduced with regional warming, and the melt onset dates have advanced.

The increasing trend in surface shortwave radiation, documented in AR5 (Hartmann et al., 2013) to have occurred since the 1980s and referred to as a brightening effect, is substantiated over Europe and the Mediterranean region (Nabat et al., 2014; Sanchez-Lorenzo et al., 2015; Cherif et al., 2020). This increasing trend has been attributed to the decrease in anthropogenic sulphate aerosols over the 1980–2012 period (Nabat et al., 2014). In model sensitivity experiments, the aerosol trend has been quantified to explain $81 \pm 16\%$ of the European surface shortwave trend and $23 \pm 5\%$

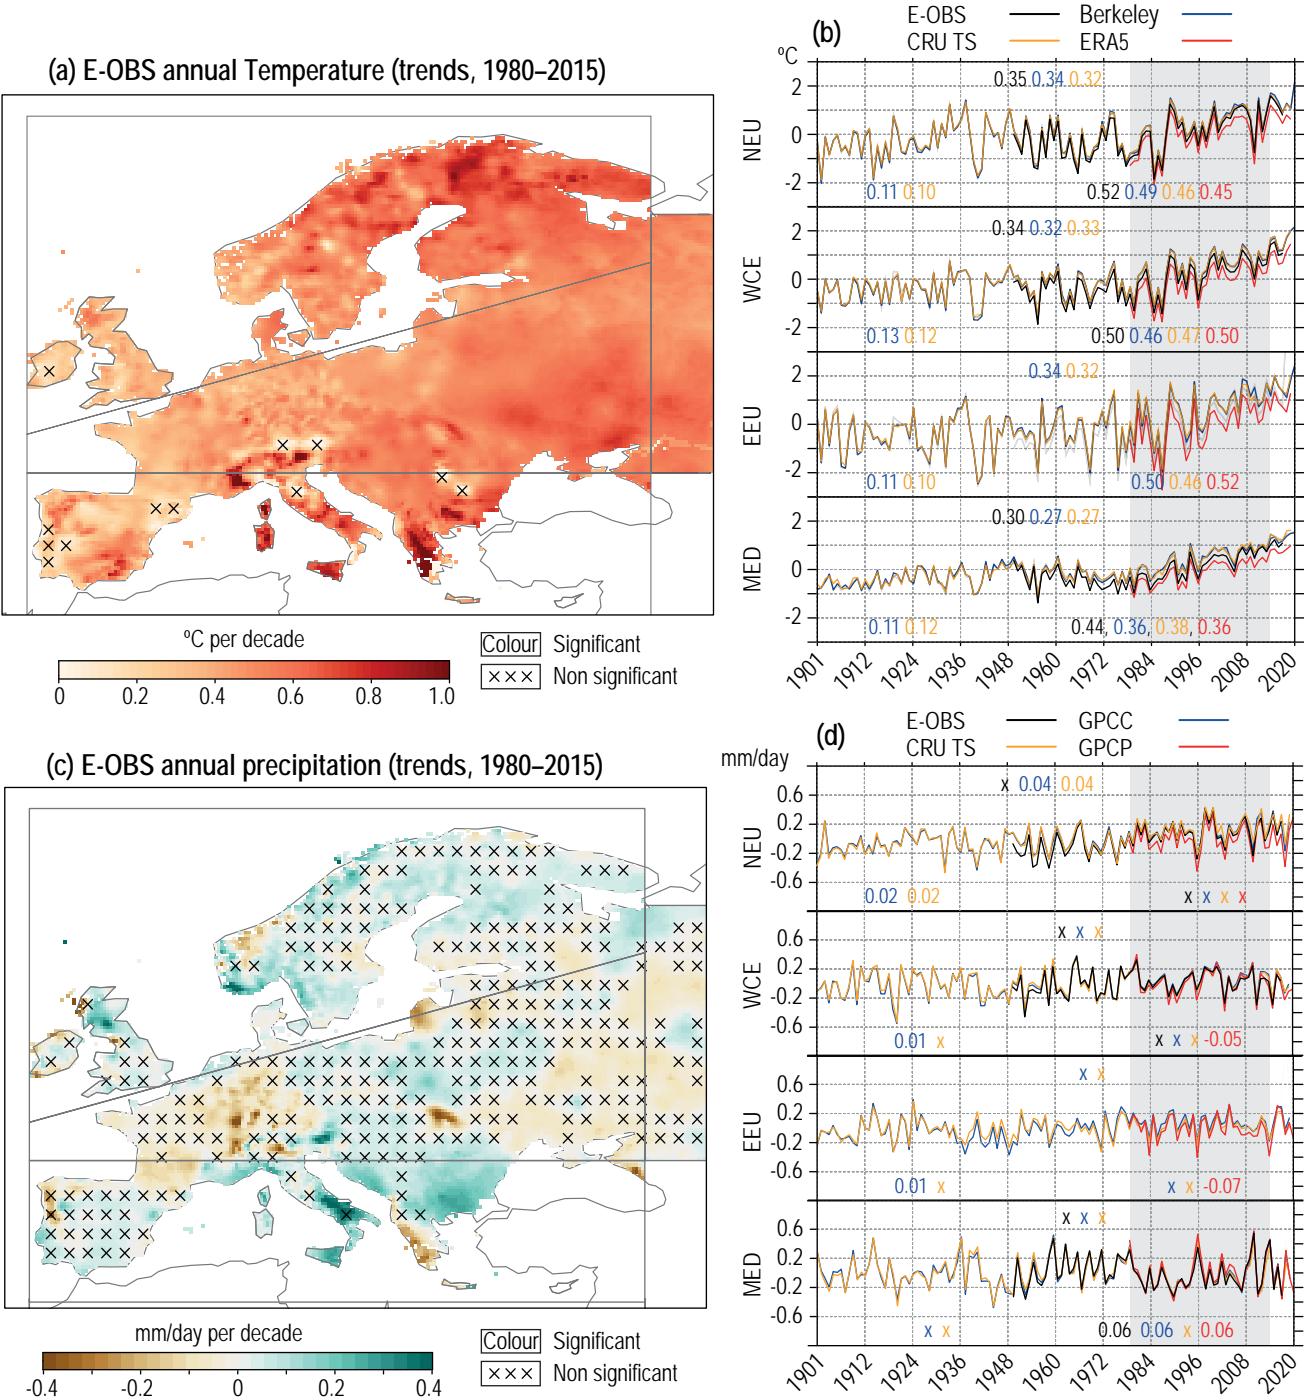

Figure Atlas.23 | (a) Mean 1980–2015 trend of annual mean surface air temperature (°C per decade) from E-OBS (Cornes et al., 2018). Data for non-European countries in the MED area are masked out. **(b)** Time series of mean annual temperature anomaly relative to the 1980–2015 period (shown with grey shading) aggregated for the land area in each of the four European sub-regions, from E-OBS, CRU, Berkeley and ERA5 (see Atlas.1.4.1 for description of global datasets). Mean trends for 1901–2015, 1961–2015 and 1980–2015 are shown for each dataset in corresponding colours in the same units as panel (a) (see legend in upper panel). **(c)** As panel (a) for annual mean precipitation (mm day⁻¹ per decade). **(d)** As panel (b) for annual mean precipitation, from datasets E-OBS, CRU, GPCP and GPCP. Note that E-OBS data are not shown in panels (b) and (d) for the region EEU. For the MED region data are aggregated over the European countries alone. Trends have been calculated using ordinary least squares regression and the crosses indicate non-significant trend values (at the 0.1 level) following the method of Santer et al. (2008) to account for serial correlation. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

of the European surface temperature warming. It is *likely* that trends in anthropogenic aerosols in Europe have generated positive trends in shortwave radiation and surface temperature since the 1980s (Sections 6.3.3.1, 8.3.1.6 and 10.6.4).

Assessments of observed European trends in meteorological extremes and CIDs are reported elsewhere in this report. Section 11.3.5 documents and attributes an increase in the frequency and extent of heatwaves and daily maximum temperatures, and Section 11.6.2

discusses the uncertainty concerning the detection of trends in meteorological droughts, and the role of increasing atmospheric evaporative demand on hydrological and ecological/agricultural droughts. Section 8.3.1.8 reports on increasing aridity trends in the Mediterranean related to soil moisture declines and increases in atmospheric water vapor demand. Section 11.4.2 reports on the increased likelihood and intensity of daily precipitation extremes, while Sections 11.5.2 and 12.4.5.2 discuss implications for peak streamflow. Section 12.4.5.5 discusses the increased likelihood of wildfires, while Section 12.4.5.3 discusses the substantial decadal variability in mean wind speed and the trends in wind storms and gusts. The acceleration of sea level rise in the Atlantic and European seas has been discussed in Section 12.4.5.5.

Atlas.8.3 Assessment of Model Performance

A global evaluation of annual mean temperature and precipitation from the CMIP6 ensemble is presented in Sections 3.3.1 and 3.3.2 respectively. In general, annual mean temperature is slightly underestimated at high latitudes and overestimated in the MED area. Temporal evolution of decadal temperature oscillations in Europe simulated by the CMIP6 historical simulations is well reproduced (Fan et al., 2020). Fernandez-Granja et al. (2021) report an overall improvement of CMIP6 compared to CMIP5 to reproduce atmospheric weather patterns over Europe.

Regional climate models (RCMs; Section 10.3.1.2) have been extensively evaluated for a range of climate features over Europe (Casanueva et al., 2016; Vaithinada Ayar et al., 2016; Krakovska et al., 2017; Terzago et al., 2017; Cavicchia et al., 2018; Drobinski et al., 2018; Fantini et al., 2018; Harzallah et al., 2018; Ivanov et al., 2018; Panthou et al., 2018a). Standard assessments of RCMs driven by reanalyses, typically run at 12–25 km spatial resolution, confirm that the Euro-CORDEX and Med-CORDEX ensembles are capable of reproducing the salient features of European climate (Kotlarski et al., 2014; Krakovska, 2018) and represent European circulation features realistically (Cardoso et al., 2016; Drobinski et al., 2018; Flaounas et al., 2018; Sanchez-Gomez and Somot, 2018). Seasonal and regionally averaged temperature biases generally do not exceed 1.5°C, while precipitation biases can be up to $\pm 40\%$ (Kotlarski et al., 2014). Extensive evaluation of a large collection of RCM–GCM combinations show a general wet, cold and windy bias compared to observations and reanalyses, but none of the models is systematically performing best or worst (Vautard et al., 2021). Higher-resolution simulations do show improved performance in reproducing the spatial patterns and seasonal cycle of not only extreme precipitation but also mean precipitation over all European regions (see Sections 10.3.3.4 and 10.3.3.5 for an extensive evaluation of the added value of increased simulation resolution; Mayer et al., 2015; Fantini et al., 2018; Soares and Cardoso, 2018; Ciarlo et al., 2021).

In line with findings reported in Section 10.3.3.8, several studies argue that both GCMs and RCMs underestimate the observed trend in European summer temperature (Dosio, 2016; Boé et al., 2020b), indicating that essential processes are missing or that the natural variability is not correctly sampled (Dell'Aquila et al., 2018).

Nabat et al. (2014) argued that including realistic aerosol variations enables climate models to correctly reproduce the summer warming trend (as is required for attributing continental annual temperature trends, Section 3.3.1.1). However, other studies showed models to be sensitive also to local effects, such as land surface processes, convection, microphysics and snow albedo (Vautard et al., 2013; Davin et al., 2016). In Euro-CORDEX the warm and dry summer bias over southern and south-eastern Europe is reduced compared to the previous ENSEMBLES simulations (Katragkou et al., 2015; Giot et al., 2016; Prein and Gobiet, 2017; Dell'Aquila et al., 2018). Natural variability has strongly affected the historical warming and large ensembles are necessary for a correct estimation of the forced signal versus natural variability (Aalbers et al., 2018; Lehner et al., 2020).

Specific assessments of convection-permitting RCMs (CPRCMs, running at a resolution of typically 1 to 3 km and designed for extreme precipitation characteristics) is undertaken in Section 10.3.3.4.1. A unique CPRCM ensemble has been applied over the great Alpine domain and improves representation of mean and extreme precipitation compared to coarser resolution models (Ban et al., 2021; Pichelli et al., 2021). The role of aerosol forcing is increasingly analysed as new and more realistic aerosol datasets become available (Nabat et al., 2013; Pavlidis et al., 2020), and as RCMs begin to include interactive aerosols (Nabat et al., 2012, 2015, 2020; Drugé et al., 2019). Explicitly accounting for aerosol effects in RCMs leads to improved representation of the surface shortwave radiation at various scales: long-term means (Gutiérrez et al., 2018), day-to-day variability (Nabat et al., 2015), and long-term trends (Nabat et al., 2014).

New, or updated, higher-resolution, coupled atmosphere-ocean-ice model systems have been found to improve simulations of observed climate features over the Baltic area compared to atmosphere-only model versions, including correlation between precipitation and SST, between surface heat-flux components and SST, and weather events like convective snow bands over the Baltic Sea (e.g., Tian et al., 2013; Van Pham et al., 2014; Gröger et al., 2015; S. Wang et al., 2015; Pham et al., 2017). Coupled atmosphere–land–river–ocean regional climate system models (RCSMs) from Med-CORDEX have similar skill as the ENSEMBLES and the Euro-CORDEX ensembles to represent decadal variability of Mediterranean climate and its extremes (Cavicchia et al., 2018; Dell'Aquila et al., 2018; Gaertner et al., 2018). Panthou et al. (2018a) showed that, over land, differences between atmosphere-only and coupled RCMs are confined to coastal areas that are directly influenced by SST anomalies. In contrast, Van Pham et al. (2014) showed significant differences in seasonal mean temperature across a widespread continental domain.

Statistical downscaling methods are assessed in Section 10.3.3.7, including the intercomparison and evaluation activities performed in the framework of VALUE and Euro-CORDEX over Europe.

Atlas.8.4 Assessment and Synthesis of Projections

Simulations from CMIP5 and CMIP6 indicate pronounced geographical patterns and scenario dependence of the projections of mean temperature and precipitation. Global warming projected under

SSP5-8.5 emissions in CMIP6 exceeds the warming projected by RCP8.5 emissions in CMIP5 (Section 4.3; Forster et al., 2020). In selected regions in Europe CMIP6 also projects a systematically higher mean temperature than CMIP5 (Seneviratne and Hauser, 2020). The annual mean projections from CMIP5, CMIP6 and 0.11° resolution EURO-CORDEX contained in the Interactive Atlas are shown for the four European regions in Figure Atlas.24. For each region and season a warming offset between the pre-industrial (1850–1900) and the recent past (1995–2014) baselines is also shown. The results confirm higher CMIP6 long-term annual mean warming rates for WCE, EEU and MED and a larger inter-model spread for each region. For given GWLs, regional annual mean temperature change in CMIP5 and CMIP6 are largely consistent and higher than the global average, most prominently in EEU. For high warming levels the CMIP5 subset of eight GCMs used to drive the EURO-CORDEX simulations show a lower annual mean temperature change than the full CMIP5 ensemble in each of the European sub-regions. This illustrates the large inter-model spread and implications for subsampling a relatively small subset from the full ensemble. Regional warming is strongest in continental EEU away from the Atlantic and in MED during summer (Lionello and Scarascia, 2018). The assessment of EURO-CORDEX projections for levels of global warming of 1.5°C and 2.0°C indicate enhanced local warming even at relatively low global warming levels, particularly towards the north in winter (Schaller et al., 2016; Dosio and Fischer, 2018; Kjellström et al., 2018; Teichmann et al., 2018).

Some signatures of climate change projected by GCMs are modified by RCMs and CPRCMs. Projections of temperature, precipitation and wind in RCMs may deviate from GCM signals dependent on the dominant atmospheric circulation (Kjellström et al., 2018). In many areas RCMs produce lower warming rates and higher precipitation (less drying) in summer (Fernández et al., 2019; Boé et al., 2020a). Also, for mean surface shortwave radiation, systematic differences between GCM and RCM outputs are found (Bartók et al., 2017; Gutiérrez et al., 2020). Although RCMs generally have a smaller bias for the present climate (Sørland et al., 2018) and better cloud representation (Bartók et al., 2017), the representation of aerosol forcing (Boé et al., 2020a; Gutiérrez et al., 2020), air-sea coupling (Boé et al., 2020a) or vegetation response to elevated atmospheric CO₂ (Schwingshackl et al., 2019) give rise to systematic biases in RCM projections. The comparison between EURO-CORDEX and the CMIP5 subset shown in Figure Atlas.24 illustrates that the RCMs primarily modify the climate change warming signal from the driving GCMs for MED and WCE in summer (Boé et al., 2020a).

Changes in precipitation clearly show a seasonal signature and a meridional gradient over Europe. Mean precipitation increases by 4–5% per °C of global warming in NEU, EEU and WCE in DJF, and decreases in summer in WCE and MED (Figure Atlas.24; Jacob et al., 2018). CMIP5 projections of precipitation change in MED are strongest in DJF in the south, while changes in JJA are dominant in the northern (European) part of MED (Lionello and Scarascia, 2018). The European north–south gradient in precipitation response is confirmed by the EURO-CORDEX experiment (Coppola et al., 2021a), but Figure Atlas.24 shows that the JJA precipitation reduction in WCE projected by CMIP5 and CMIP6 at higher warming levels has

low confidence in the CORDEX simulations. Precipitation in JJA in EEU is reduced in CMIP6, while little change is shown in CMIP5. Quantitative estimations of climate change features from regional climate projections in Eastern Europe (Partasenok et al., 2015; Kattsov et al., 2017) have *low confidence* due to the use of relatively small ensembles of GCMs and/or RCMs, and limited evaluation of model performance in the region.

Over specific geographic features such as high mountains, RCMs further modify the climate change signal of precipitation simulated by the low-resolution GCMs (Giorgi et al., 2016; Torma and Giorgi, 2020). This is especially true for summer precipitation over the Alps where opposite signs of changes in mean and extreme precipitation are generated by the CMIP5 GCM ensemble and the 12-km Med-CORDEX and EURO-CORDEX RCM ensembles (Section 10.6.4.7; Giorgi et al., 2016).

Regional warming is *virtually certain* to extend the observed downward trends in snow accumulation, snow water equivalent and length of the snow cover season in NEU and at low altitudes in mountainous areas in the Alps and Pyrenees (*very high confidence*). This is supported by regional and global multi-model and/or single-model ensemble projections including CMIP5, PRUDENCE, ENSEMBLES and EURO-CORDEX (Jylhä et al., 2008; Steger et al., 2013; Mankin and Diffenbaugh, 2015; Schmucki et al., 2015; Marty et al., 2017; Frei et al., 2018), and attributed to changes in the snowfall fraction of precipitation and to increased snowmelt. In mountain areas a strong dependence of projected snow trends on altitude is shown, with most pronounced effects below 1500 m (López-Moreno et al., 2009). Terzago et al. (2017) showed a large positive bias in the amplitude of the annual snow cycle of EURO-CORDEX 0.11° simulations driven by GCM projections, while reanalysis-driven RCMs showed good agreement with in situ observations.

Regional ocean warming in projections with RCSMs for the Baltic and North seas (Gröger et al., 2015) and for the Mediterranean (Darmaraki et al., 2019) is associated with increased intensity and frequency of marine heatwaves in the Mediterranean (Section 12.4.5.5), strong freshening in the Baltic, and, for some simulations, changes in the circulation in response to non-uniform changes in air-sea interaction (Dieterich et al., 2019). Med-CORDEX RCM and CMIP5 GCM results agree well on the Mediterranean SST warming rate (Mariotti et al., 2015; Darmaraki et al., 2019); see also the Interactive Atlas.

Assessments of projected changes in meteorological extremes and CIDs are reported elsewhere in this report. Extreme precipitation and temperature often exhibit a different response to global warming than mean values. Increased intensity and frequency of extreme temperatures and heatwaves is assessed in Sections 11.3.5 and 12.4.5.1. Changes in the hydrological cycle include enhanced soil moisture decline in southern Europe, drying in summer and autumn in Central Europe, and spring drought due to early snowmelt in Northern Europe (Sections 8.4.1, 11.6.5 and 12.4.5.2). Changes in mean and extreme wind are very uncertain (Section 12.4.5.3), while sea level rise will increase the frequency of occurrence of extreme sea level at most European coasts (Section 12.4.5.5).

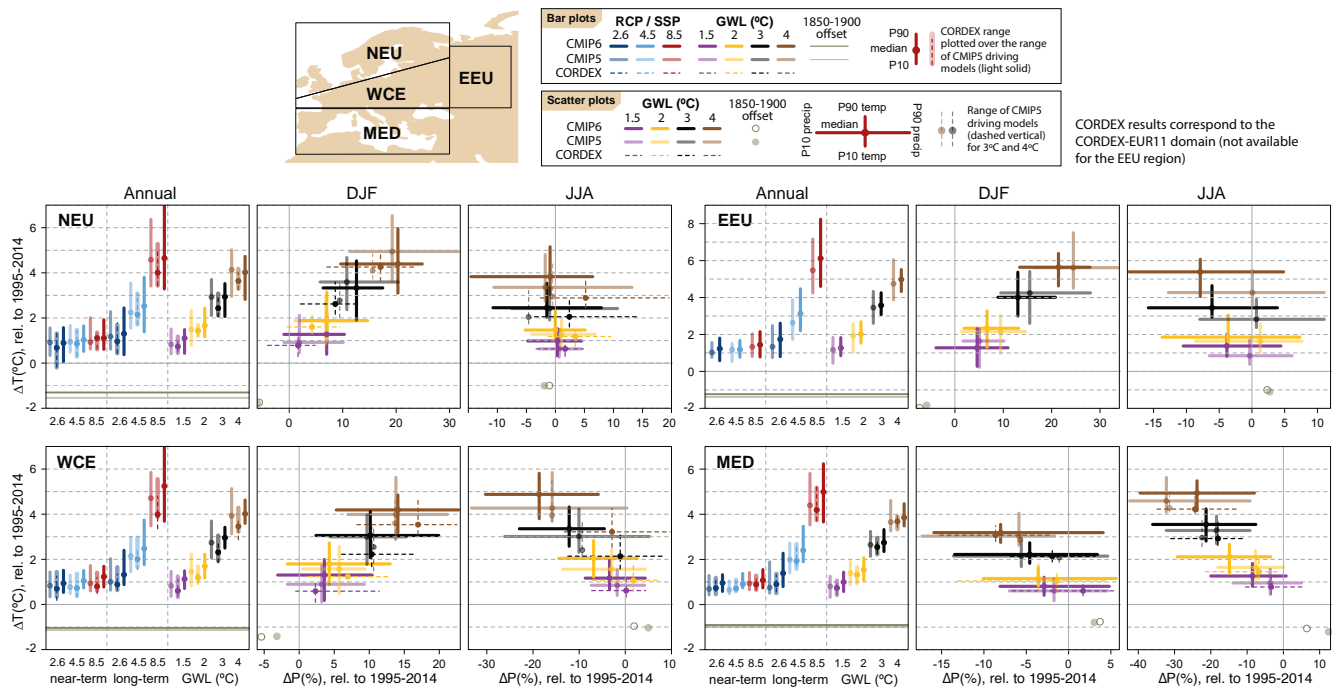

Figure Atlas.24 | Regional changes over land in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Europe (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWs: 1.5°C, 2°C, 3°C and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Atlas.8.5 Summary

An assessment of recent literature largely confirms the findings of previous IPCC reports but with additional detail and (in some cases) higher confidence due to improvements in observations, reanalyses and methods. Observational datasets with global coverage are complemented by the E-OBS gridded ensemble temperature and precipitation dataset, a range of regional observational analyses, and regional reanalysis products. New RCM experiments, including CPRCMs and regional coupled climate system models, mostly coordinated under the umbrella of CORDEX, have generated many new projections and process studies.

The representation of mean European climate features by GCMs and RCMs is improved compared to previous IPCC assessments (*medium confidence*), in spite of persisting biases in annual mean and seasonal temperature and precipitation characteristics. The added value of regional downscaling of GCMs by RCM projections for summer mean temperature, precipitation and shortwave radiation is constrained by the representation of processes that lead to a systematic difference between RCM and driving GCM, such as aerosol forcing (*medium confidence*).

It is *virtually certain* that annual mean temperature continues to increase in each European region. There is *medium confidence* that annual mean precipitation in NEU, WCE and EEU has increased since the early 20th century. In the European Mediterranean trends in annual mean precipitation contain substantial spatial and temporal variability (*medium confidence*). It is *very likely* that since the early 1980s in snow-dominated areas in NEU and EEU the length of the snowfall season is reduced with regional warming, and the melt onset dates have advanced. It is *likely* that decreasing trends in anthropogenic aerosols in Europe have generated positive trends in shortwave radiation and surface temperature since the 1980s.

At increasing levels of global warming, there is *very high confidence* that temperature will increase in all European areas at a rate exceeding global mean temperature increases, while increased mean precipitation amounts at high latitudes in DJF and reduced JJA precipitation in southern Europe will occur with *medium confidence* for global warming levels below 2°C, and with *high confidence* for higher warming levels. At high latitudes and low-altitude mountain areas in Europe strong declines in snow accumulation are *virtually certain* to occur with further increasing regional temperatures (*very high confidence*).

Atlas.9 North America

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow) for North America, including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Tables 11.19–21) and climatic impact-drivers in Chapter 12 (Table 12.8).

Atlas.9.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.9.1.1 Key Features of the Regional Climate

The recent-past climate of North America is characterized by high spatial heterogeneity and by variability at diverse temporal scales. Considering the traditional Köppen-Geiger classification, North America covers all main climate types (see reference region descriptions below). Important geographical features influence local climates over various distances, like the Rocky Mountains through cyclogenesis (Grise et al., 2013) and the Great Lakes through lake-effect snowfall (Wright et al., 2013). The cryosphere is an important component of the climate system in North America, with fundamental roles for sea ice cover, snow cover and permafrost. The ocean surrounding the continent also influences its climate, with water temperatures strongly influencing hurricane activity which impacts the coasts of eastern Mexico and south-eastern USA (Walsh et al., 2010). Temporal variability is influenced by several large-scale atmospheric modes (Table Atlas.1 and Annex IV) with the North Atlantic Oscillation (NAO) affecting north-eastern USA and eastern Canada precipitation (Whan and Zwiers, 2017), and El Niño–Southern Oscillation (ENSO) affecting temperature and precipitation in California, although in a complex and not yet fully understood manner (Yoon et al., 2015; Yeh et al., 2018).

The reference regions defined for summarising North America climate change (Figure Atlas.26) include: North-Western North America (NWN), characterized by a sub-Arctic climate with cool summers and rainfall all year round; North-Eastern North America (NEN), which also has a sub-Arctic climate with sections of tundra climate in the far north (these two northern regions are also discussed in Section Atlas.11.2, Polar Arctic); Western North America (WNA), which has a complex but mainly cold semi-arid climate; Central North America (CNA) with a mainly continental climate in the northern part of the region and a humid subtropical climate in the southern portion; Eastern North America (ENA) with a humid continental climate in the northern half and a humid subtropical climate to the south; Northern Central America (northern Mexico; NCA), has a temperate climate to the north of the Tropic of Cancer, with marked differences between winter and summer, modulated by the North American Monsoon (Peel et al., 2007).

Atlas.9.1.2 Findings From Previous IPCC Assessments

The IPCC AR5 (Bindoff et al., 2013; Hartmann et al., 2013) found that the climate of North America has changed due to anthropogenic

causes (*high confidence*), in particular with primarily increasing annual precipitation and annual temperature (*very high confidence*). Assessment of CMIP5 ensemble projections concluded that mean annual temperature over North America and annual precipitation north of 45°N will *very likely* continue to increase in the future. Also, CMIP5 projects increases in winter precipitation over Canada and Alaska and decreases in winter precipitation over the south-western USA and much of Mexico.

The CMIP5 multi-model ensemble generally reproduces the observed spatial patterns but somewhat underestimates the extent and intensity of the North American Monsoon, and also underestimates wetting over Central North America over the period of 1950–2012 during the winter season according to AR5 (Flato et al., 2013). In the long term (2081–2100), the largest changes of precipitation over North America are projected to occur in the mid- and high latitudes and during winter (Kirtman et al., 2013).

The SR1.5 (Hoegh-Guldberg et al., 2018) reported a stronger warming compared to the global mean over Central and Eastern North America, and a weakening of storm activity over North America under 1.5°C of global warming. The SROCC (Hock et al., 2019b) reported that snow depth or mass is projected to decline by 25% mainly at lower elevations over the high mountains in Western North America. The SRCLL (Mirzabaev et al., 2019) observed vegetation greening in Central North America with *high confidence*.

Atlas.9.2 Assessment and Synthesis of Observations, Trends, and Attribution

The observed trends in annual mean surface temperature (Figure Atlas.11 and the Interactive Atlas) across near-Arctic latitudes are exceptionally pronounced (>0.5°C per decade), significant and consistent across datasets except for far north-east Canada where trends are not significant in the CRU dataset. Significant positive trends are seen across the rest of North America during 1961–2015 (Figure Atlas.11) though over the shorter 1980–2015 period the regional dataset Daymet (Thornton et al., 2016) records non-significant changes over southern Alaska, western and south-central Canada, and north-central USA (Interactive Atlas). An analysis of annual mean surface temperature in the Berkeley Earth dataset aggregated over the reference regions (Figure Atlas.11) demonstrates that a temperature change signal has emerged over all regions of North America. There is a detectable anthropogenic influence (*medium confidence*) on the observed upward annual temperature trends in Western and northern North America (Vose et al., 2017; Z. Wang et al., 2017; Smith et al., 2019).

Compared to temperature, trends in annual precipitation over 1961–2015 are generally non-significant though there are consistent positive trends over parts of ENA and CNA (Figure Atlas.11 and Daymet, Interactive Atlas) (*high confidence*). The global and regional datasets in Figure Atlas.11 and the Interactive Atlas also indicate significant decreases in precipitation in parts of south-western USA and north-western Mexico (Figure 2.15) though these are not all spatially coherent so there is only *medium confidence* in a drying trend over this region.

Several factors account for the differences in temperature and precipitation trend significance. Observed trends in precipitation are relatively modest compared to the very large natural interannual variability of precipitation. Furthermore, the precipitation observing network is spatially inadequate (Section 10.2.2.3) and temporally inconsistent (Section 10.2.2.2) over some regions of North America, particularly over the Arctic and mountainous areas. So detection of multi-decadal trends is difficult, especially for regions with summer convective precipitation maxima that may be spatially patchy (Easterling et al., 2017). See Section 2.3 for further discussion of precipitation trends.

There is evidence of a recent decline in the overall North American annual maximum snow mass, with a trend for non-alpine regions above 40°N during 1980–2018 estimated from the bias-corrected GlobSnow 3.0 data (*medium confidence*) (Pulliainen et al., 2020). This is despite technical challenges with in situ measurements and remote-sensing retrievals of snow variables (Larue et al., 2017; Smith et al., 2017; X.L. Wang et al., 2017; Zeng et al., 2018), spatial heterogeneity and interpolation assumptions that affect gridded reference products, notably over alpine and forested areas (Mudryk et al., 2015; Dozier et al., 2016; Cantet et al., 2019), and breaks in instruments and procedures (Kunkel et al., 2007; Mortimer et al., 2020). Changes in snow cover have evolved in a complex way, with both positive and negative trends, and differing from one metric to another (Knowles, 2015; Brown et al., 2019). Evidence of snow cover decline includes decreases in annual maximum snow depth and in snow water equivalent (Vincent et al., 2015; Kunkel et al., 2016; Mote et al., 2018), as well as a shortening of the snow-season duration (Knowles, 2015; Vincent et al., 2015). However, reported snow-decline trends are statistically significant only for a fraction of the concerned areas or locations (*low confidence*) (Figure Atlas.25). See also Sections 2.3.2.2 and 9.5.3.1.

Rupp et al. (2013) applied a standard fingerprinting approach to CMIP5 models and determined that the decline in Northern Hemisphere spring snow cover extent could only be explained by simulations that included natural and anthropogenic forcing. In an attribution study focusing on direct physical causes, it was found that increased

spring snowmelt in northern Canada was driven by warming-induced high-latitude changes such as atmospheric moisture, cloud cover, and energy advection (Mioduszewski et al., 2014).

In an analysis of drivers of the record low snow water equivalent (SWE) values of spring 2015 in the western USA, it was found that the relative importance of greenhouse gases varies spatially (Mote et al., 2016). See also Section 3.4.2 for further discussion of anthropogenic influences on snow extent.

Atlas.9.3 Assessment of Model Performance

CMIP6 models have been evaluated in the literature, although these studies have not included the full set of CMIP6 simulations. Fan et al. (2020) established on a continental basis for North America that temperature pattern correlations were quite accurate. Thorarindottir et al. (2020) compared maximum and minimum temperatures over Europe and North America with several observational datasets and found that the CMIP6 ensemble agreed better with ERA5 data than did CMIP5. Srivastava et al. (2020) evaluated historical CMIP6 simulations for precipitation, comparing them with several observational datasets over the continental US. Most models show a wet bias over the eastern half of the continental USA and the north-east region, while dry biases persist in the central part of the country (Akisanola et al., 2020a; Almazroui et al., 2021). The spatial structure of biases is similar in CMIP5 and CMIP6, but with lower magnitudes in CMIP6. Agel and Barlow (2020) examined 16 CMIP6 models over the north-eastern USA for precipitation and did not find a distinct improvement over CMIP5, although they did find the higher-resolution models tended to perform better. On the basis of the evidence so far, there is *medium confidence* that CMIP6 models are improved compared to CMIP5 in terms of biases in mean temperature and precipitation over North America.

North America has been extensively used as a test bed for regional climate model (RCM) experiments, such as the North American Regional Climate Change Assessment Program (NARCCAP; Mearns et al., 2009), the MultiRCM Ensemble Downscaling (MRED;

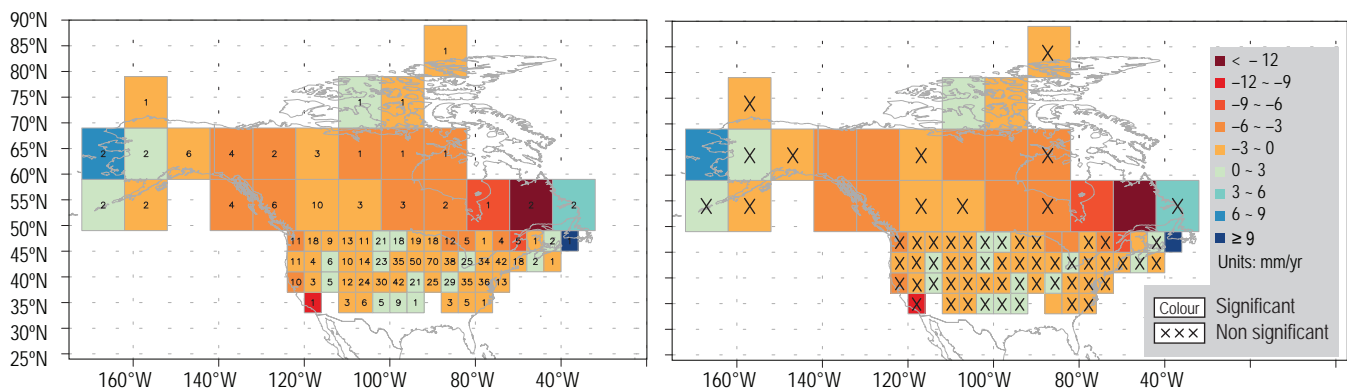

Figure Atlas.25 | Grid-box trends (mm yr^{-1}) in annual maximum snow depth for cold-season periods of 1960/1961 to 2014/2015 in North America. (Left) Numbers indicate number of stations available in that grid box. **(Right)** Boxes with 'x' indicate non-significant trends (at the $p < 0.05$ level of significance; Kunkel et al., 2016).

Yoon et al., 2012), and NA-CORDEX (Bukovsky and Mearns, 2020). Therefore, much performance evaluation has been conducted with a focus on specific climate features in North America. For the North American Monsoon region, multi-model performance evaluation (Bukovsky et al., 2013; Tripathi and Dominguez, 2013; Cerezo-Mota et al., 2016) or a single-member performance (Lucas-Picher et al., 2013; Martynov et al., 2013; Šeparović et al., 2013) demonstrated the added value of RCMs, particularly more recent CORDEX simulations, through improved simulation of summer precipitation and the climatological winter storm tracks across the western USA. NA-CORDEX simulations were more successful at reproducing weather types compared to a single model-based large perturbed-physics ensemble (Prein et al., 2019). The application of a complex evaluation tool to the full suite of NA-CORDEX simulations found that the higher-resolution simulations (25 km compared with 50 km) of precipitation were improved, particularly for daily intensity (Gibson et al., 2019).

However, deficiencies have also been reported. For example, excessive storm occurrence over the east coast of North America was found (Poan et al., 2018), and amplitude in the simulated annual cycle was generally excessive in NA-CORDEX simulations. RCMs tend to produce more (less) precipitation over mountains (the coastal plains; Cerezo-Mota et al., 2016) and winter precipitation in the western USA had large positive biases in all RegCM simulations, regardless of the driving GCM (Mahoney et al., 2021).

Recently, convective-permitting RCMs have been used to simulate North American climate features and generated better simulations of precipitation. For example, summer precipitation over the south-western USA was improved due to better representation of organized mesoscale convective systems at the sub-daily scale (Castro et al., 2012; Liu et al., 2017; Prein et al., 2017a; Pal et al., 2019), the diurnal cycle of convection (Nesbitt et al., 2008), and in terms of means (and extremes) for the north-eastern USA (Komurcu et al., 2018).

Recent studies have examined RCMs' simulation of SWE, a quantity of primary importance notably for hydrological modelling, though its ground measurements are restricted by relatively high time and monetary costs (Smith et al., 2017; Odry et al., 2020) which limit model assessment. Also, studies often emphasize that a false impression of model skill for SWE can be obtained by compensating temperature and precipitation biases. Assessment frameworks have dealt with these issues by considering observational uncertainty (Mccrory et al., 2017) and by decomposing SWE biases into their contributing processes (Rhoades et al., 2018; Xu et al., 2019). SWE biases exceed observational uncertainty in several 50-km reanalysis-driven NARCCAP simulations over several regions, for all cold months (Mccrory et al., 2017). Analyses of NA-CORDEX simulations show that refining spatial resolution from 50 to 12 km improves certain (but not all) aspects of SWE, stemming from improved mean precipitation and topography-related temperature (Xu et al., 2019). Similarly an assessment of RCM simulations of freezing rain over eastern Canada found a mix of improved and deteriorated aspects from higher resolution (St-Pierre et al., 2019).

Atlas.9.4 Assessment and Synthesis of Projections

CMIP5 and CMIP6 surface temperature and precipitation projections over the region are similar, with all regions warming more than the global average, most prominently those in the north (Figure Atlas.26). CMIP6 projects, for all scenarios and time periods, higher temperature changes (Chapter 4), with this contrast more accentuated in the long-term future and at higher global warming levels. The higher warming in the north (Interactive Atlas) is clear when comparing NEN, with increases from 2°C to over 8.5°C on an annual basis for SSP5-8.5 (near term to long term compared to a 1995–2014 baseline), to NCA, where changes range from 1.5°C to 6°C across the same periods. Maps showing changes in temperature and precipitation, and their robustness, are available in the Interactive Atlas. The number of model results (i.e., ensemble size used to generate these figures) differs, and this sample size difference may affect the results, but the patterns and magnitudes of change are generally consistent and thus it is *very likely* that temperatures will increase throughout the 21st century in all land areas, with stronger warming in the far north.

CMIP5 results have been analysed extensively (e.g., Maloney et al., 2014) and used in major climate change assessments. The most recent US National Climate Assessment analysis of CMIP5 focusing on RCP4.5 and RCP8.5 for two future time periods stated that the USA would continue to warm regardless of the scenario, but is *likely* to be higher with higher-emissions scenarios (e.g., RCP8.5). Projected changes in precipitation are somewhat complex, but increased precipitation dominates in winter and spring, whereas in summer changes are more variable and uncertain. Canada's Changing Climate Report (Bush and Lemmen, 2019) presents changes in temperature and precipitation, as well as other variables, such as snow, for future periods in Canada using results from CMIP5. It indicates that annual and winter precipitation is projected to increase everywhere in Canada over the 21st century with larger percentage increases in the north. Temperature is also projected to increase, regardless of the scenario, and with larger changes occurring in the north.

To provide the basis for generating additional information compared to that derived from CMIP5 the NA-CORDEX experiments were designed to involve a GCM-RCM matrix which included multiple GCMs that sampled the full range of climate sensitivity, multiple RCMs, at two different spatial resolutions (25 and 50 km) and a range of emissions scenarios (in most cases RCP4.5 and RCP8.5; Mearns et al., 2017). Karmalkar (2018) noted that the NA-CORDEX models cover sub-regional ranges of temperature change from the CMIP5 GCMs better than NARCCAP did for the CMIP3 models. This structural design shift provides greater confidence in the NA-CORDEX results in terms of sampling the uncertainty across the CMIP5 models (Figure Atlas.27; Bukovsky and Mearns, 2020). The pattern of warming is as seen in CMIP5 and CMIP6, which also builds confidence that the RCMs generate high-resolution results consistent with CMIP5 on large scales whilst providing added value over regions such as the complex topography of the Rocky Mountains in the western USA, which are not well resolved in the GCMs. There is *high confidence* that downscaling a subset of CMIP models that spans the range of climate sensitivities in the full ensemble is critical for producing a representative range of dynamically downscaled projections.

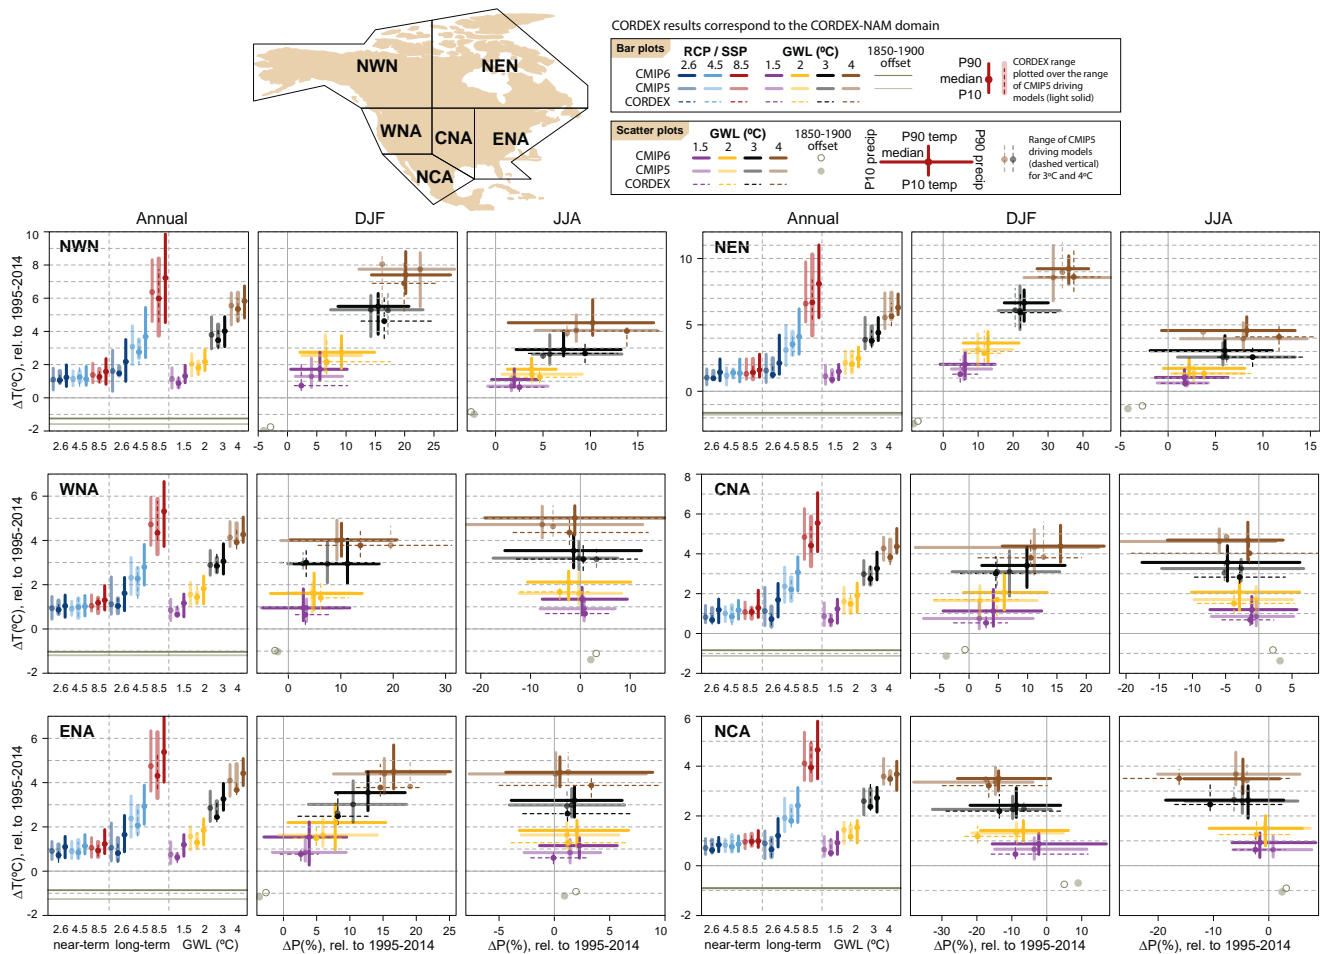

Figure Atlas.26 | Regional changes over land in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in North America (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWLs: 1.5°C, 2°C, 3°C and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

There are striking contrasts in the seasonal results for precipitation for the sub-regions (Figure Atlas.26). The northern regions and ENA all show steady increases with the global warming levels (*very high confidence*). For example, the projected increases in the NEN region range from 7% in the near term to 40% at the end of the 21st century for the SSP5-8.5 scenario. In contrast, projected changes for NCA are for significant decreases both on an annual basis (Interactive Atlas) and in winter, and which become greater as warming increases (Akisanola et al., 2020b; Almazroui et al., 2021). The other two regions (WNA and CNA) exhibit mainly increases in winter. In summer, distributions are in general less uniform except for NWN and NEN, which display steady increases with global warming levels (but smaller than in winter). WNA and CNA mainly show decreases (based on the median values) but with some models

projecting increases. Projections from the NA-CORDEX ensemble are consistent with those from the GCMs whilst providing greater detail of precipitation changes over the mountains and along the coasts (Interactive Atlas; Bukovsky and Mearns, 2020). Similar results are found in other analyses of RCM projections (Wang and Kotamarthi, 2015; Ashfaq et al., 2016; Teichmann et al., 2021). Also, further analysis of the NA-CORDEX projections showed substantial changes in weather types related to increased monsoonal flow frequency and drying of the northern Great Plains in summer (Prein et al., 2019).

In summary, NEN, NWN and most of ENA will *very likely* experience increased annual mean precipitation, with greater increases at higher levels of warming (*very high confidence*). In NCA decreases predominate on an annual basis and particularly in winter

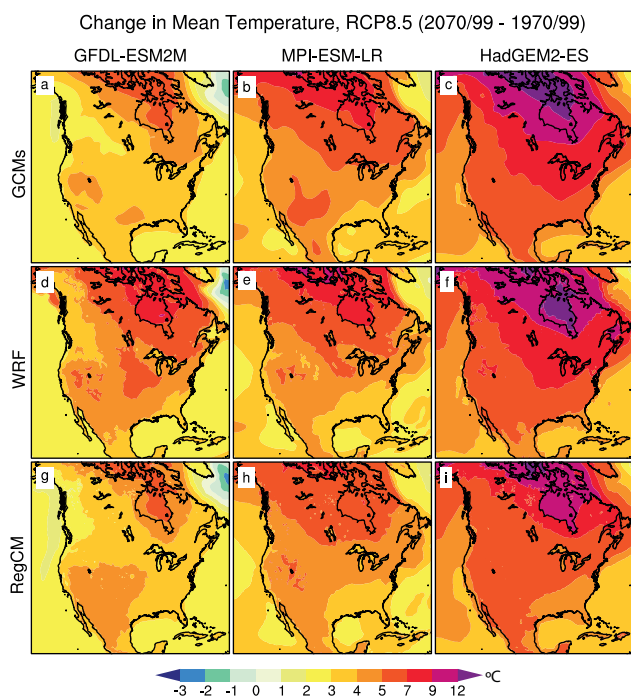

Figure Atlas.27 | Changes (2070–2099 relative to 1970–1999) in the annual mean surface air temperature by three GCMs (GFDL-ESM2M, MPI-ESM-LR, HadGEM2-ES) and two RCMs (WRF and RegCM4) nested in the GCMs, for the RCP8.5 scenario over North America (after Bukovsky and Mearns, 2020).

(*high confidence*). Projected changes in summer are highly uncertain throughout other regions apart from the far northern parts of NEN and NWN which will *likely* experience increases (*high confidence*).

As discussed in Section 10.3.3.4, an important advance in regional modelling over the past decade or so is the use of convection-permitting regional models (CPMs; Prein et al., 2015, 2017a). There have been a number of experiments using CPMs over North America (e.g., Rasmussen et al., 2014; Prein et al., 2015, 2019; Liu et al., 2017; Komurcu et al., 2018). A CPM study over North America that investigated changes in Mesoscale Convective Systems projected that by the end of the century, assuming an RCP8.5 scenario, their frequency more than tripled and associated precipitation increased by 80% (Prein et al., 2017b). A multiple nesting of WRF over the north-eastern USA, downscaling to 3 km a CESM GCM climate projection assuming an RCP8.5 scenario, found a different pattern of precipitation change of mixed increases and decreases compared to the GCM projection of increases every month (Komurcu et al., 2018). These investigations demonstrate the potential of very-high-resolution simulations to add important dimensions to our understanding of regional climate change, though not necessarily to reduce uncertainty (*high confidence*).

It is *virtually certain* that snow cover will experience a general decline across North America during the 21st century, in terms of extent, annual duration and SWE, based on CMIP5 (Maloney et al., 2014), CMIP6 (Mudryk et al., 2020), NA-CORDEX (Mahoney et al., 2021) and NARCCAP (e.g., McCrary and Mearns, 2019) simulations. For some regions the decline could be discernible over the next few decades,

for example in the western USA (Fyfe et al., 2017). It is, however, *likely* that some high-latitude regions will rather experience an increase in certain winter snow cover properties (Mudryk et al., 2018; McCrary and Mearns, 2019), due to snowfall increase (Krasting et al., 2013) prevailing over the warming effect. Discussion of changes in snow in the future is also covered in Section 9.5.3, but for larger regions.

The fraction of precipitation falling as snow is projected to decrease practically everywhere over North America, including over the western USA and south-western Canada (Mahoney et al., 2021), and in the Great Lakes basin where lake-effect precipitation is important (Suriano and Leathers, 2016). In this basin, the frequency of heavy lake-effect snowstorms is expected to decrease during the 21st century, except for a possible temporary increase around Lake Superior by mid-century, if local air temperatures remain low enough (Notaro et al., 2015). CMIP5 simulations of the periods 1981–2000 and 2081–2100 over the central and eastern USA suggest a northward shift in the transition zone between rain-dominated and snow-dominated areas, by about 2° latitude under the RCP4.5 scenario and 4° latitude under the RCP8.5 scenario (Ning and Bradley, 2015). Rain-on-snow event properties over North America should also evolve during the 21st century, with non-trivial dependencies on the positioning relative to the freezing line (Jeong and Sushama, 2018) and on elevation (Musselman et al., 2018).

Atlas.9.5 Summary

Across North America it is *very likely* that positive surface temperature trends are persistent. Across near-Arctic latitudes of North America, increases are exceptionally pronounced, greater than 0.5°C per decade (*high confidence*). In parts of Eastern and Central North America it is *likely* that annual precipitation has increased over the period 1961–2015 but with no clear trends in other regions except for parts of the south-western USA and north-western Mexico where there is *medium confidence* in drying.

Model representation of the climatology of mean temperature and precipitation has *likely* improved compared to AR5 over North America. This is aided by continuous model development, and the existence of new coordinated modelling initiatives such as NA-CORDEX. There is *high confidence* that downscaling a subset of CMIP models that spans the range of climate sensitivities in the full ensemble is critical for producing a representative range of dynamically downscaled projections.

It is *virtually certain* that annual and seasonal surface temperatures over all of North America will continue to increase at a rate greater than the global average, with greater increases in the far north. It is *very likely*, based on global and regional model future projections, that on an annual time scale precipitation will increase over most of North America north of about 45°N and in Eastern North America, and it is *likely* that it will decrease in the south-western USA and northern Mexico, particularly in winter. Elsewhere the direction of change of precipitation is uncertain. It is *virtually certain* that snow cover will experience a decline over most regions of North America during the 21st century, in terms of water equivalent, extent and

annual duration. It is, however, *likely* that some high-latitude regions will rather experience an increase in winter SWE, due to the snowfall increase prevailing over the warming effect.

Atlas.10 Small Islands

The assessment in this section focuses on changes in average temperature and precipitation for the main Small Islands regions, including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Sections 11.3.2, 11.4.2, 11.7.1.5 and, for the Caribbean, Tables 11.13–15) and of changes in climatic impact-drivers in Chapter 12 (Section, 12.4.7 and Table 12.9).

Atlas.10.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.10.1.1 Key Features of the Regional Climate

Many small islands lie in tropical regions and their climate varies depending on a range of factors with location, extent and topography having major influences. In general, their climate is determined by that of the broader region in which they lie as they have little influence on the regional climate, although steep topography can induce higher rainfall totals locally. Temperature variability tends to be low due to the influence of the surrounding ocean, most marked in the tropics where oceanic temperature ranges are small. However, seasonal rainfall variability can often be significant, both through the annual cycle and also interannually through the influence of many modes of variability (Cross-Chapter Box Atlas.2.; Annex IV and Atlas.7.1 for the Caribbean). Many small islands are exposed to tropical cyclones and the associated hazards of high winds, storm surges and extreme rainfall, and many low-lying islands are exposed to regular flooding from natural high-tide and wave activity. In the Pacific, phases of the El Niño–Southern Oscillation result in periods of warmer or cooler than average temperatures following the upper ocean warming of El Niño events or cooling of La Niña events, and respectively weaker and stronger trade winds. El Niño conditions also lead to drought in Melanesian islands and increased tropical cyclones and storm surges in French Polynesia with La Niña conditions causing drought in Kiribati. Other islands experience increased rainfall during these periods.

Atlas.10.1.2 Findings From Previous IPCC Assessments

The AR5 noted observed temperature increases of 0.1°C–0.2°C per decade in the Pacific Islands and that warming was *very likely* to continue across all Small Islands regions (Christensen et al., 2013; IPCC, 2013a). It also reported decreased rainfall over the Caribbean, increases over the Seychelles, streamflow reductions over the Hawaiian Islands and projections of reduced rainfall over the Caribbean and drier rainy season for many of the south-west Pacific Islands (Christensen et al., 2013; IPCC, 2013a; Nurse et al., 2014). The remaining findings are derived from the SROCC (IPCC, 2019a).

Ocean warming rates have *likely* increased in recent decades with marine heatwaves increasing and *very likely* to have become longer-lasting, more intense and extensive as a result of anthropogenic warming. Open ocean oxygen levels have *very likely* decreased and oxygen minimum zones have *likely* increased in extent. There is *very high confidence* that global mean sea level rise has accelerated in recent decades which, combined with increases in tropical cyclone winds and rainfall and increases in extreme waves, has exacerbated extreme sea level events and coastal hazards (*high confidence*). It is *virtually certain* that during the 21st century, the ocean will transition to unprecedented conditions with further warming and acidification *virtually certain*, increased upper ocean stratification *very likely* and continued oxygen decline (*medium confidence*). There is *very high confidence* that marine heatwaves and *medium confidence* that extreme El Niño and La Niña events will become more frequent. It is *very likely* that these changes will be smaller under scenarios with low greenhouse gas emissions. Global mean sea level will continue to rise and there is *high confidence* that the consequent increases in extreme levels will result in local sea levels in most locations that historically occurred once per century occurring at least annually by the end of the century under all RCP scenarios (*high confidence*). In particular, many small islands are projected to experience historical centennial events at least annually by 2050 under RCP2.6 and higher emissions. The proportion of Category 4 and 5 tropical cyclones, and associated precipitation rates and storm surges, along with average tropical cyclone intensity are projected to increase with a 2°C global temperature rise, thereby exacerbating coastal hazards.

Atlas.10.2 Assessment and Synthesis of Observations, Trends and Attribution

Significant positive trends in temperature ranging from 0.15°C per decade (over the period 1953–2010) to 0.18°C per decade (over the period 1961–2011) are noted in the tropical western Pacific, where the significant increasing and decreasing trends in warm and cool extremes, respectively, are also spatially homogeneous (Jones et al., 2013; Whan et al., 2014; Wang et al., 2016). Similarly, much of the Caribbean region showed statistically significant warming (at the 95% level) over the period 1901–2010 (P.D. Jones et al., 2016b). Observation records in the Caribbean region indicate a significant warming trend of 0.19°C per decade and 0.28°C per decade in daily maximum and minimum temperatures, respectively, with statistically significant increases (at the 5% level) in the number of warm days and warm nights during 1961–2010 (M.A. Taylor et al., 2012; Stephenson et al., 2014; Beharry et al., 2015).

A weather station-based annual precipitation trend analysis over 1901–2010 in the Caribbean region indicated some locations with detectable decreasing trends (Knutson and Zeng, 2018), which were attributable in part to anthropogenic forcing. These include southern Cuba, the northern Bahamas, and the Windward Islands, although significant trends were not found over the shorter periods of 1951–2010 and 1981–2010. In the Caribbean islands, a dataset of the Palmer Drought Severity Index (PDSI) from 1950 to 2016 showed a clear drying trend in the region (Herrera and Ault, 2017). The 2013–2016 period showed the most severe drought during the

period and was strongly related to anthropogenic warming, which would have increased the severity of the event by 17% and its spatial extent by 7% (Herrera et al., 2018). However, a seasonal analysis of observations grouped into large sub-regions of the Caribbean revealed no significant long-term trends in rainfall over 1901–2012 but significant inter-decadal variability (P.D. Jones et al., 2016b). Declines in summer rainfall (–4.4% per decade) and maximum five-day rainfall (–32.6 mm per decade) over 1960–2005 were reported for Jamaica (CSGM, 2012), and an insignificant decrease in summer precipitation was observed for Cuba for 1960–1995 (Naranjo-Díaz and Centella, 1998). Three of four stations examined for Puerto Rico exhibited declining JJA rainfall over 1955–2009 with the trend statistically significant at the 95% level for Canóvana (Méndez-Lázaro et al., 2014). In the Caribbean, positive regional trends in precipitation and trends in extremes during 1961–2010 were found to be not statistically significant (at the 5% level; Stephenson et al., 2014; Beharry et al., 2015). Positive trends in JJA rainfall over Cuba and Jamaica are seen in CRU, whereas they are negative over Cuba for GPCC; over eastern Hispaniola they are positive in CRU and negative in CHIRPS (Cavazos et al., 2020).

In Hawaii, between 1920 and 2012, over 90% of the islands showed reduced rainfall and streamflow, an increase in the frequency of days with zero flow (Strauch et al., 2015; Frazier and Giambelluca, 2017), and robust positive trends in drought frequency and severity (McGree et al., 2016). Over the western Pacific, interannual and decadal variabilities also drive long-term trends in rainfall. Recent analysis of station data showed spatial variations in the mostly decreasing but non-significant trends in annual and extreme rainfall over the western Pacific from 1961 to 2011 (*low confidence*) (McGree et al., 2014). Over the southern subtropical Pacific, decreases in annual, JJA, SON and extreme rainfall, and increasing drought frequency in the western region, has been observed since 1951 (Jovanovic et al., 2013; McGree et al., 2016, 2019).

Over the western Indian Ocean significant warming trends have been reported for Mauritius (1.2°C during 1951–2016; MESDDBM, 2016), La Réunion (0.18°C per decade over 1968–2019; Météo-France, 2020) and Maldives (MEE, 2016). Both Mauritius and La Réunion have experienced rainfall decreases of 8% during 1951–2016 and 1.2% per decade during 1961–2019 with generally weak, non-significant rainfall trends during 1967–2012.

Assessing observed climate change for Small Islands is often constrained by low station density (Ryu and Hayhoe, 2014; P.D. Jones et al., 2016a), digitization requirements or data-sharing limitations (P.D. Jones et al., 2016a). Station data typically have longer temporal coverage relative to satellite products but are limited in spatial coverage (Cavazos et al., 2020). For Small Island nations, spatial gaps between observations can be very large due to the isolation of the islands (Wright et al., 2016). Additionally, over past decades, the number of station observations has declined substantially in Mauritius (Dhurmea et al., 2019), Hawai'i (Bassiouni and Oki, 2013; Frazier and Giambelluca, 2017) and most Pacific Island countries since the 1980s (Jones et al., 2013; McGree et al., 2014, 2016). In Fiji, meteorological stations were located on or by the coast and are sparse in the interior (Kumar et al., 2013). Notable

topography and land use may result in changes in climatic conditions over small distances (Foley, 2018), making the observational density particularly relevant.

Moreover, many stations have little metadata available, including those in Vanuatu, the Solomon Islands and Papua New Guinea (Whan et al., 2014). Compared to earlier decades, few metadata are currently being documented in the western Pacific islands (McGree et al., 2014), which will challenge the homogenization of long-term observational records. Challenges in the Caribbean include maintaining continuous daily time series with metadata, converting climatological data into digital formats and making them freely available (Stephenson et al., 2014; Beharry et al., 2015; P.D. Jones et al., 2016a). This is also an issue in the Pacific as many data are kept in national (local) databases, with only a fraction having been incorporated into global datasets (Whan et al., 2014).

Because of the small number of stations used for interpolation and the complex mountainous topography, gridded product for these small islands should be interpreted with caution (Frazier and Giambelluca, 2017). For the Antilles, the error in estimating CRU2.0 monthly precipitation can stand locally between 20% and 40%. Over the Caribbean, Cavazos et al. (2020) found a discrepancy across gridded observational datasets (CRU, CHIRPS and GPCP) in detecting orographic precipitation, especially during boreal summer, making their use in climate model evaluation challenging (Herrera and Ault, 2017). Furthermore, some reanalysis products such as the $0.7^\circ \times 0.7^\circ$ ERA-Interim reanalysis are not adequate as many of the smaller Caribbean islands are not represented as land (P.D. Jones et al., 2016a).

Atlas.10.3 Assessment of Model Performance

An assessment of model performance for the Caribbean region is contained in Atlas.7.1 on Central America. In summary, the ability of climate models to simulate the climate over the region has improved in many key respects with the application of increased model resolution and a better representation of the land surface processes of particular importance in these advances (*high confidence*). Regional climate models (RCMs) simulate realistically seasonal surface temperature and precipitation patterns including the bimodal rainfall in the precipitation annual cycle although with some timing biases in some regions (*high confidence*). The important regional circulation and precipitation features, the Caribbean low-level jet and the midsummer drought (MSD), are well represented over a variety of RCM domains covering the region (*high confidence*).

Over the tropical Pacific, surface temperature biases in CMIP6 models remain similar to those in CMIP5, although are reduced in the higher-resolution models in the HiResMIP ensemble. CMIP6 models generally represent trends in sea surface temperatures better than CMIP5 (see Section 9.2.1 for more details). For precipitation, the persistent tropical Pacific bias of the double ITCZ (erroneous bands of excessive rainfall both sides of the equatorial Pacific) is still present in CMIP6 models although is slightly improved compared to those in CMIP3 and CMIP5 models (Section 3.3.2.3). Application of downscaling

techniques (RCMs and stretched-grid GCMs) using resolutions finer than 10 km over the Pacific can capture topographic influences on wind and rainfall to generate realistic simulations of island climates – for example over Fiji and New Caledonia (Chattopadhyay and Katzfey, 2015; Duteil et al., 2019). In both cases applying bias adjustment to the sea surface temperatures used as a lower boundary condition for the downscaling models was important to generate realistic simulations.

Atlas.10.4 Assessment and Synthesis of Projections

Projected median temperature increases for Small Islands from the CMIP5 ensemble range from 1°C (RCP4.5) to 1.5°C (RCP8.5) in the period 2046–2065, and from 1.3°C (RCP4.5) to 2.8°C (RCP8.5) by 2081–2100 relative to 1986–2005 (Harter et al., 2015). Spatial variations in the warming trend are projected to increase by the end of the 21st century, with relatively higher increases in the Arctic

CMIP5 – Precip. change (%) for JJA 2081-2100 (RCP8.5), rel. to 1995-2014

CMIP6 – Precip. change (%) for JJA 2081-2100 (SSP5-8.5), rel. to 1995-2014

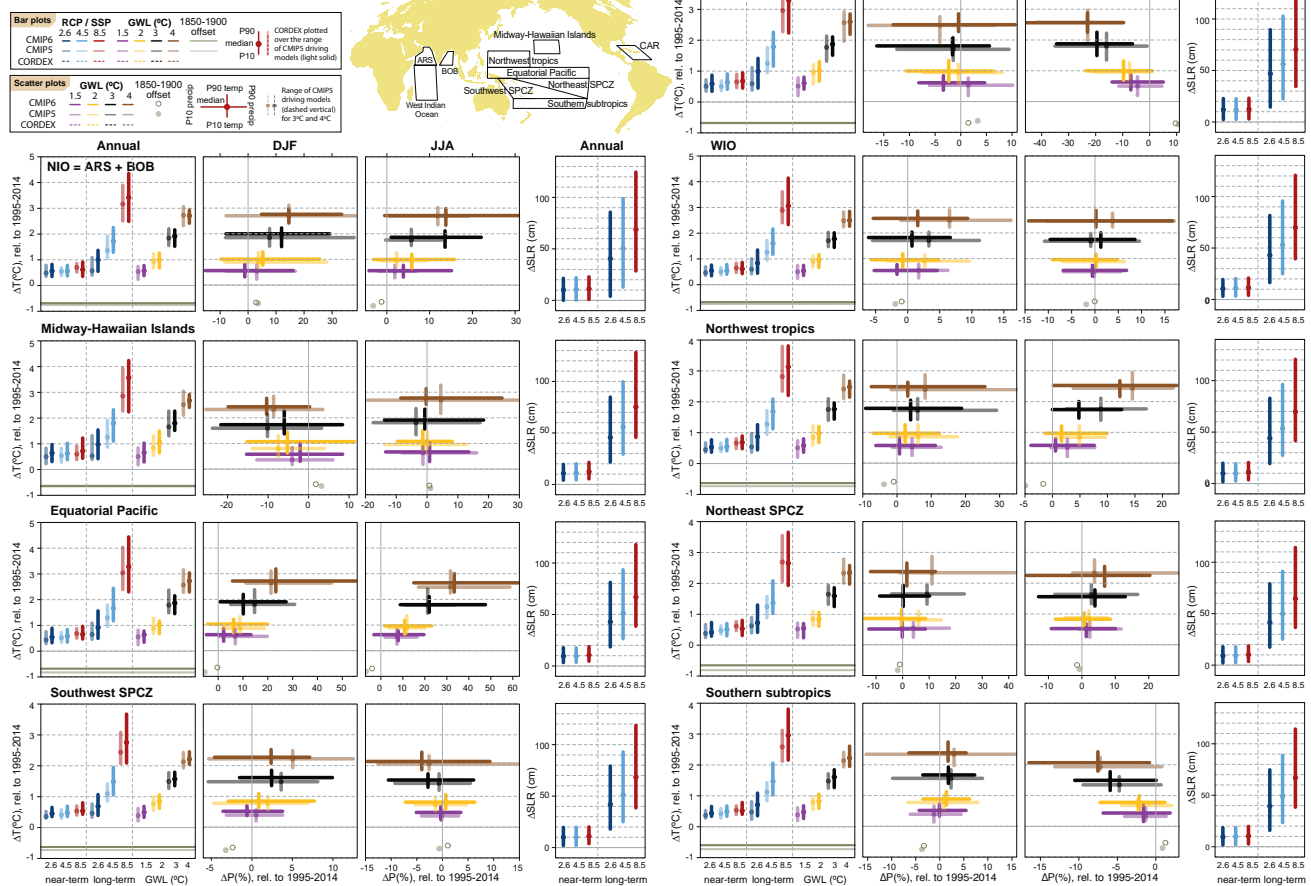

Figure Atlas.28 | Regional mean changes in annual mean surface air temperature, precipitation and sea level rise relative to the 1995–2014 baseline for the reference regions in the Small Islands (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Maps on the top show global June–July–August (JJA) precipitation changes (% relative to 1995–2014) projected for 2081–2100 under RCP8.5 (left) and SSP5-8.5 (right) for the CMIP5 and CMIP6 ensembles, respectively. Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWs: 1.5°C, 2°C, 3°C and 4°C). Bar plots in the right panel show the median (dots) and 5th–95th percentile range (bars) sea level rise from the CMIP6 ensemble (see Chapter 9 for details) for the same time periods and scenarios. The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

and sub-Arctic islands, and in the equatorial regions compared with islands in the Southern Ocean (Harter et al., 2015). In the western Pacific, temperatures are projected to increase by 2.0°C–4.5°C by the end of the 21st century relative to 1961–1990 (Wang et al., 2016). The warming over land in the Lesser Antilles is estimated to be about 1.6°C (3.0°C) by 2071–2100 for the RCP4.5 (RCP8.5) scenario, relative to 1971–2000 (Cantet et al., 2014). Projections from the CMIP6 ensemble support these findings (Figure Atlas.28) and across global warming levels from 1.5°C to 4°C CMIP5 and CMIP6 consistently project lower levels of warming for Small Islands than the global average (Interactive Atlas).

The CMIP5 ensemble median projected precipitation decreases of up to –16% over the Caribbean, parts of the Atlantic and Indian oceans, and the southern subtropical and eastern Pacific Ocean, and increases of up to 10% over parts of the western Pacific and Southern oceans, and up to 55% in the equatorial Pacific Islands under RCP6.0 in the period 2081–2100 relative to 1986–2005 (Harter et al., 2015). A projected decrease in annual precipitation is also noted over the Lesser Antilles under the RCP4.5 and RCP8.5 scenarios (Cantet et al., 2014). Seasonal rainfall is projected to decrease in most areas in Hawaii, except for the climatically wet windward side of the mountains, which would increase the wet to dry gradient over the area (Timm et al., 2015). The average precipitation changes in Hawaii are estimated to be about –11% to –28% under RCP4.5 during the wet season, and about –4% to –28% under RCP4.5 during the dry season in the period 2041–2071 relative to 1975–2005, with larger changes under RCP8.5 (Timm et al., 2015). There are still uncertainties in the projected changes, which have been attributed to factors including insufficient model skill in representing topography in the small islands, and high variability in climate drivers. However, the broad-scale pattern of projected wetter conditions in the western and equatorial Pacific, and the north Indian and Southern oceans, and of drier conditions over the Caribbean, and in parts of the Atlantic, Indian and southern subtropical and eastern Pacific oceans are further strengthened in the CMIP6 ensemble (Figure Atlas.28), which are thus *likely* regional responses as the climate continues to warm.

The negative trend in future summer rainfall in the Caribbean and Central America is projected to be strongest during midsummer

(June–August) based on studies using GCMs (Rauscher et al., 2008; Karmalkar et al., 2013; Karmacharya et al., 2017a; Taylor et al., 2018). The future summer drying over the Caribbean is associated with a projected future strengthening of the Caribbean low-level jet (Taylor et al., 2013a). Rauscher et al. (2008) hypothesized that the simulated 21st-century drying over Central America represents an early onset and intensification of the MSD. The westward expansion and intensification of the NASH associated with the MSD occurs earlier with stronger low-level easterlies. Rauscher et al. (2008) further suggested that the eastern Pacific ITCZ is also located further southward and that there are some indications that these changes could be forced by ENSO-like warming of the tropical eastern Pacific and increased land-ocean heating contrasts over the North American continent. Other studies also suggest a future intensification of the NASH due to changes in land-sea temperature contrast resulting from increased greenhouse-gas concentrations (W. Li et al., 2012).

Atlas.10.5 Summary

It is *very likely* that all Small Island regions have warmed with significant trends recorded from at least the 1960s in all territories or nations. Trends include increases of 0.15°C–0.18°C per decade in the tropical western Pacific (1953–2011), significant warming over the Caribbean (1901–2010) with trends of 0.19°C (0.28°C) per decade in daily maximum (minimum temperatures) (1961–2010) and in La Réunion of 0.18°C per decade (1968–2019). There are fewer significant trends in precipitation in these regions though several locations in the Caribbean have detectable decreasing trends (*high confidence*), in part attributable to anthropogenic forcing (*limited evidence*). Also, it is *likely* that drying has occurred since the mid-20th century in some parts of the western Indian Ocean, and in the Pacific poleward of 20° latitude in both the northern and southern hemispheres.

It is *very likely* that Small Island regions will continue to warm in the coming decades at a level slightly lower than the global mean. Small Island regions in the western and Equatorial Pacific, north Indian and Southern oceans are *likely* to be wetter in the future; and those in the Caribbean, parts of the Atlantic and west Indian oceans, and the southern subtropical and eastern Pacific Ocean drier.

Cross-Chapter Box Atlas.2 | Climate information relevant to water resources in Small Islands

Coordinators: Tannecia Stephenson (Jamaica), Faye Abigail Cruz (The Philippines)

Contributors: Donovan Campbell (Jamaica), Subimal Ghosh (India), Rafiq Hamdi (Belgium), Mark Hemer (Australia), Richard G. Jones (United Kingdom), James Kossin (United States of America), Simon McGree (Australia/Fiji), Blair Trewin (Australia), Sergio M. Vicente-Serrano (Spain)

Constructing regional climate information for Small Islands involves synthesis from multiple sources. This cross-chapter box presents information relevant to water resources, drawing on several chapters in AR6 and Atlas.10. It introduces the context and current evidence base followed by an assessment of trends and projections in rainfall, temperature and sea levels across Small Islands and it highlights key findings.

Regional context

Small Islands are predominantly located in the Pacific, Atlantic and Indian oceans, and in the Caribbean (Nurse et al., 2014; Shultz et al., 2019). They are characterized by their small physical size, being surrounded by large ocean expanses, vulnerability to natural disasters and extreme events, and relative isolation (Section 12.4.7, Atlas.10 and Glossary; Nurse et al., 2014). These and nearby larger islands (e.g., Madagascar and Cuba) are often water-scarce with low water volumes due to increasing demand (from population growth and tourism), aging and poorly designed infrastructure (Burns, 2002), and decreasing supply (from pollution, changes in precipitation patterns, drought, saltwater intrusion, regional sea level rise, inadequate water governance (Belmar et al., 2016; Mycoo, 2018) and competing and conflicting uses (Section 8.1.1.1; Cashman, 2014; Gheuens et al., 2019). In the Caribbean, groundwater is the main freshwater source and depends strongly on rainfall variability (Post et al., 2018), while rain, ground or surface water are the primary sources for the Pacific Islands depending on island type (volcanic or atoll), size and quality of groundwater reserves (Burns, 2002). Groundwater pumping and increasing sea levels also affect water availability by increasing the salinity of the aquifer (e.g., Bailey et al., 2015, 2016), thus reinforcing negative drought effects from reduced rainfall and increased evaporative demand from higher temperatures. For example, in 54% of the Marshall Islands, groundwater is highly vulnerable to droughts (Barkey and Bailey, 2017).

The climate of Small Islands and findings from previous IPCC assessments

Intra-seasonal to interannual rainfall in the Caribbean and in the Indian and Pacific oceans is influenced by the trade winds, the passage of tropical cyclones (TCs), Madden–Julian Oscillation (MJO), easterly waves, migrations of the Inter-tropical Convergence Zone (ITCZ) and the North Atlantic Subtropical High (NASH) for the Caribbean; the South Pacific Convergence Zone (SPCZ) and western North Pacific summer monsoon for the Pacific; and the South Asian monsoons for the Indian Ocean. The relevant dominant modes of climate variability (Section 8.3.2.9 and Annex IV) are El Niño–Southern Oscillation (ENSO) and the Indian Ocean Dipole (IOD) which have been associated with extreme events in the islands (Annex IV; Stephenson et al., 2014; Kruk et al., 2015; Frazier et al., 2018). The modes of climate variability are modulated by Pacific Decadal Variability (PDV), Inter-decadal Pacific Oscillation (IPO) and Atlantic Multi-decadal Variability (AMV). These modes show no sustained trend since the late 19th century (*high confidence*) (Section 2.4).

The AR5 WGI reports observed temperature increases of 0.1°C–0.2°C per decade in the Pacific Islands with these trends *very likely* to continue under high emissions, and projects a drier rainy season for many islands in the south-west Pacific (Christensen et al., 2013). The AR5 WGII reports rainfall reductions over the Caribbean, increases over the Seychelles, streamflow reductions over the Hawaiian Islands and saltwater intrusion into groundwater reserves in the Pacific Islands resulting from storm surges and high tides (Nurse et al., 2014). The SROCC (IPCC, 2019a) finds *very high confidence* that global mean sea level rise has accelerated in recent decades which has exacerbated extreme sea level events and flooding (*high confidence*). It will continue to rise with consequent increases in extreme levels so that the historical one-in-a-century extreme local sea level will become an annual event by the end of the century under all RCP scenarios (*high confidence*). In particular, many Small Islands are projected to experience historical centennial events at least annually by 2050 under RCP2.6, RCP4.5 and RCP8.5 emissions. The proportion of Category 4 and 5 TCs and associated precipitation rates along with their average intensity are projected to increase with a 2°C global temperature rise which will further increase the magnitude of resultant storm surges and flooding. The SROCC Cross-Chapter Box on Low-lying Islands and Coasts (Magnan et al., 2019) focused on sea level rise and oceanic changes and their impacts, therefore the assessment presented here on climate changes relevant to water resources, including precipitation and temperature, is complementary.

Observations and attribution of changes

Cross-Chapter Box Atlas.2: presents an overview of observed sub-regional trends relevant to water resources in some Small Islands and island regions largely from 1951. Some general observed climate trends include higher magnitude and frequency of temperatures including warm extremes (*high confidence*) (Section 12.4.7.1, Table 11.13 and Atlas.10.2), declines in high-intensity rainfall events (*low to medium confidence*) (Table 11.14), regional sea level rises with strong storm surges and waves resulting in increased coastal flood intensity (*high confidence*) (Section 12.4.7.4 and Atlas.10.2), and increased intensity and intensification rates of tropical cyclones at global scale (*medium confidence*) (Sections 11.7.1.2 and 12.4.7.3) and ocean acidification (*virtually certain*) (Chapters 2, 6 and 9, and Atlas.3.2).

No significant long-term trends are observed for annual Caribbean rainfall over the 20th century (*low confidence*) (Atlas.10.2). Over the western Pacific, generally decreasing but non-significant trends are noted in annual total rainfall from 1961 to 2011 (*low confidence*) (Atlas.10.2). June–July–August (JJA) rainfall over the Caribbean shows some drying tendencies that may be linked to the combined effect of warm ENSO events and a positive NAO phase (Giannini et al., 2000; Méndez-Lázaro et al., 2014; Fernandes et al., 2015), or to warm ENSO events and a positive PDV (Maldonado et al., 2016). However, the work of Herrera et al. (2018) suggests that anthropogenic influences may also be possible, although mechanisms proposed to date have not decoupled the influence of anthropogenic trends from natural decadal variability (Vecchi et al., 2006; Vecchi and Soden, 2007; DiNezio et al., 2009).

Cross-Chapter Box Atlas.2 (continued)

Cross-Chapter Box Atlas.2, Table 1 | Summary of observed trends for Small Island regions. SLR = sea level rise; TC = tropical cyclone; SPCZ = South Pacific Convergence Zone.

Region	Sub-region	Temperature	Rainfall	Other
Caribbean	Whole Caribbean	<i>High confidence</i> in increased frequency of hot extremes (Table 11.13)	<i>Low confidence</i> of increase in drought intensity during 1950–2016 and in the attribution of the 2013–2016 drought (Herrera and Ault, 2017; Herrera et al., 2018)	
	Jamaica, Cuba, Puerto Rico		<i>Low confidence</i> in declining JJA rainfall (CSGM, 2012) and a decreasing trend in Puerto Rico 1955–2009 (Méndez-Lázaro et al., 2014). Mixed trends 1980–2010 (Cavazos et al., 2020)	No attributable JJA rainfall trends 1951–2010 (Knutson and Zeng, 2018)
	Eastern Caribbean		<i>Low confidence</i> in an increase in periods of drought since 1999 (Van Meerbeeck, 2020)	<i>Medium confidence</i> in SLR of 1–2.5 mm yr ⁻¹ since 1950 (Van Meerbeeck, 2020)
Pacific	Midway – Hawaiian Islands	<i>High confidence</i> in the increase in mean temperature since 1917 and stronger increase in minimum temperature since 1905 (Keener et al., 2018; McKenzie et al., 2019; Kagawa-Viviani and Giambelluca, 2020)	<i>Medium confidence</i> in rainfall decreasing since 1920, drought frequency and severity increasing since 1951 and exceptional aridity since 2008 (McGree et al., 2016; Frazier and Giambelluca, 2017; X. Luo et al., 2020) <i>Low confidence</i> in extreme rainfall increasing (Kruk et al., 2015)	<i>Medium confidence</i> in relative SLR of 2.1 mm yr ⁻¹ (Mokuoloe Is. and Honolulu, Oahu Is.) over 1993–2017
	North-west tropics		<i>Low confidence</i> in JJA and SON total and extreme rainfall decreasing, increasing drought in east Micronesia and marginal increase in rainfall for western islands since 1951 (Kruk et al., 2015; McGree et al., 2019)	<i>Low confidence</i> in decrease in total TC numbers. Depends on dataset/period (Choi and Cha, 2015; Lee et al., 2020) <i>Medium confidence</i> in relative SLR of 2.8 mm yr ⁻¹ (Majuro, Marshall Is.) over 1994–2015 (Ford et al., 2018)
	Equatorial Pacific	<i>High confidence</i> in the increase in mean and extreme temperature at most locations since 1951 (Whan et al., 2014; McGree et al., 2019)	<i>Low confidence</i> in increasing annual and JJA extreme rainfall, decreasing consecutive dry days in the central region since 1951 (McGree et al., 2019) and increasing DJF total rainfall (BOM and CSIRO, 2014)	<i>Low to medium confidence</i> in relative SLR of 5.3 (Nauru) and 0.8 (Kanton, Kiribati) mm yr ⁻¹ over 1993–2015 (Albrecht et al., 2019; Martínez-Asensio et al., 2019)
	South-west SPCZ		<i>Low confidence</i> in decreasing SON total rainfall, increasing JJA and SON extreme rainfall and fewer consecutive wet days in western region since 1951 (BOM and CSIRO, 2014; McGree et al., 2019)	
	North-east SPCZ		<i>Low confidence</i> in change in mean and extreme rainfall at most locations since 1951 (Keener et al., 2012; McGree et al., 2016, 2019)	
	North-east SPCZ		<i>Low confidence</i> in change in mean and extreme rainfall at most locations since 1951 (BOM and CSIRO, 2014; McGree et al., 2016, 2019)	
	Southern subtropics		<i>Medium confidence</i> in annual, JJA and SON total and extreme rainfall decreasing and increasing drought frequency in western region since 1951 (Jovanovic et al., 2013; McGree et al., 2016, 2019) <i>Low confidence</i> in annual, SON, DJF and MAM total and extreme rainfall decreasing, increases in drought, JJA rain days and consecutive dry days in south-west French Polynesia since 1951 (McGree et al., 2016, 2019)	<i>Low confidence</i> in shift in mean SPCZ position since 1911 (Salinger et al., 2014) <i>Medium confidence</i> in increase in relative SLR of 1.7–7.7 mm yr ⁻¹ across southern Pacific Islands over period 1993–2015 (Martínez-Asensio et al., 2019)
Western Indian Ocean	Mauritius	Warming of 1.2°C over 1951–2016 (MESDDBM, 2016)	Rainfall decrease of 8% over 1951–2016 (MESDDBM, 2016)	Relative SLR at 5.6 mm yr ⁻¹ over 2007–2016 (MESDDBM, 2016)
	La Réunion	Temperature increase of 0.18°C per decade over 1968–2019 (Météo-France, 2020)	Rainfall decrease of 1.2% per decade over 1961–2019 (Météo-France, 2020)	
	Maldives	Generally warming trends from the 1970s to 2012 (MEE, 2016)	Generally weak, non-significant rainfall trends over 1967–2012 (MEE, 2016)	SLR of 2.9–3.7 mm yr ⁻¹ over 1991–2012 (MEE, 2016)

Cross-Chapter Box Atlas.2 (continued)

Southern Hemisphere subtropical Pacific June–November drying has been associated with intensification of the subtropical ridge and associated declines in baroclinicity (Whan et al., 2014). Austral summer drying in the south-west French Polynesia sub-region has been linked with increased greenhouse gas and ozone changes (Fyfe et al., 2012). The Southern Hemisphere jet stream has *likely* shifted polewards (Section 2.3.1.4.3) which is attributed largely to a trend in the Southern Annular Mode (Section 3.7.2).

These assessments are constrained by limited availability of observational datasets and of scientific studies. Assessment of observed climate change for Small Islands is often constrained by low station density (Ryu and Hayhoe, 2014; P.D. Jones et al., 2016a), short periods of record, digitization requirements or data-sharing limitations (P.D. Jones et al., 2016a), availability of metadata (McGree et al., 2014; Stephenson et al., 2014; P.D. Jones et al., 2016b), challenges in some gridded product representations of variability, for example, for complex topography (Frazier and Giambelluca, 2017), and challenges characterizing the impact of vertical land motion on sea level rise (Atlas.10.2; Wöppelmann and Marcos, 2016).

Information on future climate changes

Small Islands will *very likely* continue to warm this century, though at a rate less than the global average (Figure Atlas.28), with consequent increased frequency of warm extremes for the Caribbean and western Pacific islands, and heatwave events for the Caribbean (*high confidence*) (Table 11.13). Annual and JJA rainfall declines are *likely* for some Indian and southern Pacific ocean regions with drying over southern French Polynesia (attributed partially to greenhouse gas increases) and farther east clearly evident in CMIP5 and CMIP6 projections (*high confidence*) (Figure Atlas.28). See also Section Atlas.10.4.

Rainfall is *very likely* to decline over the Caribbean, in the annual mean and especially in JJA, with a stronger and more coherent signal in CMIP6 compared to CMIP5 (Figure Atlas.28 and Interactive Atlas) and reductions of 20–30% by the end of the century under high future emissions (SSP5-8.5). This JJA drying has been linked to a future strengthening of the Caribbean low level jet (CLLJ) (Taylor et al., 2013a), a westward expansion and intensification of the NASH, stronger low-level easterlies over the region, a southwardly-placed eastern Pacific ITCZ (Rauscher et al., 2008), and changing dynamics due to increased greenhouse gas concentrations (*very high confidence*) (W. Li et al., 2012). Projections from 15 GCM and two RCM experiments for 2080–2089 relative to 1970–1989 were for a generally drier Caribbean and a robust summer drying (Karmalkar et al., 2013). More recent downscaling studies (e.g., Taylor et al., 2018; Vichot-Llano et al., 2021a) also project a drier Caribbean and longer dry spells (Van Meerbeeck, 2020).

Sea level rise is *very likely* to continue in all Small Island regions (Sections 9.6.3.3 and 12.4.7.4, and Figure Atlas.28) and its effects will be compounded by TC surge events. In general, the most intense TCs are *likely* to intensify and produce more flood rains with warming, however detailed effects of climate change on TCs will vary by region (Section 11.7.1; Knutson et al., 2019). Bailey et al. (2016) projected a 20% decline in groundwater availability by 2050 in coral atoll islands of the Federated States of Micronesia and stressed that under higher sea level rises the decrease could be higher than 50% due to marine water intrusion into aquifers, as well as drought events.

Summary of information distilled from multiple lines of evidence

It is *very likely* that most Small Islands have warmed over the period of instrumental records. The clearest precipitation trend is a *likely* decrease in JJA rainfall over the Caribbean since 1950. There is *limited evidence* and *low agreement* for the cause of the observed drying trend, whether it is mainly caused by decadal-scale internal variability or anthropogenic forcing, but it is *likely* that it will continue over coming decades. It is *likely* that drying has occurred since the mid-20th century in some parts of the Pacific poleward of 20° latitude in both the Northern Hemisphere and the Southern Hemisphere and that these changes will continue over coming decades. Rainfall trends in most other Pacific Ocean and Indian Ocean Small Islands are mixed and largely non-significant. It is *very likely* that sea levels will continue to rise in all Small Island regions, and this will result in increased coastal flooding with the potential to increase saltwater intrusion into aquifers in Small Islands.

Whilst this assessment demonstrates that the climate of Small Islands has and will continue to change in diverse ways, constructing climate information for Small Islands is challenging. This is due to observational issues, incomplete understanding of some modes of variability and their representation by climate models and the lack of availability of large ensembles of regional climate model simulations and limited studies to decouple internal variability and anthropogenic influences.

Atlas.11 Polar Regions

The assessment in this section focuses on changes in average temperature, precipitation (rainfall and snow) and surface mass balance over the polar regions, Antarctica and the Arctic, including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 simulations and those using CMIP6 and CORDEX simulations. Findings are presented for West Antarctica (WAN) and East Antarctica (EAN), and three Arctic regions: Arctic Ocean (ARO), Greenland/Iceland (GIC) and Russian Arctic (RAR; Figure Atlas.29) with some reference also to North-Eastern North America (NEN), North-Western North America (NWN) and Northern Europe (NEU), which are covered more extensively in Atlas.9 and Atlas.8 respectively. Sub-regional changes are discussed when relevant, for example the Antarctic Peninsula (AP) as a sub-region of WAN. The Southern Ocean (SOO) region is assessed in Chapter 9 with changes in climatic impact-drivers assessed in Chapter 12 (Section 12.4.9 and Table 12.11) and some extremes in Chapter 11 (Tables 11.7–9 for RAR). Chapter 9 provides

an overall assessment of the ice-sheet processes and changes, as part of the cryosphere, ocean and sea level change assessment.

Atlas.11.1 Antarctica

Atlas.11.1.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.11.1.1.1 Key Features of the Regional Climate

The Antarctic region, covered by an ice sheet and surrounded by the Southern Ocean, is characterized by polar climate. It is the coldest, windiest and driest continent on Earth and plays a pivotal role in regulating the global climate and hydrological cycle. Antarctica has a mean temperature of -35°C (Lenaerts et al., 2016) and receives 171 mm yr^{-1} water equivalent of snowfall (north of 82°S , estimate based on satellite measurements during 2006–2011; Palerm et al., 2014). Precipitation in Antarctica occurs mostly in the form

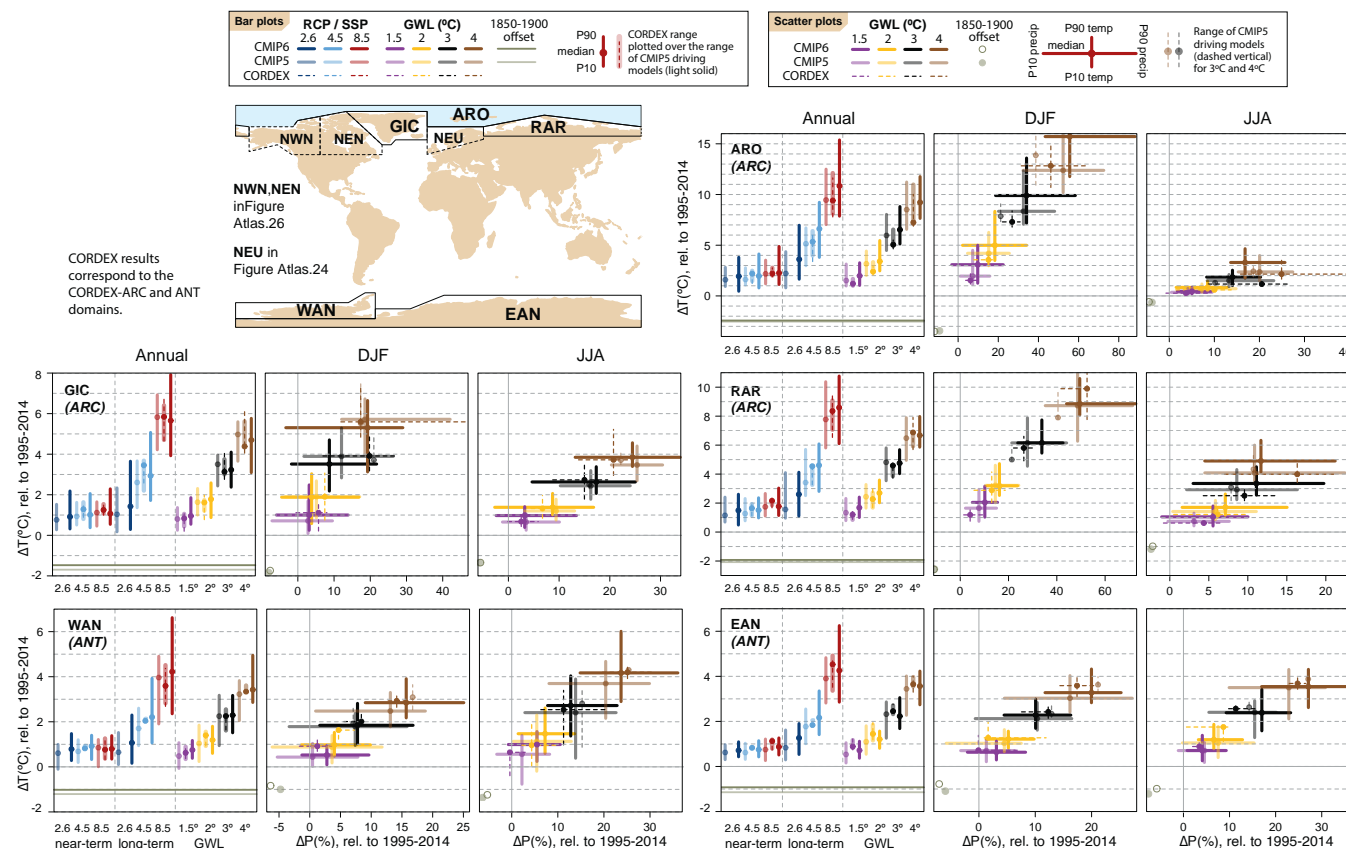

Figure Atlas.29 | Regional changes over land (except for ARO) in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Arctic and Antarctica (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWLs: 1.5°C, 2°C, 3°C and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in $^{\circ}\text{C}$) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

of snowfall and diamond dust, with sporadic coastal rainfall during the summer over the Antarctic Peninsula and sub-Antarctic islands. Drizzle events sometimes occur during warm air intrusions (Nicolas et al., 2017) at relatively low temperatures (Silber et al., 2019). Precipitation constitutes the largest component of the surface mass balance (SMB), which also includes sublimation (from the surface or drifting snow), meltwater runoff and redistribution by wind (Lenaerts et al., 2019). SMB can be considered as a proxy of precipitation if averaged over an annual cycle (Gorodetskaya et al., 2015; Bracegirdle et al., 2019). Precipitation and SMB exhibit spatial and temporal variability controlled by atmospheric large-scale low-pressure systems and moisture advection from lower latitudes. SMB is an important component of the total ice-sheet mass balance (Section 9.4.2.1). The Antarctic contribution to sea level results from the imbalance between net snow accumulation and ice discharge into the ocean (Box 9.1). Ice shelves buttress the ice sheet and are influenced by oceanic and atmospheric drivers (Box 9.1).

Antarctic climate variability is influenced by the Southern Annular Mode (SAM) and regionally by other modes, including ENSO, Pacific–South American pattern, Pacific Decadal Variability (PDV), Indian Ocean Dipole and Zonal Wave 3 (Annex IV). Climate change in Antarctica and the Southern Ocean is influenced by interactions between the ice sheet, ocean, sea ice and atmosphere (Sections 9.2.3.2, 9.3.2 and 9.4.2; Meredith et al., 2019). In addition to Chapter 9, Antarctica is discussed across the report: global climate links (Chapters 2 and 10), attribution (Chapter 3), global water cycle (Chapter 8), extremes (Chapter 11), and climatic impact-drivers (Chapter 12).

Atlas.11.1.1.2 Findings From previous IPCC Assessments

The AR5 (Vaughan et al., 2013) reported warming over Antarctica since the 1950s, mostly over the AP and WAN, attributed to the positive trend in the SAM. These trends in the Antarctic temperature were given *low confidence* due to substantial multi-annual to multi-decadal variability, as well as uncertainties in magnitude and spatial trend structure. The AR5 reported *low confidence* that anthropogenic forcing has contributed to the temperature change in Antarctica. The AR5 highlighted a large interannual variability in snow accumulation with no significant trend since 1979 around Antarctica, and *high confidence* in the overall mass loss from Antarctica, accelerated since the 1990s.

In this and the following paragraphs, findings are from SROCC (Meredith et al., 2019) unless otherwise stated. Warming trends were reported over parts of WAN with record surface warmth over WAN during the 1990s compared to the past 200 years, and AP surface melting intensifying since the mid-20th century. No significant temperature trends were reported over EAN and there was *low confidence* in both WAN and EAN trend estimates due to sparse in situ records and large interannual to inter-decadal variability. In the AP, concomitant increase in temperature and foehn winds due to positive SAM caused increased surface melting over the Larsen ice shelves (*medium confidence*). Strong warming between the mid-1950s and the late 1990s led to the collapse of the Larsen B ice shelf in 2002, which had been intact for 11,000 years (*medium confidence*).

Snowfall increased over the Antarctic Ice Sheet over AP and WAN, offsetting some of the 20th-century sea level rise (*medium confidence*). Longer records suggest either a decrease in snowfall over the Antarctic Ice Sheet over the last 1000 years or a statistically negligible change over the last 800 years (*low confidence*).

Recent warming in the AP and consequent ice-shelf collapse are *likely* linked to anthropogenic ozone and greenhouse gas forcing via the SAM and anthropogenically driven Atlantic sea surface. Also, there is *high confidence* in the influence of tropical sea surface temperature on the Antarctic temperature and Southern Hemisphere mid-latitude circulation, as well as the SAM. There is *medium agreement* but *limited evidence* of an anthropogenic forcing effect on Antarctic ice-sheet mass balance (*low confidence*) and partitioning between natural and human drivers of atmospheric and ocean circulation changes remains very uncertain.

In AR5, Church et al. (2013) gave *medium confidence* in model projections of a future Antarctic SMB increase, implying a negative contribution to global mean sea level rise, consistent with a projection of significant Antarctic warming. Church et al. (2013) also gave *high confidence* to the relationship between future temperature and precipitation increases in Antarctica on physical grounds and from ice-core evidence. In Meredith et al. (2019), the total mass balance projections derived from ice-sheet models were reported without separating the SMB, though projections were reported of increased precipitation and continued strengthening of the westerly winds in the Southern Ocean.

Atlas.11.1.2 Assessment and Synthesis of Observations, Trends and Attribution

Figure Atlas.30 (Antarctic map inset) shows near-surface air temperature trends for 1957–2016 and 1979–2016 at the stations where observations are available for at least 50 years and the detected trends have statistical significance of at least 90% according to the most recent (after SROCC) studies (Jones et al., 2019; Turner et al., 2020). It is *very likely* that the western and northern AP has been warming significantly since the 1950s ($0.49^{\circ}\text{C} \pm 0.28^{\circ}\text{C}$ per decade during 1957–2016 and $0.46^{\circ}\text{C} \pm 0.15^{\circ}\text{C}$ during 1951–2018 at Faraday-Vernadsky station; $0.29^{\circ}\text{C} \pm 0.16^{\circ}\text{C}$ per decade during 1957–2016 at Esperanza station), with no significant trends reported in the eastern AP during the same period (Gonzalez and Fortuny, 2018; Jones et al., 2019; Turner et al., 2020). Short-term cooling trends, strongest during austral summer, have been reported at AP stations during 1999–2016, but the absence of warming and cooling at some stations during 1999–2016 is consistent with natural variability, and there is no evidence of a shift in the overall warming trend observed since the 1950s (Turner et al., 2016, 2020; Gonzalez and Fortuny, 2018; Jones et al., 2019; Bozkurt et al., 2020).

Significant warming at the Byrd station ($0.29^{\circ}\text{C} \pm 0.19^{\circ}\text{C}$ per decade during 1957–2016) confirms and extends earlier trend estimates ($0.42^{\circ}\text{C} \pm 0.24^{\circ}\text{C}$ per decade during 1958–2010) and is representative of the entire WAN warming ($0.22^{\circ}\text{C} \pm 0.12^{\circ}\text{C}$ per decade from 1958 to 2012 averaged over WAN excluding AP, *medium confidence* due to lack of observations) (Bromwich et al., 2013, 2014;

Jones et al., 2019). WAN and AP show statistically significant warming in the HadCRUTv5 observational dataset (Figure 2.11b). There is *high confidence* in the long-term warming trend at the AP and WAN, and also at the century scale based on reconstructions (Zagorodnov et al., 2012; Stenni et al., 2017; Lyu et al., 2020), confirming the trends estimated by earlier studies assessed in the SROCC (Meredith et al., 2019). The century-scale warming trend in the AP is *very likely* an emerging signal compared to natural variability, while the WAN warming trend falls in the high end of century-scale trends over the last 2000 years (*medium confidence*) (Stenni et al., 2017).

In EAN, during 1957–2016, three stations showed significant warming (Scott $0.22^{\circ}\text{C} \pm 0.15^{\circ}\text{C}$, Novolazarevskaya $0.13^{\circ}\text{C} \pm 0.09^{\circ}\text{C}$, and Vostok $0.15^{\circ}\text{C} \pm 0.13^{\circ}\text{C}$ per decade), while other stations with long-term observations indicated no statistically significant trends (Figure Atlas.30). During 1979–2016, three coastal stations showed cooling, while at the South Pole a warming trend was detected, increasing to $0.61^{\circ}\text{C} \pm 0.34^{\circ}\text{C}$ per decade during 1989–2018 (Figure Atlas.30; Jones et al., 2019; Clem et al., 2020; Turner et al., 2020). The century-scale warming in Queen Maud Land coast based on ice-core reconstructions is within the range of centennial internal variability (Stenni et al., 2017).

While a trend towards a positive phase of the SAM since the 1970s *likely* explains a significant part of the warming at the northern AP, it had a cooling effect on continental WAN and EAN (particularly strong in DJF; Table Atlas.1). Warming in western AP and over WAN during 1957–2016 (Figure Atlas.30) and through to 2020 (Figure 2.11) is *likely* due to significant contribution of other factors, such as tropical Pacific forcing through PDV, ENSO, Amundsen Sea Low position/strength and also anthropogenic climate change (Jones et al., 2019; Scott et al., 2019; Wille et al., 2019; Donat-Magnin et al., 2020; Turner et al., 2020). Since SROCC, new studies confirmed the influence of foehn wind and cloud radiative forcing on Larsen C surface melt (Elvidge et al., 2020; Gilbert et al., 2020; Turton et al., 2020). In WAN, summer surface-melt occurrence over ice shelves may have increased since the late 2000s (Scott et al., 2019). It is *likely* that increased meltwater ponding and resulting hydrofracturing have been important mechanisms of the rapid disintegration of the Larsen B ice shelf (Banwell et al., 2013; MacAyeal and Sergienko, 2013; Robel and Banwell, 2019). Ice-shelf disintegration and relevant processes are discussed in Sections 9.4.2.1 and 9.4.2.3.

Direct observations of snowfall in Antarctica using traditional gauges are highly uncertain and records from precipitation radars (Gorodetskaya et al., 2015; Grazioli et al., 2017; Scarchilli et al., 2020) are not long enough to assess trends. Estimates of precipitation and SMB are largely model-based due to the paucity of in situ observations in Antarctica (Lenaerts et al., 2019; Hanna et al., 2020). Antarctic SMB is dominated by precipitation and removal by sublimation with very small amounts of melt mostly important only on the ice shelves. Climate models and satellite records (IMBIE team et al., 2018; Rignot et al., 2019; Mottram et al., 2021) suggest that strong interannual variability of Antarctic-wide SMB over the satellite period currently masks any existing trend (Figure Atlas.30) in spite of a possible ozone depletion-related precipitation increase over the 1991–2005 period (Lenaerts et al., 2018). No significant Antarctic-wide SMB trend is

inferred since 1979 (IMBIE team et al., 2018; Medley and Thomas, 2019). While ice-core reconstructions show a significant increase in the western AP SMB since the 1950s (Thomas et al., 2017; Medley and Thomas, 2019; Wang et al., 2019), this trend is not reproduced by regional climate models or the reanalyses used to drive them (Figure Atlas.30; van Wessem et al., 2016; Wang et al., 2019).

According to the ice-core reconstructions, SMB over WAN (including AP) has *likely* increased during the 20th century with trends of $5.4 \pm 2.9 \text{ Gt yr}^{-1}$ per decade (1900–2010; Wang et al., 2019) mitigating global mean sea level rise by, respectively, $0.28 \pm 0.17 \text{ mm}$ per decade (WAN excluding AP, during 1901–2000) and $0.62 \pm 0.17 \text{ mm}$ per decade (AP, during 1979–2000; Medley and Thomas, 2019). Significant spatial heterogeneity in SMB trends has been observed over AP and WAN:

- Western AP has *likely* experienced a significant increase in SMB beginning around 1930 and accelerating during 1970–2010, which is outside of the natural variability range of the past 300 years (Thomas et al., 2017; Medley and Thomas, 2019; Wang et al., 2019);
- eastern AP has no significant SMB trends during the same period (*low confidence*, observations limited to one ice core and large interannual variability) (Thomas et al., 2017; Engel et al., 2018);
- overall WAN SMB (excluding AP) was stable during 1980–2009 but exhibited high regional variability (Medley et al., 2013): significant increases (5–15 mm per decade during 1957–2000) to the east of the West Antarctic Ice Sheet divide and a significant decrease (–1 to –5 mm per decade during 1901–1956, and –5 to –15 mm per decade during 1957–2000) to the west (Medley and Thomas, 2019; Wang et al., 2019).

The SMB of EAN increased during the 20th century which mitigated global mean sea level rise by $0.77 \pm 0.40 \text{ mm}$ per decade during 1901–2000 (*medium confidence*) (Medley and Thomas, 2019). EAN SMB has been increasing at a much lower rate since 1979 as shown by observations, while regional climate models show strong interannual variability masking any trend (*low confidence* due to limited observations) (Figure Atlas.30; Medley and Thomas, 2019; Rignot et al., 2019). EAN SMB changes during the 20th century and recent decades showed large spatial heterogeneity:

- With significant increases *likely* in Queen Maud Land (QML): $5.2 \pm 3.7\%$ per decade during 1920–2011 measured in ice cores near the Kohnen station (Medley et al., 2018), an increase on the plateau (Altnau et al., 2015), and stable conditions during 1993–2010 along the annual stake line from Syowa (coast) to Dome F (plateau) (Y. Wang et al., 2015); increases during 1911–2010 (Thomas et al., 2017) with anomalously high SMB observed in 2009 and 2011 (Boening et al., 2012; Lenaerts et al., 2013; Gorodetskaya et al., 2014);
- increases in Wilkes Land and Queen Mary Land during 1957–2000 (*low confidence* due to limited observations and strong spatial variability) (Thomas et al., 2017; Medley and Thomas, 2019);
- a *likely* stable SMB in the interior of the east Antarctic plateau during the 1901–2000 period and the last decades (Thomas et al., 2017; Medley and Thomas, 2019);

- stable in Adelie Land (annual stake line during 1971–2008) (*low confidence due to limited evidence*) (Agosta et al., 2012).

Regional trends during recent 50 year (1961–2010) and 100 year (1911–2010) periods are within the centennial variability of the past 1000 years, except for coastal QML (unusual 100-year increase in accumulation) and for coastal Victoria Land (unusual 100-year decrease in accumulation) (Thomas et al., 2017). Nevertheless, the current EAN SMB is not unusual compared to the past 800 years (Frezzotti et al., 2013).

The geographic pattern of accumulation changes since the 1950s bears a strong imprint of a trend towards a more positive phase of the SAM (e.g., Medley and Thomas, 2019), which could be linked to ozone depletion (Lenaerts et al., 2018) or large-scale atmospheric warming (Frieler et al., 2015; Medley and Thomas, 2019). More evidence has emerged showing the importance of the Pacific–South American pattern, ENSO and Pacific Ocean convection, and large-scale blocking causing warm-air intrusions and both extreme precipitation and melt events, responsible for large interannual SMB variability (*high confidence*) (Gorodetskaya et al., 2014; Bodart and Bingham, 2019; Scott et al., 2019; Turner et al., 2019; Wille et al., 2019; Adusumilli et al., 2021). This strengthens evidence for an important connection between Antarctic climate and tropical sea surface temperature stated by SROCC (Meredith et al., 2019). Section 3.4.3 and SROCC (Meredith et al., 2019) provide a discussion of attribution of Antarctic ice-sheet changes.

Atlas.11.1.3 Assessment of Model Performance

This section provides evaluation of atmospheric global and regional climate models, including reanalyses. Evaluation of the ice-sheet models and relevant processes, including selection of the atmospheric models used to drive ice-sheet models, is given in Section 9.4.2.2.

One of the major systematic biases in CMIP5 and earlier GCMs was an equatorward bias in the latitude of the Southern Hemisphere mid-latitude westerly jet, which is significantly reduced in the CMIP6 ensemble (Bracegirdle et al., 2020a). GCM Southern Ocean sea ice biases are also of importance as they influence 21st-century temperature projections in Antarctica and simulations of present-day temperatures are highly sensitive to these biases (Agosta et al., 2015; Bracegirdle et al., 2015). A positive bias in near-surface temperature over the Antarctic plateau is seen in CMIP5 models (Lenaerts et al., 2016).

CMIP6 GCMs showed an improved representation of the Antarctic near-surface temperature compared to CMIP5 but little improvement (maintaining positive bias) in Antarctic precipitation estimates (Palermé et al., 2017; Roussel et al., 2020). An analysis of the 1850–2000 SMB mean, trends, and interannual and spatial variability suggests slightly worse agreement with ice-core-based reanalyses in CMIP6 than CMIP5 (Gorte et al., 2020). Comparison of CMIP5 models with CloudSat satellite products and an ice-core-based SMB reconstruction showed almost all the models overestimate current Antarctic precipitation, some by more than 100% (Palermé et al., 2017; Gorte et al., 2020). GCM simulations of surface snow-melt

processes are either of variable quality, with extremely simple representations, or non-existent (Agosta et al., 2015; Trusel et al., 2015). Though most meltwater refreezes in the snowpack in current climate simulations, this may be an issue in the future climate simulations under global warming as runoff is projected to increase (Kittel et al., 2021). Since CMIP5, representation of snow (Lenaerts et al., 2016) and stable surface boundary layers (Vignon et al., 2018) has improved in some atmospheric GCMs. In one example, the CMIP6 model CESM2 simulation of cloud and precipitation showed substantial improvements (Schneider et al., 2020), though surface melting is still considerably overestimated compared to RCMs and satellite products (Trusel et al., 2015; Lenaerts et al., 2016).

Assimilation of observations in reanalysis products yields realistic temperature patterns and seasonal variations, with the recent ERA5 reanalysis showing improved performance compared to others for mean and extreme temperature, wind and humidity, though a warm bias in near-surface air temperatures remains (Retamales-Muñoz et al., 2019; Tetzner et al., 2019; Dong et al., 2020; Gorodetskaya et al., 2020). The ability of the reanalyses to simulate precipitation and SMB is more variable; they generally overestimate the latter (Gossart et al., 2019; Roussel et al., 2020), but are well suited to provide atmospheric and sea surface boundary conditions to drive RCMs.

Recent higher-resolution simulations covering the entire Antarctic Ice Sheet with a grid spacing of 12 to 50 km include five Polar-CORDEX RCMs – RACMO2 (van Wessem et al., 2018), MAR (Agosta et al., 2019; Kittel et al., 2021), COSMO-CLM2 (Souverijns et al., 2019), HIRHAM5 (Lucas-Picher et al., 2012) and MetUM (Walters et al., 2017; Mottram et al., 2021) – and one stretched-grid GCM – ARPEGE (Beaumet et al., 2019). RCM simulations forced by ERA-Interim agree well with automatic weather station temperatures, with high correlation ($R^2 > 0.9$) and low bias ($< 1.5^\circ\text{C}$) except for high-resolution HIRHAM5 (-2.1°C) and MetUM (-3.4°C), which are not internally nudged models (Mottram et al., 2021). RCMs generally underestimate the observed SMB but with biases lower than 20%, except for COSMO-CLM2 at lower elevations (< 1200 m) and HIRHAM5 and MetUM at higher elevations (> 2200 m) (Mottram et al., 2021). These RCM simulations lead to estimates of the grounded Antarctic Ice Sheet SMB ranging from 2133 Gt yr⁻¹ to 2328 Gt yr⁻¹ when considering the four simulations compatible with the IMBIE2 Antarctic total mass budget (IMBIE team et al., 2018; Mottram et al., 2021). However, the simulated spatial pattern of SMB differs widely between models, suggesting the importance of missing or under-represented processes in the models, such as drifting-snow transport and sublimation (Agosta et al., 2019), cloud-precipitation microphysical processes (van Wessem et al., 2018) and snowpack modelling (Mottram et al., 2021). Comparisons of integrated SMB estimates between models are also complicated by different resolutions and continental ice masks, with models showing large differences in the absolute SMB (Mottram et al., 2021) but better agreement for SMB annual rates (Figure Atlas.30).

Finer-resolution RCM studies demonstrate improved representation of precipitation and temperature gradients (van Wessem et al., 2018; Bozkurt et al., 2020; Donat-Magnin et al., 2020; Elvidge et al., 2020), and strength of katabatic winds (Bintanja et al., 2014;

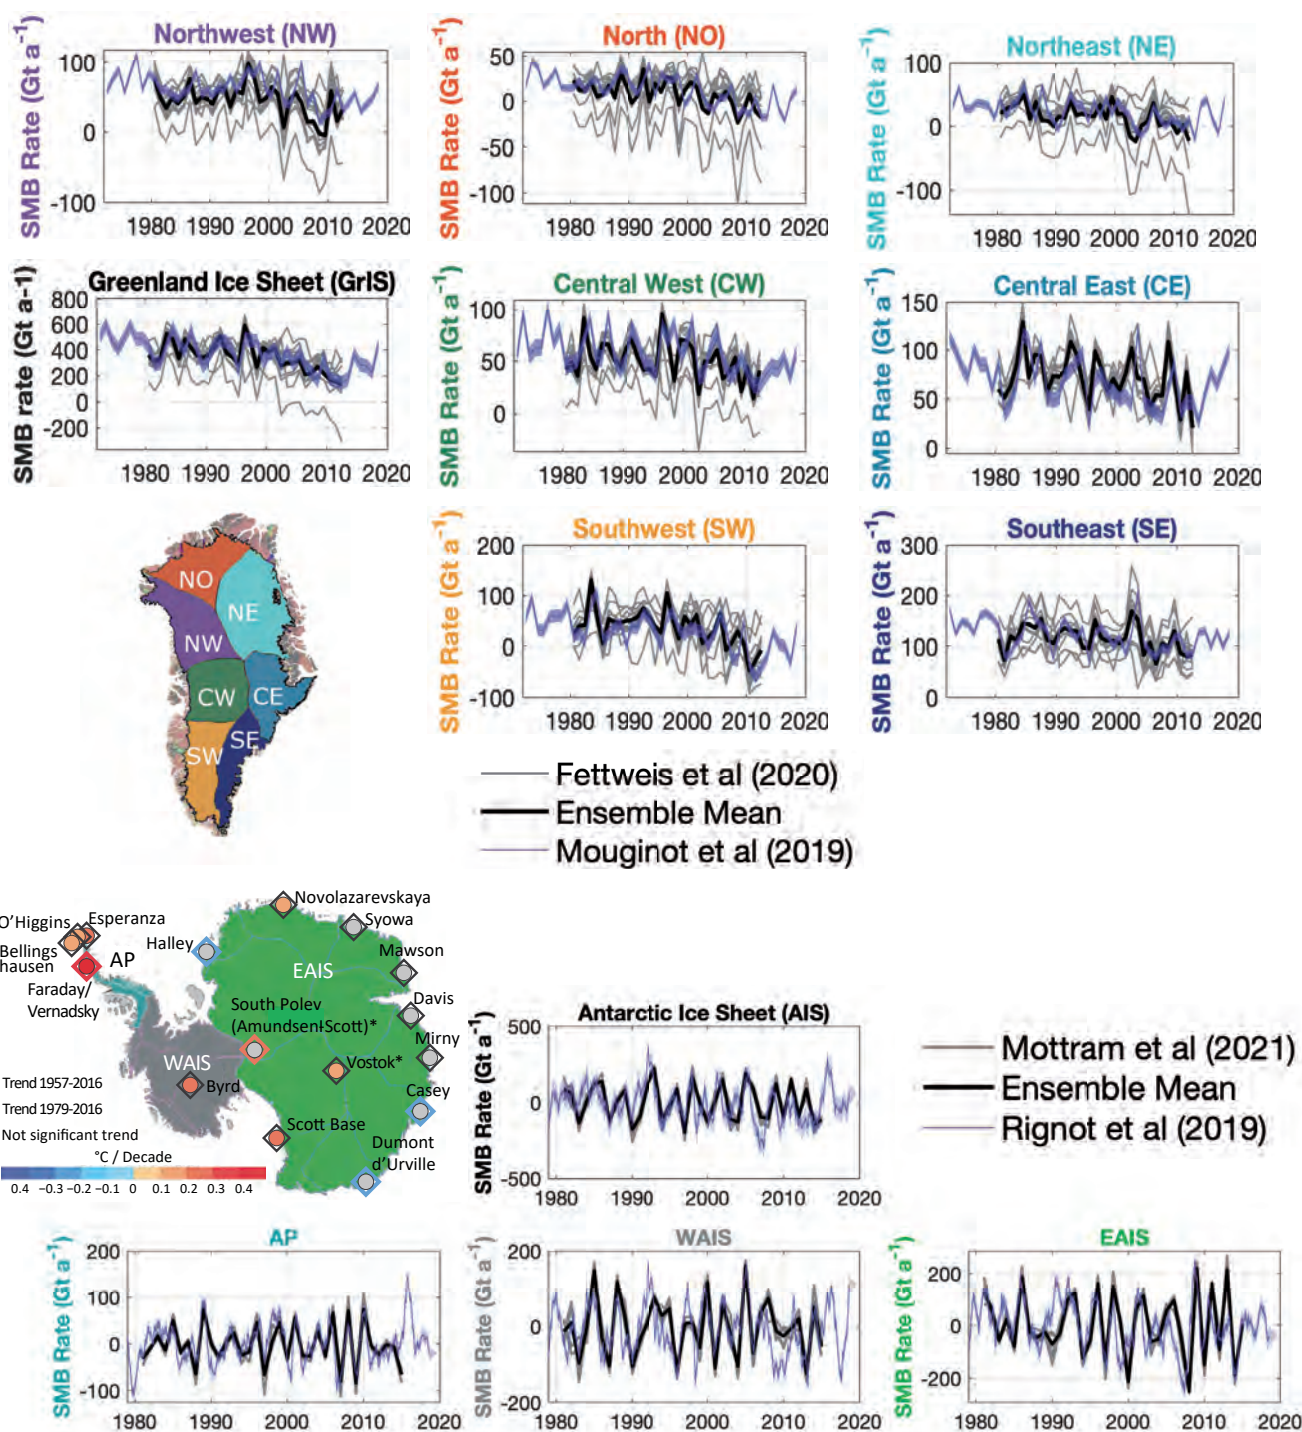

Figure Atlas.30 | (Upper panels) Time series of annual surface mass balance (SMB) rates (in Gt a^{-1}) for the Greenland Ice Sheet and its regions (shown in the inset map) for the periods 1972–2018 (Mouginit et al., 2019) and 1980–2012 (Fettweis et al., 2020) using 13 different models. **(Lower panels)** Time series of annual SMB rates (in Gt a^{-1}) for the grounded Antarctic Ice Sheet (excluding ice shelves) and its regions (shown in the inset map) for the periods 1979–2019 (Rignot et al., 2019) and 1980–2016 (Mottram et al., 2021) using five Polar-CORDEX regional climate models. The Antarctic inset map also shows the location of the stations discussed in Atlas.11.1.2 where observations are available for at least 50 years. Colours indicate near-surface air temperature trends for 1957–2016 (circles) and 1979–2016 (diamonds) statistically significant at 90% (Jones et al. 2019; Turner et al. 2020). Stations with an asterisk (*) are where significance estimates disagree between the two publications. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Souwerijns et al., 2019) in coastal and mountainous regions. Adequate representation of some processes is still lacking, including drifting snow, sublimation of falling snow or the spectral dependency of snow albedo (Lenaerts et al., 2019). Non-hydrostatic regional models, for example Polar-WRF, MetUM or HARMONIE-AROME at spatial resolutions up to 2 km further improve regional RCM simulations, but are still often unable to resolve relevant feedbacks and foehn processes (Grosvenor et al., 2014; Elvidge et al., 2015, 2020; Elvidge and Renfrew, 2016; King et al., 2017; Turton et al., 2017; Bozkurt et al., 2018b; Hines et al., 2019; Vignon et al., 2019; Gilbert et al., 2020).

Existing uncertainties in the Antarctic climate representation by both GCMs and RCMs cause significant spread in the future Antarctic climate and SMB projections (Gorte et al., 2020; Kittel et al., 2021). Run-time bias adjustment in atmospheric GCMs (Cross-Chapter Box 10.2; Krinner et al., 2019, 2020) has been proposed to provide low-bias present and consistently corrected future RCM forcing (reducing the need for coupled model selection), which could be used directly for Antarctic climate projections (Krinner et al., 2019).

Atlas.11.1.4 Assessment and Synthesis of Projections

This section provides an assessment of projections in temperature, precipitation and SMB. See Section 9.4.2 for projected changes in the ice-sheet total mass balance and relevant processes, and see Section 4.3.1 (Table 4.2) and Section 4.5.1 for Antarctic temperature projections relative to other regions.

The Antarctic region is *very likely* to experience a significant increase in annual mean temperature and precipitation by the end of this century under all emissions scenarios used in CMIP5 and CMIP6 (Figure Atlas.29; Bracegirdle et al., 2015, 2020b; Frieler et al., 2015; Lenaerts et al., 2016; Previdi and Polvani, 2016; Palermi et al., 2017). Ensemble means (and 10th–90th percentile ranges) of end-of-century (2081–2100) projected Antarctic surface air temperature change from 35 CMIP6 models and relative to 1995–2014 are 1.2°C (0.5°C–2.0°C) for the SSP1-2.6 emissions scenarios, 2.3°C (1.3°C–3.4°C) for SSP2-4.5, 3.5°C (2°C–5°C) for SSP3-7.0, and 4.4°C (2.8°C–6.4°C) for SSP5-8.5 (Interactive Atlas). Both temperature and precipitation projections are characterized by a relatively large multi-model range (Figure Atlas.29 and the Interactive Atlas). A strong regional variability is present with the projected changes over coastal Antarctica not scaling linearly with global forcing. While continental mean temperatures are linearly related to global mean temperatures in CMIP6 models, the relative increase in coastal temperatures are higher for low-emissions scenarios due to stronger relative Southern Ocean warming and relatively stronger effects of ozone recovery (Bracegirdle et al., 2020b). A higher multi-model average increase in temperature is projected by CMIP6 models compared to CMIP5, with a 1.3°C higher mean Antarctic near-surface temperature at the end of the 21st century (Kittel et al., 2021). While similar median temperature changes are projected for WAN and EAN, the former shows larger spread and higher projected temperature range in both CMIP5 and CMIP6 models and for all scenarios (Figure Atlas.29). CORDEX-Antarctica simulations show a mean and range in the future temperature changes similar to the subset of CMIP5 models used to drive them for the RCP8.5 scenario and 1.5°C, 2°C and 3°C GWLs (Figure Atlas.29).

There is *high confidence* that projected future surface air temperature increase over Antarctica will be accompanied by precipitation increase (Figure Atlas.29). CMIP6 models show a similar or larger but more constrained increase in precipitation (more models agreeing with larger precipitation increase) for the same GWLs compared to CMIP5. For example, over WAN during JJA for 3°C GWL, CMIP6 and CMIP5 models project a median 15% increase in precipitation with a 10th–90th percentile range of 7–25% in CMIP6 models and of 3–24% in CMIP5. Average precipitation changes relative to 1995–2014 over WAN and EAN are largely similar; they show projected increases for SSP2-4.5 (SSP5-8.5) of around 5% (5%) for 2021–2040, 7% (10%) for 2041–2060, and 12% (25%) for 2081–2100 with smaller increases projected for SSP1-2.6 emissions, reaching around 5% in 2081–2100. Regionally, the largest relative precipitation increase is projected (under all scenarios) for the eastern part of WAN, the western AP, large parts of the EAN plateau and over coastal EAN within 0°E–90°E longitudinal sector (Interactive Atlas). The largest increase in absolute precipitation amount is projected along the coastal regions, with the largest increase over coastal WAN and the western AP, and is projected to be largely driven by the increase in maximum five-day precipitation (Interactive Atlas), which is in line with the dominant contribution of extreme snowfall events to the total annual precipitation in the present Antarctic climate (Boening et al., 2012; Gorodetskaya et al., 2014; Turner et al., 2020). Under all emissions scenarios, the coastal precipitation increase corresponds to the snowfall increase, except for the northern and central part of the western AP, where snowfall is projected to decrease and rainfall to increase (similarly to the tendency towards increased precipitation, decreased snowfall and increase in rainfall over the Southern Ocean; Interactive Atlas).

From 2000 to 2100, the grounded Antarctic SMB is projected to mitigate sea level rise for RCP4.5 (RCP8.5) by the following sea level equivalents (SLEs), 0.03 ± 0.02 m (0.08 ± 0.04 m SLE) from 30 CMIP5 models and for SSP2-4.5 (SSP5-8.5) by 0.03 ± 0.03 m SLE (0.07 ± 0.04 m SLE) from 24 CMIP6 models (Gorte et al., 2020). Subsets or downscaling of CMIP AOGCMs lead to 21st-century cumulative projections in the range of 0.05 ± 0.03 m SLE for CMIP5 RCP8.5 and 0.08 ± 0.04 m SLE for CMIP6 SSP5-8.5 (Gorte et al., 2020; Nowicki et al., 2020; Seroussi et al., 2020; Kittel et al., 2021). Use of model subsets reduces spread leading to either lower or higher climate sensitivity in the Antarctic depending on the selection method. For example, models selected by Gorte et al. (2020) based on SMB ice-core reconstruction from Medley and Thomas (2019) tend to underestimate strongly winter sea ice area (Agosta et al., 2015; Roach et al., 2020) and show reduced 21st-century increase in Antarctic SMB compared to the full ensembles (Agosta et al., 2015; Bracegirdle et al., 2015). A different subset of models is used for ISMIP6 (Section 9.4.2.3) which gives a lower increase in Antarctic SMB than the full ensemble for CMIP5 but a larger increase for CMIP6.

Polar-CORDEX RCMs show higher variability in precipitation projections compared to CMIP5 models with a similar spatial pattern of the areas with precipitation increase over continental Antarctica but with higher local magnitude, and also showing a larger increase over the Weddell Sea ice shelves (Interactive Atlas). CMIP5 and CMIP6

models, bias adjusted based on regional climate model simulations, showed that the projected warming is expected to result in increased surface melting over the Antarctic ice shelves, with meltwater runoff under RCP8.5 and SSP5-8.5 becoming larger than precipitation over ice shelves over the period 2045–2050, surpassing intensities that were linked with the collapse of Larsen A and B ice shelves (Trusel et al., 2015; Kittel et al., 2021). Given the existing uncertainty in the present precipitation and SMB simulations and the significant range in the projected precipitation increase under various emissions scenarios in CMIP5, CMIP6 and CORDEX models, there is *medium confidence* that the future Antarctic SMB will have a negative contribution to sea level during the 21st century under all emissions scenarios (see Section 9.4.2.3 for assessment of the drivers of future Antarctic ice-sheet change and Section 9.4.2.6 for longer time scales).

Atlas.11.1.5 Summary

Observations show a *very likely* widespread, strong warming trend starting in the 1950s in the Antarctic Peninsula. Significant warming trends are observed in other West Antarctic regions and at selected stations in East Antarctica (*medium confidence*). Antarctic precipitation and SMB showed a significant positive trend over the 20th century according to the ice cores, while large interannual variability masks any existing trend over the satellite period since the end of the 1970s (*medium confidence*).

An assessment of model performance for the present day shows that high-resolution regional climate models with polar-optimized physics are important for estimating SMB and generating climate information, and show improved realizations compared to reanalyses and GCMs when evaluated against observations. At the same time, CMIP6 GCMs showed an improved representation of the Antarctic near-surface temperature compared to CMIP5, though still struggle with the representation of precipitation. There is therefore *medium confidence* in the capacity of climate models to simulate Antarctic climate and SMB changes.

Under all assessed emissions scenarios, both West and East Antarctica are *very likely* to have higher annual mean surface air temperatures and more precipitation, which will have a dominant influence on determining future changes in the SMB (*high confidence*). However, due to the challenges of model evaluation over the region and the possibility of increased meltwater runoff described above, there is only *medium confidence* that the future contribution of the Antarctic SMB to sea level this century will be negative under all greenhouse gas emissions scenarios.

Atlas.11.2 Arctic

Atlas.11.2.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.11.2.1.1 Key Features of the Regional Climate

The Arctic region comprises the Arctic Ocean (ARO), Russian Arctic (RAR), Greenland and Iceland (GIC), and other surrounding land areas

in Europe (NEU) and North America (NEN, NWN) (Figure Atlas.29). The region is one of the coldest and driest regions on Earth and plays a key role influencing global and regional climates and the hydrological cycle. A number of physical processes contribute to amplified Arctic temperature variations as compared to the global temperature, in particular thermodynamic changes that include the increase in surface absorption of solar radiation due to surface albedo feedbacks related with sea ice, ice, and snow cover retreat as well as poleward energy transports, water-vapour-radiation and cloud-radiation feedbacks (Screen and Simmonds, 2010; Serreze and Barry, 2011; Pithan and Mauritsen, 2014; Bintanja and Kriken, 2016; Graversen and Burtu, 2016; Franzke et al., 2017; Stuecker et al., 2018). Precipitation in the Arctic is dominated by snowfall, with rainfall present mostly during the summer period. Arctic climate is influenced by the North Atlantic Oscillation (NAO), the leading mode of atmospheric variability in the North Atlantic basin with a northward extension into the Arctic affecting temperature, precipitation and sea ice over the region, with ENSO and Atlantic Multi-decadal Variability (AMV) also affecting parts of the region (Annex IV). Further, the Greenland Ice Sheet contribution to sea level results from the imbalance between mass gain by net snow accumulation and mass loss by meltwater runoff and ice discharge into the ocean (IMBIE team, 2020), highlighting that the ice sheet is a major contributor to sea level changes.

Atlas.11.2.1.2 Findings From Previous IPCC Assessments

The following summary from previous IPCC reports is derived from the SROCC (IPCC, 2019a) unless otherwise stated. Arctic surface air temperatures have increased from the mid-1950s, with feedbacks from loss of sea ice and snow cover contributing to the amplified warming (*high confidence*) (IPCC, 2018c), and have *likely* increased by more than double the global average over the last two decades (*high confidence*). Arctic snow cover in June has declined from 1967 to 2018 (*high confidence*). Arctic glaciers are losing mass (*very high confidence*) and this along with changes in high-mountain snowmelt have caused changes in hydrology, including river runoff, that are projected to continue in the near term (*high confidence*). The rate of ice loss from the Greenland Ice Sheet has increased; during 2006–2015 the loss was $278 \pm 11 \text{ Gt yr}^{-1}$ with the rate for 2012–2016 higher than for 2002–2011 and several times higher than during 1992–2001 (*high confidence*).

The Arctic sea ice area is declining in all months of the year (*very high confidence*) with the September sea ice minimum *very likely* having reduced by $12.8 \pm 2.3\%$ per decade during the satellite era (1979–2018) to levels unprecedented for at least 1000 years (*medium confidence*).

The high latitudes are *likely* to experience an increase in annual mean precipitation under RCP8.5 (IPCC, 2013c). Further, changes in precipitation will not be uniform. Autumn and spring snow cover duration are projected to decrease by a further 5–10% from current conditions in the near term (2031–2050). No further losses are projected under RCP2.6 whereas a further 15–25% reduction in snow cover duration is projected by the end of century under RCP8.5 (*high confidence*).

Atlas.11.2.2 Assessment and Synthesis of Observations, Trends and Attribution

The Arctic has warmed at more than twice the global rate over the past 50 years with the greatest warming during the cold season (*high confidence*) (Davy et al., 2018; Box et al., 2019; Przybylak and Wyszynski, 2020; Xiao et al., 2020). This is based on various Arctic amplification processes, in particular the combined effect of several related feedback processes, including between various radiation components and (a) the albedo of sea ice and snow, (b) water vapour, and (c) clouds, as well as poleward energy transports. The annual average Arctic surface air temperature increased by 2.7°C from 1971 to 2017, with a 3.1°C increase in the cold season (October–May) and a 1.8°C increase in the warm season (June–September) (AMAP, 2019). Satellite-based data estimate the rate of annual warming for 1981–2012 over sea ice covered regions to be 0.47°C per decade, whereas the trend was significantly higher at 0.77°C per decade over Greenland and amplified in the northern Barents and Kara seas (Comiso and Hall, 2014). The largest Arctic warming in 2003–2017 was reported over the Barents and Kara seas with trends larger than 2.5°C per decade (Susskind et al., 2019), and Arctic temperatures from 2014 to 2018 have exceeded all previous records since 1900 (Blunden and Arndt, 2019).

Over the ARO, long-term temperature records are available from Spitsbergen (Svalbard Airport). For the period 1898–2018, the annual mean warming was 0.32°C per decade, about 3.5 times the global mean temperature for the same period and since 1991, it was 1.7°C per decade or about seven times the global average for the same period (Nordli et al., 2020). There is a positive trend in the annual temperature for all stations across Svalbard (Gjelten et al., 2016; Hanssen-Bauer et al., 2019; Dahlke et al., 2020) of 0.64°C–1.01°C per decade for 1971–2017 (Hanssen-Bauer et al., 2019), co-varying with regional changes in sea ice conditions (Dahlke et al., 2020). The largest temperature trends *very likely* occur in winter, with Svalbard Airport warming at 0.43°C per decade during 1898–2018 and 3.19°C per decade during 1991–2018 (Nordli et al., 2020), and Isaksen et al. (2016) reporting on substantial warming in western Spitsbergen, particularly in winter, while the summer warming is moderate.

A multi-dataset analysis for NEN shows a consistent warming (Rapaic et al., 2015), with the largest annual temperature trend greater than 0.3°C per decade during 1981–2010 over eastern NEN and also significant warming over northern Quebec and most of the Canadian Arctic north of the treeline. For the longer 1950–2010 period, a consistent warming is found over central and western NEN, but no trend or no consensus is found over the Labrador coast. The latter is related with cooling of the North Atlantic region during the 1970s. For western Greenland, however, summer temperatures increased (2.2°C in June, 1.1°C in July) from 1994 to 2015 (Saros et al., 2019). For neighbouring Arctic regions of NEU, WSE and ESB, datasets show a consistent warming of annual mean temperature since the mid-1970s and 1980 (Atlas.8 and Atlas.5.2).

Along with the amplified warming, the Arctic has become moister (Rinke et al., 2019; Nygård et al., 2020). AMAP reported Arctic precipitation increases of 1.5–2.0% per decade, with the strongest

increase in the cold season (October–May) (*medium confidence*) (AMAP, 2019). Also, for neighbouring Arctic regions for example NEU, EEU and North Asia, mean annual precipitation has increased since the early 20th century (Atlas.8 and Atlas.5.2). Estimated trends for precipitation and snowfall fraction are mixed for the Arctic, with increases and decreases for different regions and seasons (Vihma et al., 2016). However, annual precipitation trends derived from different reanalyses do not agree, differ in sign and have low significance (Lindsay et al., 2014; Boisvert et al., 2018). Direct precipitation measurements are difficult and include uncertainties (among others measuring frozen precipitation), therefore precipitation estimates in the Arctic rely on climate models and reanalyses.

An average of five reanalyses for 2000–2010 suggests around 40% of Arctic Ocean precipitation falls as snow, though there is large uncertainty in this estimate (Boisvert et al., 2018). Rainfall frequency is estimated to have increased over the Arctic by 2.7–5.4% over 2000–2016 (Boisvert et al., 2018) with more frequent rainfall events reported for NEU and ARO (Svalbard; Maturilli et al., 2015; AMAP, 2019), and winter rain totals and frequency have increased in Svalbard since 2000 (*medium confidence*) (Łupikasza et al., 2019). Rain-free winters have rarely occurred since 1998 (Peeters et al., 2019).

Observational records (1966–2010) for the RAR region show changing precipitation characteristics (Ye et al., 2016), with higher precipitation intensity but lower frequency and little change in annual precipitation total. Precipitation intensity is reported to have increased in all seasons, strongest in winter and spring, weakest in summer, and at a rate of about 1–3% per degree Celsius of air temperature increase.

Atlas.11.2.3 Assessment of Model Performance

Evaluating simulated temperature and precipitation is problematic in the Arctic due to sparse weather station observations. The lack of reliable observed precipitation datasets for the Arctic thus makes it *very unlikely* to be able to evaluate objectively the skill of models to reproduce precipitation patterns (Takhsha et al., 2018).

The CMIP5 models reproduce the observed Arctic warming over the past century (*medium confidence*) (Chylek et al., 2016; Hao et al., 2018; Huang et al., 2019). The simulated mean Arctic warming for 1900–2014 averaged over 40 CMIP5 models is 2.7°C compared to the observed values of 2.2°C (NASA GISS data smoothed using a 1200-km radius) or 1.7°C (using a 250-km smoothing radius) (Chylek et al., 2016). However, there are large inter-model differences in the simulated warming which ranges from 1.2°C to 5.0°C. Although the CMIP5 models reproduce the spatially averaged observed warming over the past 50 to 100 years, the pattern is different from that of observations and reanalysis (Xie et al., 2016; Franzke et al., 2017; Hao et al., 2018). Zonal mean temperature trends in the CMIP5 models overestimate the warming in the cold season over high latitudes in the Northern Hemisphere (Xie et al., 2016). Overall, the amplified Arctic warming in recent decades is overestimated by CMIP5 models (Huang et al., 2019). Possible reasons are modelled sea surface temperature biases and an overestimated temperature response to the Arctic sea ice decline. Furthermore, some models,

which have a warm or weak bias in their Arctic temperature simulations, closely relate the Arctic warming to changes in the large-scale atmospheric circulation. In other models, which show large cold biases, the albedo feedback effect plays a more important role for the temperature trend magnitude. This implies that the dominant simulated Arctic warming mechanism and trend may be dependent on the bias of the model mean state (Franzke et al., 2017). Compared to CMIP5 models, Davy and Outten (2020) found lower biases in CMIP6 models' representation of sea ice extent and volume with improved extents linked to a better seasonal cycle in the Barents Sea.

Rapid temperature changes, such as the pronounced increase of $2^{\circ}\text{C yr}^{-1}$ during 2003–2012 over the Kara and Barents seas in March is well captured in Arctic CORDEX simulations (Kohnemann et al., 2017). The models show adequate skill in capturing the general temperature patterns (Koenig et al., 2015; Matthes et al., 2015; Hamman et al., 2016; Cassano et al., 2017; Brunke et al., 2018; Diaconescu et al., 2018; Takhsha et al., 2018), but tend to show a cold temperature bias which is largest in winter and depends on the reference dataset. Cassano et al. (2017) showed a large sensitivity of the simulated surface climate to changes in atmospheric model physics. In particular, large changes in radiative flux biases, driven by changes in simulated clouds, lead to large differences in temperature and precipitation biases.

The CMIP5 models perform well in simulating 20th-century snowfall for the Northern Hemisphere, although there is a positive bias in the multi-model ensemble relative to the observed data in many regions (Krasting et al., 2013). Lack of sufficient spatial resolution in the model topography has a serious impact on the simulation of snowfall. The patterns of relative maxima and minima of snowfall, however, are captured reasonably well by the models.

Arctic CORDEX RCMs reproduce the dominant features of regional precipitation patterns and extremes (e.g., Glisan and Gutowski, 2014; Hamman et al., 2016). Due to their higher spatial resolution, RCMs simulate larger amounts of orographic precipitation compared to reanalyses. Overall, the simulated precipitation is within the reanalysis and global model ensemble spread, but the Arctic river basin precipitation is closer to observations (Brunke et al., 2018). However, Takhsha et al. (2018) show that the RCMs' precipitation bias highly depends on the observational reference dataset used.

The annual mean precipitation pattern of ensemble global atmospheric simulations with a high horizontal resolution agrees well with the observations, with precipitation maxima over the Greenland and Norwegian seas (Kusunoki et al., 2015). However, the simulated Arctic average annual precipitation shows a positive bias with excessive precipitation over Alaska and the western Arctic (Kattsov et al., 2017).

Regarding the Greenland Ice Sheet (region GIC), modelled surface mass balance (SMB) has decreased since the end of the 1990s (Fettweis et al., 2020). A multi-model intercomparison study (Fettweis et al., 2020) emphasized a simulated positive mean annual SMB of $338 \pm 68 \text{ Gt yr}^{-1}$ between 1980 and 2012, with a decreasing average rate of $7.3 \pm 2.0 \text{ Gt yr}^{-2}$, mainly driven by an increase in meltwater

runoff. Mouginit et al. (2019) stated that SMB played a strong role in the ice-sheet mass loss, where SMB dominated in the last two decades. Mottram et al. (2019) found that SMB processes dominate the ice-sheet mass budget over most of the interior, highlighting that the ice sheet is a contributor to global mean sea level rise between 1991 and 2015. More specifically, SMB models have improved (Fettweis et al., 2020; Hanna et al., 2021) due to increased availability and quality of remotely sensed (Koenig et al., 2016; Overly et al., 2016) and in situ observations (Machguth et al., 2016; Fausto et al., 2018; Vandecrux et al., 2019, 2020). Fettweis et al. (2020) showed that the models' ensemble mean provides the best estimate of the present-day SMB relative to observations. This is the case for the patterns in all seven regions (regional division after Mouginit et al., 2019) apart from the SE accumulation zone where large discrepancies in modelled snowfall accumulation occurred where the spread can reach 2-m water equivalent per year. Montgomery et al. (2020) confirmed this, highlighting that RCMs (MAR and RACMO) are underestimating accumulation in south-east Greenland and that models misrepresent spatial heterogeneity due to an orographically forced bias in snowfall near the coast. Further, for north-east Greenland, Karlsson et al. (2020) found RCMs underestimate snow accumulation rates by up to 35%. The regional time series show that SMB has been gradually decreasing in all seven regions (1979–2017), although the trend is less strong in central-eastern and south-eastern regions. In the south-west, north-east and north-west, SMB turns negative or close to zero after 2000 and remains above zero in other regions (*medium confidence*) (Figure Atlas.30).

Atlas.11.2.4 Assessment and Synthesis of Projections

Mean temperature in the Arctic is projected to continue to rise through the 21st century significantly higher than the global average (Figure Atlas.29 and the Interactive Atlas). For the regions NWN and NEN, see Atlas.9. The Arctic is projected to reach a 2°C annual mean warming above the 1981–2005 baseline about 25 to 50 years before the globe as a whole under RCP8.5 and RCP4.5 (Post et al., 2019). The Arctic warming may be as much as 4°C in the annual mean and 7°C in late autumn under 2°C global warming, regardless of which scenario is considered (*high confidence*) (Post et al., 2019).

Projections from 40 CMIP5 models of the 2014–2100 Arctic annual warming under RCP4.5 vary from 0.9°C to 6.7°C , with a multi-model mean of 3.7°C (Chylek et al., 2016). All models agree on a projected Arctic amplification (of at least 1.5 times), but they disagree on the magnitude and spatial patterns. Arctic warming trends projected by models that include a full direct and indirect aerosol effect ('fully aerosol–cloud interactive') are significantly higher than those projected by models without a full indirect aerosol effect (Chylek et al., 2016).

Projected Arctic warming exhibits a very pronounced seasonal cycle, with exceptionally strong warming in the winter. In projections from 30 CMIP5 models, winter warming over ARO varies regionally from 3°C to 5°C by mid-century and 5°C to 9°C by late-century under RCP4.5 (*high confidence*) (AMAP, 2017). Averaged over the Arctic and based on 36 CMIP5 models, winter warming is $5.8^{\circ}\text{C} \pm 1.5^{\circ}\text{C}$ by mid-century and $7.1^{\circ}\text{C} \pm 2.3^{\circ}\text{C}$ by 2100 under RCP4.5

(Overland et al., 2019), and an exceptionally strong warming of up to $14.1^{\circ}\text{C} \pm 2.9^{\circ}\text{C}$ is projected in December under RCP8.5 (Bintanja and Krikken, 2016). Bintanja and Van Der Linden (2013) estimated the Arctic winter warming over the 21st century to exceed the summer warming by at least a factor of four, irrespective of the magnitude of the climate forcing.

Overland et al. (2014) highlighted the difference between the near-term ‘adaptation timescale’ and the long-term ‘mitigation timescale’ for the Arctic. Only in the latter half of the century do the projections under RCP4.5 and RCP8.5 noticeably separate. End-of-the-century warming is approximately twice as large under RCP8.5 demonstrating the impact of the lower emissions under RCP4.5 (*high confidence*) (AMAP, 2017). More specifically under the strong forcing scenario, annual mean surface air temperature in the Arctic is projected to increase by $8.5^{\circ}\text{C} \pm 2.1^{\circ}\text{C}$ over the course of the 21st century (Bintanja and Andry, 2017), and emerges as a ‘new Arctic’ climate being significantly different from that of the mid-20th century (Landrum and Holland, 2020). The end-of-the-century warming (2080–2099 relative to 1980–1999, RCP8.5) can exceed 15°C in autumn and winter over the Arctic Ocean (Koenigk et al., 2015). Projections averaged over the four best-performing CMIP5 models show an Arctic annual warming of 4.1°C (RCP2.6), 5.7°C (RCP4.5) and 10.6°C (RCP8.5) by 2100 compared to 1951–1980 (Hao et al., 2018). Also, for neighbouring Arctic regions, for example NEU, WSB and ESB, temperature is projected to increase towards the end of the century under both RCP4.5 and RCP8.5 (Atlas.8 and Atlas.5.2).

The ensemble of CMIP6 shows *likely* greater warming compared to CMIP5 (Figure Atlas.29). There is weak agreement among the models in projected temperature change over the Arctic North Atlantic under SSPs until the mid-century, but a robust warming signal clearly emerges even there by 2100 (Interactive Atlas). Generally, the largest annual warming is simulated over the Arctic Ocean, particularly over the Barents Sea and the Kara Sea. Future warming in CORDEX RCMs and the CMIP5 models are similar (Spinoni et al., 2020). The RCM warming over the AO is smaller, while the warming over land is larger in winter and spring but smaller in summer, compared with CMIP5 (Koenigk et al., 2015).

Mean precipitation in ARO, GIC and RAR is projected to rise in a warming climate (Figure Atlas.29), with different rates for the different seasons and scenarios. For NWN and NEN, see Atlas.9. The CMIP5 multi-model mean projected precipitation increase in the Arctic is *likely* of the order of 50% under RCP8.5 by the end of the 21st century, which is among the highest globally (Bintanja and Selten, 2014). Over 70°N – 90°N , the precipitation increase is *likely* $62 \pm 20\%$ and $56 \pm 13\%$ for RCP4.5 and RCP8.5 respectively. For ARO (Svalbard), the increase in annual precipitation by 2100 is estimated to be about 45% for RCP4.5 and 65% for RCP8.5 (CMIP5 ensemble median; Van der Bilt et al., 2019). However, importantly the simulated Arctic precipitation increase varies by a factor of three to four between models (Bintanja and Selten, 2014). The projected increase is strongest in late autumn and winter (Vihma et al., 2016). The interannual variability of Arctic precipitation will likely increase markedly (up to 40% over the 21st century), especially in summer (*medium confidence*) (Bintanja et al., 2020).

The CMIP6 projections confirm precipitation will *likely* increase almost everywhere in the Arctic (Interactive Atlas). The largest increase is simulated over the Barents Sea, Kara Sea and East Siberian Sea regions, and over north-east Greenland. A pronounced uncertainty in the projection exists over the Arctic North Atlantic and south Greenland. There, the precipitation signal is not significant even by the end of the 21st century and under high-emissions scenarios (RCP8.5, SSP5-8.5). Consistent with the generally higher warming in CMIP6, compared to CMIP5, the projected precipitation increase is also higher (*high confidence*) (Figure Atlas.29).

The Arctic mean annual precipitation sensitivity has been estimated at a 4.5% increase per degree Celsius of temperature rise, compared to a global average of 1.6–1.9% per degree Celsius of temperature rise (Bintanja and Selten, 2014) based on a set of 37 CMIP5 GCMs. Koenigk et al. (2015) stress the different precipitation sensitivity in winter (0.8 mm per month per degree Celsius of temperature rise) and summer (2 mm per month per degree Celsius of temperature rise). The pattern and amplitude of precipitation changes agree in CORDEX simulations with their driving CMIP5 models (*high confidence*) (Koenigk et al., 2015; Spinoni et al., 2020). However, more small-scale variations over land and coastlines, and significantly larger precipitation changes in summer are obvious in the downscaling.

Rain is projected to become the dominant form of precipitation in the Arctic region by the end of the 21st century (Bintanja, 2018). The CMIP5 models show a decrease in annual Arctic snowfall under both RCP4.5 and RCP8.5 (*high confidence*) (Krasting et al., 2013; Bintanja and Andry, 2017). In the central Arctic, the snowfall fraction barely remains larger than 50%, with only Greenland still having snowfall fractions larger than 80% (Bintanja and Andry, 2017). The most dramatic reductions in snowfall fraction are projected to occur over the North Atlantic and, especially, the Barents Sea.

With ongoing warming and polar amplification in the Arctic, the Greenland Ice Sheet SMB will inevitably continue to change (*high confidence*) (Lenaerts et al., 2019). For the ice sheet, despite large differences between model scenarios, future projections and regions agree that increasing temperatures will increase runoff which will in turn dominate the future decrease of SMB (Rae et al., 2012; van Angelen et al., 2014; Mottram et al., 2017; Hofer et al., 2020), confirming the high sensitivity of the SMB to atmospheric warming. Changes in SMB will continue to dominate future mass loss from the ice sheet, and likely even more when marine-terminating glaciers retreat onto land, and solid ice discharge is reduced (Vizcaino, 2014; Lenaerts et al., 2019).

Atlas.11.2.5 Summary

It is *very likely* that the Arctic has warmed at more than twice the global rate over the past 50 years and *likely* that annual precipitation has increased with the highest increases during the cold season. This is based on various Arctic amplification processes, in particular, a combination of several feedback-related processes such as sea ice and snow-cover albedo, poleward energy transports, and water-vapour-cloud-radiation feedbacks. The frequency of rainfall increased over the Arctic by 2.7–5.4% over the 2000–2016 period with more

frequent rainfall events being reported for northern Europe and Svalbard (*medium confidence*).

The CMIP5 models reproduce the observed Arctic warming over the past century but overestimate the amplified Arctic warming in the recent decades (*medium confidence*). Arctic CORDEX simulations show adequate skill in capturing regional temperature and precipitation patterns and precipitation extremes (*high confidence*). SMB models have improved due to increased availability and quality of remotely sensed and in situ observations, and an ensemble mean of SMB model simulations provides the best estimate of the present-day SMB (*medium confidence*).

It is *very likely* that the Arctic annual mean temperature and precipitation will continue to increase, reaching around $11.5^{\circ}\text{C} \pm 3.4^{\circ}\text{C}$ and $49 \pm 19\%$ over the 2081–2100 period (with respect to a 1995–2014 baseline) under the SSP5-8.5 scenario or $4.0^{\circ}\text{C} \pm 2.5^{\circ}\text{C}$ and $17 \pm 11\%$ under the SSP1-2.6 scenario. These CMIP6 results show *likely* higher Arctic annual mean temperatures compared to CMIP5 for a given time-period and emissions scenario, though the projections are consistent for global warming levels.

can remain larger than model uncertainty or scenario uncertainty throughout the whole century. The Atlas (similarly to other regional chapters) uses a single realization per model (CMIP6 models provide multiple realizations, but it is not the case for CORDEX and less so for CMIP5), which allows for the comparison of the different lines of evidence but at the expense of internal variability having a larger influence on the ability to detect or quantify changes.

The assessment produced in the Atlas is based on the individual results from the different lines of global and regional evidence and the consistency amongst them, as there is a lack of literature on methodologies that combine multiple lines of evidence to distil regional climate change information.

Atlas.12 Final Remarks

Developing from the AR5 WGI Atlas Annex (IPCC, 2013a), the Atlas is an innovation in the WGI contribution to the AR6, providing a region-by-region assessment of new knowledge on changes in mean climate and an online interactive tool, the Interactive Atlas. It demonstrates the diversity in the climate changes across these regions, in the evidence base for generating information on what changes have already occurred and why, and what further changes each region is projected to face in the future based on different emissions scenarios and global warming levels. Finally, the Interactive Atlas allows for further exploration of the data underpinning the assessment material generated by many of the other chapters.

The foundation of the regional information generated by the Atlas chapter is an assessment of the significant body of new literature on regional climate change though noting substantial heterogeneity in both its availability and the involvement of regional expertise. In many regions this allows for an in-depth assessment though in some the range of information that can be provided and/or the level of confidence in the information is limited. There is similar heterogeneity in the availability of observations to assess recent trends and evaluate model performance, with a lack of curated regional datasets in the polar regions, Northern South America, Africa and the Small Islands.

Internal variability is a large contributor to the climate uncertainty at regional scales. Recent work has combined outputs of single model initial-conditions large ensembles (SMILES) with CMIP5 and CMIP6 to partition and gain insights on the modelled range and uncertainty arising from internal variability and from model-response uncertainty for a given emissions scenario (Deser et al., 2020; Lehner et al., 2020; Maher et al., 2021). The work highlights the notable role for internal variability at regional scales, particularly for precipitation in regions with weaker forced response, where internal variability

AI.1 Introduction

The purpose of this annex is to document observational datasets used by Working Group I in the Sixth Assessment Report. This includes details of the types and versions of datasets, the time period they cover, the chapters in which they appear, and citations and (where available) web links to the data.

This list includes those observational datasets that contribute to values reported in the text or in figures, unless they are citing a specific result from a paper (as opposed to an ongoing dataset for which that paper is a reference).

Reanalyses are within the scope of this annex, but historical climate model simulations are not. Proxy datasets are also outside the scope of this annex.

Datasets which are updated regularly on an operational basis are shown as ending in 2020, even if no 2020 data have yet been published at the time of writing.

Datasets are sorted alphabetically according to the dataset name or, if there is no formal name, the name of the responsible institution or lead author.

Table AI.1 | Observational products used by Working Group I in the Sixth Assessment Report.

Name	Version	Type	Resolution (Time and Space)	Section(s)	Time Period	Citation, Link and DOI (Where Available)
NOAA-CIRES 20th Century Reanalysis (20CR)	2c	Reanalysis	3-hourly 2° × 2°, 24 vertical levels	2.4.1	1851–2014	Compo et al. (2011) www.esrl.noaa.gov/psd/data/20thC_Rean/
NOAA-CIRES 20th Century Reanalysis (20CR)	3	Reanalysis	3-hourly 0.5° × 0.5°	2.3.1 3.3.3 3.7.1	1851–2020	Slivinski et al. (2019) www.esrl.noaa.gov/psd/data/20thC_Rean/
Finland Climate (Aalto)		In situ	Daily 0.1° × 0.1°	10.2.1	1961–2010	Aalto et al. (2016) www.csc.fi/~paituli
ACORN-SAT Australian temperature data	2.1	In situ	Daily Point-based	Atlas 6.2	1910–2020	Trewin et al. (2020) www.bom.gov.au/climate/data/acorn-sat/
AERONET AOD Level 2.0	3	Remote sensing	Monthly Point-based	2.2.6	1995–2020	Giles et al. (2019) https://aeronet.gsfc.nasa.gov/data_push/AOT_Level2_Monthly.tar.gz
Advanced Global Atmospheric Gases Experiment (AGAGE)		In situ	Up to 36 times per day Point-based	2.2.3 2.2.4 5.2.2 5.2.3	1978–2020	Prinn et al. (2018) http://agage.mit.edu/data
Australian Gridded Climate Data (AGCD)		In situ	Daily 0.05° × 0.05°	Atlas 6.2	1900–2020	Jones et al. (2009); Evans et al. (2020) www.bom.gov.au/climate/maps/rainfall
AIRS specific humidity	RetStd-v5	Remote sensing	Monthly 1° × 1°	3.3.2	2003–2010	Susskind et al. (2006); Tian et al. (2013) https://esgf-node.llnl.gov/search/obs4mips/
AIRS-6 climate data products		Remote sensing	Various	2.3.1	2002–2020	Susskind et al. (2014) http://disc.sci.gsfc.nasa.gov/AIRS/data-holdings
Energy balance reconstruction (Allan)		Remote sensing	Monthly 10° × 10°	7.2.2	1985–2012	Allan et al. (2014) http://met.reading.ac.uk/~sgs02rpa/research/DEEP-C/GRL/
AMOC dataset		In situ, reanalysis	Monthly Regional time series	3.5.4	2004–2017	Smeed et al. (2018)
Advanced Microwave Scanning Radiometer 2 (AMSR2)		Remote sensing	3-hourly	8.3.1	2012–2019	Kummerow et al. (2015) https://lance.nsstc.nasa.gov/amr2-science/data/level2/rainocean/
Aqua's Advanced Microwave Scanning Radiometer for Earth Observing System (AMSR-E)		Remote sensing	5.4–56 km	8.3.1	2002–2011	Kawanishi et al. (2003)
Arctic sea ice thickness from submarine transects		In situ	Intermittent Track-based	2.3.2	1975–2000	Rothrock et al. (2008)
Asian Precipitation – Highly-Resolved Observational Data Integration Towards Evaluation (APHRODITE's) Precipitation		In situ	Daily 0.05° × 0.05°	8.3.2 10.2.1 10.6.3	1900–2020	Kamiguchi et al. (2010); Yatagai et al. (2012)

Name	Version	Type	Resolution (Time and Space)	Section(s)	Time Period	Citation, Link and DOI (Where Available)
Asian Precipitation – Highly-Resolved Observational Data Integration Towards Evaluation Monsoon Asia (APHRO-MA)	V1808	In situ	Daily 0.5°	Cross-Chapter Box (CCB) 10.4	1961–2014	Yasutomi et al. (2011) http://aphrodite.st.hirosaki-u.ac.jp/products.html
Asian Precipitation – Highly-Resolved Observational Data Integration Towards Evaluation Monsoon Asia (APHRO-MA)	V1101	In situ	Daily 0.5°	10.6.3	1956–2005	Yatagai et al. (2012) http://aphrodite.st.hirosaki-u.ac.jp/products.html
Advanced Scatterometer (ASCAT)		Remote sensing	Daily 25 km	8.3.1	2006–2016	Wagner et al. (1999)
Cross-calibrated multi-platform wind dataset (Atlas)		Remote sensing, in situ	6-hourly 25 km	2.3.1	1987–2020	Atlas et al. (2011) www.remss.com/measurements/ccmp/
Australian vineyard data		In situ	Annual Point-based	2.3.4	Varies by site	Webb et al. (2011)
AVISO sea level observations		Remote sensing	Monthly 0.25°	9.2.4	1995–2020	Legeais et al. (2018) www.aviso.altimetry.fr/en/data/products/ocean-indicators-products/mean-sea-level.html
Beaune grape harvest dates		In situ	Annual Point-based	2.3.4	1354–2018	Labbé et al. (2019) www.euroclimhist.unibe.ch/en/
Berkeley Earth surface air temperature		In situ	Monthly 1° × 1° (or equivalent equal-area grid)	1.3.6 1.4.1 1.4.2 1.6.1 FAQ 1.2 2.3.1 CCB 2.3 3.3.1 3.7.3 10.3.3 10.6.4 Box 10.3 CCB 10.4 Atlas	1750–2020	Rohde and Hausfather (2020) www.berkeleyearth.org
Berlin City Measurement Network		In situ	1-minute	Box 10.3	Ongoing	www.geo.fu-berlin.de/en/met/service/stadtmetnetz/index.html
Bermuda Atlantic Time-series Study Data		In situ	Point-based	2.3.3	1988–2016	Bates et al. (2014); Bates and Johnson (2020) http://bats.bios.edu/bats-data/
Czech Republic precipitation (Bližňák)		In situ	10 min 0.01° × 0.01°	10.2.1	2002–2011	Bližňák et al. (2018)
Boulder stratospheric water vapour		In situ	Profiles approx. monthly Point-based	2.2.5	1980–2010	Hurst et al. (2011)
BUCL (Birmingham)		In situ	Hourly	Box 10.3	2013–2020	Chapman et al. (2015)
Global temperature data (Callendar)		In situ	Annual Global time series	1.3.3	1880–1935	Callendar (1938); Hawkins and Jones (2013)
Cyprus precipitation (Camera)		In situ	Daily 0.01° × 0.01°	10.2.1	1980–2010	Camera et al. (2014)
CAMS atmospheric composition reanalysis		Reanalysis	3-hourly 1° × 1°	7.3.3	2003–2018	Inness et al. (2019) http://atmosphere.copernicus.eu
Data of CARIACO ocean time-series program in the Cariaco Basin		In situ	Point-based	5.3.2	1996–2017	Bates et al. (2014) http://imars.marine.usf.edu/cariaco
CCU 'IKI-Monitoring' satellite data archive		Remote sensing	Daily Resolution varies	Atlas	1984–2020	Loupian et al. (2015)

Name	Version	Type	Resolution (Time and Space)	Section(s)	Time Period	Citation, Link and DOI (Where Available)
Community Emissions Data System (CEDS)		In situ	Monthly 50 km (nominal)	6.2.1	1750–2014	Hoesly et al. (2018) www.globalchange.umd.edu/ceds/
CERA-20C reanalysis		Reanalysis	3-hourly 125 km, 91 levels	10.3.3	1901–2010	Laloux et al. (2018) www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/cera-20c
CERES EBAF	Ed2.8	Remote sensing	Monthly 1° × 1°	3.8.2	2000–2018	Loeb et al. (2009, 2012) https://esgf-node.llnl.gov/search/obs4mips/
CERES EBAF	Ed4.0	Remote sensing	Monthly 1° × 1°	7.2.2 9.2.1	2000–2016	Loeb et al. (2017, 2020) http://ceres-tool.larc.nasa.gov/ord-tool/jsp/EBAF4Selection.jsp
NCEP Climate Forecast System Reanalysis (CFSR)		Reanalysis	Hourly T382 (approx. 38 km)	2.3.1 8.3.2	1979–2010	Saha et al. (2010) https://cfs.ncep.noaa.gov/cfsr/
High-resolution Gridded Daily Meteorological Dataset over Sub-Saharan Africa (Chaney)		Reanalysis	Daily 0.1° × 0.1°	10.2.1	1979–2005	Chaney et al. (2014)
Cheng ocean heat content		In situ	Monthly Ocean basin	2.3.3	1960–2020	Cheng et al. (2017)
Global mean sea level reconstruction (Church and White)		In situ, remote sensing	Monthly Global time series	2.3.3	1880–2009	Church and White (2011)
Climate Hazards Group InfraRed Precipitation with Station data (CHIRPS)	2.0	Remote sensing	Daily, monthly 0.25° × 0.25°	10.2.1	1981–2018	Funk et al. (2015) www.chc.ucsb.edu/data/chirps
CLIMATER		In situ	Daily Point-based	Atlas 5.2	1874–2020	Bulygina et al. (2014)
China Land Surface Air Temperature (CLSAT)		In situ	Monthly Point-based	2.3.1	1900–2020	Xu et al. (2018)
CPC Merged Analysis of Precipitation (CMAP)		Remote sensing	Monthly 2.5° × 2.5°	3.3.3 Atlas	1979–2020	Xie et al. (2007a) www.esrl.noaa.gov/psd/data/gridded/data.cmap.html
Copernicus Marine Environment Monitoring Service (CMEMS) ocean pH		In situ	Annual Global mean	2.3.3	1985–2020	Gehlen et al. (2020) https://marine.copernicus.eu/access-data/ocean-monitoring-indicators

UCAR/ NOAA radio occultation data		Remote sensing	Monthly 5° latitude bands	2.3.1	2002–2020	Steiner et al. (2020)
University of California at Irvine (UCI) atmospheric gas measurements		In situ	Several sampling periods per year Point-based	2.2.3	1984–2020	Simpson et al. (2012) http://cdiac.ornl.gov/tracegases.html
UEA-SI air–sea CO ₂ fluxes	2015	In situ	Monthly 2.5° × 2.5°	5.2.1	1985–2011	Jones et al. (2015) doi:10.1594/PANGAEA.849262
UHH sea ice product		In situ, remote sensing	Monthly Area average	2.3.2	1850–2020	Doerr et al. (2021) www.fdr.uni-hamburg.de/record/8559#.YEtN09xxXIU doi:10.25592/uhhfdm.8525
UrBAN (Helsinki)		In situ	Sub-hourly	Box 10.3	2004–2020	Wood et al. (2013) http://urban.fmi.fi
Global temperature dataset (Vaccaro)		In situ	Monthly 5° × 5°	2.3.1	1850–2020	Vaccaro et al. (2021)

Name	Version	Type	Resolution (Time and Space)	Section(s)	Time Period	Citation, Link and DOI (Where Available)
W5E5 bias-adjusted reanalysis	1.0	Reanalysis	Daily 0.5° × 0.5°	Atlas	1979–2016	Lange (2019) https://dataservices.gfz-potsdam.de/pik/showshort.php?id=escidoc:4855898 doi:10.5880/pik.2019.023
Sea ice data (Walsh)		Remote sensing, in situ	Monthly	2.3.2	1850–2020	Walsh et al. (2017)
WASWind marine wind data		In situ	Monthly 4° × 4°	2.4.4	1950–2011	Tokinaga and Xie (2011) https://climatedataguide.ucar.edu/climate-data/waswind-wave-and-anemometer-based-sea-surface-wind
WCRP/Palmer global sea level		Remote sensing, in situ	Monthly Global time series	2.3.3	1901–2018	WCRP Global Sea Level Budget Group (2018); Palmer et al. (2021)
Wegener Centre radio occultation dataset		Remote sensing	Monthly 0.1 km vertical resolution	2.3.1	2001–2020	Angerer et al. (2017)
Global mean sea level reconstruction (Wenzel and Schröter)		In situ	Monthly Global time series	2.3.3	1900–2009	Wenzel and Schröter (2014)
WFDE5	1.0	Reanalysis	Hourly 0.5°	10.3.3	1979–2018	Cucchi et al. (2020)
WMO Global Atmosphere Watch greenhouse gas measurements		In situ	Annual Point-based and global means	2.2.3	1984–2020	Tsutsumi et al. (2009); WMO (2019) https://gaw.kishou.go.jp/publications/global_mean_mole_fractions
World Ocean Atlas (WOA)	2018	In situ	Monthly 1° × 1°	3.5.1	2009	Levitus et al. (2012); Locarnini et al. (2019); Zweng et al. (2019) www.nodc.noaa.gov/OC5/woa18/woa18data.html
World Ozone and UV Data Center (WOUDC) ozone dataset		In situ	Monthly Global and zonal means	2.2.5	1964–2020	Fioletov et al. (2002) https://woudc.org/
Global Earth Observation for Integrated Water Resource Assessment (Earth2Observe) Water Resources Reanalysis v2 (WRR2)	2	Reanalysis	Monthly 0.5° × 0.5°	8.3.1	1979–2012	Schellekens et al. (2017)
Brazil gridded met data 1980–2013 (Xavier)		In situ	Daily 0.25° × 0.25°	10.2.1	1980–2013	Xavier et al. (2016) http://careyking.com/data-downloads/
Chile precipitation (Yang)		In situ	Daily 0.04° × 0.04°	10.2.1	2009–2014	Z. Yang et al. (2017) www.climatedatalibrary.cl/SOURCES/
Ocean heat content and thermosteric sea level reconstruction (Zanna)		In situ	Annual Global means	2.3.3	1871–2017	Zanna et al. (2019)

AII

This annex provides information on the numerical models used in this assessment.

AII.1 Regional Climate Models (RCMs) Participating in CORDEX

The Coordinated Regional Climate Downscaling Experiment (CORDEX; Gutowski Jr. et al., 2016) coordinates regional downscaling activities worldwide over a number of defined domains. Regional downscaling is performed using regional climate models (RCMs) run over limited geographical regions, driven at the boundaries by the output from the Coupled Model Intercomparison Project (CMIP) global model simulations. CORDEX relies on the same infrastructure as CMIP to make the multi-model output publicly available in a standardized format: the data is disseminated via the Earth System Grid Federation (ESGF; Williams et al., 2016).

Table AII.1 lists the current CORDEX domains, displaying the different resolutions (from the lowest – 0.44°, to the highest – 0.11°, typically in rotated coordinates), with data available through the ESGF. Figure Atlas.6 provides a geographical map of the domains. Note that 0.44° and 0.22° are the prioritized resolution in the CORDEX and CORDEX-CORE experimental designs, respectively, and only some domains provide information for higher resolution (0.11°); see Atlas, Atlas.1.4.4 and <https://cordex.org> for further details. Table AII.1 also displays the number of simulations available for the following experiments: ‘evaluation’ (ERA-Interim driven simulations), and the ‘historical’, ‘RCP2.6’, ‘RCP4.5’ and ‘RCP8.5’ CMIP5-driven simulations

(Taylor et al., 2012). This table illustrates the heterogeneity of information available across the different domains which limits the assessment of some scenarios in some regions.

The RCMs contributing to CORDEX (as available from ESGF) are listed in Table AII.2, including the main references and details on model components relevant for the AR6 WGI assessment.

Finally, Tables AII.3 and AII.4 provide information on the CMIP5 and RCM models used in the different CORDEX domains, respectively (the numbers in each cell indicate the number of available simulations for each scenario). Note that CORDEX information is complex to describe since each particular simulation is produced by a single combination of a CMIP5 boundary forcing, or ‘driving model’ (or reanalysis for the evaluation experiment) and an RCM model from Table AII.2. These two tables together provide comprehensive information on the GCM/RCM composition of the ensembles available in each domain, which is key to understanding the assessment done in WGI chapters (in particular the regional Chapters 10, 11 and 12, and the Atlas).

Table AII.1 | CORDEX regional domains. Column 1: name of the domain. Column 2: domain code (as in ESGF specification). Column 3: horizontal grid resolutions (11, 22 and 44 for 0.11°, 0.22° and 0.44° resolution in the native projections, and the suffix ‘i’ indicating regular interpolated domains). Columns 4–8 indicate the number of simulations available at each resolution, for the evaluation, historical, RCP2.6, RCP4.5 and RCP8.5 experiments, respectively, as archived in the ESGF as of 31 January 2021. Note that MED-CORDEX data is stored on a dedicated server (details at www.medcordex.eu) and includes experiments with only atmosphere (the standard for other domains) and atmosphere–ocean coupled regional climate models (denoted by MED and OMED, respectively). See Atlas.1.4.4 for more details on CORDEX and CORDEX-CORE experiments.

CORDEX Domains	Code	Resolutions	Evaluation	Historical	RCP2.6	RCP4.5	RCP8.5

Table AII.2 | Regional climate models contributing to CORDEX experiments. Salient features of the regional climate models (RCMs) participating in CORDEX scenario experiments (CMIP5-driven). Column 1: sponsoring institution(s). Column 2: name of the model (and versions); subsequent columns for each of the model components with main references. Column 3: atmospheric component with number of vertical levels and main reference. Column 4: aerosols component (interactive or prescribed, with component details when interactive). Column 5: land component (number of levels and component name). Column 6: ocean component (prescribed or interactive, with model details when interactive). Column 7: additional components (lake, urban or river models) and comments on versions and/or different configurations of the same model.

Institution (Country)	Model	Atmosphere	Aerosols	Land	Ocean	Additional Components/Comments
		1) Number of Levels 2) Main References	1) Interactive or Prescribed 2) Component Name (When Interactive)	1) Number of Levels 2) Component Name	1) Interactive or Prescribed 2) Component Name 3) Details	Lake (LK), Urban (UR) or River (RI) Models, etc., Comments on the Different Versions
CNRM (France)	ALADIN52_v1 ALADIN53_v1	1) 31 2) Colin et al. (2010)	1) Prescribed; Szopa et al. (2013) dataset for evaluation and GCM forcing for scenario runs, 5 classes, 2D spatial pattern, vertical profile, seasonal cycle, temporal evolution	1) 3 2) ISBA (Noilhan and Mahfouf, 1996)	1) Prescribed SST (ice cover defined by a SST threshold)	LK: no UR: no ALADIN53_v1 is same as ALADIN52_v1 except for the radiation scheme (RRTM for the LW (Mlawer et al., 1997) and FMR-6 bands for the SW (Fouquart and Bonnel, 1980; Morcrette et al., 2008)), for the turbulent air-sea fluxes (ECUME) and for the mixing length based on Lenderink's work
CNRM (France)	ALADIN63_v1 ALADIN63_v2	1) 91 2) Nabat et al. (2020)	1) Prescribed; TACTIC dataset for eval and GCM forcing for scen, 5 classes, 2D spatial pattern, vertical profile, seasonal cycle, temporal evolution	1) 14 2) SURFEX8-ISBA (Decharme et al., 2019) No land-use land cover change is taken into account	1) Prescribed SST (ice cover defined by a SST threshold)	LK: Flake (Le Moigne et al., 2016), pronostic lake ice UR: Urban areas are considered as rock (Daniel et al., 2019) ALADIN63_v1 and ALADIN63_v2 are identical. The v2 label is used to indicate that the runs driven by the CNRM-CM5 GCM use the corrected version of the CNRM-CM5 atmospheric LBCs contrary to ALADIN53_v1
RMIB-UGent (Belgium)	ALARO-0_v1	1) 46 2) Giot et al. (2016); Top et al. (2021)	1) Prescribed	1) 2 2) ISBA (Douville et al., 2000)	1) Prescribed SST	n.a.
CCCma (Canada)	CanRCM4_r2	1) 25 2) Scinocca et al. (2016)	1) Interactive 2) Described in main reference	1) 3 2) CLASS 2.7	1) Prescribed SST	Full atmospheric physics package identical to that used by parent global model, CanAM4, used by CanESM2 for CMIP5. Historical + RCP8.5 large ensemble (50 members) of 'NAM-44' available for large ensemble (50 members) of its parent model, CanESM2

Institution (Country)	Model	Atmosphere	Aerosols	Land	Ocean	Additional Components/Comments
		1) Number of Levels 2) Main References	1) Interactive or Prescribed 2) Component Name (When Interactive)	1) Number of Levels 2) Component Name	1) Interactive or Prescribed 2) Component Name 3) Details	Lake (LK), Urban (UR) or River (RI) Models, etc., Comments on the Different Versions
CSIRO (Australia)	CCAM_v1 CCAM-1704_v1	1) 27 2) Hoffmann et al. (2016)	1) Interactive 2) Sulphate, black carbon, organic aerosol, mineral dust and sea salt (Rotstayn and Lohmann, 2002; Rotstayn et al., 2011)	1) 6 2) CABLE (Kowalczyk et al., 2013)	1) Prescribed SST after bias and variance correction (CCAM_V1) or just bias correction (CCAM-1704_v1) No atmospheric nudging	UR: UCLEM (Lipson et al., 2018)
CSIRO (Australia)	CCAM-2008_v1	1) 35 2) Thatcher and McGregor (2009)	1) Interactive 2) Sulphate, black carbon, organic aerosol, mineral dust and sea salt (Rotstayn and Lohmann, 2002; Rotstayn et al., 2011)	1) 6 2) CABLE (Kowalczyk et al., 2013)	1) Prescribed SST	UR: UCLEM (Lipson et al., 2018)
CLM-Community: BTU, CMCC, DWD, ETH, GUF, HZG, JLU, KIT, WEGC ZAMG (Europe)	CCLM4-8-17-CLM3-5_v1	1) 35 2) Di Virgilio et al. (2019)	1) Prescribed	1) 9 2) CLM (Dickinson et al., 2006)	1) Prescribed SST	n.a.
CLM-Community (Europe)	CCLM4-8-17_v1	1) 35 2) Panitz et al. (2014)	1) Prescribed	1) 9 2) Soil-vegetation-atmosphere transfer TERRA-ML (Schrodin and Heise, 2002)	1) Prescribed SST	n.a.
CLM-Community (Europe)	CCLM5-0-2_v1	1) 45 2) Li et al. (2018)	1) Prescribed. Aerosol optical thickness: NASA/GISS (Global Aerosol Climatology Project)	1) 9 2) Multilayer soil model TERRA-ML (Schrodin and Heise, 2002)	1) Prescribed SST	Surface roughness: GLOBE (NOAA/NGDC); Global Land Cover 2000 Project (GLC2000)
CLM-Community: HZG and KIT (Germany)	CCLM5-0-15_v1	1) 57 2) n.a.	1) Prescribed	1) 9 2) TERRA-ML (Schrodin and Heise, 2002)	1) Prescribed SST	LK: Flake (Mironov et al., 2010)
CLM-Community: GUF (Germany)	CCLM5-0-9-NEMOMED12-3-6	1) 40 2) Akhtar et al. (2018)	1) Prescribed; AeroCom global AOD data is used for Aerosol representation (Kinne et al., 2006)	1) 9 2) TERRA-ML (Schrodin and Heise, 2002)	1) Interactive 2) NEMOMED12 ($1/12^\circ$ resolution) is the interactive ocean model component (Beuviel et al., 2012) 3) The CCLM and NEMOMED12 models are coupled via OASIS3-MCT (Valcke, 2013) with a 1-h coupling time	RI: TRIP (Total Runoff Integrating Pathways) is used as the interactive river component for rivers over the Mediterranean basin to feed runoff at the river mouths to the Mediterranean Sea (NEMOMED12)

Institution (Country)	Model	Atmosphere	Aerosols	Land	Ocean	Additional Components/Comments
		1) Number of Levels 2) Main References	1) Interactive or Prescribed 2) Component Name (When Interactive)	1) Number of Levels 2) Component Name	1) Interactive or Prescribed 2) Component Name 3) Details	Lake (LK), Urban (UR) or River (RI) Models, etc., Comments on the Different Versions
CLIM-Community: ETH (Switzerland)	COSMO-crCLIM-v1-1_v1	1) 40 (EUR-11), 57 (WAS-22) 2) Leutwyler et al. (2017)	1) Prescribed; AeroCom1 aerosol monthly climatology dataset (Kinne et al., 2006)	1) 9 2) TERRA-ML with a soil hydrology scheme (Schlemmer et al., 2018)	1) Prescribed SST	COSMO-crCLIM is similar to CCLM. Its main characteristics are that it runs on GPUs and includes the soil hydrology scheme of Schlemmer et al. (2018). Other adjustments include changing the upper level damping to only relax the vertical velocity instead of all dynamical fields (Klemp et al., 2008)
OURANOS (Canada)	CRCM5_v1	1) 56 (TOA 10 hPa) 2) Martynov et al. (2013); Šeparović et al. (2013)	1) Prescribed	1) 17 (to 15 m) 2) CLASS3.5c (Versegny et al., 1993)	1) Prescribed SST and sea ice fraction	LK: Flake
UQAM (Canada)	CRCM5_v1	1) 56 (TOA 10 hPa) 2) Martynov et al. (2013)	1) Prescribed; not varying in time; higher values at the equator, lower at the poles; higher values over land than over the ocean	1) 26 (to 60 m) 2) CLASS3.5+	1) Prescribed SST and sea ice fraction	LK: Flake
INPE (Brazil)	Eta_v1	1) 38 (TOA 25hPa) 2) Chou et al. (2014a, b)	1) Prescribed	1) 4 2) NOAA scheme (Ek et al., 2003), 12 Vegetation types and 9 soil types	1) Prescribed SST	No orography smoothing; no internal or lateral boundary relaxation nudging
DMI (Denmark)	HIRHAM5_v1 HIRHAM5_v2 HIRHAM5_v3	1) 31 2) Bøssing Christensen et al. (2007)	1) Prescribed	1) 5 2) ECHAM5	1) Prescribed SST and sea ice	The different versions v1, v2 and v3 are simulation versions due to necessary re-runs, not different model versions
MOHC (UK)	HadREM3-GA7-05_v1 HadREM3-GA7-05_v2	1) 63 2) Walters et al. (2019)	1) Prescribed. MACv2-SP dataset (Stevens et al., 2017), total aerosol properties, 9 bands. EasyAerosol (Voigt et al., 2014) RCP scenarios	1) 4 2) Walters et al. (2019)	1) Prescribed SST and sea ice from driving GCM/reanalysis	LK: no The 'v2' runs are using CNRM boundary conditions from pressure level 3d data. No differences in the RCM, only a different source of LBCs

Institution (Country)	Model	Atmosphere	Aerosols	Land	Ocean	Additional Components/Comments
		1) Number of Levels 2) Main References	1) Interactive or Prescribed 2) Component Name (When Interactive)	1) Number of Levels 2) Component Name	1) Interactive or Prescribed 2) Component Name 3) Details	Lake (LK), Urban (UR) or River (RI) Models, etc., Comments on the Different Versions
LMD (France)	LMDZ4NEMOMED8_v1 LMDZ4NEMOMED8_v2	1) n.a. 2) L'Hévéder et al. (2013); Vadsaria et al. (2020)	1) Prescribed	1) 2 2) ORCHIDEE	1) Interactive 2) NEMOMED8 (Beuvier et al., 2010) 3) Interactive Mediterranean Sea only; 43 vertical levels with a 6-m thick first level; daily coupling frequency by the OASIS coupler (Valcke, 2013)	RI: Interactive river coupling in v2. No river coupling in v1
ULg (Belgium)	MAR311_v1	1) 24 2) Agosta et al. (2019); Kittel et al. (2021)	1) Prescribed, RCP scenarios	1) 7 2) SISVAT (De Ridder, 1997; De Ridder and Schayes, 1997; Gallée and Duynkerke, 1997; Gallée et al., 2001; Lefebvre, 2003)	1) Prescribed SST and SIC (evolution of the snow properties simulated by SISVAT)	SISVAT model: 30 snow/ice layers over the ice sheet and two sub-pixels (rocs and permanent ice-covered area)
UB Belgrade (Serbia)	EBU-POM2c_v1	1) 32 2) Djurdjevic and Rajkovic (2008, 2010); Kržič et al. (2011)	1) Prescribed	1) 4 2) NOAA-LSM (Ek et al., 2003)	1) Interactive 2) POM – Princeton ocean model (30 km, L21, coupling frequency 6 min)	n.a.
ENEA (Italy)	PROTHEUS_v2	1) 18 2) Artale et al. (2010); Soto-Navarro et al. (2020)	1) No active aerosol chemical model	1) 2 2) BATS1e (Dickinson et al., 1993). Air–sea exchanges by Zeng et al. (1998) to improve excessive evaporation from warm ocean surfaces (Pal et al., 2007) in the original BATS package	1) Interactive 2) MITMED8 (1/8° resolution) is the interactive ocean model component (Sannino et al., 2009).	RI: Fully interactive (daily coupling) using the TRIP river routine model.
KNMI (Netherlands)	RACMO21P_v1 RACMO21P_v2	1) 40 2) van Meijgaard et al. (2008)	1) Prescribed (Tegen et al., 1997); 4 classes (land, maritime, dust and urban). Stratospheric and (optionally) volcanic	1) 4 2) Baseline LSM TESSEL (van den Hurk et al., 2000); land-ice tile added for ice-sheet modelling. Multilayer snow-ice-refreezing scheme (Ettema et al., 2010); snow albedo scheme (Kuipers Munneke et al., 2011); snow drift scheme (Lenaerts et al., 2012)	1) Prescribed SST and sea ice concentration; inferred from reanalysis or GCM	Model versions: simulations with RACMO21P_v2 are straight re-runs of RACMO21P_v1 employing the same model system and parameter settings. In ANT-44 simulations, v2 is only used with MOHC-HadGEM2-ES forcing to fix the remapping of SST to the RACMO grid in the v1-simulation

Institution (Country)	Model	Atmosphere	Aerosols	Land	Ocean	Additional Components/Comments
		1) Number of Levels 2) Main References	1) Interactive or Prescribed 2) Component Name (When Interactive)	1) Number of Levels 2) Component Name	1) Interactive or Prescribed 2) Component Name 3) Details	Lake (LK), Urban (UR) or River (RI) Models, etc., Comments on the Different Versions
KNMI (Netherlands)	RACMO22E_v1 RACMO22E_v2	1) 40 2) van Meijgaard et al. (2012)	1) Prescribed; inferred from CAM inventory (except volcanic); historical and RCP pathways (Lamarque et al., 2010, 2011; van Vuuren et al., 2011); also used in evaluation. Sulphate, particulate organic matter black carbon, sea salt, desert dust stratospheric aerosols and volcanic aerosol. Spatial maps and vertical profiles per species. Monthly variations and decadal trends	1) 4 2) HTESSEL (Balsamo et al., 2009)	1) Prescribed SST and sea ice concentration; inferred from reanalysis or GCM	Model versions: simulations with RACMO22E_v2 are straight re-runs of RACMO22E_v1 employing the same model system and parameter settings. Meaning of v2 depends on forcing GCM: i) MOHC-HadGEM2-ES: remapping of GCM-SST to RACMO grid erroneous in v1, corrected in v2 ii) CNRM-CERFACS-CNRM-CM5: atmospheric forcings derived from pressure-level fields, because of error in CNRM-CM5 model-level fields
KNMI (Netherlands)	RACMO22T_v1 RACMO22T_v2	1) 40 2) van Meijgaard et al. (2012)	1) Prescribed, as in RACMO22E	1) 4 2) HTESSEL (Balsamo et al., 2009)	1) Prescribed SST and sea ice concentration; inferred from reanalysis of GCM	Model versions: simulations with RACMO22T_v2 are straight re-runs of RACMO22T_v1 employing the same model system and parameter settings. In AFR-44, v2 is only used with MOHC-HadGEM2-ES forcing to fix the remapping of SST to the RACMO grid in the v1-simulation
SMHI (Sweden)	RCA4_v1 RCA4_v1a RCA4_v2 RCA4_v3 RCA4-SN_v1	1) 40 2) Samuelsson et al. (2015); Strandberg et al. (2015)	1) Prescribed; single integrated class, parametrized aerosol effect on radiation fluxes, spatially uniform, static	1) 3 2) A tile-based scheme with physiography based on ECOCLIMAP (Samuelsson et al., 2015)	1) Prescribed SST and sea ice from daily driving GCMs/reanalysis	LK: Flake (pronostic lake ice; Mironov et al., 2010) Model versions: i) RCA4-v1a is simply a re-run because a restart file to start the scenario experiment was taken from another simulation. ii) RCA4-v2 and RCA4-v3 are slightly tuned versions of RCA4-v1 (some parameters) but parametrizations are the same. RCA-SN indicates spectral nudging

Institution (Country)	Model	Atmosphere	Aerosols	Land	Ocean	Additional Components/Comments
		1) Number of Levels 2) Main References	1) Interactive or Prescribed 2) Component Name (When Interactive)	1) Number of Levels 2) Component Name	1) Interactive or Prescribed 2) Component Name 3) Details	Lake (LK), Urban (UR) or River (RI) Models, etc., Comments on the Different Versions
CNRM (France)	RCSM4_v1	1) 31 2) Sevault et al. (2014)	1) Prescribed (Szopa et al., 2013) dataset for evaluation and GCM forcing for scen runs, 5 classes, 2D spatial pattern, vertical profile, seasonal cycle and temporal evolution	1) 3 2) ISBA (Noilhan and Mahfouf, 1996)	1) Interactive 2) NEMOMED8 (Beuvier et al., 2010) 3) Mediterranean Sea only; 43 vertical levels with a 6-m thick first level; daily coupling frequency by the OASIS coupler (Valcke, 2013)	1) Interactive rivers connecting the atmosphere to the ocean 2) TRIP (Oki and Sud, 1998; Decharme et al., 2010) 3) 50-km spatial resolution
GERICS and MPI-CSC (Germany)	REMO2009_v1 REMO2015_v1 REMO2015_v2	1) 27 2) Jacob and Podzun, (1997); Jacob (2001)	1) Prescribed (Tanré et al., 1984)	1) 5 2) A tile-based scheme including annual cycle of albedo (Rechid et al., 2009)	1) Prescribed SST and SIC	REMO2009_v1 and REMO2015_v1 and V2 are essentially the same, just with some technical changes
GERICS-AWI (Germany)	ROM ROM_v1	1) 27 2) Sein et al. (2015)	See above	See above	1) Interactive 2) SST, SIC and SIT are calculated in ocean model MPIOM	1) Interactive rivers connecting the atmosphere to the ocean 2) Hydrological Discharge (HD) model 3) 50-km spatial resolution
MGO (Russia)	RRCM_v1	1) 25 2) Shkolnik and Efimov (2013)	1) Prescribed	1) 4 2) MGO-2	1) Prescribed SST	n.a.
ITU (Turkey)	RegCM4-BATS_v1	1) 18 2) Ruti et al. (2016); Turuncoglu (2019)	1) No active aerosol chemical model	1) 2 2) BATS1e	1) Prescribed; surface layer (Zeng et al., 1998)	In MED-11, Wave Model (WAM) Cycle-4 (4.5.3-MPI) coupled with atmospheric model
ITU (Turkey)	RegESM	1) 18 2) Ruti et al. (2016); Turuncoglu (2019)	See above	See above	1) Interactive 2) ROMS-revision 809; (Haidvogel et al., 2008)	In MED-11, Wave Model (WAM) Cycle-4 (4.5.3-MPI) coupled with atmospheric model
ICTP (Italy) RU-CORE (Thailand)	RegCM4-3_v4	1) 18 2) Giorgi et al. (2012)	1) No active aerosol chemical model	1) 2 2) BATS1e (SAM-44: 1) 10 2) CLM3.5)	1) Prescribed; surface layer (Zeng et al., 1998)	n.a.
ICTP (Italy) BOUN (Turkey)	RegCM4-3_v5	1) 18 2) Ozturk et al. (2017, 2018)	1) No active aerosol chemical model	1) 1 2) BATS1e	1) Prescribed; surface layer (Zeng et al., 1998)	n.a.
ICTP (Italy)	RegCM4-4_v0	1) 18 2) Giorgi et al. (2012)	1) No active aerosol chemical model	1) 2 2) BATS1e	1) Prescribed; surface layer (Zeng et al., 1998)	n.a.

Table AII.3 | CMIP5 models used for downscaling in the different CORDEX domains. Climate models participating in CMIP5 (rows) used as boundary conditions for the CORDEX regional simulations in the different domains (columns). Each cell indicates the number of simulations available for the historical, RCP2.6, RCP4.5 and RCP8.5 experiments (see the colour legend). Salient features of these models are described in IPCC AR5 Appendix 9.A (model names are taken from Table 9.A.1). Further details on these simulations (e.g., particular GCM-RCM combinations in each cell) are given in the November 2020 list of simulations available in the CORDEX website: <https://cordex.org>.^a For the Mediterranean domain, only the coupled atmosphere–ocean simulations are listed. See Table AII.1 for the codes of CORDEX domains.

AII.2 Earth System Models and General Circulation Models for Climate Projections

Detailed and structured information about climate models, simulations and their conformance to common experimental protocols is not only important for scientific interpretation but, under increased scrutiny from society, it is also demanded of climate science that purports to be mature, credible, open, transparent and reproducible (Guilyardi et al., 2013). Scientific publications remain an essential way of documenting models but remain largely scattered and not easily accessible by the growing community of users of model output. To address these challenges, the Earth System Documentation (ES-DOC) project offers an ecosystem of tools and services in support of Earth system modelling documentation creation, analysis and dissemination. ES-DOC is coordinated with other community efforts such as the Coupled Model Intercomparison Project (CMIP) via the World Climate Research Programme work group on Climate Modelling (WGCM) and its Infrastructure Panel WIP (Balaji et al., 2018).

The objective of CMIP is to better understand past, present and future global climate changes arising from natural, unforced variability or in response to changes in radiative forcing in a multi-model context (Chapter 1, Section 1.5.4). This understanding includes assessments of model performance during the historical period (Chapter 3) and quantifications of the causes of the spread in future projections (Chapters 4 and 7). Idealized experiments are also used to increase understanding of the model responses. In addition to these long time scale responses, experiments are performed to investigate the predictability of the climate system on various time and space scales, as well as making predictions from initialized climate states. The different activities (MIP) endorsed by CMIP6 are listed in Chapter 1, Table 1.3 (Eyring et al., 2016). A set of common experiments, the DECK (Diagnostic, Evaluation and Characterization of Klima) and CMIP historical simulations (1850–2014), were introduced that will maintain continuity with previous CMIP phases and help document basic and evolving characteristics of models. ScenarioMIP is the framework for future climate projections (O'Neill et al., 2016). The infrastructure panel of the World Climate Research Programme coordinates framework developments and defines data standards for CMIP. A key aspect is the dissemination of the data via the Earth System Grid Federation (ESGF; Williams et al., 2016; Petrie et al., 2021).

A new online service, ES-DOC, provides information about all aspects of CMIP6. Building on the Common Information Model concepts and standards (Lawrence et al., 2012), a number of documents are created for the CMIP6 Project, as illustrated at <https://es-doc.org/cmip6/>. These include documents to describe experiments, ensemble simulations, models, conformance to the numerical requirements of the CMIP6 protocol (see Pascoe et al., 2020 for CMIP6 experiments) and other important aspects of the CMIP6 model archive. These different documents are either produced automatically or provided in a standard way by modelling groups. Hundreds of clearly structured properties are harvested and stored on a database to be used by clients and portals (e.g., <https://search.es-doc.org/> and <https://explore.es-doc.org/>). Another entry point to the database is

provided by the one-stop-shop 'further_info_url' global attribute in each CMIP6 netCDF data file. ES-DOC also includes the CMIP6 errata system (<https://errata.es-doc.org>), which tracks issues with the model data and the potential corrections made. ES-DOC includes information at the model level and the experiment level.

Model datasets shared on ESGF are characterized by their institution, model, experiment, variable and ensemble member (the different types of ensemble strategies are introduced in Chapter 1, Section 1.4). Each ensemble member is designated by a label of four letters, each associated with a number: 'r' for realization, 'i' for initialization, 'p' for physics, and 'f' for forcing. For example, Table Atlas.SM.2 lists the ensemble member label of each CMIP6 dataset used in the Atlas. In the future, ES-DOC will document in more detail how each individual member differs from the other members of a given ensemble.

The key new model developments since AR5 are summarized in Chapter 1, Section 1.3.5, and model results are assessed in multiple chapters of this report. In this annex, Table AII.5 presents the main features of the CMIP6 coupled models, in a format comparable with AR5 Table 9.A.1 for CMIP5 (Flato et al., 2013). At the date of March 2021, 136 models had registered for CMIP6, including the 23 CMIP6-endorsed MIPs (Chapter 1, Table 1.3). For conciseness, Table AII.5 documents only the coupled models used in the CMIP6 'DECK' experiments and ScenarioMIP, excluding atmosphere-only and ocean-only components (AMIP and OMIP), radiative transfer models (RFMIP), and other MIPs. Registered coupled models that have not submitted data in time to be used in this report are not included. The high-resolution models used for HighResMIP (Haarsma et al., 2016) are listed in Table AII.6, and ice-sheet models are documented in Section AII.3. The citation information for all CMIP6 model datasets is compiled in Section AII.4, Table AII.10.

Table AII.5 | Coupled climate and Earth system models participating in CMIP6 DECK, historical simulation and ScenarioMIP. Salient features of the coupled general circulation models (GCMs) and Earth system models (ESMs) participating in the CMIP6 DECK, historical simulation and ScenarioMIP. Column 1: sponsoring institution(s). Column 2: names of model configurations. Column 3: main reference(s); subsequent columns for each of the model components, with names and main component reference(s). In addition, there are standard entries for the atmosphere component: horizontal grid resolution, number of vertical levels, grid top; and for the ocean component: horizontal grid resolution, number of vertical levels and vertical coordinate type. The horizontal resolution (rounded to 10km) is the square root of the surface area of the Earth divided by the number of grid points, or the area of the ocean surface divided by the number of surface ocean grid points, for the atmosphere and ocean, respectively. When reported in hPa, the atmosphere top heights are converted into km assuming standard atmosphere (ISO 2533:1975, 1975). Aerosols are either prescribed or computed from emissions (emissions-driven). For land carbon, a list of active processes is provided among: active land carbon cycle (Land carbon), active nitrogen cycle (N cycle), prognostic biogeography of vegetation (Prog. veg.), carbon included in a permafrost pool (Permafrost), and dynamic fires (Fires). A blank entry indicates that information was not available. The information contained in the table is consistent with version 6.2.55.10 of the CMIP6 Controlled Vocabularies (https://github.com/WCRP-CMIP/CMIP6_CVs).

Table AII.6 | High-resolution coupled models participating in HighResMIP. Full names of the institutions are found in Table AII.5. The horizontal resolution (rounded to 10 km when larger than 10 km) is the square root of the number of grid points divided by the surface area of the Earth, or the number of surface ocean grid points divided by the area of the ocean surface, for the atmosphere and ocean respectively. When reported in hPa, the atmosphere top heights are converted into kilometres assuming standard atmosphere (ISO 2533:1975, 1975).

AII.3 Models Used in Ice Sheet and Glacier Model Intercomparison Studies

Ice sheet and glacier models are used to assess the contribution of ice sheets and glaciers to future sea level rise as described in Section 9.6.3. New to AR6, the projections of the future sea level contribution from ice sheets and glaciers comes from the ensemble of model intercomparison studies (Sections 9.4.1.2, 9.4.2.2 and 9.5.1.3, and Box 9.3). The tables here describe the models used for Greenland ISMIP6 (Table AII.7), Antarctica ISMIP6 and LARMIP-2 (Table AII.8) and GlacierMIP (Table AII.9).

More specific information on the model capabilities and parameter choices used for each ice sheet and glacier MIP are presented in the following papers: ISMIP6 initMIP-Greenland (Goelzer et al., 2018), ISMIP6 projection-Greenland (Goelzer et al., 2020), ISMIP6 initMIP-Antarctica (Seroussi et al., 2019), ISMIP6 Antarctica projection (Seroussi et al., 2020), LARMIP-2 Antarctica projections (Levermann et al., 2020) and GlacierMIP (Hock et al., 2019; Marzeion et al., 2020).

ULB Université Libre de Bruxelles Belgium	ULB-FETISH	Pattyn (2017)	16–32 km	initMIP ISMIP6 LARMIP-2
UNN University of Northumbria UK	UNN-UA	Gudmundsson et al. (2012)	1–40 km	LARMIP-2
UTAS University of Tasmania, Australia University of Lapland, Finland CSC-IT Center for Science, Finland	UTAS-ELMER	Gillet-Chaulet et al. (2016)	4–40 km	ISMIP6
VUB Vrije Universiteit Brussel Belgium	VUB-AISPALAO	Huybrechts (2002)	20 km	initMIP ISMIP6 LARMIP-2
VUW Victoria University of Wellington New Zealand	VUW-PISM	Bueler and Brown (2009); Golledge et al. (2019)	16 km	initMIP ISMIP6 LARMIP-2

Table AII.9 | Models used in the GlacierMIP2 model intercomparison.

Institution Full Name, Country	Model Name	Reference	Resolution	Domain (Global/Regional)
Nagoya University, Japan	GLIMB	Sakai and Fujita (2017)	0.5° grid and 50 m elevation bands for mass balance, each glacier for geometry change	Global
ETH Zurich, Switzerland University of Fribourg, Switzerland University of Alaska Fairbanks, USA Uppsala University, Sweden	GloGEM	Huss and Hock (2015)	Each glacier, 10 m elevation bands	Global
University of British Columbia, Canada University of Alaska Fairbanks, USA Scott Polar Research Institute, UK Trent University, Canada	RAD2014	Radić et al. (2014)	Each glacier, 20–25 m elevation bands	Global
Utrecht University, Netherlands ETH Zurich, Switzerland	WAL2001	Van de Wal and Wild (2001)	Each glacier	Global
University of Exeter, UK University of Bristol, UK University of Reading, UK Met Office, UK University of Fribourg, Switzerland ETH Zurich, Switzerland University of Crete, Greece University of Exeter, UK	JULES	Shannon et al. (2019)	0.5° grid, 250 m elevation bands	Global except Antarctica
University of Innsbruck, Austria	MAR2012	Marzeion et al. (2012)	Each glacier, considering elevation range	Global except Antarctica
University of Innsbruck, Austria University of Bremen, Germany University of Grenoble Alpes, France ETH Zurich, Switzerland WSL, Switzerland University of Natural Resources and Life Sciences, Austria University of Canterbury, New Zealand	OGGM	MauSSION et al. (2019)	Each glacier, 20–400 m spacing of grid points on flow line	Global except Antarctica
Utrecht University, Netherlands FutureWater, Netherlands ICIMOD, Nepal	KRA2017	Kraaijenbrink et al. (2017)	Each glacier, variable elevation bands	High Mountain Asia
University of Alaska Fairbanks, USA University of Washington, USA	PyGEM	Rounce et al. (2020)	Each glacier, 20 m elevation bands	High Mountain Asia
Victoria University of Wellington, New Zealand	AND2012	Anderson and Mackintosh (2012)	100 m	New Zealand
ETH Zurich, Switzerland WSL, Switzerland University of Fribourg, Switzerland	GloGEMflow	Zekollari et al. (2019)	Each glacier, 10–202 m spacing of grid points on flow line	Central Europe

AII.4 Coupled Model Intercomparison Project Model Datasets Used in the Report

Pirani, S.L. Connors, C. Péan, S. Berger, N. Caud, Y. Chen, L. Goldfarb, M.I. Gomis, M. Huang, K. Leitzell, E. Lonnoy, J.B.R. Matthews, T.K. Maycock, T. Waterfield, O. Yelekçi, R. Yu, and B. Zhou (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 2139–2152, doi:[10.1017/9781009157896.017](https://doi.org/10.1017/9781009157896.017).

AIII.1 Introduction

Annex III presents, in tabulated form, data related to historical and projected changes in greenhouse gas (GHG) mixing ratios and effective radiative forcing (ERF) of all climate forcers as assessed and used throughout Chapters 1–7. Where available 90% confidence level uncertainties on observed GHG mixing ratios are given. For each species, the abundance is given as dry air mole fraction: ppm = micromoles per mole (10^{-6}); ppb = nanomoles per mole (10^{-9}); and ppt = picomoles per mole (10^{-12}). ERF is given in W m^{-2} for CO_2 , N_2O , and CH_4 and in 10^{-3} W m^{-2} (mW m^{-2}) for other components.

Pre-instrumental mixing ratios are estimated from ice-core and firn air records that are described in Machida et al. (1995); Flückiger et al. (1999); Sowers (2001); Siegenthaler et al. (2005); Ahn et al. (2012); Mitchell et al. (2013); Bauska et al. (2015); Meinshausen et al. (2017); Rubino et al. (2020); Ryu et al. (2020).

Observed (instrumental) mixing ratios are described in Masarie and Tans (1995); Trudinger et al. (2004); Worton et al. (2006);

Montzka et al. (2009); Dlugokencky et al. (2011); Hall et al. (2011); Rigby et al. (2014); Laube et al. (2016); Simmonds et al. (2017); Adcock et al. (2018); Prinn et al. (2018); Leedham Elvidge et al. (2018); Mühle et al. (2019); Naus et al. (2019); Droste et al. (2020).

Projected concentrations for the five core scenarios discussed in the report (Section 1.6.1) are from Gidden et al. (2019), Meinshausen et al. (2017, 2020) and Velders et al. (2015). These scenarios span a wide range of plausible societal and climatic futures from potentially below 1.5°C best-estimate warming to over 4°C warming by 2100 (Section 4.3.4). Computational methods and assumptions to calculate historical and projected ERF are described in Chapter 7 and detailed information can be found in Chapter 7 Supplementary Material 7.SM.1.3 and 7.SM.1.4.

Extended datasets and further auxiliary data are made available via <https://doi.org/10.5281/zenodo.5705391> (Smith et al., 2021).

Tables AIII.1a–f provide historical abundances (mixing ratios) and effective radiative forcing (ERF) values for greenhouse gases assessed in this report.

Chemical Abbreviations and Symbols of Components Regulated Under the Kyoto¹ and Montreal Protocols.

CO_2	carbon dioxide	Kyoto
CH_4	methane	Kyoto
N_2O	nitrous oxide	Kyoto
HFC	hydrofluorocarbon (a class of compounds: HFC-32, HFC-134a ...)	Kyoto, Montreal
PFC	perfluorocarbon (a class of compounds: CF_4 , C_2F_6 , C_4F_{10} ...)	Kyoto
SF_6	sulphur hexafluoride	Kyoto
NF_3	nitrogen trifluoride	Kyoto
CFC	chlorofluorocarbon (a class of compounds: CFCl_3 , CF_2Cl_2 ...)	Montreal
HCFC	hydrochlorofluorocarbon (a class of compounds: HCFC-22, HCFC-141b ...)	Montreal
CCl_4	carbon tetrachloride	Montreal
CH_3CCl_3	methyl chloroform	Montreal
CH_3Br	Methyl bromide	Montreal
Halons	bromo(chloro)fluorocarbon (a class of compounds: CF_2ClBr – ‘Halon-1211’; CBrF_3 – ‘Halon-1301’; $\text{C}_2\text{Br}_2\text{F}_4$ – ‘Halon-2402’)	Montreal

List of Tables:

Table AIII.1a	Historical abundances and ERF (W m^{-2}) for CO_2 (ppm), CH_4 (ppb) and N_2O (ppb)
Table AIII.1b	Historical abundances (ppt) and ERF (mW m^{-2}) of NF_3 , SF_6 , SO_2F_2 , and PFCs
Table AIII.1c	Historical abundances (ppt) and ERF (mW m^{-2}) of HFCs
Table AIII.1d	Historical abundances (ppt) and ERF (mW m^{-2}) of HCFCs
Table AIII.1e	Historical abundances (ppt) and ERF (mW m^{-2}) of CFCs
Table AIII.1f	Historical abundances (ppt) and ERF (mW m^{-2}) of CH_3CCl_3 , CCl_4 , CH_3Br , CHCl_3 and halons
Table AIII.2	Future abundances of CO_2 , CH_4 and N_2O for selected SSP scenarios [2020–2500]
Table AIII.3	Effective radiative forcing (W m^{-2}) time series of all climate forcers from 1750–2019
Table AIII.4a	Effective radiative forcing (W m^{-2}) time series of all climate forcers for SSP1-1.9
Table AIII.4b	Effective radiative forcing (W m^{-2}) time series of all climate forcers for SSP1-2.6
Table AIII.4c	Effective radiative forcing (W m^{-2}) time series of all climate forcers for SSP2-4.5
Table AIII.4d	Effective radiative forcing (W m^{-2}) time series of all climate forcers for SSP3-7.0
Table AIII.4e	Effective radiative forcing (W m^{-2}) time series of all climate forcers for SSP5-8.5
Table AIII.4f	Effective radiative forcing (mW m^{-2}) time series of halogenated compounds for selected scenarios and Kyoto and Montreal gases
Table AIII.5	Total anthropogenic and natural ERF relative to 1750 assessed in AR5 (RCP scenarios) and AR6 (SSP scenarios)

¹ The Kyoto protocol (1 December 1997–31 December 2020) regulated a basket of seven GHGs. The term Kyoto gases is widely used in the scientific literature.

Notes: ^a 1750/1850 CO_2 , CH_4 and N_2O from multiple ice cores assessed in Chapter 2. Uncertainties (90% CI) for 1750 are 2.9 ppm, 9.4 ppb and 6.0 ppb for CO_2 , CH_4 and N_2O , respectively. Uncertainties for 1850 are 2.1 ppm, 13.8 ppb and 5.7 ppb, based on variations of ice cores.

^b Mixing ratios from 1851–1980/1984 are updated from the CMIP6 (Meinshausen et al., 2017) dataset, using a linear time-dependent offset correction function.

^c CO_2 from NOAA network; CH_4 and N_2O from merged NOAA and AGAGE networks. Uncertainties (90% CI) in 2019, derived from multiple global networks, are 0.36 ppm, 3.3 ppb and 0.4 ppb for CO_2 , CH_4 and N_2O , respectively, and do not include estimates of analytical accuracy. Uncertainties for other years may differ.

^d ERF (2019–1750) from Chapter 7.

Notes: Data merged from AR5 (1750; 1850); CMIP6 compilation by Meinshausen et al. (2017) until about 1995, and data directly taken from merged AGAGE and NOAA networks, depending on date of availability. Perfluorocarbons from CMIP6 dataset (Meinshausen et al., 2017) or estimated from Droste et al. (2020), with CMIP6 n-C₆F₁₄ and C₇F₁₆ scaled to account for calibration changes in Droste et al. (2020). Uncertainties pertain to 2019, derived from observations made by global networks and literature, and do not include estimates of analytical accuracy. Uncertainties are not available for n-C₄F₁₀, n-C₅F₁₂, n-C₆F₁₄, i-C₆F₁₄, C₇F₁₆ or C₈F₁₈. ERF (2019–1750) from Chapter 7, except for n-C₄F₁₀, n-C₅F₁₂, n-C₆F₁₄, i-C₆F₁₄ and C₇F₁₆, uses 2015 abundances and C₈F₁₈ which uses 2010 abundance.

Notes: 1750/1850 from AR5; 1900–1970 from CMIP6 dataset in Meinshausen et al. (2017). 1980–1995 AGAGE, or data directly taken from merged AGAGE and NOAA networks, depending on the date of availability for various components; CFC-13 from Vollmer et al. (2018) until 2015, then AGAGE; CFC-114 and CFC-114a from AGAGE and Laube et al. (2016). CFC-112 and CFC-112a from Laube et al. (2014) and Engel et al. (2018); CFC-113a from Adcock et al. (2018). Uncertainties pertain to 2019, derived from observations made by global networks, and do not include estimates of analytical accuracy. For CFC-112, CFC-112a, CFC-113a and CFC-114a abundances and uncertainties for 2019 are not available. ERF (2019–1750) from Chapter 7, except for CFC-112, CFC-112a, CFC-113a and CFC-114a for 2015.

Table AIII.1f | Historical abundances (ppt) and ERF (mW m⁻²) of CH₃CCl₃, CCl₄, CH₃Cl, CH₃Br, CHCl₃, CHCl₃ and halons.

Year	CH ₃ CCl ₃	CCl ₄	CH ₃ Cl	CH ₃ Br	CH ₂ Cl ₂	CHCl ₃	Halon-1211	Halon-1301	Halon-2402

Notes: O₃ includes tropospheric and stratospheric O₃, dominated by tropospheric O₃. Stratospheric water vapour from methane oxidation is a linear function of the methane ERF (Section 7.3.2.6). Contrail forcing is a linear scaling of aviation NO_x emissions, scaled to ERF in 2018 (Lee et al., 2021). Present-day aerosol forcing is assessed in Section 7.3.3 as -0.3 [-0.6 to 0.0] W m⁻² for aerosol-radiation interactions and -1.0 [-1.7 to -0.3] W m⁻² for aerosol-cloud interactions for the 2005–2014 mean relative to 1750. Land-use change considers albedo and irrigation effects (Section 7.3.4.1). BC on snow forcing is linear with emissions of BC (Section 7.3.4.3). Volcanic forcing is positive in years without large volcanic eruptions, such that the long-term pre-industrial (500 BCE to 1749 CE) mean volcanic forcing is zero. Solar forcing is derived from the ¹⁴C reconstruction of total solar irradiance in the combined PMIP4/CMIP6 dataset (Jungclaus et al., 2017; Matthes et al., 2017). Present-day solar forcing is assessed in Section 7.3.4.4 as +0.01 [-0.06 to +0.08] W m⁻², based on the mean total solar irradiance from solar cycle 24 (2009–2019) compared a long pre-industrial baseline period (6754 BCE to 1744 CE); the 2019 ERF value differs from this as it represents a single year near the solar minimum. Natural is the sum of volcanic and solar forcing, while anthropogenic includes all others. Further details on methods for computing ERF are in Chapter 7 Supplementary Material 7.SM.1.3.

Table AIII.4a | Effective radiative forcing (W m⁻²) time series of all climate forcers for SSP1-1.9.

Year	CO ₂	CH ₄	N ₂ O	Halogenated Compounds	O ₃	Stratospheric Water Vapour	Contrail-cirrus	Aerosol-radiation Interactions	Aerosol-cloud Interactions	Black Carbon on Snow	Land use	Volcanic	Solar	Total Anthropogenic	Total Natural	Total

Notes: ERF based on future abundancies of well-mixed greenhouse gases (WMGHGs) listed in AIII.2. See notes of AIII.3. Future ozone forcing uses projected emissions of carbon monoxide, volatile organic carbon, nitrogen oxides, and concentrations of methane, nitrous oxide and halogenated compounds with relationships to forcing derived from Thornhill et al. (2021a, b). Future contrail forcing is a linear scaling of future NO_x emissions (Smith et al., 2018) and scaled to year-2018 ERF (Lee et al., 2021). Future aerosol forcing is based on emissions of black carbon, organic carbon, sulphur dioxide and ammonia using a method described in Smith et al. (2018). Land-use forcing scales with cumulative emissions of future land-use CO₂ (Smith et al., 2018). Future volcanic forcing set to zero from a 10-year linear transition from the end of the historical period following Eyring et al. (2016). Solar forcing is set to zero from 2300 CE. Further details on methods for computing SSP-projection ERF are in Chapter 7 Supplementary Material 7.SM.1.4.

Notes: ERF for 2019 was calculated using the concentrations list in Table AIII.1; 2020 and onward are scenario projections. ERF was calculated using concentrations of individual halogenated compounds. Updated from Meinshausen et al. (2017, 2020) available at greenhousegases.science.unimelb.edu.au. Minor halogenated compounds SO₂F₂, CH₃Cl, CH₂Cl₂, CHCl₃ and Kyoto gases CO₂, CH₄, and N₂O are not included in this table.

Table AIII.5 | Total anthropogenic and natural effective radiative forcing relative to 1750 assessed in AR5 (RCP scenarios) and AR6 (SSP scenarios).

		2030			2050			2090		
		Anthropogenic	Natural	Total	Anthropogenic	Natural	Total	Anthropogenic	Natural	Total

Notes: ^a Tables AII.6.8 and 6.10 in Annex II of the IPCC AR5 WG1 report (IPCC, 2013), for which total ERF is derived from CMIP5 models and anthropogenic ERF from a simple climate model emulator. ^b RCPs calculated for ERF as described in Chapter 7 Supplementary Material 7.SM.1.4. Similar to AR5, an emulator was used in AR6 to derive anthropogenic ERF (Cross-Chapter Box 7.1 and Chapter 7 Supplementary Material 7.SM.1.4). Further discussion on the difference between AR5 and AR6 radiative forcing is in Section 4.6.2. ^c ScenarioMIP (O'Neill et al., 2016), ^d AerChemMIP (Collins et al., 2017), ^e Allen et al. (2021).

AIV.1 Introduction

This annex describes the fundamental features of the main modes of large-scale climate variability assessed across chapters in the AR6 WGI Report. Modes are defined as recurrent space-time structures of variability of the climate system with intrinsic spatial patterns, seasonality and time scales. They can arise through the dynamical characteristics of atmospheric circulation, but also through coupling between the ocean and the atmosphere, with some interactions with land surfaces and sea ice. The variability of the climate system at ocean- or continental-basin scales, and in particular, on seasonal-to-multi-decadal time scales, can be described to a large extent by the occurrence and often combination of several modes of climate variability which lead to local impacts and remote responses through teleconnection processes on top of externally forced trends. More precisely, the concept of ‘teleconnection’ refers to the ability of modes of variability to relate climate in remote regions through associated atmospheric or oceanic pathways. Regional climate variations are thus the complex outcome of local physical processes, such as thermodynamical and land–atmosphere feedback processes, and non-local large-scale phenomena.

Historically, modes have been identified based on evidence of correlations between regional climate variations at widely separated, mostly geographically fixed spatial locations. One of the oldest known space-time structured patterns of variability is the North Atlantic Oscillation (NAO; Section AIV.2.1), with some early description from seafaring activities available since several centuries ago (Stephenson et al., 2003). Similarly, empirical, albeit remarkably precise, documentation of trans-Pacific coherent variability in atmospheric and oceanic conditions can be traced back to the 19th century for the El Niño–Southern Oscillation (ENSO; Section AIV.2.3). The Southern Oscillation was named in 1924 and the first use of the name ‘El Niño’ to describe a climatic phenomenon appeared in South America in 1893 (see for instance Philander, 1983 for ENSO history). Since then, the increased spatial coverage of observations and the measurement of new climatic parameters have improved significantly. These advancements, along with the development of new theoretical background and statistical methods for combining different sources of information, have allowed substantial improvements in our understanding of the characteristic spatial scale of the coherent structures of variability as well as of the characteristic temporal expression of the modes.

There are several ways to document and describe the modes of climate variability based on more or less sophisticated statistical techniques and the dynamical nature, interpretation and understanding of the variability (i.e., Feldstein and Franzke, 2017; Hannachi et al., 2017; Franzke et al., 2020; Ghil and Lucarini, 2020). The simplest method to evaluate the temporal evolution of a spatially coherent phenomenon is to take one or more spatial averages of a climate variable such as sea surface temperature (SST) or sea level pressure (SLP), as examples, within a latitude-longitude box. Another classical technique relies on principal component analysis (PCA), also known as empirical orthogonal function (EOF) analysis, to extract the patterns in the chosen climate variable with maximal spatial covariance. The method also extracts an associated climate

index time series, that is, principal component (PC), describing the temporal evolution tied to the spatial pattern. PCA/EOF is widely used with gridded datasets and model outputs. Correlation or regression maps between the climate index time series and other space-time variables, such as precipitation, temperature or wind, are then calculated to quantify the teleconnection patterns. Altogether, beyond their physical relevance, modes of climate variability and their teleconnection patterns provide a simplified representation of climate variation affecting weather, from regional (i.e., oceanic or continental scale) to worldwide scales (i.e., for some specific phenomena like ENSO), having important impacts on human activities and ecosystems. Modes are often associated with climatic impact-drivers (CIDs, as defined in Chapter 12, Section 12.1) including droughts, heavy rains, storms, heatwaves and cold spells, affecting agriculture, water resources, availability and consumption of energy, and fire risks.

Many modes of variability are driven by internal climate processes and provide a substantial potential source of climate predictability on sub-seasonal to decadal time scales. It is essential to understand the physical processes behind the past evolution of the modes of climate variability in order to assess, with confidence, their future changes. External forcing may affect their temporal (occurrence, variance, seasonality and persistence, etc.) or spatial properties and associated teleconnections.

Previous IPCC reports have described the observed and modelled behaviour of a large number of modes of variability over the instrumental period and in a paleoclimate context. The projected evolution of those modes has been also documented based on future climate scenarios. In AR5, large-scale modes of variability and teleconnections were assessed in depth in Chapter 14, setting the physical basis of future regional climate changes contingent on global mean temperature increase. Modes were defined through so-called ‘indices of climate variability’ in AR5 Chapter 2, dedicated to observed atmospheric and surface changes. Two boxes (AR5 Box 2.5 and AR5 Box 14.1) introduced the main concepts. AR4 had a similar structure, with a specific section on modes in the chapter dedicated to the observations (Chapter 3). In AR6, a different perspective has been adopted because the modes are discussed in various chapters and assessed with respect to the specific objectives of each of them. Space-time past changes of the modes using proxy records and instrumental data are assessed in Chapter 2. Human influence on modes is assessed in Chapter 3 over the instrumental period, while their future changes are addressed in Chapter 4. Their influence at regional scale through large-scale teleconnection is assessed in Chapters 10, 11 and 12, and in the Atlas, while the contribution of the modes in past and future hydrological changes and related uncertainties are assessed in Chapter 8. Chapter 9 focuses on oceanic expression of the modes. The aim of this annex is to set a common background for the assessment of the modes of climate variability and related regional climate anomalies for all the AR6 WG1 chapters, and to provide this information for the readers of the report. In doing so, the annex provides a more accessible summary of the main modes of variability allowing a more coherent assessment of this important aspect of the climate system.

The annex summarizes the fundamental features of spatial structure, seasonality and teleconnections for a selection of modes of climate variability corresponding to those addressed in the report, namely: the NAO and Northern Annular Mode, the Southern Annular Mode, ENSO, the Indian Ocean Basin and Dipole modes, the Atlantic Meridional and Zonal modes, the Pacific Decadal Variability, the Atlantic Multi-decadal Variability, and the Madden–Julian Oscillation. For each mode, the description follows a common structure, starting with a short definition of the mode (based on simple box-averaged indices and EOF) and related key physical mechanisms, then a description of the associated teleconnections (based on regression techniques), and when relevant, finishes with a short summary of paleoclimate reconstruction of the mode based on proxy-based records. An illustrative figure including patterns and time series is also provided for each mode.

AIV.2 The Main Modes of Climate Variability Assessed in AR6

AIV.2.1 North Atlantic Oscillation and Northern Annular Mode

AIV.2.1.1 Definition of the Mode

The North Atlantic Oscillation (NAO) is the leading mode of large-scale atmospheric variability in the North Atlantic basin. It is characterized by alternating (seesaw) variations in SLP between the Azores High in the subtropics and the Icelandic Low in the mid- to high latitudes, with some northward extension deep into the Arctic (Hurrell et al., 2003). The positive phase of the NAO corresponds to an anomalously strong Azores High and concomitant deepening of the Icelandic Low with some penetration in the sub-Arctic basin (Greenland/Norwegian/Barents Sea), accompanied by a reinforced and northward-shifted jet and storm track over a broad North Atlantic-European sector (Figure AIV.1a). The opposite, notwithstanding marginal spatial asymmetries, occurs for the negative phase.

The NAO is the main mode of climate variability over a broad North Atlantic-European region in all seasons (Hurrell and Deser, 2009) for intra-seasonal to multi-decadal time scales, albeit with seasonally dependent physical characteristics (fraction of explained variance, latitudinal shift and intensity of the related anomalous atmospheric circulation and SST fingerprint, etc.; Folland et al., 2009; Woollings et al., 2015). The phases of the NAO control a significant fraction of the variance of temperature and precipitation over the North Atlantic and surrounding continents, and of the prevailing westerly winds and the related storm tracks (Woollings et al., 2014). It is also strongly related to the occurrence and intensity of blocking conditions, especially over Greenland (Woollings et al., 2010; Davini et al., 2012), and controls a large part of the incidence of extremes (cold waves, very strong wind episodes related to explosive storminess, heavy precipitation events, etc.) over Europe (Matthews et al., 2014; Yiou et al., 2017) and eastern North America (Durkee et al., 2008; Whan and Zwiers, 2017).

The NAO can be viewed as the regional expression of a hemispheric-scale mode of atmospheric variability that was identified in the late 1990s known as the Arctic Oscillation (AO; Thompson and Wallace, 1998) or Northern Annular Mode (NAM; Thompson and Wallace, 2000; Ambaum et al., 2001) to reflect the longitudinal scale that transcends the entire hemisphere. An additional centre of action is present for NAM over the North Pacific, albeit much weaker than its Atlantic counterpart, with a slackened Aleutian Low in the positive phase (Figure AIV.1b). The AO/NAM can be defined as the leading mode of variability across a range of atmospheric levels from the surface to the stratosphere (Baldwin and Dunkerton, 1999; Gerber et al., 2010). In the stratosphere, the AO/NAM corresponds to fluctuations in the strength of the boreal winter polar vortex over the Arctic. In the troposphere, the AO/NAM primarily corresponds to fluctuations in the position of the mid-latitude westerly jet stream. Interactions between the stratospheric and tropospheric annular modes have been extensively studied and are important for the variability and predictability of the mode at intra-seasonal time scales (i.e., see Domeisen, 2019).

Despite the fact that NAM and NAO indices are strongly correlated (Figure AIV.1c), the debate on the relevance of the NAM as a mode of variability *per se* (Deser, 2000; Honda and Nakamura, 2001; Itoh, 2008) is not closed yet, despite progress in understanding the dynamical mechanisms linking the Pacific and Atlantic SLP cores on the basis of wave breaking theory that prevails at intra-seasonal time scales (e.g., Rivière and Drouard, 2015). Consequently, NAO and NAM are treated as indistinguishable in some studies (Feldstein and Franzke, 2006) while others still consider the NAO as a stand-alone mode even if associated circumpolar patterns exist (García-Serrano and Haarsma, 2017). In the latter case, the NAM is interpreted as a statistical artefact of two regional independent modes, namely the NAO and the Pacific-North American pattern (Ambaum et al., 2001; Douville et al., 2017). Throughout the report, NAO and NAM are often considered as the same entity because the NAO explains most of the variance on the zonally-averaged hemispheric circulation and because the associated time series are highly correlated.

The NAO/NAM arises as large-scale signals primarily driven by the internal atmospheric variability of mid-latitude dynamics (e.g., Lorenz and Hartmann, 2003). By nature, these signals correspond to barotropic phenomena being partly controlled by eddy-mean flow interaction (Feldstein and Franzke, 2017). Their fingerprint can be found along the entire atmospheric column with maximum amplitude in the winter season when storminess is the most pronounced. In addition, the tropospheric NAO/NAM variability has been shown in boreal winter to be linked to the strength of the stratospheric polar vortex (Baldwin and Dunkerton, 1999), including sudden stratospheric warmings (Domeisen, 2019). On intra-seasonal time scales, downward propagation of associated geopotential height anomalies occurs from the lower stratosphere to the troposphere through wave-mean flow interaction resulting in some predictability at the surface for CIDs, through temperature, precipitation and wind anomalies at large spatial scales (e.g., Karpechko et al., 2017 over Europe).

The North Atlantic Oscillation (NAO)/Northern Annular Mode (NAM)

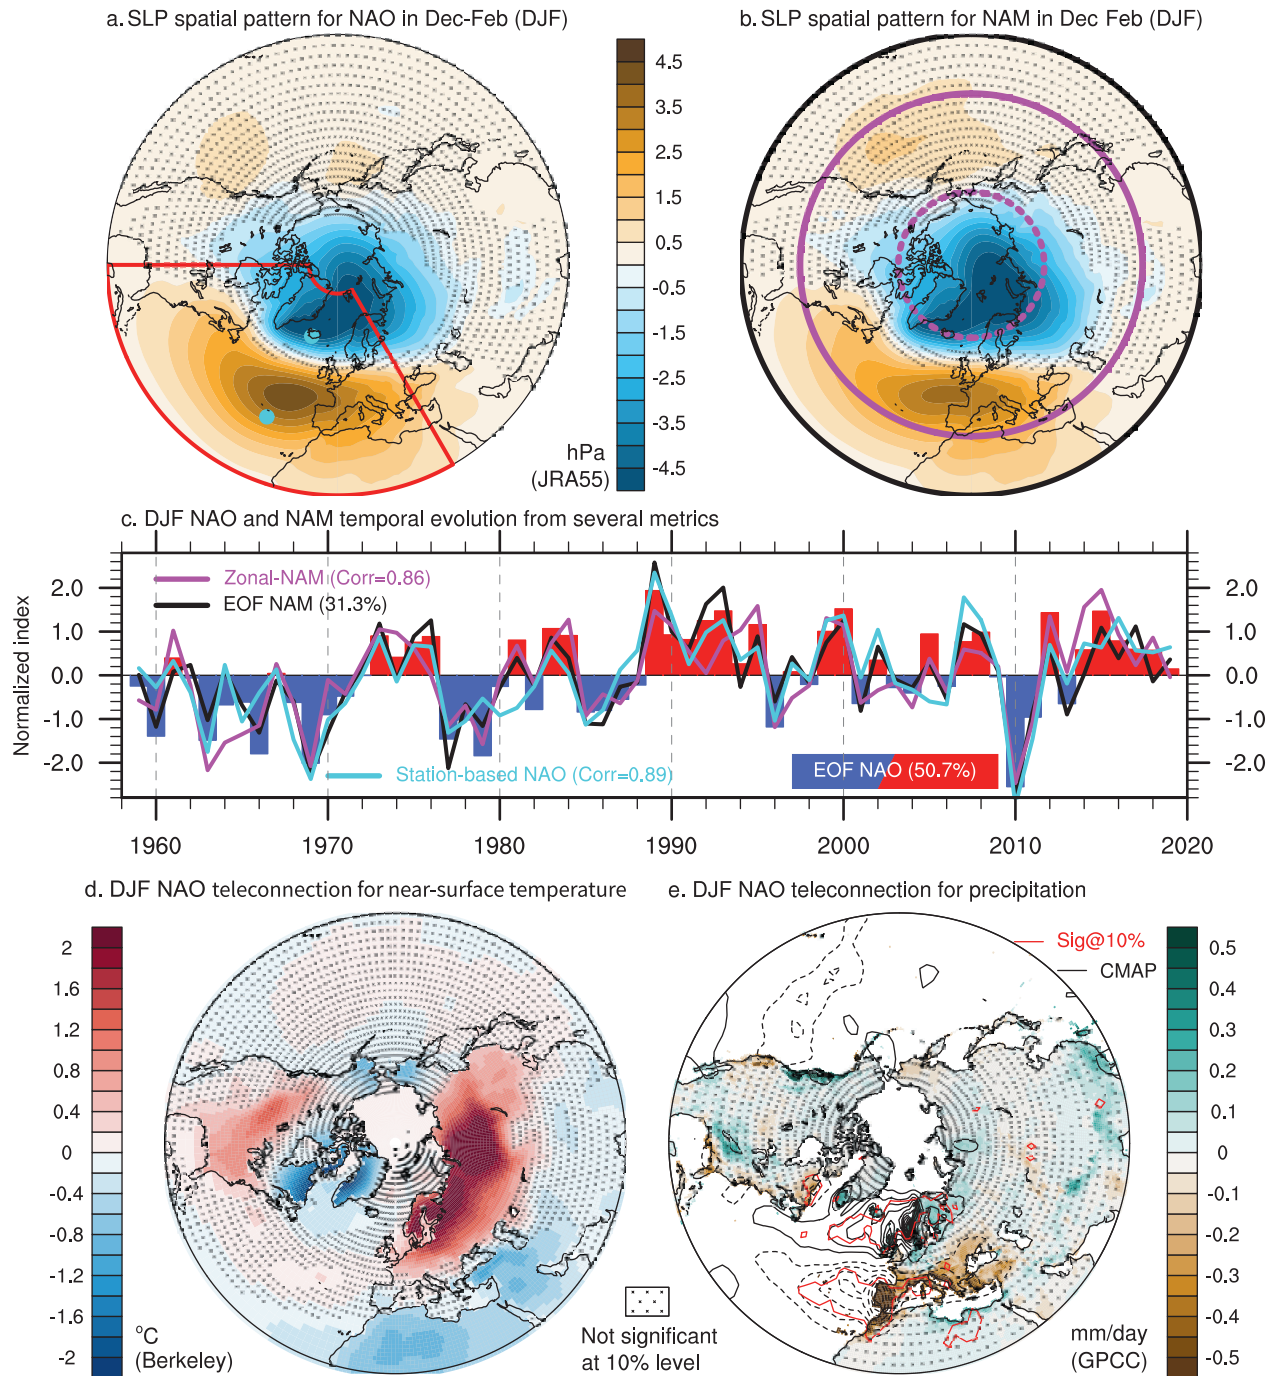

Figure AIV.1 | The boreal winter North Atlantic Oscillation (NAO) and Northern Annular Mode (NAM) extracted as the leading empirical orthogonal function (EOF) of December–January–February (DJF) sea level pressure (SLP) anomalies over (a) the North Atlantic–Europe sector (20°N–80°N, 90°W–30°E, indicated by the red box) and (b) the Northern Hemisphere (north of 20°N, black domain), respectively, based on JRA-55 reanalysis over 1959–2019. (a, b) SLP anomalies regressed onto the leading principal component (PC) time series shown in (c). The NAO-PC is represented by red and blue bars, the NAM-PC by the black curve in (c); the percentages of variance explained by the mode are shown in the legends. The NAO index based on weather stations (cyan dots in (a)) is given in cyan and the zonal-NAM index (latitude circles in (b)) is given in purple. Correlation between each index and the NAO-PC time series is given in the legend. (d, e) Regression maps of blended sea surface temperature and surface air temperature over land from the ERSST and Berkeley Earth datasets, respectively, for 1959–2019 (d) and of precipitation anomalies (e); shading based on GPCC for 1959–2016 and contours based on CMAP for 1979–2019 for every 0.1 mm day⁻¹. On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicate no significance. Significance for CMAP precipitation is materialized by red contours in (e). All fields have been linearly detrended prior to computation.

The NAO/NAM includes a forced component arising from SST anomalies: key oceanic regions are identified but are dependent on the time scale of variability that is investigated (Baker et al., 2019). There is also growing evidence for the importance of cryosphere-atmosphere coupling to explain part of the observed variability of the NAO in response to recent Arctic sea ice decline (Cohen et al., 2014), even if discrepancies remain in model estimates (Screen et al., 2018) and may not be stationary in time (Blackport and Screen, 2020). Finally, part of the NAO/NAM variability has also been documented to be influenced by external forcing such as volcanic eruptions (Swingedouw et al., 2017) and solar forcing (Ineson et al., 2011; Gray et al., 2016; Le Mouél et al., 2019) as well as anthropogenic factors (Gillett et al., 2003). However, internal variability is predominant and, because of signal-to-noise issues, very long observational records and large ensembles of climate simulations are needed to clearly evaluate the fraction of the forced component in the observed NAO/NAM, as assessed in detail in Sections 2.4.1.1 and 3.7.1. Sea ice-NAO/NAM coupling is comprehensively assessed in Cross-Chapter Box 10.1.

Given their equivalent barotropic structure, the NAO/NAM is usually defined from SLP fields or geopotential height anomalies at various levels (Fu et al., 2016). The NAO/NAM can be defined using pattern-based statistical techniques such as EOF or clustering techniques applied to seasonal gridded atmospheric circulation fields (SLP or geopotential height anomalies) from observations or reanalysis data. The NAM pattern is traditionally defined as the leading EOF of pressure fields computed over the entire hemisphere, northward of 20°N (Figure AIV.1b) and its related PC defines the NAM index (Figure AIV.1c). Similarly the NAO index can be defined as the PC of the leading EOF of the pressure field over the North Atlantic sector (Figure AIV.1a) or the temporal occurrence of the seasonal weather regimes extracted from clustering (Corti et al., 1999; Cassou et al., 2011; Hannachi et al., 2017).

An alternative and simpler estimate of the NAM/NAO uses differences in SLP between fixed locations. The NAM index can be calculated from the difference in normalized zonally averaged SLP anomalies between 35°N and 65°N (Li and Wang, 2003), which reflects the latitudinal fluctuation of the position and strength of the mid-latitude westerlies at the hemispheric scale. Similarly, for the NAO, a weather station-based index is traditionally calculated as the difference of normalized SLP anomalies located in the Azores (Ponta Delgada) or continental Iberia (Lisbon/Gibraltar) minus those along the northern centre of action around Iceland (Stykkisholmur/Reykjavik) (Jones et al., 1997). Cornes et al. (2013) alternatively uses the Paris-London difference because of data availability back to the 17th century. The station-based NAO index is simple to compute, extends the longest over the instrumental period, and can be used year round, but caveats stand in its limitation to capture the seasonal latitudinal migration of the NAO variability pattern as well as potential shifts in the North Atlantic pressure centres of action at interannual to decadal time scales (Ulbrich and Christoph, 1999). Because it uses fixed locations, the index captures part of the variability that is not directly related to the latitudinal seesaw pressure balance and associated large-scale fluctuations of the zonal flow that characterize the NAO dynamics, and it also fails representing the spatial asymmetries between the positive and negative phases of the mode (Cassou et al., 2004).

The temporal correlation between the EOF and fixed latitude-based zonal NAM estimations is equal to 0.91 for the December–January–February (DJF) average and both are strongly correlated with the NAO indices (Figure AIV.1c). Correlations between all the NAO estimates are spatially and temporally very high in all the observational products over the modern reanalyses period (Gerber and Martineau, 2018); for instance, the correlation between the station-based and EOF-based NAO indices over 1959–2018 in boreal winter using JRA-55 is equal to 0.89 (Figure AIV.1c). EOF-based NAO and NAM indices are used in Section 3.7.1 for model evaluation. The fixed-latitude NAM index is used in Sections 2.4.1.1, 4.3.3.1, 4.4.3.1 and 4.5.3.1, and in Section 3.7.1 for attribution of past changes.

AIV.2.1.2 Teleconnections and Regional Influence

Large-scale changes in the position and strength of the North Atlantic jet stream and storm tracks associated with the NAO/NAM, as well as the related incidence in blocking episodes traditionally linked to extreme events, affect surface climate conditions over the entire North Atlantic and surrounding land masses from daily to multi-decadal time scales (Hurrell, 1995). Warmer and wetter weather over Northern Europe extending eastward in western Siberia with simultaneous cooler and drier conditions over a broad Mediterranean basin are distinct features of the positive boreal winter NAO/NAM (Figure AIV.1d,e). Over North America, regions around the Labrador Sea are significantly colder, with excess sea ice formation, while milder conditions dominate the Great Plains, forming altogether a typical quadripolar anomaly pattern for temperature linked to the winter NAO/NAM. The latter structure is tightly related to the latitudinal shift of the storm tracks that is particularly marked in precipitation over the ocean (Figure AIV.1e). More remotely, changes in North Atlantic storm track position and transient eddy activity associated with the positive (negative) phase of the NAO contribute downstream to negative (positive) SLP anomalies in north-eastern East Asia during boreal summer (Linderholm et al., 2011).

Related changes in both westerly winds at mid-latitudes and trade winds in the tropics over the North Atlantic result in anomalous fluxes of sensible and latent heat at sea surface, which create ocean temperature anomalies that extend down to the base of the deep mixed layer during boreal winter (Deser and Timlin, 1997; Seager et al., 2000). The SST imprint of the NAO has a tripolar shape with positive anomalies at mid-latitudes straddled by colder surface ocean in the subtropics and along the entire subpolar gyre (Figure AIV.1d). Weak feedbacks from SST on boreal winter NAO are found through the forced Rossby wave mechanism (Baker et al., 2019) and local phenomena such as oceanic re-emergence in the North Atlantic Nordic seas (Cassou et al., 2007). Negative NAO phases are characterized by a wavier jet stream and a southward shift of storm tracks, which favours cold outbreaks over Northern Europe (Cattiaux et al., 2010) and reinforced storminess along the Mediterranean basin leading to heavy precipitation events (Sanchez-Gomez et al., 2008) and storm surges in southern Europe (Cid et al., 2016). Those are also often related to a collapse/split/displacement of the low-level stratospheric polar vortex and the occurrence of stratospheric sudden warming (Sections 2.3.1.4.5 and 3.3.3.4). In boreal winter, NAM and NAO teleconnections are very similar over the Atlantic-surrounding continents.

There is a strong seasonal asymmetry in observed NAO teleconnection patterns and NAO temporal evolution. Impacts over Europe are opposite between summer and winter months with dominant warmer and drier weather conditions over northwestern Europe in summer concurrently with wetter conditions over southern Europe during positive NAO phases (Folland et al., 2009; Bladé et al., 2012). Extreme events (heatwave occurrence, droughts, etc.) are also linked to NAO phases (Cassou et al., 2005; Drouard et al., 2019) due to the related latitudinal shift of the North Atlantic storm tracks (Dong et al., 2013). Summer NAO trends also affect the Arctic climate as assessed in Sections 3.4.1 and 9.4.1. The NAO is associated with storms or periods of persistent mild winds and dry/sunny spells affecting availability and power consumption (Jerez et al., 2013; Zubiate et al., 2017).

NAO fluctuations generate ocean responses due to altered buoyancy fluxes and wind stress anomalies (Barrier et al., 2014). Signatures of the NAO can be found in the gyre circulations (Marshall et al. 2001) and in the Atlantic Meridional Overturning Circulation (AMOC; Yeager and Danabasoglu, 2014), with a sea level imprint in observations (Han et al., 2017). The oceanic response is dependent on the time scale of the NAO variability (Delworth and Zeng, 2016), especially for AMOC in connection with the so-called Atlantic Multi-decadal Variability (AMV; Section AIV.2.7). This is assessed in Section 9.2.3.1.

Implications of NAO/NAM variability in terms of observed and projected precipitation at a regional scale (Europe, Mediterranean basin, etc.) is comprehensively assessed in Sections 8.3.2.9, 8.4.2.9 and 8.5.2. NAO implications on extremes are assessed in Sections 11.3.1 and 11.4.1, and regional manifestations of NAM/NAO are further assessed in Atlas.5, Atlas.7, Atlas.8 and Atlas.9, and Cross-Chapter Box Atlas.2.

AIV.2.1.3 Available Proxy-based Reconstruction

Sea level pressure records from Stykkisholmur, Akureyri, Reykjavik and from Gibraltar, Lisbon and Ponta Delgada weather stations, all located close to the NAO centres of action (i.e., the Icelandic Low and the Azores High), allowed the reconstruction of the NAO index back to the mid-19th Century (Cropper et al., 2015; Hernández et al., 2020). The Paris–London sea level pressure difference used by Cornes et al. (2013) extends back to 1692, but it captures only part of the large-scale NAO phenomena because of the spatial proximity of the weather stations used. More reliable NAO reconstructions were recently developed based on the reconstruction of the sea level pressure field all over the North Atlantic and Europe (Delaygue et al., 2019; Mellado-Cano et al., 2019). Other long-term reconstructions involve proxy-based information from documents (Barriopedro et al., 2014), tree rings (Cook et al., 2019), ice cores (Sjolte et al., 2018), stalagmites (Baker et al., 2015), sediments (Faust et al., 2016) and a combination of multi-proxy information (Ortega et al., 2015), with large uncertainties due to the diverse methodological approaches used for reconstruction (Michel et al., 2020) and disparate correlations between proxies and associated temporal resolution (Hernández et al., 2020). An additional difficulty for reconstruction lies on the fact that the spatial structure of North Atlantic variability might be time-scale dependent (Woollings et al., 2015). It is shown that on the

shorter time scale (interannual), the NAO is dominated by variations in the latitude of the North Atlantic jet and storm track, whereas on the longer time scale (multi-decadal and beyond) it represents changes in their strength. The two time scales also exhibit different regional impacts on temperature and precipitation, and different relationships to SSTs, which makes proxy reconstructions of the NAO problematic.

Most of the reconstructed NAO/NAM indices describe the boreal winter patterns of the last 500 years because the variability is the most pronounced and is on a larger scale for that season (Luterbacher, 2001; Dezileau et al., 2011). Tree rings can however allow NAO boreal summer reconstruction back to the 16th century (Folland et al., 2009; Linderholm et al., 2009). Recent efforts to develop reconstructions of the NAO phases using pollen data (Mauri et al., 2014), speleothems (Ait Brahimi et al., 2019) and lake sediments (Olsen et al., 2012) provide new evidence for multi-centennial NAO-type variability along the Holocene (Hernández et al., 2020). A detailed description of the latest proxy-based reconstructions of the NAO and related conclusions placing the observations since the pre-industrial period in a broader context of variability are given in Section 2.4.1.1.

AIV.2.2 Southern Annular Mode

AIV.2.2.1 Definition of the Mode

The Southern Annular Mode (SAM), sometimes called the Antarctic Oscillation (AAO), is the leading mode of large-scale atmospheric circulation variability in the Southern Hemisphere extratropics in all seasons and at intra-seasonal to multi-decadal time scales, albeit with season-dependent physical characteristics such as fraction of explained variance, latitudinal shift and intensity of the related anomalous atmospheric circulation and SST fingerprint. It is characterized by synchronous SLP or geopotential height anomalies of opposite signs between the mid- and high latitudes, modulating the mean westerly winds near 50°S. The SAM affects the frequency, strength and position of cold fronts, and extratropical synoptic to mesoscale weather systems (Thompson et al., 2000; Manatsa et al., 2016; Mariani and Fletcher, 2016; Cerrone and Fusco, 2018). It controls a significant fraction of seasonal to multi-annual variance of the zonal mean precipitation in the Southern Hemisphere subtropics and extratropics (Kang et al., 2011). The SAM is also tightly linked to the fluctuations in the thermohaline properties of the Southern Ocean as well as its dynamics (Sen Gupta and England, 2006; Spence et al., 2014), and it modulates the Antarctic sea ice extent from interannual to multi-decadal time scales (Ferreira et al., 2015).

Given its equivalent barotropic structure, the SAM is commonly quantified as the first EOF mode of extratropical geopotential height anomalies at various tropospheric levels or of SLP anomalies. However, it extends into the stratosphere, coupling lower- and middle-atmosphere dynamics. As it essentially represents a meridional atmospheric mass transfer, an alternative definition is the difference in normalized zonal mean SLP anomalies at middle (40°S) and high (65°S) southern latitudes (Gong and Wang, 1999; Marshall, 2003). The polarity of the SAM is defined such that it is

The Southern Annular Mode (SAM)

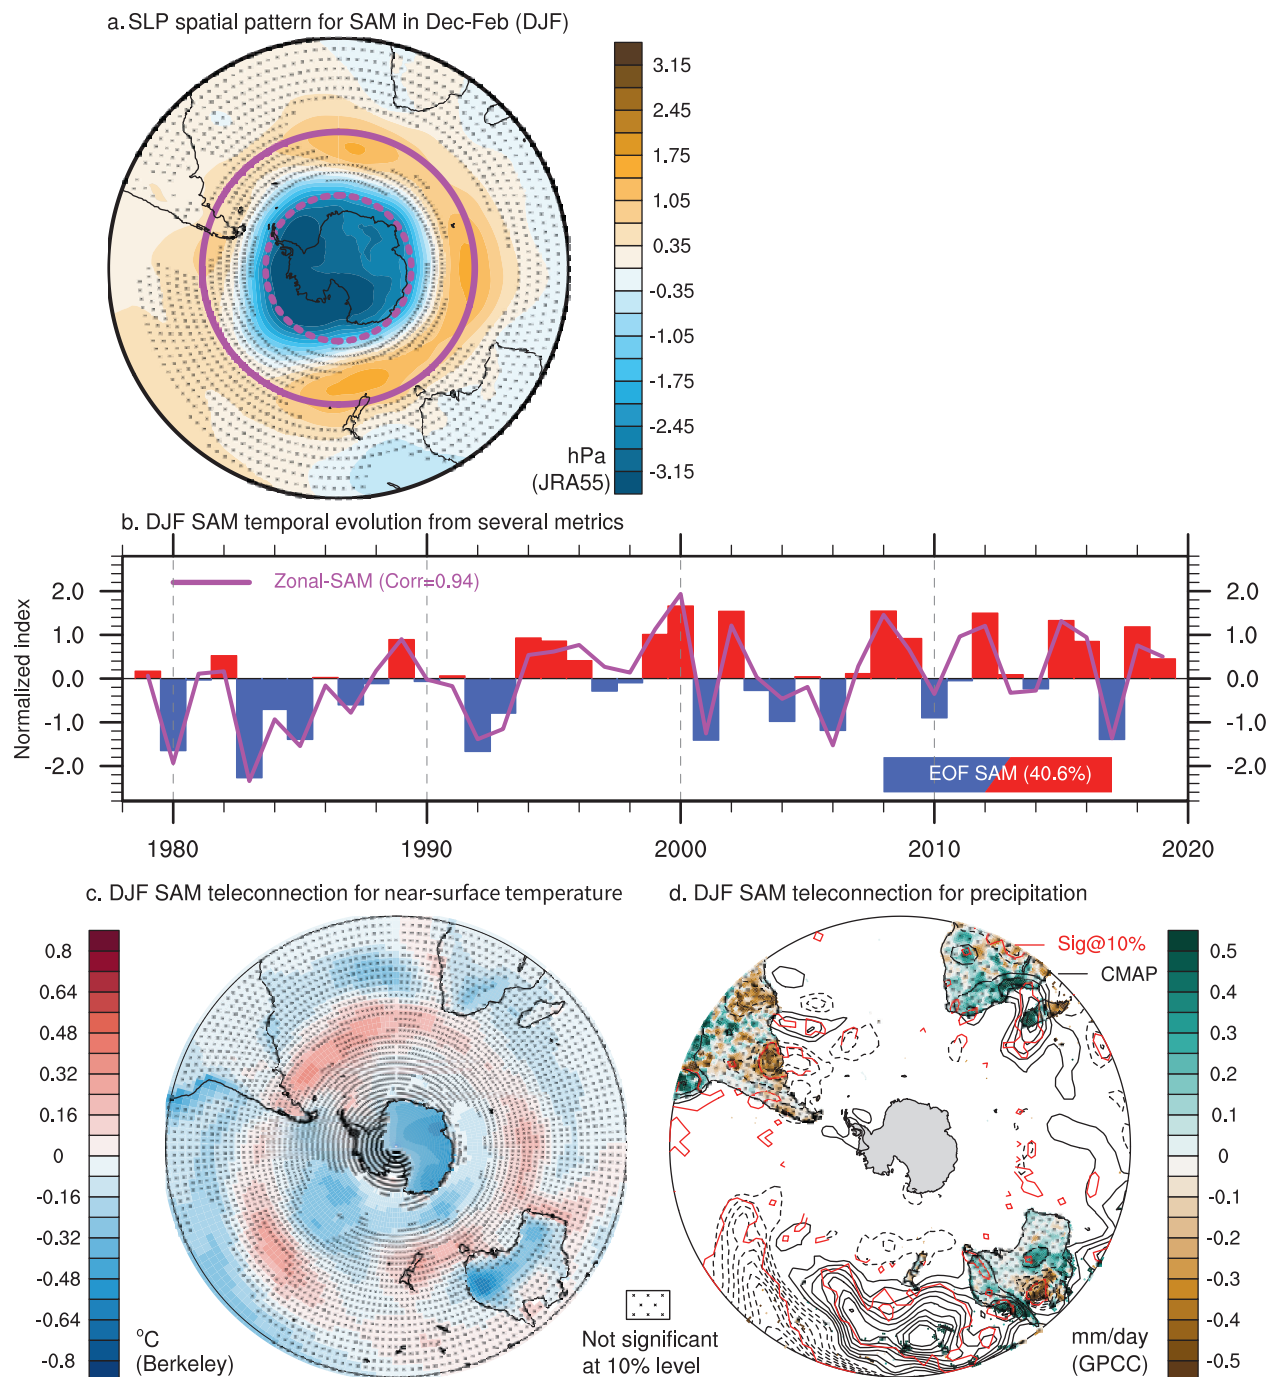

Figure AIV.2 | The austral summer Southern Annular Mode (SAM) extracted as the leading empirical orthogonal function (EOF) of December–January–February (DJF) sea level pressure (SLP) anomalies over the Southern Hemisphere (south of 20°S, a) based on JRA-55 reanalysis over 1979–2019. (a) SLP anomalies regressed onto the leading principal component (PC) time series shown in (b); the variance explained is given in the legend in (b). The SAM-PC is represented by red and blue bars and the zonal-SAM index (latitude circles in a) is given in purple. Correlation between the zonal SAM index and the SAM PC time series is given in the legend. (c) same as (a) but for sea surface temperature and surface air temperature anomalies over land from the ERSST and Berkeley Earth datasets, respectively, over 1979–2019. (d) same as (a) but for precipitation anomalies (shading based on GPCC for 1979–2016 and contours based on CMAP for 1979–2019 for every 0.1 mm day⁻¹). On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicate no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

positive when pressure over Antarctica is anomalously low, and vice versa. While the SAM pattern is more zonally symmetric than its Northern Hemisphere counterpart (NAM; Section AIV.2.1), it does exhibit some asymmetries particularly in the mid-latitude node over the Pacific Ocean and Indian Ocean sectors (Fogt et al., 2012). Alternative interpretations of the SAM as a regional variability pattern in the South Pacific are also considered (Spensberger et al., 2020). The zonal asymmetries are present for all seasons, and illustrated in Figure AIV.2a for austral summer, to support the assessment in Section 3.7.2. A number of different SAM indices have been produced, and several are compared by Ho et al. (2012) and Barrucand et al. (2018), showing good agreement after the second half of the 20th century. Over the 1979–2019 period, the correlation between the EOF-based and zonal SLP-based indices for the summer SAM reaches 0.94 (Figure AIV.2b).

During the positive phase of the SAM, the Antarctic air mass is isolated by an enhanced westerly jet that is located further south than during the negative phase. This leads to colder conditions over the entire continent and negative SST anomalies along the surrounding ocean (Figure AIV.2). During the opposite, negative phase, an equatorward displacement of the jet and related storm track brings low-pressure systems toward the north with a strong effect on the southern tip of South America (Mariani and Fletcher, 2016). The SAM is often used as a proxy for the location of the mid-latitude westerly wind belt at seasonal to interannual time scales. However, Swart et al. (2015) noted that trends in the SAM and the Southern Hemisphere surface westerly jet are not directly interchangeable because multiple factors other than SAM can affect trends in the position, width and strength of the jet and surface wind.

The SAM is mainly driven by extratropical atmospheric dynamics, but its phase is affected by remote SST anomalies such as ENSO (Section AIV.2.3) and anthropogenic forcing as assessed in Section 3.7.2.

The EOF-based SAM index is used for model evaluation in Section 3.7.2. The fixed-latitude SAM index is used for the attribution assessment of the observed positive trend of the SAM that is maximum over the second half of the 20th century but reduced since about 2000 (Section 2.4.1.2) due to slackened ozone influence (Section 3.7.2). The fixed-latitude SAM index is also used in Sections 4.3.3.1, 4.4.3.1 and 4.5.3.1 to assess the future changes in Southern Hemispheric zonal circulation as a function of emissions scenarios and lead times.

AIV.2.2.2 Teleconnections and Regional Influence

Recent observational studies have enriched our understanding of the widespread influence of SAM variability on mean climate and related environmental parameters of the entire Southern Hemisphere extratropics (e.g., Manatsa et al., 2013; Waugh et al., 2013; Raut et al., 2014; Jones et al., 2016; Holz et al., 2017; Kostov et al., 2017; Marshall et al., 2017). The influence of the SAM extends over the mid-latitude continental land masses with precipitation anomalies over southern Australia (Cai and Watterson, 2002) and South-Eastern South America (Silvestri and Vera, 2003) in connection with the latitudinal migration and strength of the extratropical storm and mean westerly circulation. Consistently with NAM/NAO (Section AIV.2.1), there is a strong seasonality in the teleconnection associated with

SAM. In austral summer, during a positive phase of the SAM, drier conditions affect most of the southern Patagonia region and the southernmost tip of South America, while wetter conditions are found in South Africa and Madagascar, as well as in south-eastern Australia where colder temperatures also prevail (Figure AIV.2c, d). Positive temperature anomalies are found in New Zealand, Tasmania and the southern tip of South America. These anomalies appear as the continental fingerprint of a warmer belt located around 40°S that is characterized by significant hemispheric-scale SST changes consistent with the southern shift of the summer storm track.

Moreover, several studies have described equatorward teleconnections linking the SAM to Asian precipitation across the equator (e.g., Prabhu et al., 2017; Liu et al., 2018). Coupling of seasonal stratospheric anomalies to the SAM can influence spring heat extremes in eastern Australia (Lim et al., 2019). Marshall et al. (2013) described a reversal in the relationship between the SAM and East Antarctic temperatures during austral summer/autumn in the first decade of the 21st century, due to regional variability of the pressure pattern associated with the zonal wavenumber 3. Other studies have analysed the temporal variability in the interactions between the SAM and ENSO at different time scales (e.g., Yu et al., 2015; Clem et al., 2016), being positive and significant during 1986–2014 (Vera and Osman, 2018).

Implications of SAM on observed and projected changes in the water cycle and specific regional influences are assessed in Sections 8.3.2.9 and 8.4.2.9, and in Sections 12.4, Atlas.7 and Atlas.11, respectively.

AIV.2.2.3 Available Proxy-based Reconstruction

The regional influence of the SAM is recorded in tree rings (Holz et al., 2017; Dätwyler et al., 2018), lake sediments (Fletcher et al., 2018; Moreno et al., 2018), ice cores (Goodwin et al., 2004) and corals (Goodwin and Harvey, 2008) across the Southern Hemisphere extratropics. Multi-proxy-based reconstructions of the SAM have been developed using temperature-sensitive proxy records that cover the last millennium (Villalba et al., 2012; Abram et al., 2014; Dätwyler et al., 2018). Villalba et al. (2012) used tree ring records to reconstruct the summer SAM since 1409, while Abram et al. (2014) combined ice-core records with tree ring data to derive a weighted composite-plus-scale reconstruction of the annual SAM index for the past millennium. Dätwyler et al. (2018) further included proxies from corals, speleothems and lake sediments using different stationarity criteria for the proxy record selection to build an austral summer SAM reconstruction. Hessel et al. (2017) compared three paleoclimatic reconstructions of the SAM, highlighting the need for additional proxy records over the Indian Ocean sector, to fully account for the annular structural properties of this mode of variability. Uncertainties also arise from the lack of proxy data related to cold season conditions, given that reconstructions relying on tree rings might be biased towards summer thus accounting only for SAM austral summer variability (Hernández et al., 2020). Several studies attempted to reconstruct the SAM behaviour during the Holocene, inferred through changes in the Southern Hemisphere westerly wind belt, but uncertainties remain large without consensus in the SAM phases for most of the periods at multi-decadal time scales (Hernández et al., 2020). These SAM reconstructions are assessed in Section 2.4.1.2 and compared with simulations in Section 3.7.2.

AIV.2.3 El Niño–Southern Oscillation

AIV.2.3.1 Definition of the Mode

The El Niño–Southern Oscillation (ENSO) refers to the large-scale alternation between anomalous warming and cooling of central/eastern equatorial Pacific SSTs that coincide with changes in the overlying winds and precipitation (Philander, 1990; Neelin et al., 1998; Wang, 2018). The main features of ENSO are displayed in Figure AIV.3. ENSO is the primary mode of tropical variability on interannual time scales and is considered as an internally occurring coupled ocean–atmosphere phenomenon. Whilst the ENSO phenomenon itself largely occurs in the tropical Pacific, it triggers climate teleconnections over the entire basin and in many other parts of the world (Figure AIV.3c,d). ENSO is consistently the main modulator of the global surface temperature at interannual time scales (Pan and Oort, 1983; Trenberth et al., 2002). ENSO is the main source of climate predictability on seasonal to interannual time scales (Philander, 1990; Smith et al., 2012) and its status is consequently closely monitored by meteorological institutes around the globe. El Niño events are typically identified by warmer than normal central/eastern equatorial Pacific SSTs, negative SLP anomaly difference between the eastern and western portions of the tropical Pacific Ocean, anomalous westerly surface winds, and increases in cloudiness and precipitation over the central and eastern equatorial Pacific and adjacent land areas. By contrast, La Niña events are typically identified by cooler than normal central/eastern equatorial Pacific SSTs, positive surface pressure anomaly difference between the eastern and western portions of the tropical Pacific Ocean and anomalous easterly surface winds reflecting altogether an intensification of the climatological east–west thermal gradient across the equatorial Pacific Ocean.

ENSO has been monitored through a range of indices, which are based on SST or SLP anomalies during the instrumental period, and various proxies on longer time scales. Differences between indices and thresholds used to define the occurrence of an El Niño or La Niña event imply that there is no commonly accepted list of events and associated magnitude. The three most prominent (Pepler, 2016; L'Heureux et al., 2017) indices used to monitor ENSO are the averaged SST anomalies over the so-called NINO3 (5°S–5°N, 150°W–90°W) or NINO3.4 (5°S–5°N, 170°W–120°W) regions and the Southern Oscillation Index (SOI) based on the normalized SLP difference between Darwin and Tahiti (Troup, 1965). Decomposition into EOFs of the tropical SST is also used in the literature. Those indices are highly correlated, as shown in Figure AIV.3b. The correlation between NINO3.4 SST and the EOF-SST index is about 0.97, and between NINO3.4 and SOI it is about 0.89 over the 1959–2019 period.

SST anomalies from the NINO3 and NINO3.4 regions provide a direct measure of the events via its surface ocean fingerprint, while the SOI provides a measure in terms of atmospheric perturbation. Data are available back to 1876 for the SOI computation, whilst the uncertainty in SST-based indices, particularly those associated with the central equatorial Pacific, is large prior to the 1950s when the number of SST observations was much lower (Kennedy et al., 2019). The complexity of ENSO is at least partly demonstrated by the observed events,

which are all different in the magnitude, spatial structure and/or seasonal timing. As a direct consequence, it is difficult to accurately represent ENSO with one single index. Over time, further indices have been introduced to monitor ENSO event evolution (i.e., Trans Niño Index – TNI, Trenberth and Stepaniak, 2001) and spatial structure (i.e., El Niño Modoki Index – EMI, G. Li et al., 2010). The limited length and quality of the observational records may further affect the choice of the index, whose relevance can depend on the specific application. The variety in ENSO indices also explains the non-universality in the qualification of ENSO status delivered by meteorological agencies responsible for operational monitoring, operational forecast and climate services for users.

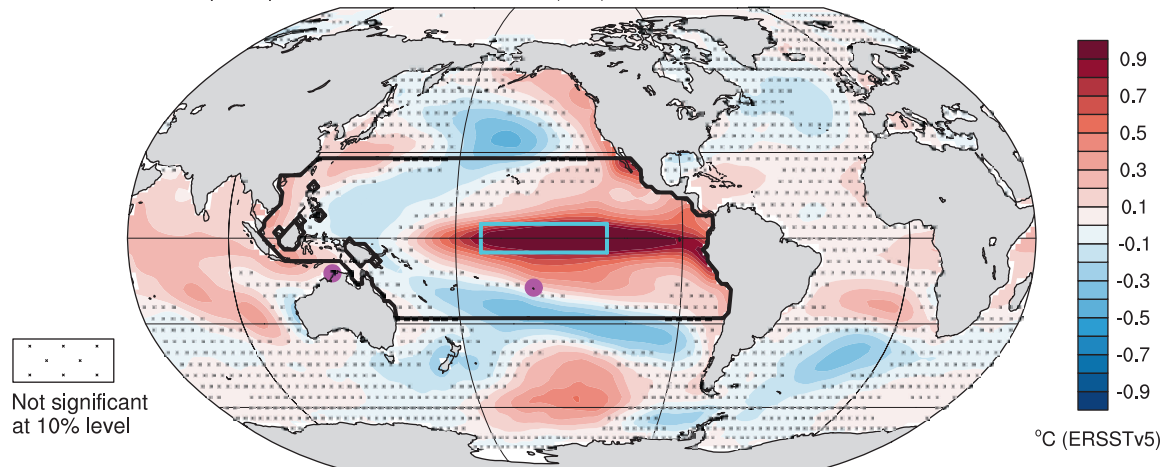

A particular aspect of ENSO diversity is whether the event is centred in the eastern Pacific (EP events) or central Pacific (CP or ‘Modoki’ events). This distinction is important as the type of event leads to different large-scale teleconnections and worldwide climatic impacts (e.g., Ashok et al., 2007; Ratnam et al., 2014; Capotondi et al., 2015; Timmermann et al., 2018; Taschetto et al., 2020). Differences can be significant at regional scale because of the displaced source of diabatic heating associated with the position of the main SST anomalies. For instance, stronger precipitation teleconnections occur over Australia during CP than during EP events (Wang and Hendon, 2007; Taschetto et al., 2009). It is noteworthy that central and eastern Pacific SST indices are more highly correlated with each other during La Niña than during El Niño events. This indicates that La Niña events have less geographic diversity than El Niño events (Kug and Ham, 2011) and that the CP/EP distinction is therefore more relevant for the latter. In the historical instrumental records, Banholzer and Donner (2014) found that CP events had a weaker influence on global surface temperature than EP events did.

However, the distinction between CP and EP events is not necessarily clearly defined, as different methods yield an inconsistent classification of the events, which implies that no robust consensus on the classification of CP or EP events is possible (Wiedermann et al., 2016). Furthermore, Giese and Ray (2011) found that the central longitude of peak SST anomalies associated with individual El Niño events had a distribution indistinguishable from a Gaussian distribution peaked at 140°W, as opposed to a bimodal distribution implied by the EP/CP paradigm. There are also occasional ‘coastal Niño’ events, such as those of 1925 (Takahashi and Martínez, 2019) or 2017 (Rodríguez-Morata et al., 2019), where abnormally warm waters are confined to the South American coast. Even though these events are not conventionally classified as El Niños, they have some El Niño-like teleconnections in South America. Instrumental data have historically been of limited value in assessing the classification of events before 1955, because of the almost total lack of SST measurements in the western half of the NINO3.4 region (L'Heureux et al., 2013). It is not yet known whether newer SST dataset versions, which benefit from improved data archives (Section 2.3.1.1), have reduced this uncertainty.

The description of ENSO in this Annex supports the assessments of Sections 2.4.2, 3.7.3, 4.3.3.2, 4.4.3.2 and 4.5.3.2. ENSO's influence on ocean circulation, heat transport and sea levels are assessed in Sections 9.2 and 9.6.

The El Niño-Southern Oscillation (ENSO)

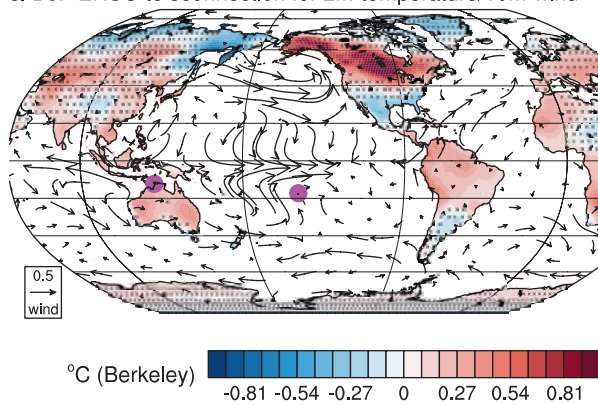

a. SST spatial pattern for ENSO in Dec-Feb (DJF)

b. DJF ENSO temporal evolution from several metrics

c. DJF ENSO teleconnection for 2m-temperature/10m-wind

d. DJF ENSO teleconnection for precipitation

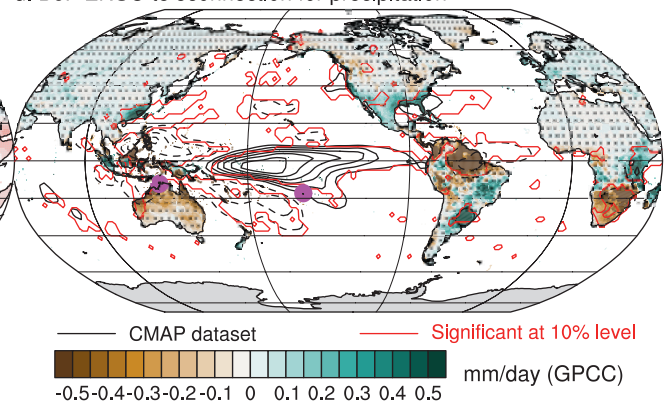

Figure AIV.3 | The boreal winter El Niño–Southern Oscillation (ENSO) mode defined by December–January–February (DJF) sea surface temperature (SST) anomalies averaged over the NINO3.4 region (5°S–5°N, 170°W–120°W, cyan box) or extracted as the leading EOF mode over the tropical Pacific Ocean (the region denoted by the black box in a) for 1958–2019 using ERSSTv5. (a) SST anomalies regressed onto the NINO3.4 time series, which is shown in (b) as red and blue bars. Black curve in (b) represents the standardized leading principal component and the purple curve stands for the SOI index. The percentage of explained variance of the leading EOF is given in the legend, as well as the correlation between all indices and the NINO3.4 time series. **(c)** Same as (a) but for land surface air temperature (shading; based on Berkeley Earth) and 10 m level wind (arrows; m s^{-1} based on JRA-55) anomalies over 1958–2018. **(d)** Same as (a) but for precipitation anomalies (shading based on GPCC for 1958–2016 and contours based on CMAP for 1979–2019 for every 0.5 mm day^{-1}). Magenta dots in (c, d) stands for the Darwin and Tahiti weather station used for the SOI computation. On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicate no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

AIV.2.3.2 Teleconnections and Regional Influence

ENSO has a broad range of teleconnections, both in and outside the Pacific region (Figure AIV.3c,d). Amongst the best-known teleconnections are the association of El Niño events with increased precipitation in the south-western and south-eastern USA, eastern Africa, coastal Ecuador and Peru, and northern Argentina, and with decreased precipitation in eastern Australia and the Maritime Continent, southern Africa, the Amazonian basin and much of the Indian subcontinent. A general reverse association is found during La Niña events although there are some asymmetries (Cai et al., 2010; Taschetto et al., 2020). ENSO also has a substantial impact on tropical cyclone occurrence (Wang and Chan, 2002; Chu, 2004; Kuleshov et al., 2008), with El Niño typically being associated with reduced tropical cyclone activity in the North Atlantic, and an eastward displacement of western North Pacific and South Pacific tropical cyclone genesis away from the Philippine Sea and the Australian continent and into the central Pacific. ENSO has been shown to control part of the interannual variability of fire, including wildfire and human-triggered fires, in many regions of the world including all the continents surrounding the Pacific (see for instance the devastating extreme fire emissions in Indonesia in 2015; Chisholm et al., 2016) but also remotely, for example, over the Arctic (Monks et al., 2012).

Tropical climate impacts during ENSO events are largely driven by a reorganization of the zonal Walker circulation that results from anomalous diabatic heating associated with deep atmospheric convection changes (e.g., Gill, 1980; Klein et al., 1999; Chiang and Sobel, 2002; Choi et al., 2015). The latter are also responsible for atmospheric teleconnections to higher latitudes (Yeh et al., 2018), acting as a source of forced large-scale Rossby waves (Hoskins and Karoly, 1981). Specific phases of the Pacific-North American (PNA) pattern (Horel and Wallace, 1981) and Pacific-South American (PSA) pattern (Karoly, 1989) are then favoured in the Northern and Southern hemispheres, respectively, and are associated with shift and modulation of the mean storm tracks. These teleconnections influence temperature and rainfall around the globe, including extreme events (King et al., 2014). For instance, mild winter conditions dominate Alaska/Canada, connected to the south-eastward displacement and reinforcement of the Aleutian Low during El Niño, which generates anomalous southerlies and advects warmer air northward. By contrast, the anomalous cyclonic circulation favours cold outbreaks over the far-east Siberian region and Kamtchaka (Figure AIV.3c,d).

Being the dominant actor of variability at interannual time scales, ENSO is linked to many other modes of variability both in the tropics and mid-latitudes, either in phase or with some seasonal lag. For instance, connection has been documented between EP ENSO events and SAM during austral summer (Ciaasto et al., 2015). A relationship exists between ENSO and the NAO/NAM in boreal winter through various mechanisms such as stratosphere–troposphere coupling (Domeisen et al., 2015) and tropospheric pathways, including the eastward extension of the PNA during El Niño events and also through the alteration of the propagation of tropical Rossby wave trains from the Pacific to the Atlantic (Drouard et al., 2015). The tropical-extratropical teleconnection is not symmetrical with the phase of ENSO and non-stationary with considerable dependence on epochs being

modulated by the inherent strong internal variability (Deser et al., 2017; Drouard and Cassou, 2019). In the Atlantic, a relationship between ENSO and Atlantic Niño (Section AIV.2.5) is found in boreal spring (Tokinaga et al., 2019) while the South Atlantic Subtropical Dipole mode is mostly connected to ENSO in austral summer (Rodrigues et al., 2015).

Implications of ENSO in water cycle changes are further assessed in Sections 8.3.2.9 and 8.4.2.9. The association of ENSO with extremes and specific regional climate anomalies is assessed in Sections 11.4, 11.6, 11.7 and 12.4, in Box 11.4, and in Atlas.4, Atlas.5, Atlas.6, Atlas.7 and Atlas.9.

AIV.2.3.3 Available Proxy-based Reconstruction

Model evidence suggests that ENSO characteristics vary on decadal to centennial time scales (e.g., Lewis and LeGrande, 2015; Deser et al., 2017), implying that a minimum of several hundred years of observations, which is much longer than the instrumental record, are required to determine the full natural range of ENSO complexity (Wittenberg, 2009). Thus, one way to understand if anthropogenic forcing has modulated ENSO is to understand ENSO behaviour prior to the observational record. Paleoclimate archives can be used to fill this gap as they provide quantitative estimates of ENSO behaviour during the pre-industrial era, while also providing information of ENSO characteristics under a variety of past natural climate background states controlled by external forcings. Extensive proxy-based studies, using a range of ENSO-sensitive records, have been carried out to assess the ENSO changes on various paleoclimate time scales, specifically the last few hundred years and back to the mid-Holocene (Section 2.4.2).

Reconstructions of past ENSO behaviour traditionally merges information from multiple proxies that are considered sensitive to ENSO (Lu et al., 2018). This merging process may have multiple purposes, but it is generally used to extend the reconstruction length and also to increase its signal-to-noise ratio. The resulting reconstructions can be broadly placed into two main categories: (i) those that utilize proxies in the central and eastern equatorial Pacific itself; and (ii) those that utilize proxies from other regions impacted through teleconnections, along with those that mix both categories. ENSO reconstructions from category (i) are considered to be a more accurate measure of ENSO behaviour. However, proxies from the central and eastern equatorial Pacific are generally rarer than those outside the region, due to the small number of land/reefs, and they also tend to be of shorter duration. Thus, the ideal case is a combination of both categories to get a robust quantitative estimate of ENSO behaviour in the past.

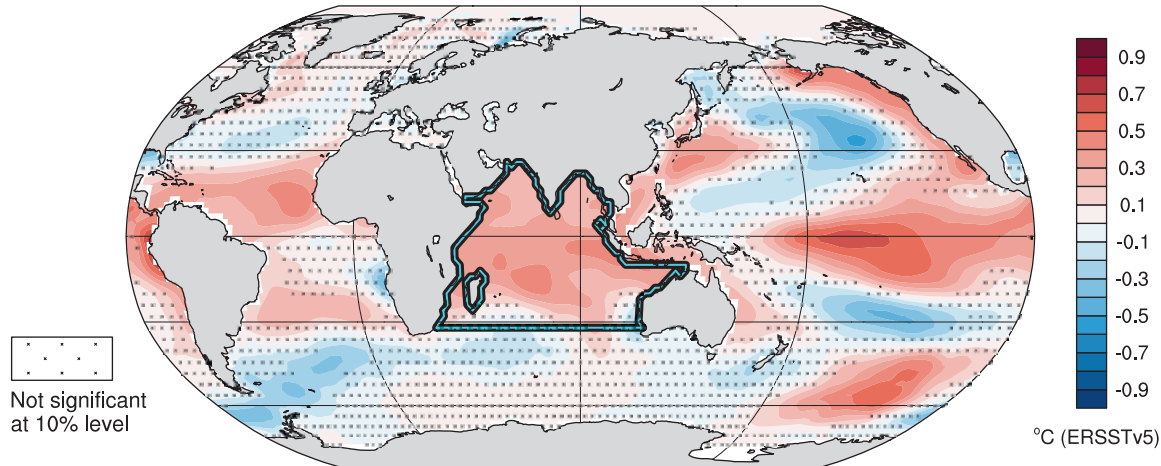

AIV.2.4 Indian Ocean Basin and Dipole Modes

AIV.2.4.1 Definition of the Mode

The Indian Ocean Basin (IOB) and Indian Ocean Dipole (IOD) modes are the two dominant modes of interannual climate variability in the Indian Ocean. The IOB mode features the temporal alternation of basin-wide warming and cooling of sea surface in the positive and negative phases, respectively (Figure AIV.4), while the IOD mode is

The Indian Ocean Basin Mode (IOB)

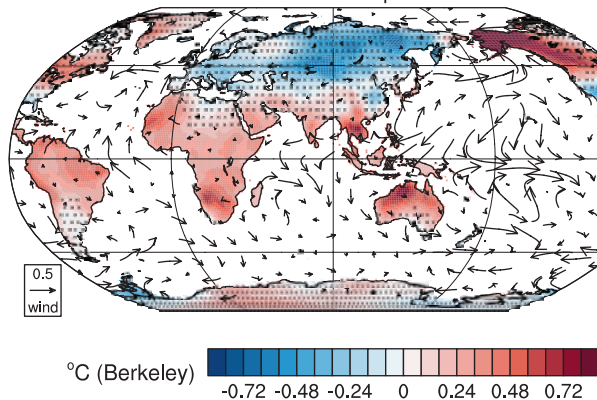

a. SST spatial pattern for IOB in March-May (MAM)

b. MAM IOB temporal evolution from several metrics

c. MAM IOB teleconnection for 2m-temperature/10m-wind

d. MAM IOB teleconnection for precipitation

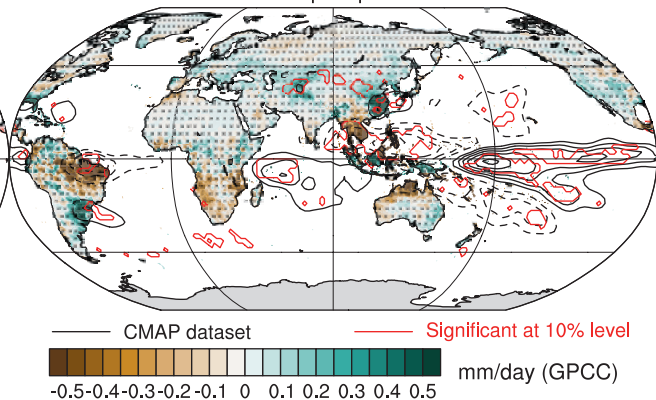

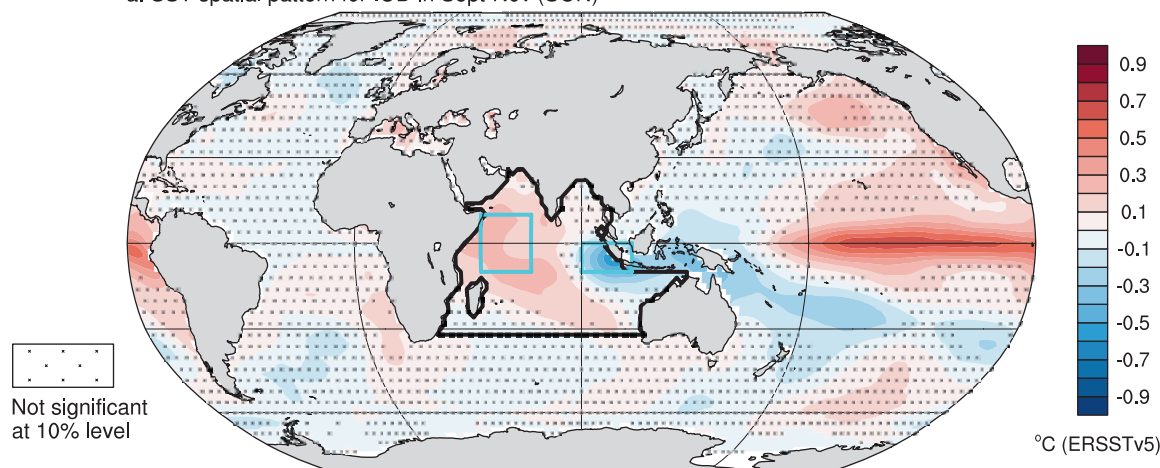

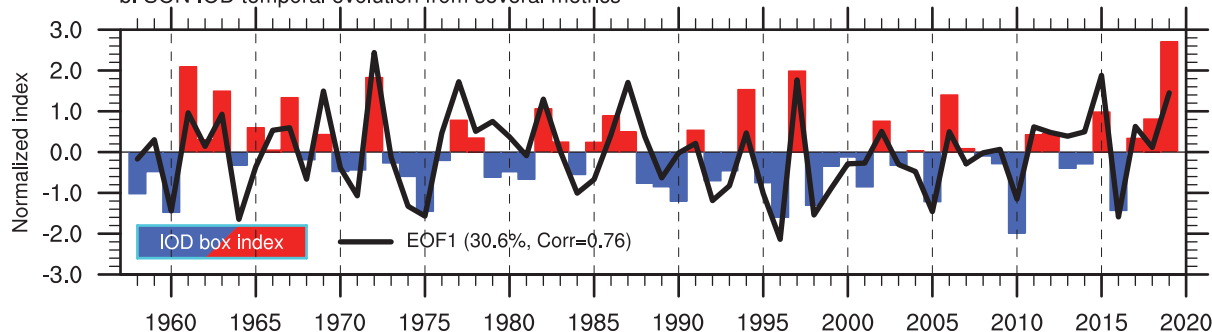

Figure AIV.4 | The boreal spring Indian Ocean Basin (IOB) mode defined by March–April–May (MAM) SST anomalies averaged over the Indian Ocean (the region denoted by the cyan box in a) or extracted as the leading EOF mode over the same domain (black lines) for 1958–2019 using ERSSTv5. (a) SST anomalies regressed onto the IOB index time series shown in (b) in red and blue bars, while the black curve in (b) represents the leading principal component time series. Explained variance and correlation between indices are given in the legend in (b). **(c)** Same as (a) but for land surface air temperature (shading; based on Berkeley Earth) and 10 m level wind (arrows; m s^{-1} based on JRA-55) anomalies for 1958–2018. **(d)** Same as (a) but for precipitation anomalies (shading based on GPCP for 1958–2016 and contours based on CMAP for 1979–2019 for every 0.3 mm day^{-1}). On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

The Indian Ocean Dipole Mode (IOD)

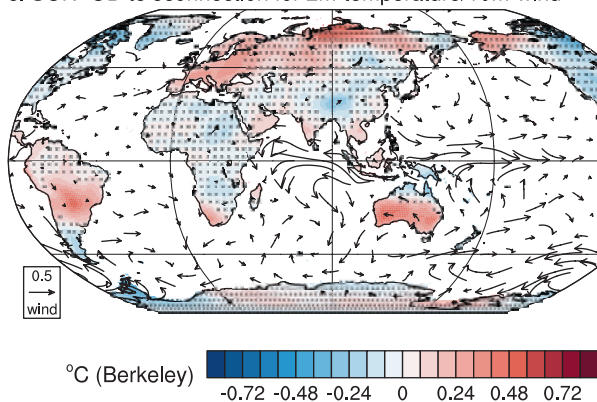

a. SST spatial pattern for IOD in Sept–Nov (SON)

b. SON IOD temporal evolution from several metrics

c. SON IOD teleconnection for 2m-temperature/10m-wind

d. SON IOD teleconnection for precipitation

(a) SST anomalies regressed onto the IOD index time series shown in (b) in red and blue bars, while the black curve represents the leading principal component time series. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land surface air temperature (shading; based on Berkeley Earth) and 10 m level wind (arrows; m s⁻¹ based on JRA-55) anomalies for 1958–2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958–2016 and contours based on CMAP for 1979–2019 for every 0.3 mm day⁻¹). On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

characterized by a zonal dipole of SST anomalies in the tropics, with one lobe centred off Sumatra and Java and the other covering a large portion of the western basin (Figure AIV.5). The two modes mostly vary on interannual time scales and are both correlated positively with ENSO. In particular, the IOD tends to emerge during ENSO development from boreal summer to autumn (Stuecker et al., 2017), followed by the IOB which grows in ENSO peak season and persists for a few subsequent seasons (Tokinaga and Tanimoto, 2004).

The IOB mode is considered primarily as a response to ENSO associated with large-scale alteration of the Walker circulation, and thus matures in boreal spring, a season after the typical ENSO peak (Klein et al., 1999; Lau and Nath, 2000, 2003). By contrast, the Bjerknes feedback is key to the formation of the IOD. This feedback requires background surface easterlies and thermocline shallowing in the eastern part of the basin along the equator, and this condition sets in boreal spring and persists until autumn, then dissipating by early winter in association with climatological monsoon wind swing. The IOD mode therefore develops in boreal summer and reaches its maximum amplitude in autumn, then rapidly terminates before winter (Schott et al., 2009). Differently from the IOB, strong internal feedbacks enable the IOD mode to develop also without influence from ENSO, as noted for some specific events (Saji and Yamagata, 2003b; Meyers et al., 2007).

The IOB and IOD are identified as the first and second EOF modes, respectively, of monthly SST variability in the tropical Indian Ocean (Weare, 1979; Saji et al., 1999). The IOD can be extracted also as the first EOF of SST variability in boreal autumn, although the pattern depends on the analysis period (Pillai et al., 2019). The IOD mode has a sub-surface signature and can be also calculated as the leading EOF mode of the 20°C isotherm depth of the Indian Ocean seawater temperature (Saji et al., 2006). Apart from the EOF definitions, the tropical Indian Ocean averaged SST (20°S–20°N, 40°E–100°E or 40°E–120°E) is often used as the IOB mode index (Figure AIV.4a). For March–April–May (MAM), its correlation with the leading PC of Indian Ocean SST (Figure AIV.4b) reaches 0.98. For the IOD, the difference between normalized SST anomalies between the western (10°S–10°N, 50°E–70°E) and eastern (10°S–0°, 90°E–110°E) equatorial Indian Ocean is a widely used index (Saji et al., 1999; Figure AIV.5). It is highly correlated (at 0.76) with the leading principal component of the Indian Ocean September–October–November SST when assessed over 1958–2019 (Figure AIV.5b).

The IOB-like (Han et al., 2014) and IOD-like (Ashok et al., 2004a; Tozuka et al., 2007) variability can also be identified at decadal time scales. The decadal IOB mode is defined as the leading EOF mode of linearly detrended monthly SST after decadal time filtering (Han et al., 2014; Dong and McPhaden, 2017). Ten-year low-pass filtered Indian Ocean basin-mean SST is an alternative index for the decadal IOB mode (Dong et al., 2016), with the global-mean SST subtracted in some cases as an estimation of the response component to radiative forcing (Huang et al., 2019). The decadal IOD mode can be extracted as the second EOF mode of 10-year low-pass filtered Indian Ocean SST in boreal autumn (Yang et al., 2017), while other studies use the 10-year low-pass filtered SST anomaly difference between the western and eastern equatorial Indian Ocean (Ashok et al., 2004a; Tozuka et al., 2007).

Paleo fluctuations of IOB and IOD as well as the changes over the instrumental record period are assessed in Section 2.4.3, while their model representations are assessed in Section 3.7.4. Future variations under global warming are assessed in Sections 4.4.3.3 (near term) and 4.5.3.3 (mid- to long terms).

AIV.2.4.2 Teleconnections and Regional Influence

Since the IOB mode is tightly associated with ENSO, related climate anomalies can be viewed as part of ENSO's influence from boreal winter to subsequent spring. Still, the IOB mode plays an important role in modulating the ENSO influence on several regions. The positive phase of the IOB plays a major role in suppressing precipitation in the Maritime Continent from boreal winter to spring (Watanabe and Jin, 2002; Annamalai et al., 2005) and in Northern Australia in austral summer (Taschetto et al., 2011) in conjunction with El Niño events (Figure AIV.3d). An anomalous surface anticyclone then forms over the Philippine Sea linked to the precipitation reduction in the tropical western Pacific and brings more precipitation to East Asia during El Niño winter and spring (Figure AIV.3d; Wang et al., 2000).

ENSO's equatorial Pacific SST anomalies typically dissipate by boreal summer, when the lingering IOB then plays the leading role in exerting climate anomalies in Asia and the western North Pacific (the Indian Ocean capacitor effect; Xie et al., 2009). The boreal summer IOB induces meridionally dipolar anomalies of precipitation and surface air temperature in South East and East Asia, with wetter and cooler summers in mid-latitude East Asia and drier and warmer summers in South East Asia during positive IOB events (Kosaka et al., 2013; Wang et al., 2013). These conditions affect the occurrence of extremes such as heavy rainfall (often caused through atmospheric rivers; Kamae et al., 2017) and heatwaves (Hu et al., 2012; Deng et al., 2019). The positive IOB suppresses summer tropical cyclone formation in the western North Pacific (Du et al., 2011; Ueda et al., 2018), leading to a delayed onset of the typhoon season (Zhao et al., 2019). These regional influences are already present in the spring season (Figure AIV.4c,d) but tend to persist and even get reinforced due to the persistence of the IOB, while following the seasonal climatological displacement of tropical dynamics (monsoon, etc.). In South Asia, tripolar precipitation anomalies form in boreal summer, with precipitation increase along the Western Ghats and in Bangladesh, and decrease around the Ganges Delta during the positive IOB (Chowdary et al., 2013, 2019).

The IOD is associated with climate anomalies in broad regions (Figure AIV.5c,d). However, the related anomalies are affected by influences from concomitant ENSO. The IOD affects rainfall in eastern Africa, South Asia, Indonesia and Australia (Figure AIV.5c,d). The IOD in the positive phase increases rainfall in eastern tropical Africa in boreal autumn to early winter (Figure AIV.5d), while the negative phase induces the opposite anomalies. These anomalies are also found in association with ENSO (Figure AIV.3d), but the explained variance by IOD is larger (Saji and Yamagata, 2003a). Both positive IOD and El Niño events reduce precipitation and temperature over the entire Maritime Continent (Figures AIV.5c,d and AIV.3c,d) because of strong low-level divergence coupled with upper-level convergence related to diminished convection, while the opposite anomalies are induced by negative IOD and La Niña episodes (Saji and Yamagata, 2003a).

The positive phase of the IOD also decreases rainfall in western to south-eastern Australia (Ashok et al., 2003; Risbey et al., 2009), acting as preconditioning for fires (Cai et al., 2009). The rainfall anomalies cover the whole of Australia when combined with simultaneous ENSO with the same polarity (Risbey et al., 2009). The IOD influences South Asian summer monsoon rainfall either directly through moisture transport over the western Indian Ocean or modification of the local Hadley cell (e.g., Ashok et al., 2001; Gadgil et al., 2004; Ashok and Saji, 2007; Behera and Ratnam, 2018), or indirectly in the framework of the tropospheric biennial oscillation (e.g., Meehl et al., 2003; Li et al., 2006; Webster and Hoyos, 2010). IOD and ENSO often interfere in their influence on the South Asian summer monsoon (e.g., Ashok et al., 2001, 2004b; Pepler et al., 2014; Crétat et al., 2017). Opposing influences of IOD and ENSO have been found on surface temperature in summer in northern East Asia (Saji and Yamagata, 2003a).

Implications of these modes on water cycle changes and specific regional influences are further assessed in Sections 8.3.2.9, 8.4.2.9 and 12.4, and Atlas.5, Atlas.6, Atlas.7 and Cross-Chapter Box Atlas.2, respectively.

AIV.2.4.3 Available Proxy-based Reconstruction

Corals record interannual and longer variability in the Indian Ocean (Zinke et al., 2005, 2009). Several studies have developed IOD reconstructions based on oxygen isotope ratios from corals. These reconstructions include those based on samples from Kenya since 1887 (Kayanne et al., 2006), from the Mentawai Islands in western Indonesia for the last 6500 years (Abram et al., 2007), and in combination with samples from Bali in southern Indonesia and the Seychelles since 1846 (Abram et al., 2008). Abram et al. (2020) developed a coral-based reconstruction of the IOD for the last millennium, albeit with some discontinuity. Niedermeyer et al. (2014) use isotope compositions in terrestrial plant wax to reconstruct rainfall changes over north-western Sumatra, which are highly correlated with the IOD. Compared to the IOD, proxy-based IOB reconstruction is limited. Yet Du et al. (2014) find that coral oxygen isotope records from the Seychelles are well correlated with the IOB, suggesting that they can be used as an IOB proxy. Evidence from other proxies that are potentially associated with the Indian Ocean variability is assessed in Section 2.4.3.

AIV.2.5 Atlantic Meridional and Zonal Modes

AIV.2.5.1 Definition of the Mode

The Atlantic Zonal Mode (AZM), also commonly referred to as the Atlantic Niño, and the Atlantic Meridional Mode (AMM) are the two dominant modes of tropical Atlantic climate variability on interannual to decadal time scales. The AZM peaks during the boreal summer upwelling season with maximum SST anomalies in the eastern equatorial Atlantic and is commonly regarded as the Atlantic counterpart of the Pacific El Niño (Zebiak, 1993; Keenlyside and Latif, 2007; Lübbecke et al., 2018; Foltz et al., 2019). The AMM, which is more active on longer time scales, peaks during boreal spring and exhibits a cross-equatorial gradient of SST with opposite signs in

the northern and southern portion of the Atlantic. Both modes are associated with changes in the Inter-tropical Convergence Zone (ITCZ) and related winds, and exert a strong influence on the climate in adjacent and remote regions.

The AMM is thought to be primarily driven by air-sea heat fluxes and therefore thermodynamic in nature (Chang et al., 2000; Foltz and McPhaden, 2010), while various mechanisms for generating AZM events have been discussed. They mainly concern fluctuations in the wind field over the equatorial Atlantic. These wind-stress anomalies can be excited by local SST changes, as part of Bjerknes feedback (i.e., weakening of trade winds and thermocline slope adjustments via oceanic equatorial Kelvin wave propagation; Keenlyside and Latif, 2007; Deppenmeier et al., 2016). They can also be excited by meridional advection of temperature anomalies (Richter et al., 2013), generated remotely as a response to ENSO (Latif and Grötzner, 2000; Tokinaga et al., 2019) or to variations in the South Atlantic Subtropical High (Lübbecke et al., 2014), or occur as stochastic wind variability (Richter et al., 2014). In contrast to previous mechanisms involving coupled atmosphere–ocean dynamics, Bellomo et al. (2015) and Nnamchi et al. (2015) suggested that a large part of the SST variability in the eastern equatorial Atlantic can be explained by thermodynamic feedbacks excited by stochastic atmospheric perturbations. A recent study based on observational and reanalysis products by Nnamchi et al. (2021) indicates that the seasonality of AZM is indeed largely controlled by the variability of the atmospheric diabatic heating. However, the balance between thermodynamic and dynamic processes determining SST variability in the equatorial Atlantic is subtle, and other studies (e.g., Jouanno et al., 2017; Dippe et al., 2018) conclude that, even if the thermodynamic component is not negligible, the dynamics is the dominant driver of the AZM.

The AZM and AMM represent the first and second EOF patterns of the tropical Atlantic variability identified using SST anomalies in this region (Figures AIV.6a and AIV.7a). These modes may also be defined using box averages, with the AZM defined as SST anomalies averaged over the equatorial Atlantic region called ATL3 (3°S–3°N, 0°–20°W), and the AMM defined as the difference between the normalized SST anomalies averaged over the tropical North Atlantic and tropical South Atlantic (i.e., 5°N–30°N, 20°W–60°W minus 5°N–20°S, 5°E–25°W). In boreal summer, the ATL3 and the EOF-AZM PC are correlated at 0.87 during 1958–2019 (Figure AIV.6b). The correlation between the AMM-box index and the EOF-AMM PC is lower at 0.39 (Figure AIV.7b) but increases to 0.67 over 1900–2019.

For the AMM, the latitudinal polarity in SST anomalies is associated with wind gradient and flow from the cooler to the warmer hemisphere (Figure AIV.7c; Ruiz-Barradas et al., 2000; Chiang and Vimont, 2004; Lübbecke et al., 2018; Foltz et al., 2019). For the AZM, similarly to ENSO in the Pacific Ocean, anomalous westerlies lead to low-level convergence over warmer SST along the climatological cold tongue (Figure AIV.6c).

The temporal evolution of the Atlantic modes of variability and their model representation are assessed in Sections 2.4.4 and 3.7.5, respectively. Their near-term and long-term evolution is assessed in Sections 4.4.3.4 and 4.5.3.4, respectively.

The Atlantic Zonal Mode (AZM)

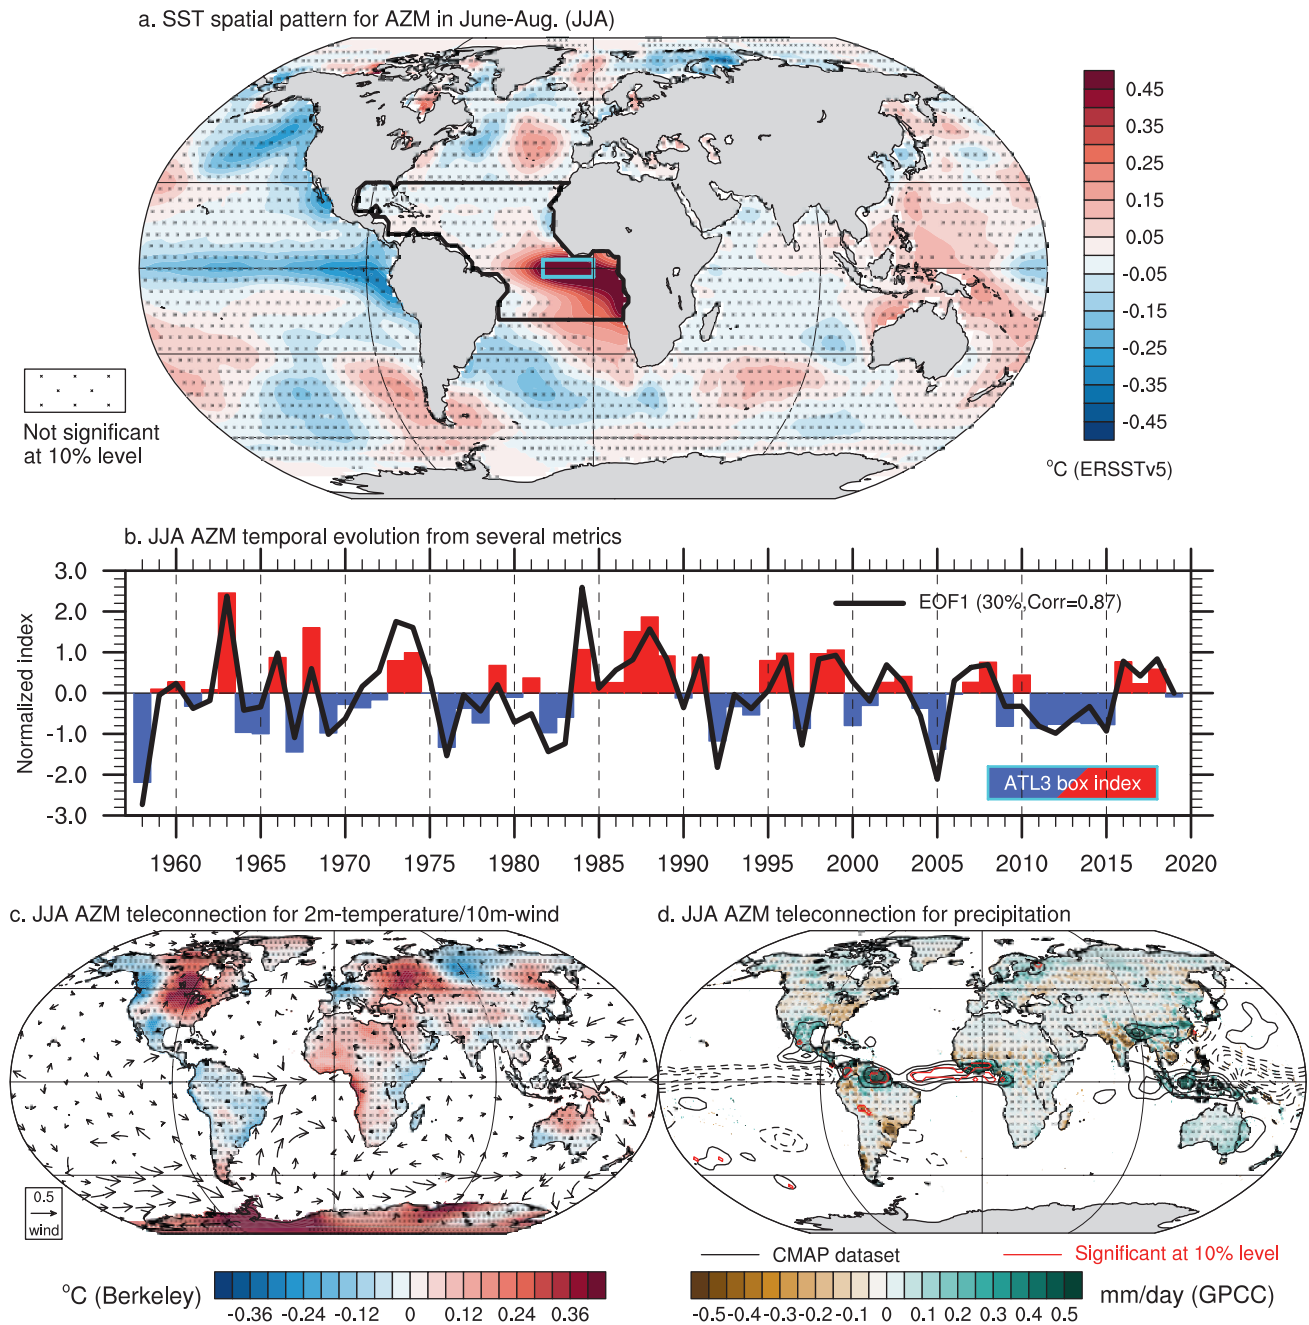

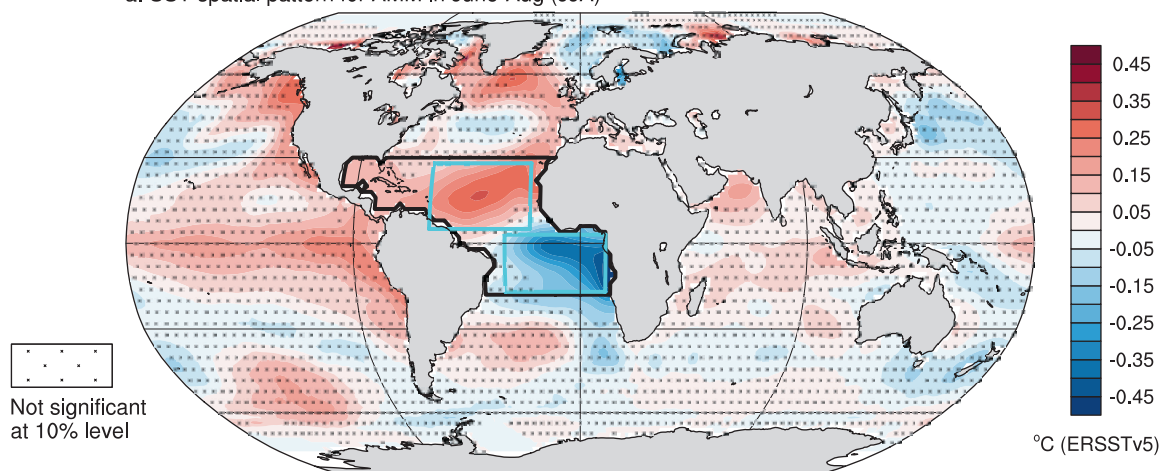

Figure AIV.6 | The boreal summer Atlantic Zonal Mode (AZM) defined by June–July–August (JJA) box-averaged sea surface temperature (SST) anomalies over the ATL3 region (3°S–3°N, 0°–20°W, cyan box in a) or estimated as the leading empirical orthogonal function (EOF) over the tropical Atlantic Ocean (the region denoted by the black box in a) for 1958–2019 using ERSSTv5. (a) SST anomalies regressed onto the ATL3 time series, which is shown in **(b)** as red and blue bars, while the black curve represents the leading principal component time series. Explained variance and correlation between indices are given in the legend in **(b)**. **(c)** Same as **(a)** but for land surface air temperature (shading; based on Berkeley Earth) and 10 m level wind (arrows; m s⁻¹ based on JRA-55 for 1958–2019) anomalies. **(d)** Same as **(a)** but for precipitation anomalies (shading based on GPCC for 1958–2016 and contours based on CMAP for 1979–2019 for every 0.2 mm day⁻¹). On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in **(d)**. All fields have been linearly detrended prior to computation.

c. JJA AMM teleconnection for 2m-temperature/10m-wind

d. JJA AMM teleconnection for precipitation

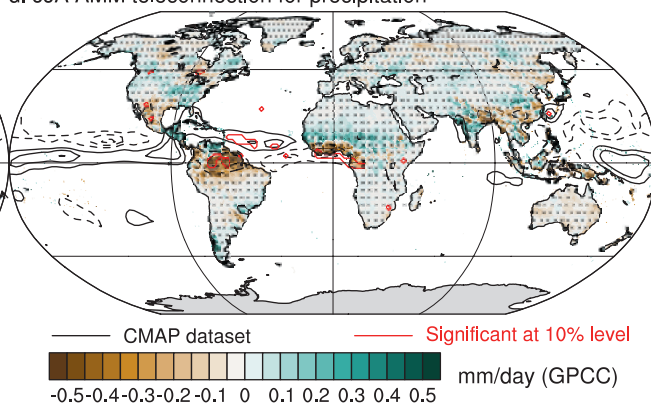

Figure AIV.7 | The boreal summer Atlantic Meridional Mode (AMM) defined by June–July–August (JJA) standardized sea surface temperature (SST) difference between the north (5°N–30°N, 20°W–60°W) and south (5°N–20°S, 5°E–25°W) tropical Atlantic Ocean shown by the cyan boxes in (a) or estimated as the leading empirical orthogonal function (EOF) over the tropical Atlantic Ocean (the region denoted by the black box in a) for 1958–2019 using ERSSTv5. (a) SST anomalies regressed onto the AMM time series, which is shown in (b) as red and blue bars, while the black curve represents the leading principal component time series. Explained variance and correlation between indices are given in the legend in (b). **(c)** Same as (a) but for land surface air temperature (shading; based on Berkeley Earth) and 10 m level wind (arrows; m s⁻¹ based on JRA-55 for 1958–2019) anomalies. **(d)** Same as (a) but for precipitation anomalies (shading based on GPCC for 1958–2016 and contours based on CMAP for 1979–2019 for every 0.2 mm day⁻¹). On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

AIV.2.5.2 Teleconnections and Regional Influence

The tropical Atlantic variability has robust teleconnections with climate variability across the global tropics and beyond. There is evidence for two-way teleconnections between the tropical Atlantic and Pacific on interannual to decadal time scales, such that the tropical Atlantic variability responds and feeds back to the Pacific ENSO (Section AIV.2.3) and Pacific Decadal Variability (PDV; Section AIV.2.6). A number of studies suggest the existence of a possible connection between the tropical North Atlantic and tropical Pacific variability (Wu et al., 2007; Ham et al., 2013a, b; L. Wang et al., 2017) at interannual time scales. This teleconnection appears to be modulated at a decadal time scale by the AMV phases (L. Wang et al., 2017) and it is also affected by global warming (Dong and Zhou, 2014).

The AZM-related boreal summer variability is linked with ENSO in the following boreal winter (Polo et al., 2008; Rodríguez-Fonseca et al., 2009; Ding et al., 2012; Keenlyside et al., 2013; Martín-Rey et al., 2015; Cai et al., 2019). This relationship is strongest during negative AMV phases due to enhanced equatorial Atlantic variability (Martín-Rey et al., 2014, 2018; Polo et al., 2015). On the other hand, the persistence of SST anomalies during multi-year ENSO events affects the equatorial Atlantic variability through modifications of the Walker circulation (Tokinaga et al., 2019). An exhaustive analysis of the AZM characteristics and related teleconnections is given in Lübbecke et al. (2018) and by Cabos et al. (2019).

The AZM affects the Indian summer monsoon (ISM), altering the ENSO-ISM connection (Kucharski et al., 2007, 2008; Wang et al., 2009; Barimalala et al., 2012, 2013; Kucharski and Joshi, 2017). Specifically, warm SST in the equatorial Atlantic leads to decreased monsoon rainfall over central India, and the opposite occurs for negative Atlantic SST anomalies via strengthening of the Somali Jet and low-level convergence (Kucharski et al., 2007, 2008; Pottapinjala et al., 2016). This latter relationship opens up the possibility of using AZM phases to predict ISM rainfall (Sabeerali et al., 2019). In this framework, the AZM modulates SST variability in the Indian Ocean (Kajtar et al., 2017). The number of monsoon depressions over the Bay of Bengal increases during the cold phase of the AZM, which is remotely responsible for changes in low-level cyclonic vorticity and mid-tropospheric humidity (Pottapinjala et al., 2014). A relationship between AZM and the West African Monsoon is documented as well, with a reduction of rainfall over the Sahel and an increase over Guinea (Losada et al., 2010). But the relationship with the Sahel shows significant changes across the 20th century (Joly and Voldoire, 2010; Losada et al., 2012), which is strongly indicative for non-stationarity of the teleconnection.

On the western side of the basin, a warm equatorial Atlantic delays the northward migration of the ITCZ and can thus influence rainfall over North-Eastern South America (Nobre and Srukla, 1996), even before the peak of the AZM (Losada et al., 2010; Mohino et al., 2011; Martín-Rey et al., 2018). When the Atlantic and Pacific basins act together, the response over North-Eastern South America is found to be strongly enhanced (Torralba et al., 2015). In the extratropics, the decaying phase of the AZM in boreal autumn can modify the atmospheric circulation over Europe via a circum-global

teleconnection pattern (Haarsma and Hazeleger, 2007; García-Serrano et al., 2011), and can remotely affect the NAO (Dréevillon et al., 2003; Peng et al., 2005). The AZM can also increase precipitation over southern Europe and the Mediterranean Sea during boreal summer through extratropical Rossby waves (Losada et al., 2012).

The fluctuation of the meridional SST gradient in the tropical Atlantic modulates the seasonal march of the ITCZ, thus influencing regional rainfall over north-eastern Brazil and the Sahel (Hastenrath and Heller, 1977; Folland et al., 1986; Foltz et al., 2012). During a negative phase of the AMM, northerly wind anomalies are associated with a southward shift of the ITCZ (Cabos et al., 2019). During boreal spring, warmer SST over the tropical North Atlantic modulates winds over the western Indian Ocean and may strengthen the monsoon circulation over India, affecting the continental rainfall (Vittal et al., 2020). The AMM is also well known to affect the Atlantic hurricane activity (Vimont and Kossin, 2007; Patricola et al., 2014) and tropical cyclones over the western North Pacific (Zhang et al., 2017).

AIV.2.5.3 Available Proxy-based Reconstruction

Only a few paleo-reconstructions of AMM and AZM are available. Inter-hemispheric cross-equatorial SST gradients linked to changes in ITCZ locations characteristic of the AMM have been found during the Last Glacial Maximum, Heinrich Stadial 1 and the mid-Holocene (McGee et al., 2014). Similarly, the dipole-like SST pattern in the South Atlantic subtropics, which is related to the AZM (Lübbecke et al., 2018; Foltz et al., 2019), has been reconstructed with SST proxies from marine sediment cores during the past 12 kyr (Wainer et al., 2014).

Evidence from proxies associated with the AZM and AMM is assessed in Section 2.4.4.

AIV.2.6 Pacific Decadal Variability

AIV.2.6.1 Definition of the Mode

The Pacific Decadal Variability (PDV) describes the large-scale fluctuations typically observed beyond ENSO time scales in a variety of instrumental records and proxy reconstructions over the entire Pacific Ocean and surrounding continents.

Historically, climate variability of the Pacific Ocean on time scales longer than 8–10 years has been described in terms of statistical modes, usually assessed through the decomposition into EOFs of the SST over oceanic sub-basins. The leading EOF mode of SST decadal variability in the extratropical North Pacific is called the Pacific Decadal Oscillation (PDO; Mantua et al., 1997; Mantua and Hare, 2002). The PDO is recognized to correspond to a collection of multiple processes (Newman et al., 2016). On interannual-to-decadal time scales, the PDO is thought to be driven by atmospheric forcing linked to stochastic changes in the Aleutian Low integrated by ocean mixed layer dynamics and related re-emergence processes, as well as to ENSO-forced teleconnections (Schneider and Cornuelle, 2005; Nidheesh et al., 2017). On decadal-to-inter-decadal time scales, subpolar-subtropical gyre dynamics and related zonal advection

of temperature anomalies in the Kuroshio-Oyashio extension and westward-propagating oceanic Rossby waves are thought to be key mechanisms (Qiu et al., 2007; Taguchi et al., 2007; Wills et al., 2019).

The PDO's South Pacific counterpart, called the South Pacific Decadal Oscillation (SPDO; Chen and Wallace, 2015) is defined as the leading EOF mode of SST in the extratropical South Pacific. As for the PDO, the SPDO is thought to be driven by internal climate variability associated with extratropical atmospheric modes (e.g., SAM; Section AIV.2.2), ENSO teleconnections (Section AIV.2.3) and ocean dynamics through gyre circulation (Shakun and Shaman, 2009; Zhang et al., 2018).

In the tropical Pacific, while ENSO has a clear interannual spectral peak, decadal variability is also present with a similar spatial structure (Zhang et al., 1997), called tropical Pacific Decadal Variability (TPDV) or decadal ENSO. Relative occurrence of El Niño and La Niña events in a given decade correlates with the phase of the TPDV (Power and Colman, 2006).

Despite the PDO, SPDO and TPDV being considered to be physically distinct modes (Newman et al., 2016), they are highly correlated in observations (Chen and Wallace 2015) and they collectively constitute an equatorially symmetric pattern of basin-wide variability, often called the Inter-decadal Pacific Oscillation (IPO; Power et al., 1999; Folland et al., 2002; Henley et al., 2015). There is evidence that ENSO and the TPDV drive the PDO and SPDO in the North and South Pacific through tropical–extratropical teleconnections and the ‘reddening’ (i.e., selective retainment of decadal and longer variability) in the ocean, ensuring the synchronization of decadal variability in both hemispheres (Newman et al., 2016). Besides, positive feedbacks are suggested between the TPDV and the extratropical North Pacific through the Pacific Meridional Mode (Stuecker, 2018), which is the Pacific analogue of the AMM (Section AIV.2.5; Chiang and Vimont, 2004), and modulations of the shallow subtropical cell of the Pacific ocean circulation (Farneti et al., 2014).

Whether the IPO is a distinct mode of climate variability (Henley et al., 2017) or not (Tung et al., 2019) remains to be further assessed and clarified. However, since the PDO, SPDO, TPDV and IPO modes are highly correlated both spatially and temporally, they can be referred to collectively as the Pacific Decadal Variability mode (PDV; Henley, 2017; Liu and Di Lorenzo 2018), similarly to the Atlantic (Section AIV.2.7). Besides, it is noteworthy that none of these modes are actually oscillations with clear spectral peaks in the instrumental period (Mann et al., 2020), which advocates for the use of the PDV acronym across the report.

De facto, there is no unique way to assess the PDV. It can be extracted from the IPO, defined as the leading EOF mode of decadal low-pass filtered SST variability over the entire Pacific to remove the overwhelming influence of ENSO at interannual time scales. Henley et al. (2015) introduced the tripole index (TPI) as the difference of SST anomalies between an equatorial Pacific domain (10°S–10°N, 170°E–90°W) and an average of mid-latitude North (25°N–45°N, 140°E–145°W) and South (50°–15°S, 150°E–160°W) Pacific domains (Figure AIV.8a). Section 2.4.5 describes the changes in the PDV phases over the instrumental record using a variety of SST products.

A positive phase of the PDV is characterized by warm conditions in the central-eastern tropical Pacific from the dateline to the coasts of the Americas, encircled to the west in the mid-latitudes by negative SST anomalies forming a so-called horseshoe pattern. The pattern has a certain similarity with ENSO and related anomalous SST fingerprints through atmospheric teleconnections. However, the PDV features meridionally broader SST anomalies in the tropical Pacific extending to the subtropics compared to ENSO, and relatively stronger extratropical SST anomalies. Alternatively, the low-pass filtered SST regression on the PDO index, defined as the leading principal components of SST (Mantua et al., 1997) or sea surface height (Di Lorenzo et al., 2008) over the extratropical North Pacific north of 20°N, are used in literature for PDV. Their corresponding spatial patterns are, by definition, weighted to the respective hemisphere of the Pacific. Figure AIV.8b provides evidence that they are all highly correlated to each other. The correlation value between the TPI and the PDO index is equal to 0.76, and when low-pass filtered, it is greater than 0.9 for all the combination of indices.

In the following paragraphs and in Section 3.7.6 evaluating the model performance in reproducing PDV and assessing the human influence on the mode evolution, the TPI index is preferred. The latter definition is found to be less sensitive than classical EOF analysis to the possible interplay between internal processes that intrinsically drive the PDV (Wills et al., 2018) and the externally-forced SST response simulated in historical simulations. There is no unique way to remove the impact of the external forcing in the observations at decadal to multi-decadal time scales, and any chosen method may have significant implications for the interpretation of the PDV expression during the instrumental era.

Since AR5, there has been considerable progress in the understanding of PDV itself, but also in its critical role in modulating the evolution of observed global surface temperature (Cross-Chapter Box 3.1) as well as regional climate through teleconnections. On interannual time scales, ENSO is the leading internal driver of global surface temperature variability (Section AIV.2.3). Since PDV encompasses decadal modulations of El Niño versus La Niña occurrences, PDV affects global surface temperature on decadal time scales, with its positive and negative phases tied to higher and lower global surface temperature, respectively. Indeed, studies identify PDV as the leading mode of variability associated with unforced decadal global surface temperature fluctuations in observations and a majority of CMIP5 models (Brown et al., 2015; Dai et al., 2015), with additional influence from AMV (Section AIV.2.7; Tung and Zhou, 2013). PDV thus plays an important role in decadal acceleration and slowdown of global surface temperature trends (Cross-Chapter Box 3.1). So far, little predictability has been found for decadal PDV, despite its global relevance, and decadal prediction in the Pacific remains challenging with the current decadal forecast system (Section 4.4.3.5). Finally, there is an increasing body of evidence about the existence of a network of teleconnections related to decadal climate-variability phenomena (Cassou et al., 2018; Cai et al., 2019). For instance, AMV has been hypothesized to influence in part the phase of the PDV (McGregor et al., 2014; Ruprich-Robert et al., 2017), and consistently there is a significant negative correlation between PDV and AMV. Other studies suggest that the PDV may be the main driver of the

The Pacific Decadal Variability (PDV)

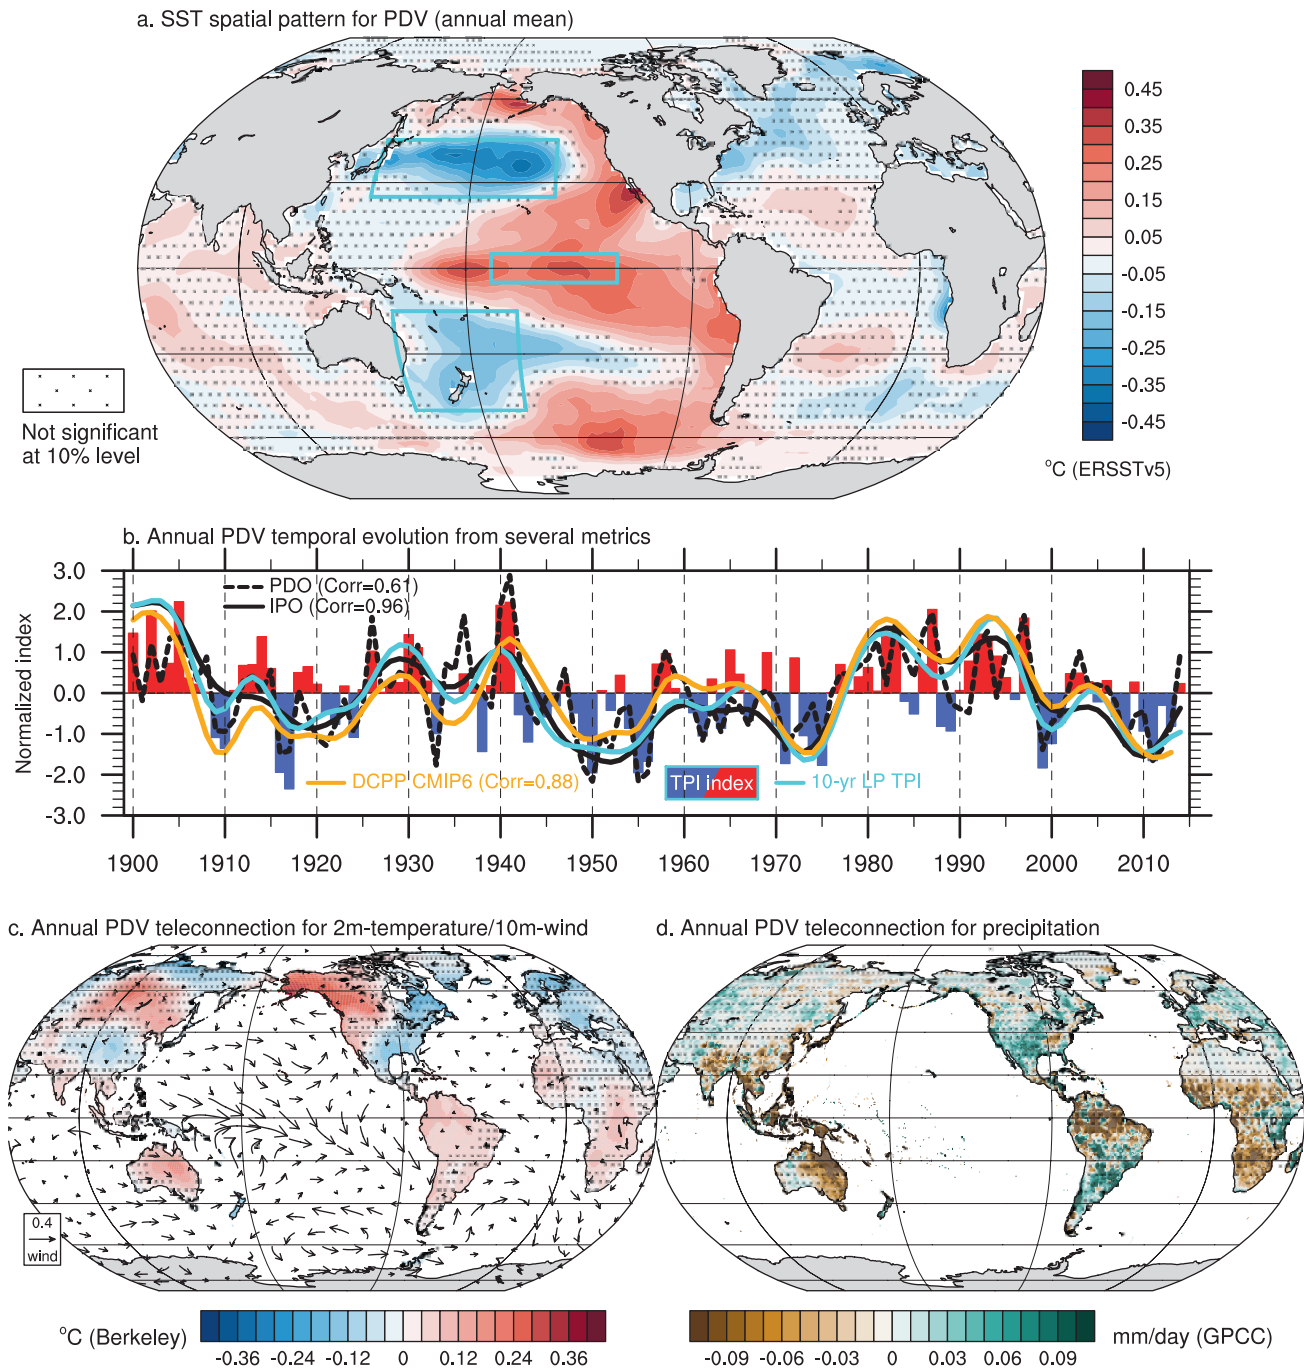

Figure AIV.8 | The Pacific Decadal Variability (PDV) based on the tripole index (TPI) for 1900–2014 after 10-year low-pass filtering. (a) Sea surface temperature (SST) anomalies regressed onto TPI based on ERSSTv5. The cyan boxes indicate regions for the TPI definition. (b) Temporal evolution of the raw TPI (bars), the 10-year low-pass filtered TPI (cyan curve), the empirical orthogonal function (EOF)-based Pacific Decadal Oscillation (PDO) index (dashed black) and two estimations of the Inter-decadal Pacific Oscillation (IPO) EOF-based indices. In solid black, linear detrending is applied to annual data prior to the computation of the EOF of the low-pass filtered SST to remove the forced component in the SST field. In orange, the forced signal is estimated from CMIP5 historical simulations following Ting et al. (2009). The latter metric is used in CMIP6 DCP6-C sensitivity experiments (Boer et al. 2016). The correlation between the low-pass filtered TPI and all PDV indices is given in the legend. (c) Same as (a) but for land surface air temperature (shading; based on Berkeley Earth for 1900–2014) and 10 m level wind (arrows; m s^{-1} based on JRA-55 for 1958–2014) anomalies. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1900–2014). All are based on annual mean. On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicates no significance.

decadal IOB and IOD modes (Section AIV.2.4), while influence from the Indian Ocean SST on PDV has been also suggested (Luo et al., 2012; Mochizuki et al., 2016).

The temporal evolution of PDV in the instrumental records and its model representation are assessed in Sections 2.4.5 and 3.7.6, respectively. Skill in predicting near-term temporal evolution of the PDV and mid- to long-term PDV changes are assessed in Sections 4.4.3.5 and 4.5.3.5, respectively.

AIV.2.6.2 Teleconnections and Regional Influence

Due to the similarity of the SST-anomaly pattern with ENSO in the tropical Pacific, atmospheric teleconnections associated with the PDV are rather similar to those of ENSO but with a longer temporal expression. This includes the long-term alteration of the Walker circulation, the modification of the extratropical background driven by tropically forced Rossby waves then favouring particular phases of the PNA and PSA patterns of atmospheric internal variability that are responsible for persistent influences over the continents (e.g., persistent drought over California and Australia, etc.). Those atmospheric patterns imprint PDO-like and SPDO-like SST patterns with a reddening by the extratropical oceans, forming the pan-Pacific SST anomaly pattern of the PDV as described above (Newman et al., 2016; Henley, 2017; Liu and Di Lorenzo, 2018).

A positive phase of the PDV brings anomalously warm conditions in the north-western corner of North America, with maximum loading over Alaska linked to reinforced and eastward-displaced Aleutian Low and related anomalous southerlies (Figure AIV.8c). In contrast, concurrent cold conditions dominate far-eastern Siberia due to strengthened advection of Arctic air. The tail end of the storm track is strengthened leading to more precipitation along the Pacific coast of North America, especially in boreal winter. A positive PDV also induces a cooler and wetter climate in the southern part of the North American continent, with the wet anomalies being the most pronounced in boreal summer (Figure AIV.8d). The negative phase of the PDV is an important cause of droughts in the western and central USA (Dai, 2013). Besides the direct influence of atmospheric teleconnections from the tropical branch of the mode, extratropical SST anomalies have been shown to modulate the amplitude of the precipitation anomalies in North America (Burgman and Jang, 2015).

In the tropics, a positive PDV is associated with warm and dry anomalies in the Maritime Continent and Amazon (Meehl and Teng, 2014; Figure AIV.8c, d). The Indian and African monsoons also tend to weaken (Meehl and Hu, 2006; Figure AIV.8d). Warm and dry anomalies also cover most of Australia while wet anomalies dominate in South America south of 15°S. In particular, a positive PDV increases drought risk in Australia (Power et al., 1999; Vance et al., 2015). In the oceans, a positive PDV increases the occurrence of marine heatwaves in the Bering Sea and subtropical eastern Pacific, while a negative PDV increases ocean heatwaves in the Kuroshio–Oyashio extension, Melanesia and over the tropical Indian Ocean (Holbrook et al., 2019). PDV also modulates tropical cyclone activity: a positive PDV increases tropical cyclone genesis over the Philippine Sea and the tropical eastern North Pacific and decreases it over the tropical North

Atlantic and western South Pacific (Grant and Walsh, 2001; Liu and Chan, 2008; Li et al., 2015; Zhao et al., 2018, 2020). PDV, together with ENSO, have been shown to control part of the interannual to multi-decadal wildfire variability, through PDV-related persisting droughts and severe heatwaves acting as preconditioning in many regions (see for instance, Kitzberger et al., 2007; Ward et al., 2016).

Implications of PDV on water cycle changes are further assessed in Sections 8.3.2.4 and 8.4.2.4. Section 10.4 highlights the importance of PDV in regional climate change attribution, with an example in Section 10.6. The influence of PDV climate anomalies in specific regions, including extremes, are assessed in Sections 11.3, 11.4, 11.6 and 11.7, and in Atlas.4, Atlas.5, Atlas.7 and Cross-Chapter Box Atlas.2. Its implications for ocean circulation and sea levels are assessed in Sections 9.2 and 9.6.

AIV.2.6.3 Available Proxy-based Reconstruction

PDV reconstructions have been developed with tree rings in North America and Asia (Biondi et al., 2001; D'Arrigo et al., 2001; Gedalof and Smith, 2001; MacDonald and Case, 2005; D'Arrigo and Wilson, 2006; D'Arrigo and Ummenhofer, 2015; Buckley et al., 2019), corals in the Pacific (Linsley et al., 2015; Williams et al., 2017) and Indian Ocean (Crueger et al., 2009), historical documents in China (Shen et al., 2006), ice cores (Vance et al., 2015), and multi-proxy approaches (Verdon and Franks, 2006; Mann et al., 2009; McGregor et al., 2010) covering the past several centuries up to a millennium. Comparing 12 of these reconstructions, it has been found that respective correlations are generally low (Henley, 2017), indicating large uncertainty in the PDV temporal history before instrumental records. On longer time scales, a variety of proxies consistently capture the variations of the Aleutian Low intensity throughout the Holocene, which can be used to reconstruct the PDV (Section 2.4.5).

AIV.2.7 Atlantic Multi-decadal Variability

AIV.2.7.1 Definition of the Mode

The Atlantic Multi-decadal Variability (AMV) describes the large-scale slow fluctuations observed from one decade to the next in a variety of instrumental records and proxy reconstructions over the entire North Atlantic Ocean and surrounding continents. Fingerprints of the AMV can be found at the surface ocean, which is characterized by swings in basin-scale SST anomalies reflecting the interaction with the atmosphere, with a nominal period in the order of 70 years (Deser et al., 2010). AMV markers can be also tracked in the subsurface ocean in terms of heat content and density anomalies. The latter have been traditionally linked to the low-frequency fluctuations in the Atlantic Meridional Overturning Circulation (AMOC) and related oceanic meridional heat/salinity transport and water masses formation through deep convection in the sub-Arctic Seas (Zhang, 2017).

The positive phase of the AMV is characterized by anomalous warming over the entire North Atlantic, with the strongest amplitude in the subpolar gyre and along sea ice margin zones in the Labrador Sea and Greenland/Barents Sea (approximately +0.5°C) and in the

The Atlantic Multidecadal Variability (AMV)

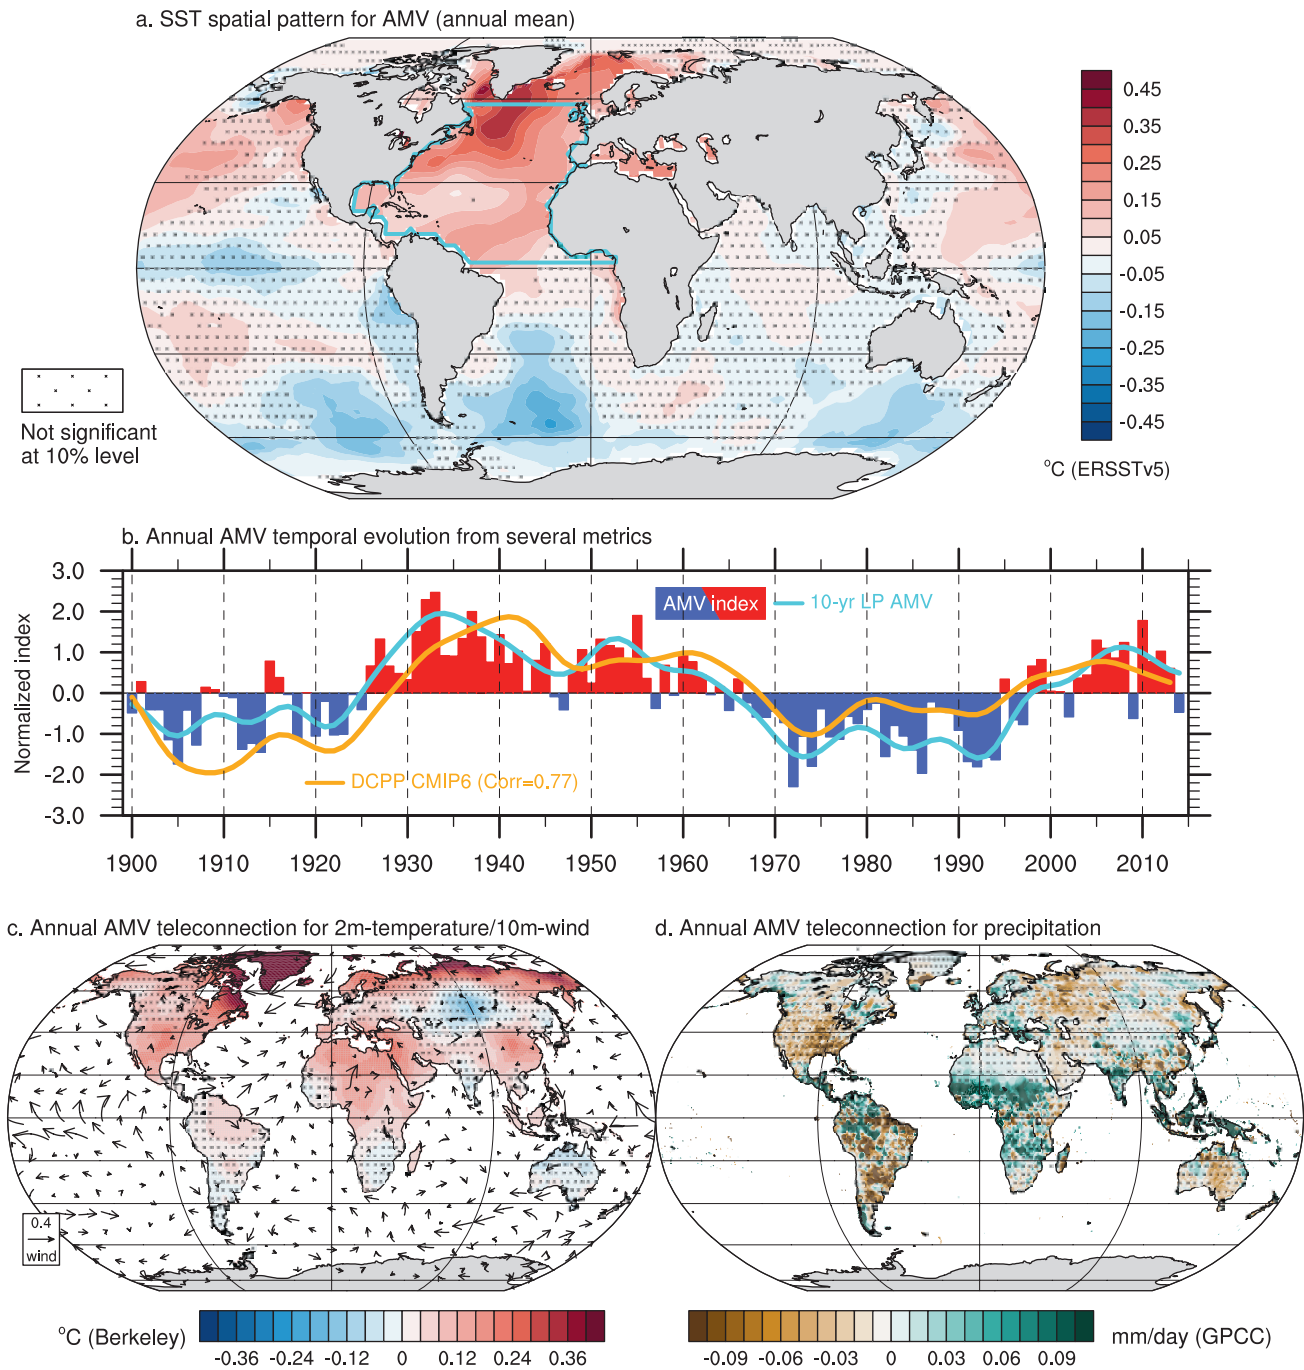

Figure AIV.9 | The Atlantic Multi-decadal Variability (AMV) based on the AMV index defined from Trenberth and Shea (2006) for 1900–2014 after 10-year low-pass filtering. The index corresponds to the annual sea surface temperature (SST) averaged over the North Atlantic domain (cyan box) minus the near-global average (60°N–60°S). **(a)** SST anomalies regressed onto the AMV index based on ERSSTv5. **(b)** The cyan curve indicates the 10-year low-pass filtered AMV index shown in bars. The orange curve stands for the AMV index used for the CMIP6 DCPP-C sensitivity experiments (Boer et al. 2016). **(c)** Same as (a) but for land surface air temperature (shading; based on Berkeley Earth for 1900–2014) and 10 m level wind (arrows; m s^{-1} based on JRA-55 for 1958–2014) anomalies. **(d)** Same as (a) but for precipitation anomalies (shading based on GPCC for 1900–2014). All is based on annual mean. On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rates at 10% and crosses indicates no significance.

subtropical North Atlantic basin to a lower extent (Figure AIV.9a). Concurrent, albeit weaker, anomalous cooling is found over the South Atlantic but also along the Pacific cold tongue sandwiched by warmer SST, a pattern reminiscent of the PDV (Section AIV.2.6). What stands out is the apparent inter-basin connectivity in AMV-related SST anomalies, which is strongly indicative of the existence of a network of teleconnections linking neighbouring ocean basins, the tropics and the extratropics, including Northern Hemisphere polar regions, and the oceans and land regions (Cassou et al., 2018). The AMV, together with the PDV, has been shown to modulate the observed time-evolving global surface temperature on multi-decadal time scales since pre-industrial time (Cross-Chapter Box 3.1), whilst the level of their respective influence remains difficult to quantify because of their inter-connectivity (Tung and Zhou, 2013; Wu et al., 2019; Li et al., 2020).

The term 'Atlantic Multi-decadal Oscillation' (AMO) has been introduced in the literature (Kerr, 2000) and used in previous IPCC reports to describe this phenomenon and in particular to make the distinction with the so-called North Atlantic tripole pattern connected to the NAO (Section AIV.2.1) at interannual time scales (Enfield et al., 2001). However, since the observed slow variations of the North Atlantic SSTs consist of a broad band of low-frequency signals (Zhang, 2017; Sutton et al., 2018) rather than a single preferred time scale, as also confirmed from last-millennium reconstructions (e.g., Singh et al., 2018), the denomination 'Atlantic Multi-decadal Variability' wherein a distinct oscillatory time scale is less clearly implied, appears more appropriate to describe decadal climate variability phenomena as also suggested for the Pacific (Section AIV.2.6). The term AMV will be accordingly used subsequently and throughout the entire report.

The observed AMV is interpreted as the regional residual imprint in SST anomalies after removal of the externally forced signal. There is no unique and preferred way to remove the impact of external forcing in observations. Linear detrending is used in the traditional definition of the AMV index, which corresponds to the average over the entire North Atlantic basin of the linearly detrended SST yearly anomalies on which a 10-year running mean is applied, as proposed by Enfield et al. (2001). To remove the residual nonlinear global-scale signal from the North Atlantic mean SST, different approaches have been proposed either based on observations applying specific statistics (e.g., Trenberth and Shea, 2006; Frajka-Williams et al., 2017; Frankignoul et al., 2017; Sutton et al., 2018; Yan et al., 2019) or based on model estimates of the externally forced signal including both natural (solar and volcanoes) and anthropogenic (greenhouse gases and aerosols) influence assessed from historical simulations (Ting et al., 2009; Terray, 2012; Steinman et al., 2015; Tandon and Kushner, 2015). More specifically, in Trenberth and Shea (2006), the annual observed global-mean SST anomaly time series is subtracted from the observed annual North Atlantic spatially averaged time series to obtain the raw unfiltered AMV index. In Ting et al. (2009), a signal-to-noise maximizing EOF analysis is applied to global annual mean SSTs derived from the CMIP5 multi-model ensemble to extract an estimation of the forced component, which is a priori removed before computation of the AMV index, then defined as a low-frequency residual. The latter technique has been retained in the so-called CMIP6 DCP-C sensitivity experiments (Boer et al., 2016) aimed at

furthering a better understanding of the teleconnections associated with the AMV. The two latter indices are shown in Figure AIV.9b and compared to the traditional AMV index.

All AMV time series consistently show a few distinct phases over the approximately 120-year instrumental record, namely warm periods over 1930–1965 and since 1995, and cool periods between 1900 and 1925 and over 1965–1995 (Figure AIV.9b). The uncertainty introduced by the different definitions of the index is mainly related to the strength of the phase of the AMV and in particular the most recent ones, which are the most sensitive to the estimation of the externally forced signal.

The temporal evolution of AMV in the instrumental records is assessed in Section 2.4.6. The transition between phases has been shown to involve various atmospheric and oceanic processes, leading to some predictability, but also influences from external forcing (both anthropogenic and natural), whose respective weight and interplay remain outstanding issues, as assessed in detail in Sections 3.7.7 and 9.2.3.

AIV.2.7.2 Teleconnections and Regional Influence

The important role of the AMV in observed low-frequency climate signals at a regional scale has been recognized for decades. The AMV is a key driver of temperature and precipitation anomalies along the continents surrounding the North Atlantic but also remotely through global atmospheric teleconnections (e.g., monsoons). Considering AMV-induced regional influence is crucial because the AMV acts as a pronounced modulator of the impacts driven by external natural and anthropogenic forcings. For instance, the AMV can have a pronounced fingerprint in time-integrating processes, such as river flows, and could explain the largest fraction of observed variance in some specific local areas since the 1900s (e.g., Bonnet et al., 2020). It is thus a key phenomenon for regional-scale or process-based attribution of past observed climate variations as introduced in Cross-Chapter Box 1.4 and extensively developed in Section 10.4.1.

Positive AMV is associated with much warmer conditions over the north-western corner of the Atlantic, with marked positive anomalies on land around the Labrador Sea (Figure AIV.9c). There is a strong seasonality in the AMV teleconnection and this pattern is mostly explained by boreal winter atmospheric dynamics and a local reduction of sea ice formation. There is a large-scale decrease of the winter mid-latitude westerlies and, concurrently, a weakening of the trade winds in the North Atlantic tropical basin, which is reminiscent of a negative phase of the NAO (Peings and Magnusdottir, 2014; Gastineau and Frankignoul, 2015). Over Europe, AMV-related signals are weak on yearly average (Figure AIV.9c) but mask a pronounced seasonality of the teleconnection as well as some interplay between dynamical (i.e., atmospheric circulation) versus thermodynamical changes controlled by the AMV (O'Reilly et al., 2017; Ruprich-Robert et al., 2017; Qasmi et al. 2020). Summer tends to be warmer during positive AMV in Europe (Sutton and Dong, 2012; Nicoli et al., 2020) with constructive contribution of both dynamical and thermodynamical responses while destructive interference prevails in boreal winter leading to colder conditions

with a reinforced occurrence of blocking (Rimbu et al., 2014; Davini et al., 2015) and a southward shift of the jet (Simpson et al., 2018). Anomalies are positive all year round over a broad Mediterranean region, including North Africa and the Middle East. Reduction of Arctic sea ice is also found during positive AMV with local warming extension over the adjacent polar land (Day et al., 2012; Yu et al., 2017; Castruccio et al., 2018).

In terms of precipitation (Figure AIV.9d), positive AMV is associated with a northward shift of the Atlantic ITCZ in response to changes in the meridional SST gradient with respect to the equator (Martin and Thorncroft, 2014; Friedman et al., 2017; Green et al., 2017). The AMV influence is the strongest in the boreal summer affecting the West African Monsoon, leading to reinforced Sahel rainfall, and wetter conditions in the Caribbean basin through the modulation of the occurrence of hurricanes (Dunstone et al., 2011; Hermanson et al., 2014). By contrast, dry conditions prevail in north-eastern Brazil and in the south-eastern corner of South America as well as in the Great Plains in North America. The signal of the positive AMV lead to intensified precipitation and river runoff over northern Eurasia (Nicoli et al., 2020) and controls the multi-decadal variations in river flows over much of Europe (Boé and Habets, 2014; Hodgkins et al., 2017). Because of global teleconnections, especially in the tropics, the AMV also affects the other monsoon systems with signals found over India, South East Asia and the Maritime Continent and, more broadly, over the entire tropical Pacific (Chylek et al., 2014; Kucharski et al., 2016; Ruprich-Robert et al., 2017).

The weight of the AMV in observed low-frequency variations is assessed in detail in Section 10.4.2 for specific regional case studies, including the sectors listed above. Because of its long time scale due to persistent heat content anomalies, the AMV can be considered as a potential source of near-term climate predictability. The skill of the current decadal forecast systems in predicting the AMV temporal evolution and associated teleconnection at various lead times is assessed in Section 4.4.3.6, while long-term changes are assessed in Section 4.5.3.6.

AIV.2.7.3 Available Proxy-based Reconstruction

Paleoclimate reconstructions of AMV-related signals have been developed using terrestrial, marine and ice-core proxies. The AMV reconstruction in the last 1200 years by J. Wang et al. (2017), using terrestrial proxy records, shows a clear broad band of enhanced spectral power at multi-decadal time scales but no evidence of a distinct multi-decadal or centennial spectral peak (Singh et al., 2018). This is largely consistent with the record of the instrumental period and with previous proxy-based studies (Gray et al., 2004; Mann et al., 2009) in the overlapping periods. Studies focusing on marine proxies also show persistent multi-decadal variability over the last three centuries (Kilbourne et al., 2014; Svendsen et al., 2014; Moore et al., 2017). Multi-decadal Arctic temperature variability related to the AMV is also evident in ice-core records over the last millennium (Chylek et al., 2011; Zhou et al., 2016) and beyond (Knudsen et al., 2011). High-resolution sedimentary records from the Arctic were recently analysed to reconstruct the AMV over the last 2900 years (Lapointe et al., 2020). However, this new reconstruction refers to

the raw North Atlantic SST variability rather than to the residual of the Atlantic signal obtained after removal of the estimation of the external forcing influence. A multi-perspective assessment of the North Atlantic variability is thus necessary for understanding the origin of the AMV, its physics and its climatic implications over the paleoclimatic period.

The temporal evolution of the AMV is described and assessed in detail in Section 2.4.6.

AIV.2.8 Madden–Julian Oscillation

AIV.2.8.1 Definition of the Mode

The Madden–Julian Oscillation (MJO) is the leading mode of tropical intra-seasonal variability with 20–90 days' time scale (Madden and Julian, 1994), and it is an important source of regional climate variability and predictability across the globe at sub-seasonal time scales from a week to months (Madden and Julian, 1994; Zhang, 2005; Vitart, 2017; Wheeler et al., 2017; Kim et al., 2018). It is characterized by planetary-scale disturbances (zonal wavenumber 1–3) of pressure, wind, clouds and rainfall moving predominantly eastward along the equator at average speed of 5 m s^{-1} (Roxy et al., 2019). More precisely, the MJO is characterized by alternating regions of suppressed and enhanced convection coupled to an anomalous zonal overturning circulation of the atmosphere (Zhang, 2005). The MJO is driven by internal ocean–atmosphere processes that occur all year round but it exhibits prominent seasonality with more pronounced signals in boreal winter. During boreal summer, centres of convective activity associated with the MJO are shifted away from the equator to 10°N – 20°N and propagate northward in the Asian monsoon region (Yasunari, 1980; Madden, 1986) in addition to eastward propagation, often called as the boreal summer intra-seasonal oscillation (BSISO; Madden, 1986; Kikuchi et al., 2012). Whereas the MJO is considered present in all seasons, albeit with weaker amplitude in boreal summer, the BSISO tends to prevail during boreal summer, with influences on monsoons, tropical cyclones and other water cycle aspects (Kikuchi et al., 2012; Lee et al., 2013).

The real-time multivariate MJO (RMM) index has been widely used to detect the MJO, based on the first two combined EOF modes of daily outgoing longwave radiation (OLR) and zonal winds at 850 and 200 hPa averaged over 15°N – 15°S (Wheeler and Hendon, 2004). The OLR represents convective activity and zonal winds at the lower and upper troposphere depict the overturning zonal circulation along the equator. The composite maps of convective activity and atmospheric circulation (Figure AIV.10a) and the phase diagram (Figure AIV.10b) based on eight phases constructed by the two PCs time series provide effective ways to understand and monitor spatial and temporal evolution of the MJO event. In general, the MJO disturbances are initiated in the equatorial western Indian Ocean and travel eastward mainly over the Indo-Pacific warm pool region. However dynamical fields in composite maps indicate that the MJO also propagates over climatological non-convective regions (e.g., the eastern Pacific, part of the tropical Atlantic; Figure AIV.10a), then manifesting the planetary nature of the tropical intra-seasonal oscillation (Cassou, 2008).

The Madden–Julian Oscillation (MJO)

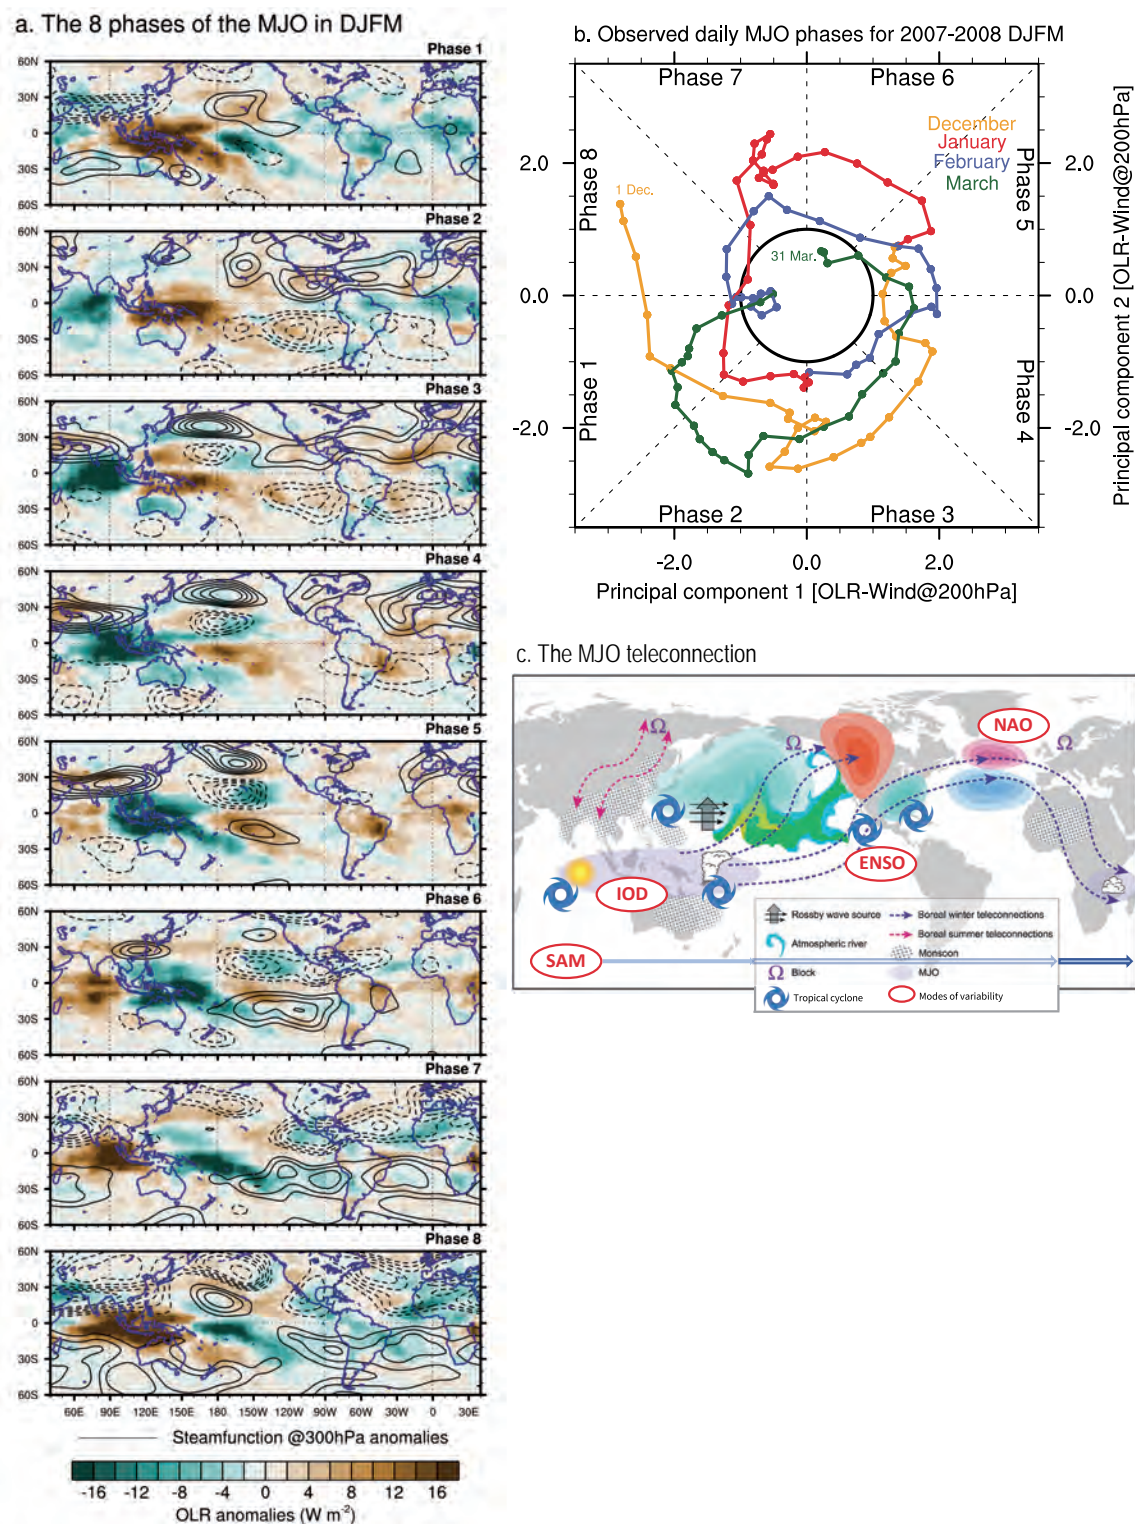

Figure AIV.10 | (a) The spatio-temporal properties of the Madden–Julian Oscillation (MJO). Daily composites of outgoing longwave radiation (OLR, W m^{-2} , shaded) anomalies and stream-function anomalies at 300 hPa (STF, contours every $0.5 \times 10^6 \text{ m}^2 \text{ s}^{-1}$) for the eight MJO phases in boreal winter (1 December to 31 March) based on NOAA interpolated satellite products and NCEP–NCAR reanalysis over 1979–2019, respectively. Greenish (brownish) colours indicate enhanced (reduced) convective activity associated with wet (dry) conditions. Solid (dashed) contours show for positive (negative) STF anomalies which stand for anomalous anticyclonic circulation in the Northern (Southern) Hemisphere. **(b)** Phase diagram of the MJO constructed from the two leading principal components drawn from empirical orthogonal decomposition of combined wind at 300 hPa + OLR fields following Wheeler and Hendon (2004) for winter 2007–2008 chosen as an example of active MJO years. **(c)** Schematic representation of MJO-related tropical–Northern Hemisphere interactions and teleconnections inferred from observational and numerical studies (adapted from Stan et al., 2017). Because the interactions and teleconnections of the Southern Hemisphere are not as well understood except for the Southern Annular Mode, they are not included in the current schematic.

Each phase has a nominal persistence of about seven to eight days and the anti-clockwise rotation in this two-dimensional diagram materializes the propagation of the MJO packets from west to east. Figure AIV.10b provides an example of that RMM index computed for the year 1997, with months highlighted in colours. When the value of the index lies in the centre of the diagram, the MJO is considered to be inactive; outside the circle, its distance from the centre quantifies the amplitude and spatial coherence of the MJO episode.

The evaluation of the MJO in climate models is done through phenomenological (Waliser et al., 2009) and process-oriented (Xavier, 2012) diagnostics. MJO simulation remains a challenge in both CMIP3 and CMIP5 models, even though overall improvements have been reported in the most recent model versions (Waliser et al., 2003; Lin et al., 2006; Sperber and Annamalai, 2008; Kim et al., 2009; Xavier et al., 2010; Jiang et al., 2016). Poor MJO simulation in coupled climate models has been attributed to many factors, including an insufficient buildup of atmospheric moisture for large-scale organized convection to occur (Kim et al., 2012; Mizuta et al., 2012), biases in models' mean state (Inness et al., 2003; Hannah et al., 2015; Kim, 2017), coupling frequency with the ocean and representation of air–sea interactions (Bernie et al., 2008; DeMott et al., 2015). In CMIP5 simulations, the eastward propagation of boreal winter MJO convection from the Indian Ocean into the western Pacific (Hung et al., 2013) and the northward propagation during boreal summer (Sperber et al., 2013) are slightly better represented, even if major biases persist and still affect the monsoon systems. These improvements have been attributed to advances in parametrizing moist turbulence and convection (Hohenegger and Bretherton, 2011; Mapes and Neale, 2011; Del Genio et al., 2012; Kim et al., 2012; Hourdin et al., 2013), leading to greater MJO predictive skill of up to four weeks in operational sub-seasonal prediction centres (Vitart, 2014). Super-parametrized models (Benedict and Randall, 2009), global cloud system-resolving models (Miyakawa et al., 2014) and high-resolution global climate models with an improved seasonal cycle (Mizuta et al., 2012) have been shown to produce a more realistic simulation of the MJO. Progresses in the representation of the MJO across model generations are assessed in Sections 1.5.4.6 and 8.3.2.9.1.

The assessment of changes in the MJO and related processes, mostly in terms of its implication for water cycle changes in the recent past and in future projections is provided in Sections 8.3.2.9 and 8.4.2.9, respectively. The MJO influence over South East Asia and Central and South America is further assessed in Atlas.4, Atlas.5 and Atlas.7, and Cross-Chapter Box Atlas.2.

AIV.2.8.2 Teleconnections and Regional Influence

In AR5, the MJO has been described as a tropical phenomenon, yet with prominent impacts across the globe through teleconnections. The MJO exerts a strong influence on occurrences of extreme weather events in the tropics, including tropical cyclones, droughts, flooding, heatwaves and fires, among others (Zhang, 2013), as well as those in the extratropics via teleconnections (Stan et al., 2017). This has opened new opportunities and scientific endeavours in the emerging field of sub-seasonal to seasonal forecasts of extremes

(Vitart and Robertson, 2018) and for the development of new observational networks needed to initialize the forecast systems (Subramanian et al., 2019). The MJO can also impact the atmospheric composition, such as ozone, CO, CO₂ and aerosols (Tian et al., 2007, 2011; K.-F. Li et al., 2010; Lau et al., 2012).

The schematic in Figure AIV.10c shows the main regions of influence of the MJO. During boreal winter, the MJO fingerprint is mostly confined to the deep tropics with a zonal alternation of wet and dry zones depending on the MJO phase. For instance, in phase 4, enhanced rainfall is found over the Maritime Continent while suppression of convection is present over the central Pacific, northeast Brazil and equatorial Africa (Figure AIV.10a). The opposite is found during phase 8. Anomalous upper-level divergence in the deep tropics associated with altered convection and diabatic heating leads to anomalous vorticity in the subtropics (shown by stream-function dipoles straddling the equator in Figure AIV.10a) acting as an efficient and primary source of teleconnections outside the tropics (L'Heureux and Higgins, 2008; Lin et al., 2009; Lukens et al., 2017). The extratropical influence of the MJO may occur via the excitation of forced tropospheric Rossby waves (Ferranti et al., 1990; Matthews et al., 2004; Cassou, 2008; Stan et al., 2017) that affect the climate variability over the North Pacific (Ferranti et al., 1990; Higgins and Mo, 1997), the North Atlantic (Ferranti et al., 1990; Cassou, 2008) and the Arctic (Zhou and Miller, 2005). For example, tropical convective heating associated with MJO phase 5 contributes to Arctic warming, while the opposite occurs for MJO phase 1 (Yoo et al., 2011, 2012). Phase 2–3 of the MJO is clearly associated with the prevalence of the positive phase of the NAO with a 10- to 15-day lag after the MJO forcing. Stratospheric pathways are also reported to support tropical–extratropical teleconnections through the modified occurrence of sudden stratospheric warming (Liu et al., 2014; Garfinkel and Schwartz, 2017) with 15- to 20-day delay leading to sub-seasonal predictability.

During boreal summer, the MJO/BSISO convective activities and related impacts propagate northward/north-eastward over the Indian Ocean–South Asia region (Yasunari, 1980; Annamalai and Sperber, 2005), and northward/north-westward over the western North Pacific–East Asia region (Kemball-Cook and Wang, 2001; Lee et al., 2013). The MJO/BSISO significantly modulate occurrences of extreme rainfall and heatwaves over Asia (Hsu et al., 2016, 2017; Chen and Zhai, 2017; Diao et al., 2018) and North America (Moon et al., 2013; Lee and Grotjahn, 2019). They also regulate tropical cyclone activities in the Indian (Frank and Roundy, 2006), Pacific (Maloney and Hartmann, 2000; Diamond and Renwick, 2015; Zhao et al., 2015) and Atlantic (Klotzbach and Oliver, 2015) tropical oceans. They contribute to the intra-seasonal fluctuations of monsoons, including timing of onset and termination during summer (Maloney and Shaman, 2008; Wheeler et al., 2009; Lee et al., 2013; Grimm, 2019), and active/break phases (Pohl and Camberlin, 2006; Maloney and Shaman, 2008; Joseph et al., 2009; Lee et al., 2017).

AV.1 Introduction

A monsoon refers to a seasonal transition of regimes in atmospheric circulation and precipitation in response to the annual cycle of solar insolation and the distribution of moist static energy (Wang and Ding, 2008; Wang et al., 2014; Biasutti et al., 2018). A global monsoon can be objectively identified based on precipitation contrasts in the solstice seasons to encompass all monsoon regions (Wang and Ding, 2008). In AR5, regional monsoon domains were identified starting from the definition of the global monsoon tailored over the continents and adjacent oceans, as in Kitoh et al. (2013). This annex contains the definition of the global monsoon as used in the Sixth Assessment Report (AR6; see Section AV.2); it explains the rationale for the different definition of AR6 regional monsoons compared to Fifth Assessment Report (AR5; see Section AV.3), and provides the definition and basic characteristics of each regional monsoon assessed (Section AV.4).

AV.2 Definition of the Global Monsoon

The concept of the global monsoon (GM) emerged during the second half of the 20th century. The GM represents the leading empirical orthogonal function (EOF) mode of the annual variations of precipitation and circulation in the global tropics and subtropics as a forced response of the coupled climate system to the annual cycle of solar insolation (Wang and Ding, 2008; An et al., 2015; Wang et al., 2017). GM variability represents, to a large extent, changes in the Inter-tropical Convergence Zone (ITCZ) and associated Hadley circulation (Wang et al., 2014). Changes in the GM have been attributed to both internal variability and external forcings, ranging from interannual to millennial and orbital time scales (Wang et al., 2014, 2017; An et al., 2015; Geen et al., 2020). In AR6, the global monsoon is defined as the area in which the annual range (local summer minus local winter) of precipitation is greater than

2.5 mm day⁻¹ (Kitoh et al., 2013), and the domain is represented by the black contour lines in Figure AV.1. Simulation of the global monsoon and its variability is the subject of coordinated modelling experiments in the Global Monsoon Model Intercomparison Project (GMMIP; Zhou et al., 2016). Past changes, simulation and attribution, and projections of the GM are assessed in Sections 2.3.1.4.2, 3.3.3.2 and 4.4.1.4, respectively.

AV.3 Rationale for Regional Monsoon Definitions in AR6

The definition of the regional monsoons has been slightly modified in AR6 with respect to AR5, starting from the consideration that some of the continental areas identified using the global metric have a seasonality in precipitation that is not necessarily of monsoon origin. In particular, the dotted regions in Figure AV.1 located over South Africa, Central America and equatorial South America have a strong seasonality in precipitation but their qualification as monsoons is a subject of discussion. In the assessment of the regional monsoons in Sections 8.3.2.4 and 8.4.2.4, these regions are not considered as distinct regional monsoons, but they are discussed in Box 8.2, which is dedicated to changes in water cycle seasonality. The domains of the regional monsoons in AR6 are defined based on published literature and expert judgement, and accounting for the fact that the climatological summer monsoon rainy season varies across the individual monsoon regions. As shown in Figure AV.1, the AR6 regional monsoons are: South and South East Asian (Section AV.4.1), East Asian (Section AV.4.2), West African (Section AV.4.3), North American (Section AV.4.4), South American (Section AV.4.5) and Australian–Maritime Continent (Section AV.4.6) monsoons. For each region, the definition, regional justification and key features are provided, along with cross references to the main areas of assessment in AR6.

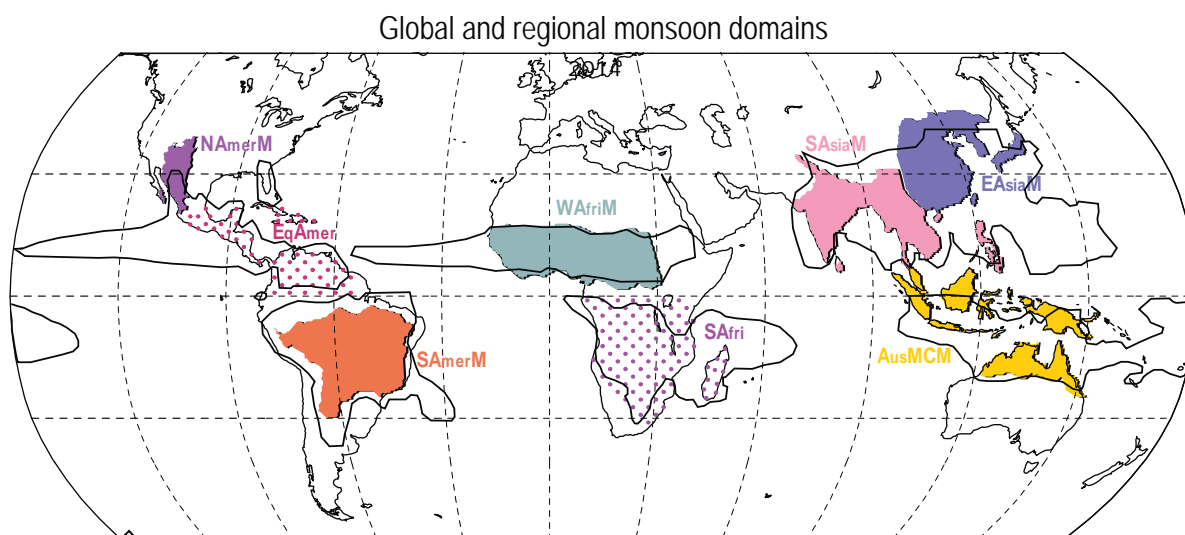

Figure AV.1 | Global and regional monsoon domains. The AR6 global monsoon area is represented by the black contour lines. The AR6 regional monsoons are: North American monsoon (NAmerM, shaded magenta), South American monsoon (SAmerM, shaded dark orange), West African monsoon (WAfriM, shaded grey), South and South East Asian monsoon (SAsiaM, shaded pink), East Asian monsoon (EAsiaM, shaded purple) and Australian–Maritime Continent monsoon (AusMCM, shaded yellow). Areas over Central America and equatorial South America and southern Africa (dotted red and dotted magenta, respectively) are highlighted but not identified as specific regional monsoons (see explanation in the main text). For each regional monsoon, the seasonal characteristics associated with each domain are specified in the main text.

AV.4 Definition of Regional Monsoons

AV.4.1 The South and South East Asian Monsoon

The South and South East Asian monsoon (SAsiaM) is characterized by pronounced seasonal reversal of wind and precipitation. It covers vast geographical areas and several countries including India, Bangladesh, Nepal, Myanmar, Sri Lanka, Pakistan, Thailand, Laos, Cambodia, Vietnam and the Philippines (Pant and Rupa Kumar, 1997; Goswami, 2006; Gadgil et al., 2010; Shige et al., 2017), with a domain roughly extending across 60°E–110°E and 10°S–25°N as shown in Figure AV.1 (shaded pink). The SAsiaM is unique in its geographical features because of the orography surrounding the area (i.e., the Himalayas, Western Ghats and Arakan Yoma mountains, and the Tibetan Plateau to the north) and the adjacent Indian Ocean.

The SAsiaM rainy season from June to September contributes to more than 75% of the annual rainfall over much of the region, including the southern slopes of the central and eastern Himalayas (Krishnan et al., 2019b). Considering the spatial domain of the SAsiaM, monsoon precipitation maxima are located over the west coast, north-east and central/north India as well as Myanmar and Bangladesh, whereas minima are located over north-west and south-eastern India, western Pakistan, and south-eastern and northern Sri Lanka (Pant and Rupa Kumar, 1997; Gadgil et al., 2010). Prior to the SAsiaM rainy season, areas in the north-western Himalaya receive precipitation during winter and early spring from so-called 'western disturbances', which are extratropical synoptic systems originating over the Mediterranean region and propagating eastward along the subtropical westerly jet (Madhura et al., 2014; Cannon et al., 2015; Dimri et al., 2015; Hunt et al., 2018; Krishnan et al., 2019a, b).

The climatological onset of the SAsiaM occurs around 20 May over the Andaman and Nicobar Islands and covers the central Bay of Bengal around 25 May, while it simultaneously advances into mainland India from the south through Kerala (Pai et al., 2020). The normal date of monsoon onset over Kerala is 1 June and the monsoon rains progress into India both from south to north and east to west, so as to cover the entire country by 15 July (Pai et al., 2020), although with large interannual and inter-decadal variations (Ghanekar et al., 2019). Retreat of the SAsiaM typically begins from far north-west India around 1 September and withdraws completely from the country by 15 October; this is followed by the establishment of the north-east monsoon rainy season over south peninsular India from October through December (Pai et al., 2020).

The SAsiaM exhibits prominent rainfall variability on sub-seasonal, interannual and inter-decadal time scales with teleconnections to modes of climate variability (see Webster et al., 1998; Turner and Annamalai, 2012). While the gross features of the SAsiaM are simulated in GCMs, there are several large biases that have persisted over generations of climate models, in CMIP3 and CMIP5, including a large dry bias over India coupled to a lower-tropospheric circulation that is too weak (Sperber et al., 2013) and a related wet bias over the western Equatorial Indian Ocean (Bollasina and Ming, 2013). In CMIP5, cold Arabian Sea SST (sea surface temperature)

biases in coupled GCMs were shown to worsen the monsoon dry bias by limiting the available moisture (Levine et al., 2013; Sandeep and Ajayamohan, 2015). Some improvements to the spatial pattern have been noted in CMIP6, particularly near orography (Gusain et al., 2020). The teleconnection to the El Niño–Southern Oscillation (ENSO) provides the main prospect for seasonal prediction and was too weak in CMIP5 (Sperber et al., 2013). The boreal summer intra-seasonal oscillation (BSISO) controls the majority of sub-seasonal variations in SAsiaM rainfall, as well as affecting the East Asian monsoon region. While CMIP5 models represented the BSISO better than CMIP3 (especially its characteristic northward propagation), the spatial pattern is still poorly simulated in most models (Sabeerali et al., 2013).

The SAsiaM is assessed in Sections 8.3.2.4.1, 8.4.2.4.1, Atlas.5.3.2 and Atlas.5.3.4. One of its main components, the Indian summer monsoon, is assessed in Section 10.6.3 as a case study on the construction of regional climate information from the distillation of multiple lines of evidence. Climate change over the Hindu Kush Himalaya is assessed in Cross-Chapter Box 10.4.

AV.4.2 The East Asian Monsoon

The East Asian monsoon (EAsiaM) is the seasonal reversal in wind and precipitation occurring over East Asia, including eastern China, Japan and the Korean Peninsula. The continental area influenced by this monsoon is roughly bounded by 102.5°E–140°E and 20°N–40°N (e.g., Wen et al., 2000; Wang and LinHo, 2002; Wang et al., 2010), and is shaded purple in Figure AV.1. Unlike other monsoons, it extends quite far north, out of the tropical belt, and it is largely influenced by subtropical systems, such as the western North Pacific subtropical high, East Asian subtropical westerly jet, and by disturbances from the mid-latitudes (Chang et al., 2000; Lee et al., 2006; Yim et al., 2008; Zhou et al., 2009; S.-S. Lee et al., 2013).

The EAsiaM manifests during boreal summer with warm and wet southerly winds, but also during boreal winter with cold and dry northerly winds (Ha et al., 2012). The winter component has been linked to the subsequent summer (e.g., Wen et al., 2000, 2016; Ge et al., 2017; Yan et al., 2020).

AV.4.2.1 The East Asian Summer Monsoon

The East Asian summer monsoon is a subtropical monsoon system (e.g., Wang and LinHo, 2002; Ding et al., 2007). It is characterized by low-level southerly winds prevailing over eastern China, Korea and Japan in boreal summer. The monsoon flow brings abundant water vapour into East Asia that converges and forms the Meiyu/Baiu/Changma rain belt over the region (Zhou et al., 2009; Jin et al., 2013; Lee et al., 2017). Rainfall onset occurs in late April/early May in the central Indochina Peninsula, and in mid-June the rainy season arrives over East Asia with the formation of the Meiyu front along the Yangtze River valley, Changma in Korea, and Baiu in Japan. Later in July, the monsoon advances up to north China, the Korean Peninsula and central Japan (Zhang et al., 2004; Yihui and Chan, 2005; Zhou et al., 2009).

Intra-seasonal variability of the EAsiaM has been mostly related to the Madden–Julian Oscillation (MJO) (Yasunari, 1979; Zhang et al., 2009; Chen et al., 2015), to the phase of the Pacific–Japan mode (Nitta, 1987) or the Indian summer monsoon (Li et al., 2018) and to the BSISO (Kikuchi et al., 2012; Chen et al., 2015), particularly for its onset (J.-Y. Lee et al., 2013). At interannual time scales, changes in East Asian summer monsoon intensity lead to a position shift of the monsoon rain belt under the influence of ENSO (Wang et al., 2000) and the western North Pacific subtropical high (Kosaka et al., 2013; Wang et al., 2013), Arctic sea ice (Guo et al., 2014), and solar and volcanic forcing (Peng et al., 2010; Man et al., 2012; Cui et al., 2014). Variability at inter-decadal time scales is more prominent in the second half of the 20th century (Jiang, 2005; Ding et al., 2008; Wang et al., 2018), and a specific assessment about this aspect is provided in Section 8.3.2.4.2.

The basic features and interannual variations of the East Asian summer monsoon are well reproduced in climate models. For example, the climatological circulation structure is well reproduced in both atmospheric and coupled GCMs (Song and Zhou, 2013; Song et al., 2013; Jiang et al., 2016, 2020), and the relationship between the monsoon and ENSO is well represented (Sperber et al., 2013; Fu and Lu, 2017). In CMIP5 models, the main shortcomings relate to missing rainfall bands around 30°N and the northward shift of the western North Pacific subtropical high (Huang et al., 2013). Most coupled models show an inadequate strength of monsoon circulation over southern East Asia, and with little change in model performance from the Third Assessment Report (TAR) to AR6 (Jiang et al., 2016, 2020). In coupled model simulations, air–sea coupling helps improve the climatology and interannual variability of rainfall over the East Asia monsoon region (Wang et al., 2005; Song and Zhou, 2014).

The summer (June–July–August) component of the EAsiaM is assessed in Sections 8.3.2.4.2, 8.4.2.4.2, Atlas.5.1.2 and Atlas.5.1.4.

AV.4.2.2 The East Asian Winter Monsoon

The East Asian winter monsoon (EAWM) is characterized by strong north-westerlies over north-east China, Korea and Japan, and by strong north-easterlies along the coast of East Asia (Huang et al., 2003). The northerly winds extend from mid-latitude East Asia to the equatorial South China Sea (Wen et al., 2000; Wang et al., 2010). The EAWM has one component mostly linked to mid-to-high latitude circulation systems and another mostly linked to the tropical circulation and largely controlled by ENSO (Ge et al., 2012; Chen et al., 2014a). The mid-latitude component has a close relationship with autumn Arctic sea ice concentration changes (Chen et al., 2014b).

The EAWM exhibits significant variability ranging from intra-seasonal to inter-decadal time scales. Its intra-seasonal variability is suggested to be influenced by both high-latitude and subtropical Eurasian wave trains (Jiao et al., 2019). At the interannual time scale, ENSO is an important factor modulating the EAWM (Wang et al., 2000), while the relationship between them is not stable (Wang and He, 2012; Fan et al., 2020). In addition, Arctic Oscillation (Gong et al., 2001), Arctic sea ice (Ge et al., 2012), Eurasian snow (Luo and Wang, 2019), and strong volcanic eruptions (Miao et al., 2016) also play vital roles in

changing the EAWM intensity. At the inter-decadal time scale, the EAWM weakened significantly in the mid-1980s, which resulted from atmospheric intrinsic quasi-stationary planetary waves (Wang et al., 2009) and external forcings (Miao et al., 2018). In the mid-2000s, the EAWM was observed to recover from its weak epoch (Wang and Chen, 2014).

The large-scale features of the EAWM are well reproduced by climate models, although the strength of monsoon circulation is underestimated. The ability of coupled models to simulate the EAWM shows little difference through the TAR to AR5, but has improved from AR5 to AR6 (Jiang et al., 2016, 2020). In CMIP5 models, reasonable simulations of the Siberian High and Aleutian Low intensities and the relationship with ENSO help improve the climatology and interannual variability of the EAWM (Gong et al., 2014).

Model simulations of the winter component of the EAsiaM are assessed in chapter Atlas.5.1.3.

AV.4.3 The West African Monsoon

The West African monsoon (WAFriM) is a seasonal reversal in wind and precipitation extending over a vast and contrasted geographical region, from the equator to the margins of the Sahara, and from the Atlantic coast inland. The WAFriM domain includes Togo, Guinea Bissau, Gambia, Senegal, Mauritania, Guinea, Sierra Leone, Liberia, Mali, Ivory Coast, Burkina Faso, Ghana, Benin, Chad, Cape Verde, northern Cameroon, Niger, Nigeria and the northern Central African Republic. It is roughly bounded by 18°W–30°E, 5°N–18°N, and is shaded grey in Figure AV.1 (e.g., Adedokun, 1978). The West African monsoon and Sahel are sometimes considered interchangeably. However, the Sahel lies in the northern part of the WAFriM region, often limited to the west and central north Africa (e.g., Nicholson et al. (2018) considered the domain to be 20°W–30°E, 10°N–20°N) or sometimes extended to the east (e.g., Giannini and Kaplan (2019) considered the domain to be 20°W–40°E, 10°N–20°N). The East African region with the Greater Horn of Africa, which includes Ethiopia, Sudan and South Sudan, lies on the fringes of both the West African and Indian monsoons (Nicholson, 2017).

The WAFriM is characterized by the northward progression from May to September of moist low-level south-westerlies from the Gulf of Guinea, meeting the dry north-easterlies (Harmattan) from the Saharan Heat Low at the inter-tropical discontinuity (e.g., Hamilton et al., 1945; Omotosho, 1988). In May and June, rainfall remains essentially along the Guinean coast with a maximum occurring near 5°N, then the rainfall maximum jumps suddenly over the Sudan–Sahel zone near 12°N, followed by a ‘little dry season’ over the Guinea coast (Adejuwon and Odekunle, 2006). This apparent shift is known as the West African monsoon jump and it is concomitant with the monsoon onset over the Sahel (Sultan and Janicot, 2003; Cook, 2015). Rainfall continues to progress towards the north up to about 18°N–20°N. The rainfall maximum occurs in the Sahel in August/September, followed by a rapid retreat of rainfall to the Guinean coast and a second maximum occurs over this region in October/November.

The WAFriM features variability at different time scales. Unprecedented droughts occurred in West Africa and particularly over the Sahel from the late 1960s to the mid-1990s, and a specific assessment of the understanding of mechanisms related to these changes is provided in Sections 8.3.2.4.3 and 10.4.2.1.

At interannual time scales, tropical oceans (Atlantic, Pacific and Indian) appear to be the major drivers with their SST anomalies leading to variations in the accumulated seasonal rainfall (e.g., Lamb, 1978; Diakhaté et al. 2019). At intra-seasonal time scales, equatorial waves (e.g., Mekonnen et al., 2008; Janicot et al., 2010) and interactions with mid-latitudes and the Mediterranean (e.g., Vizi and Cook, 2009; Roehrig et al., 2011) have an effect on WAFriM activity. African Easterly Waves (AEWs) and mesoscale convective systems (MCSs), including squall lines, are the prominent weather synoptic scale aspects of the WAFriM, supplying almost all rainfall in the Sahel. The strong coupling between AEWs and MCSs has been investigated in depth, as well as their interactions with the Saharan Heat Low, the moisture supply from East Africa and the Mediterranean region or from near the equator (e.g., Diongue et al., 2002; Brammer and Thorncroft, 2017; Lafore et al., 2017). Land surface processes are known to influence WAFriM precipitation (Boone et al., 2016).

Simulation of West African climate, including the monsoon, has received specific attention under coordinated programmes in the recent past: the African Multidisciplinary Monsoon Analysis Model Intercomparison Project (AMMA-MIP), the AMMA Land-surface Model Intercomparison Project (ALMIP), the West African Monsoon Modelling and Evaluation (WAMME) project and the Coordinated Regional Downscaling Experiment (CORDEX; Raj et al., 2019). CMIP5 and CMIP6 struggle to reproduce the amplitude of observed decadal variability in the 20th century and to represent the mean climatology including the northward propagation of the monsoon (Roehrig et al., 2013; Monerie et al., 2020; Sow et al., 2020). A higher horizontal resolution improves the representation of the intensity and spatial distribution of WAFriM rainfall and related circulation, because of the effects of vegetation, orography and coastlines (Hourdin et al., 2010; Sylla et al., 2010; Xue et al., 2010; Raj et al., 2019).

The WAFriM is assessed in Sections 8.3.2.4.3 and 8.4.2.4.3. The observed Sahel and West African monsoon drought and recovery is assessed as a regional climate change attribution example in Section 10.4.2.1.

AV.4.4 The North American Monsoon

The North American monsoon (NAmerM) is a regional-scale atmospheric circulation system dominated by boreal summer precipitation over north-western Mexico and south-west USA, where it contributes to almost 70% and 40% of the total annual precipitation, respectively (Douglas et al., 1993; Higgins et al., 1997). The NAmerM domain is shaded magenta in Figure AV.1, is roughly bounded by 15°N–35°N, 100°W–115°W and is defined where the July–August–September minus June mean precipitation exceeds 25 mm month⁻¹ (Douglas et al., 1993; Adams and Comrie, 1997; Barlow et al., 1998; Cook and Seager, 2013).

The identification of a regional monsoon regime in North America dates back to the 1990s (Douglas et al., 1993; Adams and Comrie, 1997; Higgins et al., 1997; Barlow et al., 1998), although consideration of the monsoonal character of the south-western USA precipitation goes back considerably further (e.g., Bryson and Lowry, 1955). The monsoonal characteristics of the region include a pronounced annual maximum of precipitation in boreal summer (June–July–August) accompanied by a surface low-pressure system and an upper-level anticyclone, although the seasonal reversal of the surface winds is primarily limited to the northern Gulf of California. In particular, the summer precipitation in the NAmerM region is dictated by the location of the upper-level anticyclone (Reed, 1933; Castro et al., 2001). The decay phase of the NAmerM is typically observed during late September to October, when convection migrates from Central to South America (Vera et al., 2006).

Mesoscale variability of the NAmerM comes from the pulsing of the Gulf of California low-level jet, the intensification/reduction of the land–sea contrast (Torres-Alavez et al., 2014) and moisture surges over the Gulf of California (Vera et al., 2006). Synoptic variability of the NAmerM is mainly associated with the activity of tropical cyclones and of easterly waves (Stensrud et al., 1997; Fuller and Stensrud, 2000). In addition, the NAmerM is strongly influenced by ENSO variability at both interannual (Higgins et al., 1999; Higgins and Shi, 2001) and decadal (e.g., Castro et al., 2001) time scales.

The region is challenging for climate modelling for several reasons, including complex topography, the importance of Mesoscale Convective Systems (MCSs), and sensitivity to SST bias (e.g., Pascale et al., 2019). Many CMIP3 and CMIP5 models with resolutions coarser than 100 km are unable to realistically resolve the topography of the NAmerM region, thus inducing biases in simulating the monsoon (Geil et al., 2013). Among other factors, these biases are due to deficiencies in the simulation of the Gulf of California summer low-level flow (Kim et al., 2008; Pascale et al., 2017) and to failures in representing properly the diurnal cycle (Risanto et al., 2019) and the decay (Bukovsky et al., 2015) of the NAmerM precipitation. Simulations at higher horizontal resolution (i.e., with at least 0.25° grid) exhibit an improved representation of the regional topography, which provides a better representation of the regional circulation and therefore of the NAmerM (Varuolo-Clarke et al., 2019).

The NAmerM is assessed in Sections 8.3.2.4.4, 8.4.2.4.4, Atlas.7.1.3 and Atlas.9.1.

AV.4.5 The South American Monsoon

The South American monsoon (SAmerM) is a regional circulation system characterized by inflow of low-level winds from the Atlantic Ocean toward South America, involving Brazil, Peru, Bolivia and northern Argentina, associated with the development of surface pressure gradients (and intense precipitation) during austral summer (December–January–February; DJF). Based on climatological precipitation intensity, the SAmerM region is roughly

bounded by 5°S–25°S and 70°W–50°W (Zhou and Lau, 1998; Vera et al., 2006; Raia and Cavalcanti, 2008) and is shaded dark orange in Figure AV.1.

During austral spring (September–October–November; SON), areas of intense convection migrate from north-western South America to the south (Raia and Cavalcanti, 2008), forming the South Atlantic Convergence Zone (SACZ) during austral summer (Kodama, 1992; Jones and Carvalho, 2002; Vera et al., 2006). Associated with this regime, an upper-tropospheric anticyclone (the Bolivian High) forms over the Altiplano region during the monsoon onset (Lenters and Cook, 1997). The establishment of this upper-level anticyclone has been related to the transition from southerly to northerly winds and the occurrence of strong convective heating over the Amazon (Lenters and Cook, 1997; Wang and Fu, 2002). The SAmerM then retreats during austral autumn (March–April–May) with a north-eastward migration of the convection (e.g., Vera et al., 2006).

The SAmerM displays considerable variability on time scales ranging from intra-seasonal to decadal (Vera et al., 2006; Marengo et al., 2012; Vuille et al., 2012; Novello et al., 2017). The Madden-Julian Oscillation (MJO, Section AIV.2.8) influences the SACZ via changes in mid-latitude synoptic disturbances (Jones and Carvalho, 2002; Liebmann et al., 2004). At interannual time scales, ENSO explains most of the SAmerM variability (e.g., Paegle and Mo, 2002; Marengo et al., 2012). Tropical Atlantic temperatures also affect the SAmerM, with reduced atmospheric moisture transport to feed the monsoon under warmer tropical North Atlantic conditions (e.g., Marengo et al., 2008; Zeng et al., 2008). In addition to SSTs, interannual variability of the SAmerM is linked to changes in land surface processes, cold-air incursions, the latitudinal location of the subtropical jet, and the Southern Annular Mode (Section AIV.2.2; e.g., Silvestri and Vera, 2003; Li and Fu, 2004; Collini et al., 2008; Yin et al., 2014). At inter-decadal time scales, the SAmerM is influenced by important modes of climate variability (e.g., Robertson and Mechoso, 2000; Paegle and Mo, 2002; Chiessi et al., 2009; Silvestri and Vera, 2009).

The general large-scale features of the SAmerM are reasonably well simulated by coupled climate models although they do not adequately reproduce maximum precipitation over the core of the monsoon, even when considering simulations under past natural forcings, such as those during the last millennium (Rojas et al., 2016; Díaz and Vera, 2018). However, CMIP5 models featured an improved representation of the SAmerM with respect to CMIP3 (Joetzer et al., 2013; Jones and Carvalho, 2013; Gulizia and Camilloni, 2015; Díaz and Vera, 2017).

The SAmerM is assessed in Sections 8.3.2.4.5 and 8.4.2.4.5.

AV.4.6 The Australian-Maritime Continent Monsoon

The Australian-Maritime Continent monsoon (AusMCM) occurs during austral summer (December–January–February), with the large-scale shift of the ITCZ into the Southern Hemisphere. It covers northern Australia and the Maritime Continent up to 10°N (e.g., McBride, 1987; Suppiah, 1992; Robertson et al., 2011), and it corresponds

to the yellow shaded region in Figure AV.1. The identification of the Australian monsoon by meteorologists dates back to the early 20th century (see review of Suppiah, 1992), with later studies providing classifications of monsoon circulation regimes (e.g., McBride, 1987) and definitions of monsoon onset (Troup, 1961; Holland, 1986; Hendon and Liebmann, 1990; Drosowsky, 1996).

The AusMCM is characterized by the seasonal reversal of prevailing easterly winds to westerly winds and the onset of periods of active convection and heavy rainfall (Zhang and Moise, 2016). Over northern Australia, the monsoon season generally lasts from December to March and is associated with the west to north-westerly inflow of moist winds, producing convection and heavy precipitation. Over the Maritime Continent, the main rainy season south of the equator is centred on December to February with north-westerly monsoon flow at low levels.

Over Australia, the monsoon is strongly influenced by ENSO on interannual time scales: during El Niño years the monsoon onset tends to be delayed (Nicholls et al., 1982; McBride and Nicholls, 1983; Drosowsky, 1996). This relationship breaks down after the onset of the wet season, leading to little correlation between ENSO phase and total monsoon rainfall or duration (e.g., Hendon et al., 2012). The Maritime Continent also experiences a delay in monsoon onset during El Niño years and monsoon rainfall is correlated with ENSO during the dry and transition seasons (Robertson et al., 2011). The AusMCM is also influenced by the Indian Ocean Dipole (peaking in September to November) that tends to weaken the following monsoon when in its positive phase (Cai et al., 2005).

The ability of climate models to simulate the Australian monsoon has improved in successive generations of coupled models (i.e., from CMIP3 to CMIP6, Moise et al., 2012; Brown et al., 2016; Narsey et al., 2020), with sensitivity of monsoon rainfall to the magnitude of SST biases in the Equatorial Pacific (Brown et al., 2016).

The AusMCM is assessed in Sections 8.3.2.4.6 and 8.4.2.4.6.

AVI.1 Introduction

This annex provides background information on indices used within Chapter 11, Chapter 12 and the Atlas, including technical details of calculation and related references.

In the climate science literature, a number of indices are used to characterize and quantify one or several aspects of climate phenomena occurring due to natural variability or due to long-term changes in the system. There is an extremely large number of examples. One can cite mean global climate indices, such as global mean sea level rise or global surface temperature, which characterize the state of the climate system and act as a shifting baseline for regional changes. One can also examine mean regional trends, for example in mean spring precipitation, which reflect large-scale patterns and alter the background conditions within which episodic hazards may occur. One can also calculate indices of extremes characterizing episodic events within the tail of the distributions of specific variables within their variability range, for instance the annual maximal temperature at a given location or the 100-year return value of river discharge characterizing extreme floods. Such extreme indices have been the subject of a number of studies and have been used to characterize how climate change modifies extreme values of climate variables and subsequent impacts in the IPCC Special Report on 'Managing the risks of Extreme Events and Disasters to Advance Climate Change Adaptation' (IPCC, 2012), as well other recent IPCC reports.

Indices can also characterize aspects of climatic impact-drivers (CIDs; see Chapter 1 for the definition) that are key to impacts and risks to society and ecosystems. Chapter 12 proposes a definition of 'climatic impact-driver indices' as 'numerically computable indices using one or a combination of climate variables designed to measure the intensity of the climatic impact-driver, or the probability of exceedance of a threshold. For instance, an index of heat inducing human health stress is the Heat Index (HI) that combines temperature and relative humidity (e.g., Burkart et al., 2011; Lin et al., 2012; Kent et al., 2014) and is used by the US National Oceanic and Atmospheric Administration (NOAA) for issuing heat warnings'.

Climatic impact-drivers may not be related only to extremes, and therefore require a much broader set of indices. For instance, the rate of coastline recession, due to sea level rise, assessed in Chapter 12, is involved in the risk of damage and losses in coastal settlements and infrastructures. Mean trends and changes themselves are considered throughout the report as CIDs. For instance, beyond the warming trend that has a large number of consequences, changes in other indices such as 'snow season length' are often used to study economic impacts on winter tourism (Damm et al., 2017). Furthermore, Mora et al. (2018) used a set of 11 very different key CID indices, among which about half are related to extremes to characterize broader threats to society. Section 12.3 in Chapter 12 reviews the CIDs described in the literature which drive impacts and risks, and reveal the wide variety of indices used to characterize them.

Indices are, in principle, computable from observations, reanalyses or model simulations, although it is important to consider scale in comparing across datasets. For example, an extreme precipitation event has a lower magnitude across a large grid cell than it would at a single station within that grid cell. In many cases, CIDs are simply characterized by the exceedance of a threshold for an Essential Climate Variable (ECV). For instance, the probability of crop failure dramatically increases as temperature rises above certain thresholds, which may differ from one species to another (Hatfield and Prueger, 2015; Grotjahn, 2021). To assess the effect of climate change on threshold-based indices (e.g., the change in the number of days with maximum temperature above 35°C), a bias adjustment of model outputs should be considered where sensible as model simulations can have biases compared to observations and reanalyses (Section 10.3.1.3 and Cross-Chapter Boxes 10.2).

Indices are used in many chapters of this Report: in Chapter 4 for assessing changes in the global climate, in Chapter 8 for water cycle changes assessment, in Chapter 9 for oceans and the cryosphere, in Chapter 11 for assessing changes in extreme conditions, and in Chapter 12 for assessing CIDs and their changing characteristics due to climate change. The Atlas assesses changes in mean variables/indices (temperature, precipitation and snow). The Interactive Atlas includes indices of mean changes (for temperatures, precipitation, snowfall and wind) and a number of extreme indices and CIDs, allowing for flexible spatial and temporal analysis of the results.

AVI.2 Extreme Indices Selection

In Chapter 11, extreme weather and climate events (collectively referred to as extremes) are assessed and the main focus is on extreme events over land. Since the analysis of extremes often involves the examination of the tails of the statistical distributions, a parametric or non-parametric approach can be used to define extremes. The non-parametric approach is largely adopted in most of the literature to characterize moderate temperature and precipitation extremes with shorter return periods. The Expert Team on Climate Change Detection and Indices (ETCCDI; <https://www.wcrp-climate.org/etccdi>) defined 27 indices to characterize different aspects of moderate temperature and precipitation extremes, which are described by Frich et al. (2002), Alexander et al. (2006), Zhang et al. (2011), Donat et al. (2013), and Sillmann et al. (2013), and were also extensively used in previous IPCC reports. In Chapter 11, a subset of these indices is assessed in detail (Sections 11.3 and 11.4). For events with longer return periods (e.g., events that occur once in 20 years or even more rarely), the parametric approach based on Extreme Value Theory (EVT; Coles, 2001) is used and adopted in the literature (e.g., Kharin and Zwiers, 2000; Brown et al., 2008; Kharin et al., 2013). These events are also assessed throughout the chapter. Aside from temperature and precipitation, the chapter also assesses indices used to characterize droughts. Table AVI.1 lists the indices used.

Table AVI.1 | Table listing extreme indices used in Chapter 11.

Extreme	Label	Index Name	Units	Variable
Temperature	TXx	Monthly maximum value of daily maximum temperature	°C	Maximum temperature
	TXn	Monthly minimum value of daily maximum temperature	°C	Maximum temperature
	TNn	Monthly minimum value of daily minimum temperature	°C	Minimum temperature
	TNx	Monthly maximum value of daily minimum temperature	°C	Minimum temperature
	TX90p	Percentage of days when daily maximum temperature is greater than the 90th percentile	%	Maximum temperature
	TX10p	Percentage of days when daily maximum temperature is less than the 10th percentile	%	Maximum temperature
	TN90p	Percentage of days when daily minimum temperature is greater than the 90th percentile	%	Minimum temperature
	TN10p	Percentage of days when daily minimum temperature is less than the 10th percentile	%	Minimum temperature
	ID	Number of icing days: annual count of days when TX (daily maximum temperature) <0°C	Days	Maximum temperature
	FD	Number of frost days: annual count of days when TN (daily minimum temperature) <0°C	Days	Minimum temperature
	WSDI	Warm spell duration index: annual count of days with at least six consecutive days when TX >90th percentile	Days	Maximum temperature
	CSDI	Cold spell duration index: annual count of days with at least six consecutive days when TN <10th percentile	Days	Minimum temperature
	SU	Number of summer days: annual count of days when TX (daily maximum temperature) >25°C	Days	Maximum temperature
	TR	Number of tropical nights: annual count of days when TN (daily minimum temperature) >20°C	Days	Minimum temperature
	DTR	Daily temperature range: monthly mean difference between TX and TN	°C	Maximum and minimum temperature
	GSL	Growing season length: annual (1 Jan to 31 Dec in Northern Hemisphere (NH), 1 July to 30 June in Southern Hemisphere (SH)) count between first span of at least six days with daily mean temperature TG >5°C and first span after July 1 (Jan 1 in SH) of six days with TG <5°C	Days	Mean temperature
	20TXx	One-in-20 year return value of monthly maximum value of daily maximum temperature	°C	Maximum temperature
	20TXn	One-in-20 year return value of monthly minimum value of daily maximum temperature	°C	Maximum temperature
	20TNn	One-in-20 year return value of monthly minimum value of daily minimum temperature	°C	Minimum temperature
	20TNx	One-in-20 year return value of monthly maximum value of daily minimum temperature	°C	Minimum temperature
Precipitation	Rx1day	Maximum one-day precipitation	mm	Precipitation
	Rx5day	Maximum five-day precipitation	mm	Precipitation
	R5mm	Annual count of days when precipitation is greater than or equal to 5 mm	Days	Precipitation
	R10mm	Annual count of days when precipitation is greater than or equal to 10 mm	Days	Precipitation
	R20mm	Annual count of days when precipitation is greater than or equal to 20 mm	Days	Precipitation
	R50mm	Annual count of days when precipitation is greater than or equal to 50 mm	Days	Precipitation
	CDD	Maximum number of consecutive days with less than 1 mm of precipitation per day	Days	Precipitation
	CWD	Maximum number of consecutive days with more than or equal to 1 mm of precipitation per day	Days	Precipitation
	R95p	Annual total precipitation when the daily precipitation exceeds the 95th percentile of the wet-day (>1 mm) precipitation	mm	Precipitation
	R99p	Annual precipitation amount when the daily precipitation exceeds the 99th percentile of the wet-day precipitation	mm	Precipitation
	SDII	Simple precipitation intensity index	mm day ⁻¹	Precipitation
	20Rx1day	One-in-20 year return value of maximum one-day precipitation	mm day ⁻¹	Precipitation
	20Rx5day	One-in-20 year return value of maximum five-day precipitation	mm day ⁻¹	Precipitation
Drought	SPI	Standardized precipitation index	Months	Precipitation
	EDDI	Potential evaporation, evaporative demand drought index	Months	Evaporation
	SMA	Soil moisture anomalies	Months	Soil moisture
	SSMI	Standardized soil moisture index	Months	Soil moisture
	SRI	Standardized runoff index	Months	Streamflow
	SSI	Standardized streamflow index	Months	Streamflow
	PDSI	Palmer drought severity index	Months	Precipitation, evaporation
	SPEI	Standardized precipitation evapotranspiration index	Months	Precipitation, evaporation, temperature

Some of these indices are included in the Interactive Atlas allowing further analysis (seasons, regions, baselines and future periods – using both time slices/scenarios and global warming levels): TXx, TNn, Rx1day, Rx5day, FD, CDD and SPI.

AVI.3 Selection of Climatic Impact-drivers Indices

In Chapter 12, 33 CID categories are identified on the basis of relevance for risks and impacts and available literature. They are classified into seven types: heat and cold, wet and dry, wind, snow and ice, coastal, open ocean, and other (see Tables 12.1 and 12.2). It would be impossible to cover all indices that have been developed in the literature. However, in order to illustrate how indices can provide information about future regional climate, Chapter 12 and the Atlas use a limited number of indices to illustrate the main CIDs and their evolution with climate change.

The selection of indices, as displayed in Chapter 12 and the Atlas, is based on expert judgement using the following guiding principles. The set of indices should:

- describe the evolution of a manageable and illustrative number of indices;
- cover these categories, while giving more weight to those with a higher number of potential impacts as described in the literature;
- be used broadly in the literature;
- allow easy computation from publicly available model outputs and observations, or be accessible from published material through contact with the authors;
- be well evaluated in model simulations, or based on ECVs that are well evaluated in model simulations; and
- represent CIDs of interest to regional impacts and risk assessments.

The selection results in 13 regional indices that are reported in Table AVI.2. The description of the formulae used for processing is described below.

AVI.3.1 Regional CID Indices Used in Chapter 12 and the Atlas

Climatic Impact-drivers Indices

Cooling degree days (CD): Energy consumption in hot environments typically depends on the excess of temperature above a given threshold, where cooling is required. In Chapter 12 and the Atlas we used the formulation of Spinoni et al. (2015), which uses the mean (T_M), max (T_X) and min daily (T_N) temperature with the formula taken from this reference:

$$CD_i = \begin{cases} 0 & T_X \leq T_b \\ \frac{4}{T_X - T_b} & T_M \leq T_b < T_X \\ \frac{T_b - T_N}{4} & T_N \leq T_b < T_M \\ T_M - T_b & T_N \geq T_b \end{cases} \quad \text{if}$$

With $T_b = 22^\circ\text{C}$, then

$$CD = \sum_{i=1}^{365} CD_i$$

The difference between Chapter 12, the Atlas and the previous reference is that in this Report the sum is cumulated over the entire year instead of six months, so it applies to all hemispheres. This index is included in the Interactive Atlas.

Number of days with maximum daily temperature above threshold (TXnn): The number of days with maximum temperature above a threshold can be critical for human health, infrastructure, ecosystems and agriculture. Different thresholds are used for different crops, generally varying between 30°C and 40°C (Hatfield and Prueger, 2015; Grotjahn, 2021). Chapter 12 uses the 35°C threshold globally (Figure 12.4), which was identified as a critical temperature for maize pollination and production (Wolfe et al., 2008; Schlenker and Roberts, 2009; Hatfield et al., 2011, 2014; Lobell and Gourdji, 2012; Gourdji et al., 2013; Lobell et al., 2013; Deryng et al., 2014; Hatfield and Prueger, 2015; Tripathi et al., 2016; Schauburger et al., 2017; Tesfaye et al., 2017), as well as a notable threshold for human health hazards (Kingsley et al., 2016; Petitti et al., 2016). The Interactive Atlas includes both TX35 and TX40 (both raw and bias adjusted; see Atlas 1.4.5).

NOAA heat index (HI): HI is used by the US National Oceanic and Atmospheric Administration (NOAA) for issuing heat warnings and was applied in several studies that investigated adverse health impacts due to heat stress (e.g., Burkart et al., 2011; Lin et al., 2012; Kent et al., 2014). HI is calculated as multiple linear regression with

temperature (T_F in °F) and relative humidity (RH) as input variables (Steadman, 1979; Rothfus, 1990):

$$HI = \begin{cases} HI_1 + HI_{A1}, & \text{if RH} < 13 \% \text{ and } 80^\circ\text{F} < T_F < 112^\circ\text{F} \\ HI_1 + HI_{A2}, & \text{if RH} > 85 \% \text{ and } 80^\circ\text{F} < T_F < 87^\circ\text{F} \\ HI_1, & \text{otherwise} \end{cases}$$

with:

$$HI_1 = c_0 + c_1 \cdot T_F + c_2 \cdot RH + c_3 \cdot T_F \cdot RH + c_4 \cdot T_F^2 + c_5 \cdot RH^2 + c_6 \cdot T_F^2 \cdot RH + c_7 \cdot T_F \cdot RH^2 + c_8 \cdot T_F^2 \cdot RH^2$$

$$HI_{A1} = (13 - RH)/4 \cdot \sqrt{(17 - |T_F - 95^\circ\text{F}|)/17}$$

$$HI_{A2} = (RH - 85)/10 \cdot (87^\circ\text{F} - T_F)/5$$

$$c_0 = -42.379^\circ\text{F}, c_1 = 2.04901523, c_2 = 10.14333127^\circ\text{F}, \\ c_3 = -0.22475541, c_4 = -0.00683783^\circ\text{F}^{-1}, c_5 = -0.05481717^\circ\text{F}, \\ c_6 = 0.00122874^\circ\text{F}^{-1}, c_7 = 0.00085282, c_8 = -0.00000199^\circ\text{F}^{-1}$$

If $HI < 80^\circ\text{F}$, the following equation is used:

$$HI = 0.5 \cdot (T_F + 61^\circ\text{F} + 1.2 \cdot (T_F - 68^\circ\text{F})) + 0.094^\circ\text{F} \cdot RH$$

The calculated HI is converted into °C.

HI is calculated for CMIP5, CMIP6 and CORDEX using daily mean near-surface specific humidity, daily mean surface pressure, and daily maximum near-surface air temperature. For CMIP5 and CMIP6, daily mean surface pressure is calculated from daily mean sea level pressure by applying a height adjustment (see Schwingshackl et al. (2021) for details). Additionally, HI is calculated for WFDE5, which is a bias-adjusted version of the ERA5 reanalysis (Cucchi et al., 2020). Daily maximum temperature is calculated as the maximum of the hourly WFDE5 near-surface temperature values. Relative humidity is calculated using daily means of the hourly WFDE5 variables for near-surface air temperature, near-surface specific humidity, and surface air pressure.

To quantify heat stress, yearly numbers of daily HI-threshold exceedances are calculated using a threshold of 41°C , which corresponds to conditions that the US National Weather Service classifies into the category of 'Danger' (Blazejczyk et al., 2012). Bias-adjusted model simulations are used for calculating threshold exceedances of HI, employing the quantile delta mapping (QDM) approach as described by Cannon et al. (2015). The QDM approach adjusts the model data in the application period to fit the reference data in the reference period (using quantile mapping). Subsequently, the climate change signal is added for each quantile by considering the change between the model's reference and application periods. QDM is directly applied to the HI data using WFDE5 as the reference dataset and 1981–2010 as the reference period. WFDE5 HI data are conservatively remapped to each model's grid before bias adjustment is performed. QDM is applied on each grid point individually and for

each month separately. The application periods are the IPCC periods 1995–2014, 2041–2060 and 2081–2100, and 20-year periods for specific warming levels (1.5°C , 2°C , 3°C and 4°C).

Heating degree days (HDD): symmetrical to the cooling degree days index, the HDD index is used for illustrating energy demand for heating. It has been used in several studies of the impacts of climate change on the energy sector. The Atlas follows the formulation proposed by Spinoni et al. (2015). The calculation follows:

$$HDD_i = \begin{cases} \frac{T_b - T_M}{2} - \frac{T_X - T_b}{4} & \text{if } \begin{cases} T_X \leq T_b \\ T_M \leq T_b < T_X \\ T_N \leq T_b < T_M \\ T_N \geq T_b \end{cases} \\ \frac{T_b - T_N}{4} & \\ 0 & \end{cases}$$

With $T_b = 15.5^\circ\text{C}$, then

$$HDD = \sum_{i=1}^{365} HDD_i$$

Where T_M , T_X and T_N correspond to daily mean, maximum and minimum temperature, respectively.

To account for various geographic zones, however, the HDD index is cumulated over the entire year, instead of six months, as in the previous reference. This index is included in the Interactive Atlas.

Number of frost days (FD): Frost affects crops (Barlow et al., 2015; Crimp et al., 2016; Craddock-Henry, 2017; Mäkinen et al., 2018), and there has been a number of studies investigating changes in the number of frost days, with various thresholds, mostly between -10°C and $+2^\circ\text{C}$. In Chapter 12 and the Atlas, we use the simple threshold of 0°C for the daily minimum temperature to define frost days as in Table AVI.1. This index is included in the Interactive Atlas.

River flood index using runoff (FI): As a flood indicator, the 100-year return value of discharge value (Q_{100}) has been used. The computation of the index follows Alfieri et al. (2015):

1. Annual maximum river discharges are selected and an Extreme Value Type I (Gumbel) distribution is fitted on time slices of 30 years and an analytical function is obtained.
2. The analytical function is used to estimate extreme discharge peaks with chosen return period $Q(RP)$, by inverting the formulation of the Gumbel distribution:

$$Q(RP) = \xi - \alpha \ln \left(-\ln \left(1 - \frac{1}{RP} \right) \right)$$

where α and ξ are the scale and location parameters of the analytical Gumbel distribution.

3. The peak discharge corresponding to the 100-year return period, $Q_{100}=Q(RP=100)$, is then calculated.

For CORDEX regional models the total runoff of each of the models has been used as an input of the hydrological model CHyM (Coppola et al., 2007, 2018) to produce the river discharge. The Q(RP=100) value has been computed for each of the river segments and each of the 29 CHyM simulations. The results are shown in the regional figures in Section 12.4.

Standardized precipitation index (SPI): The SPI is a statistical index that compares cumulated precipitation for n months ($n = 6$) with the long-term precipitation distribution for the same location and cumulation period. The SPI months have been selected so that SPI represents the medium-term cumulated value and can be used to measure the medium-term impact on river flow and reservoir storage (McKee et al., 1993).

The index is computed in this way:

1. A monthly precipitation time series is selected (at least 30 years).
2. The running average for the n -months window is computed.
3. The Gamma distribution is used to fit the data. The fitting can be achieved through the maximum likelihood estimation of the Gamma distribution parameters.
4. The values from this probability distribution are then transformed into a normal distribution, so that the mean SPI for the location and desired period is zero and the standard deviation is 1 (Edwards and McKee, 1997).

Once SPI has been computed, the calculation of the drought frequency (DF) follows the method in Spinoni et al. (2014): a drought event starts in the month when SPI falls below -1 and it ends when SPI returns to positive values, for at least two consecutive months.

It has to be noted that the SPI index has been recognized to be difficult to interpret in high latitudes and arid areas due to statistical issues linked to inaccuracies in the estimation of the Gamma function (Spinoni et al., 2014). The duration of six months is considered in Figure 12.4. This index is included in the Interactive Atlas.

Soil moisture (SM): The soil moisture index is used in Chapter 12 figures. It is using the total soil moisture content integrated over the soil depth, normalized by the recent past climatological values at each grid point.

Snow season length (SWE100): Several studies use the snow water equivalent (SWE) variable (variable *snw* in model outputs) in order to define a 'snow season length' as the number of days with enough snow on the ground. This index is particularly important for the winter tourism sector (Damm et al., 2017; Jacob et al., 2018). Several thresholds are used to define a day with 'enough snow on the ground', with Wobus et al. (2017) marking 100 mm as a key threshold for skiing. However, this index is important not only for winter tourism but also in other sectors such as water management. In several figures of Chapter 12, the snow season length is calculated then as the number of days with $SWE > 100$ mm, following the definition of Damm et al. (2017) and Wobus et al. (2017). Seasonal limits are given (November through March) for studies in the Northern Hemisphere, and the index for the Southern Hemisphere is taken over

the opposite season (May through September). SWE was assessed in several studies and its simulation depends on the representation of surface processes dealing with snow. Despite limitations, SWE was found to be useful in giving insight into the sign of changes (McCrary et al., 2017). When interpreting the figures shown in Chapter 12, one should also keep in mind that 'altitudes' are model altitudes and may not correspond to real ones due to the coarse resolution, and the changes can be quite sensitive to such effects.

Extreme Total Water Level (ETWL): Factors contributing to extreme sea levels (ETWL) are sea level rise, storm surge (e.g., associated with tropical cyclones and extratropical cyclones), tide, and extreme waves (resulting in high-wave setup at the shoreline). The ETWL used here is the summation of the aforementioned factors (Vitousek et al., 2017; Vousdoukas et al., 2018) and the commonly used 1-in-100-year ETWL (the 100-year ETWL return value) is adopted here as the index relevant to episodic coastal flooding. Here, the median ETWL, together with the associated 5–95% confidence interval, resulting from a fully probabilistic model that incorporates storm surge and waves derived from models forced by an ensemble of six GCMs, is used as the index relevant for long-term coastal erosion.

Coastal erosion (CE): Coastal erosion is generally accompanied by shoreline retreat, which can occur as a gradual process (e.g., due to sea level rise) or as an episodic event due to storm surge and/or extreme waves, especially when combined with high tide (Ranasinghe, 2016). The most commonly used shoreline retreat index is the magnitude of shoreline retreat by a predetermined planning horizon such as 50 or 100 years into the future. Here, the median shoreline retreat, together with the associated 5–95% confidence interval, resulting from a fully probabilistic model that incorporates storm surge and waves derived from models forced by an ensemble of six GCMs, is used as the index relevant for long-term coastal erosion.

Some of these indices are included in the Interactive Atlas allowing flexible analysis (seasons, regions, baselines and future periods – using both time slices/scenarios and global warming levels): TX35 and TX40 (both raw and bias adjusted; see Atlas 1.4.5), FD, CDD, HDD, SPI-6 (CDD and HDD are labelled as CD and HD, respectively, in the Interactive Atlas).

Table AVI.2 | Regional CID indices table and relevant references.

CID Category	Climatic Impact-driver (from Table 12.1) and Potential Affected Sectors	Index	Required ECVs	Way to Calculate	Bias Adjustment	References
Heat	Change in cooling demand for energy demand and building consumption	Cooling degree days above 22°C	Tas, tasmin, tasmax	From projections	Yes	Spinoni et al. (2015, 2018)
	Heat, with thresholds important for agriculture	Number of days with Tmax >35°C or 40°C (TX35, TX40)	Tasmax	From projections	Yes	Hatfield and Prueger (2015); Hatfield et al., (2015); Grotjahn (2021)
	Heat stress index combining humidity used in occupational and industrial health	NOAA heat index (HI): number of days above 41°C threshold	Tasmax, huss, ps	From projections	Yes	Burkart et al. (2011); Lin et al. (2012); Kent et al. (2014)
Cold	Heating degree day for energy consumption	Heating degree days below 15.5°C	Tas, tasmin, tasmax	From projections	Yes	Spinoni et al. (2015, 2018)
	Frost	Number of frost days below 0°C (FD)	Tasmin	From projections	Yes	Barlow et al. (2015); Rawlins et al. (2016)
Wet	River flooding	Flood index (FI)	srroff/mrro	From projections and simplified routing model	No	Forzieri et al. (2016); Alfieri et al. (2017)
Drought	Aridity	Soil moisture (SM)	mrso	From projections	No	Cook et al. (2020)
	Droughts	Standardized Precipitation Index accumulated over 6 months (SPI-6)	Pr	From projections	No	Naumann et al. (2018)
Wind & storm	Mean wind speed	Annual mean wind speed	sfcWind	From projections	No	Karnauskas et al. (2018); Li et al. (2018)
Snow/ice	Snow season length	Number of days with snow water equivalent >100 mm (SWE100) over the snow season (Nov–Mar for NH)	Snw	From projections	No	Damm et al. (2017); Wobus et al. (2017)
Coastal	Extreme sea level (ETWL) inducing storm surges	1-in-100-year return period level (ETWL)		Data from authors	No	Vousdoukas et al. (2018)
	Coastal erosion	Shoreline retreat by mid- and end of century		Data from authors	No	Vousdoukas et al. (2020)

Annex VII: Glossary

Coordinating Editors:

J.B. Robin Matthews (France/United Kingdom), Vincent Möller (Germany), Renée van Diemen (The Netherlands/United Kingdom), Jan S. Fuglestad (Norway), Valérie Masson-Delmotte (France), Carlos Méndez (Venezuela), Sergey Semenov (Russian Federation), Andy Reisinger (New Zealand)

Editorial Team:

Rondrotiana Barimalala (South Africa/Madagascar), Roxana Bojariu (Romania), Annalisa Cherchi (Italy), Peter M. Cox (United Kingdom), Sergio Henrique Faria (Spain/Brazil), Piers Forster (United Kingdom), Christopher Jones (United Kingdom), Nana Ama Browne Klutse (Ghana), Charles Koven (United States of America), Svitlana Krakovska (Ukraine), Sawsan K. Mustafa (Sudan), Friederike Otto (United Kingdom/Germany), Matthew D. Palmer (United Kingdom), Tamzin Palmer (United Kingdom), Wilfried Pokam Mba (Cameroon), Roshanka Ranasinghe (The Netherlands/Sri Lanka, Australia), Pedro Scheel Monteiro (South Africa), Joeri Rogelj (United Kingdom/ Belgium), Sharon L. Smith (Canada), Ying Sun (China), Andrew Turner (United Kingdom), Bart van den Hurk (The Netherlands), Émilie Vanvyve (United Kingdom/Belgium), Martin Wild (Switzerland), Cunde Xiao (China), Prodromos Zanis (Greece)

Note:

This glossary defines some specific terms as the Lead Authors intend them to be interpreted in the context of this report. Italicized words in definitions indicate that the italicized term is defined in the Glossary.

Subterms appear in italics beneath main terms.

This annex should be cited as:

IPCC, 2021: Annex VII: Glossary [Matthews, J.B.R., V. Möller, R. van Diemen, J.S. Fuglestad, V. Masson-Delmotte, C. Méndez, S. Semenov, A. Reisinger (eds.)]. In *Climate Change 2021: The Physical Science Basis. Contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change* [Masson-Delmotte, V., P. Zhai, A. Pirani, S.L. Connors, C. Péan, S. Berger, N. Caud, Y. Chen, L. Goldfarb, M.I. Gomis, M. Huang, K. Leitzell, E. Lonnoy, J.B.R. Matthews, T.K. Maycock, T. Waterfield, O. Yelekci, R. Yu, and B. Zhou (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 2215–2256, doi:[10.1017/9781009157896.022](https://doi.org/10.1017/9781009157896.022).

1.5°C pathway See *Pathways*.

Ablation (of glaciers, ice sheets, or snow cover) See *Mass balance/budget (of glaciers or ice sheets)*.

Abrupt change A change in the system that is substantially faster than the typical rate of the changes in its history. See also *Abrupt climate change* and *Tipping point*.

Abrupt climate change A large-scale *abrupt change* in the climate system that takes place over a few decades or less, persists (or is anticipated to persist) for at least a few decades and causes substantial impacts in human and/or natural systems. See also *Abrupt change* and *Tipping point*.

Accumulation (of glaciers, ice sheets, or snow cover) See *Mass balance/budget (of glaciers or ice sheets)*.

Active layer Layer of ground above *permafrost* subject to annual thawing and freezing.

Adaptation In *human systems*, the process of adjustment to actual or expected *climate* and its effects, in order to moderate harm or exploit beneficial opportunities. In *natural systems*, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate and its effects. See also *Adaptation options*, *Adaptive capacity* and *Maladaptive actions (Maladaptation)*.

Adaptation options The array of strategies and measures that are available and appropriate for addressing *adaptation*. They include a wide range of actions that can be categorized as structural, institutional, ecological or behavioural.

Adaptive capacity The ability of systems, institutions, humans and other organisms to adjust to potential damage, to take advantage of opportunities, or to respond to consequences (MA, 2005).

Added value Improvement of the representation of some climatic aspects by one methodology compared to another methodology. For instance, *downscaling* a coarse resolution global *climate model* may improve the representation of regional *climate* in complex terrain.

Adjustments (in relation to effective radiative forcing) The response to an agent perturbing the *climate system* that is driven directly by the agent, independently of any change in *global surface temperature*. For example, *carbon dioxide* and *aerosols*, by altering internal heating and cooling rates within the *atmosphere*, can each cause changes to cloud cover and other variables thereby producing an *effective radiative forcing* even in the absence of any surface warming or cooling. Adjustments are usually rapid in the sense that they begin to occur right away, before *climate feedbacks* which are driven by global surface warming (although some adjustments may still take significant time to proceed to completion, for example those involving vegetation or *ice sheets*).

Adjustment time See *Response time or adjustment time*.

Advection Transport of water or air along with its properties (e.g., temperature, chemical tracers) by winds or currents. Regarding the general distinction between advection and *convection*, the former describes transport by large-scale motions of the *atmosphere*

or *ocean*, while convection describes the predominantly vertical, locally induced motions.

Aerosol A suspension of airborne solid or liquid particles, with typical particle size in the range of a few nanometres to several tens of micrometres and *atmospheric lifetimes* of up to several days in the *troposphere* and up to years in the *stratosphere*. The term aerosol, which includes both the particles and the suspending gas, is often used in this report in its plural form to mean ‘aerosol particles’. Aerosols may be of either natural or *anthropogenic* origin in the troposphere; stratospheric aerosols mostly stem from volcanic eruptions. Aerosols can cause an *effective radiative forcing* directly through scattering and absorbing radiation (*aerosol–radiation interaction*), and indirectly by acting as *cloud condensation nuclei* or ice nucleating particles that affect the properties of clouds (*aerosol–cloud interaction*), and upon deposition on snow- or ice-covered surfaces. Atmospheric aerosols may be either emitted as primary particulate matter or formed within the atmosphere from gaseous *precursors* (secondary production). Aerosols may be composed of sea salt, organic carbon, *black carbon (BC)*, mineral species (mainly desert dust), sulphate, nitrate and ammonium or their mixtures. See also *Short-lived climate forcers (SLCFs)*.

Aerosol effective radiative forcing (ERF_{ari+aci}) See *Aerosol–radiation interaction*.

Aerosol optical depth (AOD) Wavelength-dependent aerosol optical depth is a measure of the *aerosol* contribution to extinction of top-of-the-atmosphere solar intensity measured at the ground. AOD is unitless.

Fine-mode aerosol optical depth

Aerosol optical depth due to *aerosol* particles smaller than 1 µm in radius.

Aerosol–cloud interaction A process by which a perturbation to *aerosol* affects the microphysical properties and evolution of clouds through the aerosol role as *cloud condensation nuclei* or ice nuclei, particularly in ways that affect radiation or precipitation; such processes can also include the effect of clouds and precipitation on aerosol. The aerosol perturbation can be *anthropogenic* or come from some natural *source*. The *radiative forcing* from such interactions has traditionally been attributed to numerous indirect aerosol effects, but in this report, only two levels of radiative forcing (or effect) are distinguished:

Effective radiative forcing (or effect) due to aerosol–cloud interactions (ERF_{aci})

The final *radiative forcing* (or effect) from the *aerosol* perturbation, including the adjustments to the initial change in droplet or crystal formation rate. These adjustments include changes in the strength of *convection*, precipitation efficiency, cloud fraction, *lifetime* or water content of clouds, and the formation or suppression of clouds in remote areas due to altered circulations.

Instantaneous radiative forcing (or effect) due to aerosol–cloud interactions (IRF_{aci})

The *radiative forcing* (or radiative effect, if the perturbation is internally generated) due to the change in number or size distribution of cloud droplets or ice crystals that is the proximate result of an

aerosol perturbation, with other variables (in particular total cloud water content) remaining equal. In liquid clouds, an increase in cloud droplet concentration and surface area would increase the cloud *albedo*. This effect is also known as the cloud albedo effect, first indirect effect, or Twomey effect. It is a largely theoretical concept that cannot readily be isolated in observations or comprehensive process models due to the ubiquity of adjustments.

See also *Aerosol–radiation interaction*.

Aerosol–radiation interaction An interaction of *aerosol* directly with radiation produces radiative effects. In this report, two levels of *radiative forcing* (or effect) are distinguished:

Aerosol effective radiative forcing (ERF_{ari+aci})

The total effective *radiative forcing* due to both *aerosol*–cloud and aerosol–radiation interactions is denoted aerosol effective radiative forcing (ERF_{ari+aci}).

Effective radiative forcing (or effect) due to aerosol–radiation interactions (ERF_{ari})

The final *radiative forcing* (or effect) from the *aerosol* perturbation, including adjustments to the initial change in radiation. These adjustments include changes in cloud caused by the impact of the radiative heating on convective or larger-scale atmospheric circulations, traditionally known as semi-direct aerosol forcing (or effect).

Instantaneous radiative forcing (or effect) due to aerosol–radiation interactions (IRF_{ari})

The *radiative forcing* (or radiative effect, if the perturbation is internally generated) of an *aerosol* perturbation due directly to aerosol–radiation interactions, with all environmental variables remaining unaffected. Traditionally known in the literature as the direct aerosol forcing (or effect).

See also *Aerosol–cloud interaction*.

Afforestation Conversion to *forest* of land that historically has not contained forests. [Note: For a discussion of the term forest and related terms such as afforestation, *reforestation* and *deforestation*, see the 2006 IPCC Guidelines for National Greenhouse Gas Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019; UNFCCC, 2021a, b).] See also *Deforestation*, *Reforestation*, *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

Agreement In this Report, the degree of agreement within the scientific body of knowledge on a particular finding is assessed based on multiple lines of *evidence* (e.g., mechanistic understanding, theory, data, models, expert judgement) and expressed qualitatively (Mastrandrea et al., 2010). See also *Confidence*, *Likelihood*, *Uncertainty* and *Evidence*.

Agricultural and ecological drought See *Drought*.

Air mass A widespread body of air, the approximately homogeneous properties of which (i) have been established while that air was situated over a particular *region* of the Earth's surface, and (ii) undergo specific modifications while in transit away from the source region (AMS, 2021).

Air pollution Degradation of air quality with negative effects on human health or the natural or built environment due to the introduction, by natural processes or human activity, into the *atmosphere* of substances (gases, *aerosol*) which have a direct (primary pollutants) or indirect (secondary pollutants) harmful effect. See also *Short-lived climate forcers (SLCFs)*.

Airborne fraction The fraction of total *carbon dioxide (CO₂)* emissions (from *fossil fuels* and *land-use change*) remaining in the *atmosphere*.

Albedo The proportion of sunlight (*solar radiation*) reflected by a surface or object, often expressed as a percentage. Clouds, snow and ice usually have high albedo; soil surfaces cover the albedo range from high to low; vegetation in the dry season and/or in *arid zones* can have high albedo, whereas photosynthetically active vegetation and the *ocean* have low albedo. The Earth's planetary albedo changes mainly through changes in cloudiness and of snow, ice, leaf area and *land cover*.

Alkalinity See *Total alkalinity*.

Altimetry A technique for measuring the height of the Earth's surface with respect to the geocentre of the Earth within a defined terrestrial reference frame (geocentric sea level). See also *Geocentric sea level change*.

Annular modes Hemispheric scale patterns of atmospheric variability characterized by opposing and synchronous fluctuations in sea level pressure between the polar caps and mid-latitudes, with a structure exhibiting a high degree of zonal symmetry, and with no real preferred time scales ranging from days to decades. In each hemisphere, these fluctuations reflect changes in the latitudinal position and strength of the mid-latitude jets and associated storm tracks. Annular modes are defined as the leading mode of variability of extratropical sea level pressure or geopotential heights and are known as the *Northern Annular Mode (NAM)* and *Southern Annular Mode (SAM)* in the two hemispheres, respectively.

Northern Annular Mode (NAM)

A see-saw latitudinal fluctuation in Northern Hemisphere sea level pressure or geopotential height between the Arctic and the mid-latitudes. The NAM has some links with the *stratospheric polar vortex* and is related to the fluctuation in strength and latitude of the mean westerlies. Its variance is maximum in winter and its pattern has a strong regional expression in the North Atlantic, being strongly correlated with the *North Atlantic Oscillation* index. The NAM is also known as the Arctic Oscillation (AO). In its positive phase, the NAM is characterized by anomalously low pressure over the Arctic and high pressure over the mid-latitudes/subtropics, with a strengthening of the zonally averaged westerly winds on their polar flank that confines colder air across the Arctic. The negative NAM phase is characterized by a more distorted wind pattern and jet meanders that increase storminess in the mid-latitude regions. See Section AIV.2.1 in Annex IV of the AR6 WGI report.

Southern Annular Mode (SAM)

The leading mode of *climate variability* of Southern Hemisphere sea level pressure and geopotential height, which is associated with the strength and latitudinal shifts in the mid- to high-latitudes westerly wind belt. The SAM is also known as the Antarctic Oscillation (AAO).

A positive SAM phase is defined as lower-than-normal pressures over the polar regions and higher-than-normal pressures in the southern mid-latitudes, with a contraction towards Antarctica and strengthening of the westerly wind belt. The negative SAM phase exhibits positive high-latitude pressure anomalies, negative mid-latitude pressure anomalies and a weaker westerly flow expanded towards the equator. See Section AIV.2.2 in Annex IV of the AR6 WGI report. See also [Annular modes](#).

Anomaly The deviation of a variable from its value averaged over a [reference period](#).

Antarctic amplification See [Polar amplification](#).

Antarctic Ice Sheet (AIS) See [Ice sheet](#).

Antarctic oscillation (AAO) See [Southern Annular Mode \(SAM\)](#) (under [Annular modes](#)).

Anthropocene A proposed new geological epoch resulting from significant human-driven changes to the structure and functioning of the Earth System, including the [climate system](#). Originally proposed in the Earth system science community in 2000, the proposed new epoch is undergoing a formalization process within the geological community based on the stratigraphic [evidence](#) that human activities have changed the Earth system to the extent of forming geological deposits with a signature that is distinct from those of the [Holocene](#), and which will remain in the geological record. Both the stratigraphic and Earth system approaches to defining the Anthropocene consider the mid-20th century to be the most appropriate starting date (Steffen et al., 2016), although others have been proposed and continue to be discussed. The Anthropocene concept has already been informally adopted by diverse disciplines and the public to denote the substantive influence of humans on the Earth system.

Anthropogenic Resulting from or produced by human activities.

Anthropogenic emissions Emissions of [greenhouse gases \(GHGs\)](#), [precursors](#) of GHGs and [aerosols](#) caused by human activities. These activities include the burning of [fossil fuels](#), [deforestation](#), [land use](#) and [land-use changes](#) (LULUC), livestock production, fertilization, waste management, and industrial processes. See also [Anthropogenic](#) and [Anthropogenic removals](#).

Anthropogenic removals The withdrawal of [greenhouse gases \(GHGs\)](#) from the [atmosphere](#) as a result of deliberate human activities. These include enhancing biological [sinks](#) of CO₂ and using chemical engineering to achieve long-term removal and storage. Carbon dioxide capture and storage (CCS), which alone does not remove CO₂ from the atmosphere, can help reduce atmospheric CO₂ from industrial and energy-related sources if it is combined with bioenergy production (BECCS), or if CO₂ is captured from the air directly and stored (DACCS). [Note: In the 2006 IPCC Guidelines for national GHG Inventories (IPCC, 2006), which are used in reporting of emissions to the UNFCCC, ‘anthropogenic’ land-related GHG fluxes are defined as all those occurring on ‘managed land’, i.e., ‘where human interventions and practices have been applied to perform production, ecological or social functions’. However, some removals (e.g., removals associated with CO₂ fertilization and N deposition) are not considered as ‘anthropogenic’, or are referred to as ‘indirect’ anthropogenic effects, in some of the scientific literature assessed

in this report. As a consequence, the land-related net GHG emission estimates from global models included in this report are not necessarily directly comparable with land use, land-use change and forestry (LULUCF) estimates in national GHG Inventories.] See also [Carbon dioxide removal \(CDR\)](#), [Afforestation](#), [Enhanced weathering](#), [Ocean alkalization/Ocean alkalinity enhancement](#) and [Reforestation](#).

Anthropogenic subsidence Downward motion of the land surface induced by [anthropogenic](#) drivers (e.g., loading, extraction of hydrocarbons and/or groundwater, drainage, mining activities) causing sediment compaction or subsidence/deformation of the sedimentary sequence, or oxidation of organic material, thereby leading to relative [sea level rise](#).

Apparent hydrological sensitivity (η_a) The change in global mean precipitation per degree Celsius of [global mean surface air temperature \(GSAT\)](#) change with units of % per °C, although it can also be calculated as W m⁻² per °C. See also [Hydrological sensitivity](#) (η).

Arctic amplification See [Polar amplification](#).

Arctic oscillation (AO) See [Northern Annular Mode \(NAM\)](#) (under [Annular modes](#)).

Arid zone Areas where vegetation growth is severely constrained due to limited water availability. For the most part, the native vegetation of arid zones is sparse. There is high rainfall variability, with annual averages below 300 mm. Crop farming in arid zones requires irrigation.

Aridity The state of a long-term climatic feature characterized by low average precipitation or available water in a [region](#). Aridity generally arises from widespread persistent atmospheric subsidence or anticyclonic conditions, and from more localized subsidence in the lee side of mountains (adapted from Gbeckor-Kove, 1989; Türkeş, 1999). See also [Drought](#).

Artificial ocean upwelling (AOUpw) A potential [carbon dioxide removal \(CDR\)](#) method that aims to artificially pump up cooler, nutrient-rich waters from deep in the [ocean](#) to the surface. The aim is to stimulate phytoplankton activity and thereby increase ocean CO₂ uptake.

Assets Natural or human-made resources that provide current or future utility, benefit, economic or intrinsic value to natural or human systems.

Atlantic Equatorial Mode See [Atlantic Zonal Mode \(AZM\)](#) under [Tropical Atlantic Variability \(TAV\)](#).

Atlantic Meridional Mode (AMM) See [Tropical Atlantic Variability \(TAV\)](#).

Atlantic Meridional Overturning Circulation (AMOC) See [Meridional overturning circulation \(MOC\)](#).

Atlantic Multi-decadal Oscillation (AMO) See [Atlantic Multi-decadal Variability \(AMV\)](#).

Atlantic Multi-decadal Variability (AMV) Large-scale fluctuations observed from one decade to the next in a variety of instrumental records and [proxy](#) reconstructions over the entire North Atlantic ocean and surrounding continents. Fingerprints of

AMV can be found at the surface *ocean*, which is characterized by swings in basin-scale *sea surface temperature* anomalies reflecting the interaction with the *atmosphere*. The positive phase of the AMV is characterized by anomalous warming over the entire North Atlantic, with the strongest amplitude in the subpolar gyre and along sea ice margin zones in the Labrador Sea and Greenland/Barents Sea and in the subtropical North Atlantic basin to a lower extent. In the AR6 WGI report, the term AMV is preferred to *Atlantic Multi-decadal Oscillation (AMO)* used in previous IPCC reports because there is no preferred time scale of *decadal variability* as the term oscillation would indirectly imply. See Section AIV.2.7 in Annex IV of the AR6 WGI report.

Atlantic Niño See *Atlantic Zonal Mode (AZM)* under *Tropical Atlantic Variability (TAV)*.

Atlantic Zonal Mode (AZM) See *Tropical Atlantic Variability (TAV)*.

Atmosphere The gaseous envelope surrounding the Earth, divided into five layers – the *troposphere* which contains half of the Earth's atmosphere, the *stratosphere*, the mesosphere, the thermosphere and the exosphere, which is the outer limit of the atmosphere. The dry atmosphere consists almost entirely of nitrogen (78.1% volume mixing ratio) and oxygen (20.9% volume mixing ratio), together with a number of trace gases, such as argon (0.93% volume mixing ratio), helium and radiatively active *greenhouse gases (GHGs)* such as *carbon dioxide (CO₂)* (0.04% volume mixing ratio), *methane (CH₄)*, *nitrous oxide (N₂O)* and *ozone (O₃)*. In addition, the atmosphere contains the GHG water vapour (H₂O), whose concentrations are highly variable (0–5% volume mixing ratio) as the sources (*evapotranspiration*) and sinks (precipitation) of water vapour show large spatio-temporal variations, and atmospheric temperature exerts a strong constraint on the amount of water vapour an air parcel can hold. The atmosphere also contains clouds and *aerosols*. See also *Hydrological cycle*, *Stratosphere* and *Troposphere*.

Atmosphere–ocean general circulation model (AOGCM) See *General circulation model (GCM)*.

Atmospheric boundary layer The atmospheric layer adjacent to the Earth's surface that is affected by friction against that boundary surface, and possibly by transport of heat and other variables across that surface (AMS, 2021). The lowest 100 m of the boundary layer (about 10% of the boundary layer thickness), where mechanical generation of turbulence is dominant, is called the surface boundary layer or surface layer.

Atmospheric lifetime See *Lifetime*.

Atmospheric rivers (ARs) Long, narrow (up to a few hundred km wide), shallow (up to a few km deep) and transient corridors of strong horizontal water vapour transport that are typically associated with a low-level jet stream ahead of the cold front of an *extratropical cyclone (ETC)* (Ralph et al., 2018).

Attribution Attribution is defined as the process of evaluating the relative contributions of multiple causal factors to a change or event with an assessment of *confidence*.

Australian and Maritime Continent monsoon (AusMCM) See *Global monsoon*.

Autotrophic respiration *Respiration* by photosynthetic (see *photosynthesis*) organisms (e.g., plants and algae).

Avalanche A mass of snow, ice, earth or rocks, or a mixture of these, falling down a mountainside.

Barystatic See *Sea level change (sea level rise/sea level fall)*.

Basal lubrication Reduction of friction at the base of an *ice sheet* or *glacier* due to lubrication by meltwater. This can allow the glacier or ice sheet to slide over its base. Meltwater may be produced by pressure-induced melting, friction or geothermal heat, or surface melt may drain to the base through holes in the ice.

Baseline/reference See *Reference scenario* (under *Scenario*) and *Reference period*.

Baseline scenario See *Reference scenario* (under *Scenario*).

Bifurcation point See *Tipping point*.

Biodiversity Biodiversity or biological diversity means the variability among living organisms from all sources including, among other things, terrestrial, marine and other aquatic *ecosystems*, and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems (UN, 1992). See also *Ecosystem*.

Bioenergy with carbon dioxide capture and storage (BECCS) *Carbon dioxide capture and storage (CCS)* technology applied to a bioenergy facility. Note that depending on the total emissions of the BECCS supply chain, *carbon dioxide (CO₂)* can be removed from the *atmosphere*. See also *Carbon dioxide capture and storage (CCS)*, *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

Biogenic volatile organic compounds (BVOCs) See *Volatile organic compounds (VOCs)*.

Biogeophysical potential See *Mitigation potential*.

Biological (carbon) pump A series of *ocean* processes through which inorganic carbon (as *carbon dioxide, CO₂*) is fixed as organic matter by *photosynthesis* in sunlit surface water and then transported to the ocean interior, and possibly the sediment, resulting in the storage of carbon.

Biomass Organic material excluding the material that is fossilized or embedded in geological formations. Biomass may refer to the mass of organic matter in a specific area (ISO, 2014).

Biosphere (terrestrial and marine) The part of the Earth system comprising all *ecosystems* and living organisms, in the *atmosphere*, on land (terrestrial biosphere) or in the *oceans* (marine biosphere), including derived dead organic matter, such as litter, soil organic matter and oceanic detritus.

Bipolar seesaw (also inter-hemispheric seesaw, inter-hemispheric asymmetry, hemispheric asymmetry) A phenomenon in which temperature changes in the Northern and Southern hemispheres are related but out of phase, generally inferred to represent a change in the magnitude or sign of net heat transport across the equator. Originally called hemispheric asymmetry and linked to changes in thermohaline overturning

circulation on multi-millennial scales (Mix et al., 1986), later named bipolar seesaw and applied to millennial scales (Broecker, 1998) with a similar thermohaline mechanism (Stocker and Johnsen, 2003). See also *Meridional overturning circulation (MOC)* and *Deglacial or deglaciation or glacial termination*.

Black carbon (BC) A relatively pure form of carbon, also known as soot, arising from the incomplete combustion of fossil fuels, biofuel, and biomass. It only stays in the *atmosphere* for days or weeks. BC is a climate *forcing* agent with strong warming effect, both in the atmosphere and when deposited on snow or ice. See also *Aerosol* and *Atmosphere*.

Blocking Associated with persistent, slow-moving high-pressure systems that obstruct the prevailing westerly winds in the middle and high latitudes and the normal eastward progress of extratropical transient storm systems. It is an important component of the intra-seasonal *climate variability* in the extratropics and can cause long-lived weather conditions such as cold spells in winter and summer *heatwaves*.

Blue carbon Biologically driven carbon fluxes and storage in marine systems that are amenable to management. Coastal blue carbon focuses on rooted vegetation in the coastal zone, such as tidal marshes, mangroves and seagrasses. These *ecosystems* have high carbon burial rates on a per unit area basis and accumulate carbon in their soils and sediments. They provide many non-climatic benefits and can contribute to *ecosystem*-based adaptation. If degraded or lost, coastal blue carbon ecosystems are likely to release most of their carbon back to the *atmosphere*. There is current debate regarding the application of the blue carbon concept to other coastal and non-coastal processes and ecosystems, including the open *ocean*. See also *Sequestration*.

Brewer–Dobson circulation The meridional overturning circulation of the *stratosphere* transporting air upward in the tropics, poleward to the winter hemisphere, and downward at polar and subpolar latitudes. The Brewer–Dobson circulation is driven by the interaction between upward propagating planetary waves and the mean flow.

Burden The total mass of a substance of concern in the *atmosphere*.

Business as usual (BAU) The term business as usual scenario has been used to describe a *scenario* that assumes no additional policies beyond those currently in place and that patterns of socioeconomic development are consistent with recent trends. The term is now used less frequently than in the past. See also *Reference scenario* (under *Scenario*).

¹³C Stable *isotope* of carbon having an atomic weight of approximately 13. Measurements of the ratio of ¹³C/¹²C in *carbon dioxide (CO₂)* molecules are used to infer the importance of different *carbon cycle* and *climate* processes and the size of the terrestrial carbon *reservoir*.

¹⁴C Unstable *isotope* of carbon having an atomic weight of approximately 14 and a half-life of about 5700 years. It is often used for dating purposes going back some 40 kyr. Its variation in time is affected by the magnetic fields of the Sun and Earth, which influence its production from cosmic rays.

Calcification The process of biologically precipitating calcium carbonate minerals to create organism shells, skeletons, otoliths, or other body structures. The chemical equation describing calcification is $\text{Ca}^{2+}(\text{aq}) + 2\text{HCO}_3^{-}(\text{aq}) \rightarrow \text{CaCO}_3(\text{s}) + \text{CO}_2 + \text{H}_2\text{O}$. Aragonite and calcite are two common crystalline forms of biologically precipitated calcium carbonate minerals that have different solubilities.

Calving (of glaciers or ice sheets) The breaking off of discrete pieces of ice from a *glacier*, *ice sheet* or an *ice shelf* into lake or seawater, producing *icebergs*. This is a form of mass loss from an ice body.

Canopy temperature The temperature within the canopy of a vegetation structure.

Carbon budget Refers to two concepts in the literature: (i) an assessment of carbon cycle *sources* and *sinks* on a global level, through the synthesis of evidence for *fossil fuel* and cement emissions, emissions and removals associated with *land use* and *land-use change*, *ocean* and natural land sources and sinks of *carbon dioxide (CO₂)*, and the resulting change in atmospheric CO₂ concentration. This is referred to as the global carbon budget; (ii) the maximum amount of cumulative net global *anthropogenic* CO₂ emissions that would result in limiting *global warming* to a given level with a given probability, taking into account the effect of other anthropogenic climate forcers. This is referred to as the total carbon budget when expressed starting from the *pre-industrial* period, and as the remaining carbon budget when expressed from a recent specified date.

Note 1: Net anthropogenic CO₂ emissions are anthropogenic CO₂ emissions minus anthropogenic CO₂ removals. See also *Carbon dioxide removal (CDR)*.

Note 2: The maximum amount of cumulative net global anthropogenic CO₂ emissions is reached at the time that annual net anthropogenic CO₂ emissions reach zero.

Note 3: The degree to which anthropogenic climate forcers other than CO₂ affect the total carbon budget and remaining carbon budget depends on human choices about the extent to which these forcers are mitigated and their resulting *climate* effects.

Note 4: The notions of a total carbon budget and remaining carbon budget are also being applied in parts of the scientific literature and by some entities at regional, national, or sub-national levels. The distribution of global budgets across individual different entities and emitters depends strongly on considerations of equity and other value judgements.

Carbon cycle The flow of carbon (in various forms, e.g., as *carbon dioxide (CO₂)*, carbon in biomass, and carbon dissolved in the *ocean* as carbonate and bicarbonate) through the *atmosphere*, *hydrosphere*, terrestrial and marine *biosphere* and *lithosphere*. In this report, the reference unit for the global carbon cycle is GtCO₂ or GtC (one Gigatonne = 1 Gt = 10¹⁵ grams; 1 GtC corresponds to 3.664 GtCO₂). See also *Ocean carbon cycle*.

Carbon dioxide (CO₂) A naturally occurring gas, CO₂ is also a by-product of burning *fossil fuels* (such as oil, gas and coal), of burning *biomass*, of *land-use change* (LUC) and of industrial processes (e.g., cement production). It is the principal anthropogenic

greenhouse gas (GHG) that affects the Earth's radiative balance. It is the reference gas against which other GHGs are measured and therefore has a *global warming potential (GWP)* of 1.

Carbon dioxide (CO₂) fertilization The increase of plant *photosynthesis* and water-use efficiency in response to increased atmospheric *carbon dioxide (CO₂)* concentration. Whether this increased photosynthesis translates into increased plant growth and carbon storage on land depends on the interacting effects of temperature, moisture and nutrient availability.

Carbon dioxide capture and storage (CCS) A process in which a relatively pure stream of *carbon dioxide (CO₂)* from industrial and energy-related sources is separated (captured), conditioned, compressed and transported to a storage location for long-term isolation from the *atmosphere*. Sometimes referred to as carbon capture and storage. See also *Bioenergy with carbon dioxide capture and storage (BECCS)*, *Sequestration*, *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

Carbon dioxide removal (CDR) *Anthropogenic* activities removing *carbon dioxide (CO₂)* from the *atmosphere* and durably storing it in geological, terrestrial, or *ocean* reservoirs, or in products. It includes existing and potential anthropogenic enhancement of biological or geochemical CO₂ *sinks* and direct air carbon dioxide capture and storage (DACCS), but excludes natural CO₂ *uptake* not directly caused by human activities. See also *Anthropogenic removals*, *Afforestation*, *Enhanced weathering*, *Ocean alkalization/Ocean alkalinity enhancement*, *Reforestation*, *Bioenergy with carbon dioxide capture and storage (BECCS)* and *Carbon dioxide capture and storage (CCS)*.

Carbon neutrality Condition in which *anthropogenic* CO₂ emissions associated with a subject are balanced by anthropogenic CO₂ removals. The subject can be an entity such as a country, an organization, a district or a commodity, or an activity such as a service and an event. Carbon neutrality is often assessed over the life cycle including indirect ('scope 3') emissions, but can also be limited to the emissions and removals, over a specified period, for which the subject has direct control, as determined by the relevant scheme.

Note 1: Carbon neutrality and *net zero CO₂ emissions* are overlapping concepts. The concepts can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms carbon neutrality and net zero CO₂ emissions are equivalent. At sub-global scales, net zero CO₂ emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while carbon neutrality generally includes emissions and removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant CO₂ emissions and removals.

Note 2: In some cases, achieving carbon neutrality may rely on the supplementary use of offsets to balance emissions that remain after actions by the reporting entity are taken into account.

See also *Greenhouse gas neutrality* and *Net zero CO₂ emissions*.

Carbon sequestration See *Sequestration*.

Carbon sink See *Sink*.

Carbon source See *Source*.

Carbon–climate feedback See *Climate–carbon cycle feedback*.

Carbonaceous aerosol *Aerosol* consisting predominantly of organic substances and *black carbon*.

Carbonate counter pump See *Carbonate pump*.

Carbonate pump Ocean carbon fixation through the biological formation of carbonates, primarily by plankton that generate bio-mineral particles that sink to the *ocean* interior, and possibly the sediment. It is also called carbonate counter-pump, since the formation of calcium carbonate (CaCO₃) is accompanied by the release of *carbon dioxide (CO₂)* to surrounding water and subsequently to the *atmosphere*.

Catchment An area that collects and drains precipitation.

Cenozoic Era The third and current geological Era, which began 66.0 Ma. It comprises the Paleogene, Neogene and *Quaternary* Periods.

Central Pacific El Niño See *El Niño–Southern Oscillation (ENSO)*.

Chaotic A *dynamical system* such as the *climate system*, governed by non-linear deterministic equations, may exhibit erratic or chaotic behaviour in the sense that very small changes in the initial state of the system lead to large and apparently unpredictable changes in its temporal evolution. Such chaotic behaviour limits the *predictability* of the state of a non-linear dynamical system at specific future times, although changes in its statistics may still be predictable given changes in the system parameters or boundary conditions.

Charcoal Material resulting from charring of *biomass*, usually retaining some of the microscopic texture typical of plant tissues; chemically it consists mainly of carbon with a disturbed graphitic structure, with lesser amounts of oxygen and hydrogen.

Chlorofluorocarbons (CFCs) An organic compound that contains chlorine, carbon, hydrogen and fluorine and is used for refrigeration, air conditioning, packaging, plastic foam, insulation, solvents or aerosol propellants. Because they are not destroyed in the lower *atmosphere*, CFCs drift into the upper *atmosphere* where, given suitable conditions, they lead to *ozone (O₃)* depletion. They are some of the *greenhouse gases (GHGs)* covered under the 1987 *Montreal Protocol*, as a result of which manufacturing of these gases has been phased out, and they are being replaced by other compounds, including *hydrofluorocarbons (HFCs)*.

Chronology Arrangement of events according to dates or times of occurrence.

Cirrus cloud thinning (CCT) See *Solar radiation modification (SRM)*.

Clathrate (methane) A partly frozen slushy mix of *methane* gas and ice, usually found in sediments.

Clausius–Clapeyron equation/relationship The thermodynamic relationship between temperature and the vapour pressure of a substance in which two phases of the substance are in equilibrium (e.g., liquid water and water vapour). For gases such as water vapour,

this relation gives the increase in equilibrium (or saturation) vapour pressure per unit change in air temperature.

Climate Climate in a narrow sense is usually defined as the average weather, or more rigorously as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The classical period for averaging these variables is 30 years, as defined by the World Meteorological Organization (WMO). The relevant quantities are most often surface variables such as temperature, precipitation and wind. Climate in a wider sense is the state, including a statistical description, of the *climate system*.

Climate change A change in the state of the *climate* that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external *forcings* such as modulations of the solar cycles, volcanic eruptions and persistent *anthropogenic* changes in the composition of the *atmosphere* or in *land use*. Note that the *United Nations Framework Convention on Climate Change (UNFCCC)*, in its Article 1, defines climate change as: ‘a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods’. The UNFCCC thus makes a distinction between climate change attributable to human activities altering the atmospheric composition and *climate variability* attributable to natural causes. See also *Climate variability*, *Detection and attribution*, *Global warming* and *Ocean acidification (OA)*.

Climate change commitment Climate change commitment is defined as the unavoidable future *climate change* resulting from inertia in the geophysical and socio-economic systems. Different types of climate change commitment are discussed in the literature (see subterms). Climate change commitment is usually quantified in terms of the further change in temperature, but it includes other future changes, for example in the *hydrological cycle*, in *extreme weather events*, in extreme climate events, and in sea level.

Constant composition commitment

The constant composition commitment is the remaining *climate change* that would result if atmospheric composition, and hence *radiative forcing*, were held fixed at a given value. It results from the thermal inertia of the *ocean* and slow processes in the *cryosphere* and land surface.

Constant emissions commitment

The constant emissions commitment is the committed *climate change* that would result from keeping *anthropogenic emissions* constant.

Zero emissions commitment

The zero emissions commitment is an estimate of the subsequent *global warming* that would result after *anthropogenic emissions* are set to zero. It is determined by both inertia in physical *climate system* components (*ocean*, *cryosphere*, land surface) and *carbon cycle* inertia. In its widest sense it refers to emissions of each climate forcer, including *greenhouse gases*, *aerosols* and their *precursors*. The climate response to this can be complex due to the different time scale of response of each climate forcer.

A specific subcategory of zero emissions commitment is the Zero CO₂ Emissions Commitment which refers to the climate system response to CO₂ emissions after setting these to net zero. The CO₂-only definition is of specific use in estimating *remaining carbon budgets*.

Climate extreme (extreme weather or climate event) The occurrence of a value of a weather or *climate* variable above (or below) a threshold value near the upper (or lower) ends of the range of observed values of the variable. By definition, the characteristics of what is called *extreme weather* may vary from place to place in an absolute sense. When a pattern of extreme weather persists for some time, such as a season, it may be classified as an extreme climate event, especially if it yields an average or total that is itself extreme (e.g., high temperature, *drought*, or heavy rainfall over a season). For simplicity, both extreme weather events and extreme climate events are referred to collectively as ‘climate extremes’.

Climate feedback An interaction in which a perturbation in one *climate* quantity causes a change in a second, and the change in the second quantity ultimately leads to an additional change in the first. A negative feedback is one in which the initial perturbation is weakened by the changes it causes; a positive feedback is one in which the initial perturbation is enhanced. The initial perturbation can either be externally forced or arise as part of *internal variability*. See also *Climate–carbon cycle feedback*, *Cloud feedback* and *Ice–albedo feedback*.

Climate feedback parameter A way to quantify the radiative response of the *climate system* to a change induced by a *radiative forcing*. It is quantified as the change in net energy flux at the top of atmosphere for a given change in annual global surface temperature. It has units of W m⁻² °C⁻¹.

Climate forecast See *Climate prediction*.

Climate index A time series constructed from *climate* variables that provides an aggregate summary of the state of the *climate system*. For example, the difference between sea level pressure in Iceland and the Azores provides a simple yet useful historical *North Atlantic Oscillation (NAO)* index. Because of their optimal properties, climate indices are often defined using principal components – linear combinations of climate variables at different locations that have maximum variance subject to certain normalization constraints (e.g., the *Northern Annular Mode (NAM)* and *Southern Annular Mode (SAM)* indices, which are principal components of Northern Hemisphere and Southern Hemisphere gridded pressure anomalies, respectively). Definitions of observational indices for *Modes of climate variability* can be found in Annex IV of the AR6 WGI report.

Climate indicator Measures of the *climate system*, including large-scale variables and climate *proxies*. See also *Climate metrics*.

Key climate indicators

Key indicators constitute a finite set of distinct variables that may collectively point to important overall changes in the *climate system* of broad societal relevance across the atmospheric, oceanic, cryospheric and biospheric domains, with land as an implicit cross-cutting theme. Taken together, these indicators would be expected to both have changed and continue to change in the future in a

coherent and consistent manner. See Cross-Chapter Box 2.2, Table 1 in the AR6 WGI report.

Climate information Information about the past, current state or future of the *climate system* that is relevant for *mitigation*, *adaptation* and *risk management*. It may be tailored or 'co-produced' for specific contexts, taking into account users' needs and values.

Climate metrics Measures of aspects of the overall *climate system* response to *radiative forcing*, such as *equilibrium climate sensitivity (ECS)*, *transient climate response (TCR)*, *transient climate response to cumulative CO₂ emissions (TCRE)* and the *airborne fraction* of *anthropogenic* carbon dioxide. See also *Greenhouse gas emission metric*, *Climate indicator* and *Key climate indicators* (under *Climate indicator*).

Climate model A qualitative or quantitative representation of the *climate system* based on the physical, chemical and biological properties of its components, their interactions and feedback processes and accounting for some of its known properties. The climate system can be represented by models of varying complexity; that is, for any one component or combination of components, a spectrum or hierarchy of models can be identified, differing in such aspects as the number of spatial dimensions, the extent to which physical, chemical or biological processes are explicitly represented, or the level at which empirical parametrizations are involved. There is an evolution towards more complex models with interactive chemistry and biology. Climate models are applied as a research tool to study and simulate the *climate* and for operational purposes, including monthly, seasonal and interannual *climate predictions*. See also *Earth system model (ESM)*, *Earth system model of intermediate complexity (EMIC)*, *Energy balance model (EBM)*, *Simple climate model (SCM)*, *Regional climate model (RCM)*, *Dynamic global vegetation model (DGVM)*, *General circulation model (GCM)* and *Emulators*.

Climate pattern A set of spatially varying coefficients obtained by 'projection' (regression) of *climate* variables onto a *climate index* time series. When the climate index is a principal component, the climate pattern is an eigenvector of the covariance matrix, referred to as an empirical orthogonal function (EOF) in climate science.

Climate prediction A climate prediction or climate forecast is the result of an attempt to produce (starting from a particular state of the *climate system*) an estimate of the actual evolution of the *climate* in the future, for example, at seasonal, interannual or decadal time scales. Because the future evolution of the climate system may be highly sensitive to initial conditions, has *chaotic* elements and is subject to *natural variability*, such predictions are usually probabilistic in nature.

Climate projection Simulated response of the *climate system* to a *scenario* of future emissions or concentrations of *greenhouse gases (GHGs)* and *aerosols* and changes in *land use*, generally derived using *climate models*. Climate projections are distinguished from *climate predictions* by their dependence on the emission/concentration/*radiative forcing* scenario used, which is in turn based on assumptions concerning, for example, future socio-economic and technological developments that may or may not be realized.

Climate response A general term for how the *climate system* responds to a *radiative forcing*.

Climate sensitivity The change in the surface temperature in response to a change in the atmospheric *carbon dioxide (CO₂)* concentration or other *radiative forcing*. See also *Climate feedback parameter*.

Earth system sensitivity

The equilibrium surface temperature response of the coupled *atmosphere–ocean–cryosphere–vegetation–carbon cycle* system to a doubling of the atmospheric *carbon dioxide (CO₂)* concentration is referred to as Earth system sensitivity. Because it allows *ice sheets* to adjust to the external perturbation, it may differ substantially from the *equilibrium climate sensitivity* derived from coupled atmosphere–ocean models.

Effective equilibrium climate sensitivity

An estimate of the surface temperature response to a doubling of the atmospheric *carbon dioxide (CO₂)* concentration that is evaluated from model output or observations for evolving non-equilibrium conditions. It is a measure of the strengths of the *climate feedbacks* at a particular time and may vary with *forcing* history and climate state, and therefore may differ from *equilibrium climate sensitivity*.

Equilibrium climate sensitivity (ECS)

The equilibrium (steady state) change in the surface temperature following a doubling of the atmospheric *carbon dioxide (CO₂)* concentration from *pre-industrial* conditions.

Transient climate response (TCR)

The surface temperature response for the hypothetical scenario in which atmospheric *carbon dioxide (CO₂)* increases at 1% yr⁻¹ from *pre-industrial* to the time of a doubling of atmospheric CO₂ concentration (year 70).

Transient climate response to cumulative CO₂ emissions (TCRE)

The transient surface temperature change per unit cumulative *carbon dioxide (CO₂)* emissions, usually 1000 GtC. TCRE combines both information on the *airborne fraction* of cumulative CO₂ emissions (the fraction of the total CO₂ emitted that remains in the *atmosphere*, which is determined by *carbon cycle* processes) and on the *transient climate response (TCR)*.

Climate services Climate services involve the provision of *climate information* in such a way as to assist decision-making. The service includes appropriate engagement from users and providers, is based on scientifically credible information and expertise, has an effective access mechanism and responds to user needs (Hewitt et al., 2012).

Climate simulation ensemble A group of parallel model simulations characterizing historical *climate* conditions, *climate predictions*, or *climate projections*. Variation of the results across the ensemble members may give an estimate of modelling-based uncertainty. Ensembles made with the same model but different initial conditions characterize the uncertainty associated with internal *climate variability*, whereas multi-model ensembles including simulations by several models also include the effect of model differences. Perturbed parameter ensembles, in which model parameters are varied in a systematic manner, aim to assess the uncertainty resulting from internal model specifications within a single model. Remaining sources of uncertainty unaddressed with model ensembles are related to systematic model errors or biases,

which may be assessed from systematic comparisons of model simulations with observations wherever available.

Climate system The global system consisting of five major components: the *atmosphere*, the *hydrosphere*, the *cryosphere*, the *lithosphere* and the *biosphere* and the interactions between them. The climate system changes in time under the influence of its own internal dynamics and because of *external forcings* such as volcanic eruptions, solar variations, *orbital forcing*, and *anthropogenic forcings* such as the changing composition of the atmosphere and *land-use change*.

Climate threshold A limit within the *climate system* (or its *forcing*) beyond which the behaviour of the system is qualitatively changed. See also *Abrupt climate change* and *Tipping point*.

Climate variability Deviations of *climate* variables from a given mean state (including the occurrence of extremes, etc.) at all spatial and temporal scales beyond that of individual weather events. Variability may be intrinsic, due to fluctuations of processes internal to the *climate system* (*internal variability*), or extrinsic, due to variations in natural or anthropogenic *external forcing* (forced variability). See also *Climate change* and *Modes of climate variability*.

Decadal variability

Decadal variability refers to *climate variability* on decadal time scales. See also *Pacific Decadal Variability (PDV)*, *Atlantic Multi-decadal Oscillation/Variability (AMO/AMV)* and *Pacific Decadal Oscillation (PDO)* (under *Pacific Decadal Variability (PDV)*).

Internal variability

Fluctuations of the climate dynamical system when subject to a constant or periodic *external forcing* (such as the annual cycle). See also *Climate variability*.

Natural variability

Natural variability refers to climatic fluctuations that occur without any human influence, that is, *internal variability* combined with the response to external natural factors such as volcanic eruptions, changes in *solar activity* and, on longer time scales, orbital effects and plate tectonics. See also *Orbital forcing*.

Climate velocity The speed at which isolines of a specified *climate* variable travel across landscapes or seascapes due to changing climate. For example, climate velocity for temperature is the speed at which isotherms move due to changing climate (km yr^{-1}) and is calculated as the temporal change in temperature ($^{\circ}\text{C yr}^{-1}$) divided by the current spatial gradient in temperature ($^{\circ}\text{C km}^{-1}$). It can be calculated using additional climate variables such as precipitation or can be based on the climatic niche of organisms.

Climate–carbon cycle feedback A *climate feedback* involves changes in the properties of the land and ocean *carbon cycle* in response to *climate change*. In the *ocean*, changes in oceanic temperature and circulation could affect the *atmosphere*–ocean *carbon dioxide (CO₂)* flux; on the continents, *climate change* could affect plant *photosynthesis* and soil microbial *respiration* and hence the flux of CO₂ between the atmosphere and the land *biosphere*.

Climatic impact-driver (CID) Climatic impact-drivers (CIDs) are physical *climate system* conditions (e.g., means, events, extremes) that affect an element of society or *ecosystems*. Depending on system

tolerance, CIDs and their changes can be detrimental, beneficial, neutral or a mixture of each across interacting system elements and *regions*. See also *Risk*, *Hazard* and *Impacts (consequences, outcomes)*.

Cloud condensation nuclei (CCN) The subset of *aerosol* particles that serve as an initial site for the condensation of liquid water, which can lead to the formation of cloud droplets, under typical cloud formation conditions. The main factor that determines which *aerosol* particles are CCN at a given supersaturation is their size.

Cloud feedback A *climate feedback* involving changes in any of the properties of clouds as a response to a change in the local or global surface temperature. Understanding cloud feedbacks and determining their magnitude and sign requires an understanding of how a change in *climate* may affect the spectrum of cloud types, the cloud fraction and height, the radiative properties of clouds, and finally the Earth's radiation budget.

Cloud radiative effect The radiative effect of clouds relative to the identical situation without clouds.

Cloud-resolving models (CRMs) Numerical models that are that are of high enough *resolution* and have the necessary physics to represent the dynamical and physical processes of cloud formation.

CMIP6 See *Coupled Model Intercomparison Project (CMIP)*.

CO₂ equivalent (CO₂-eq) emission The amount of *carbon dioxide (CO₂)* emission that would have an equivalent effect on a specified key measure of *climate change*, over a specified time horizon, as an emitted amount of another *greenhouse gas (GHG)* or a mixture of other GHGs. For a mix of GHGs, it is obtained by summing the CO₂-equivalent emissions of each gas. There are various ways and time horizons to compute such equivalent emissions (see *greenhouse gas emission metric*). CO₂-equivalent emissions are commonly used to compare emissions of different GHGs, but should not be taken to imply that these emissions have an equivalent effect across all key measures of climate change. [Note: Under the Paris Rulebook (Decision 18/CMA.1, annex, paragraph 37), parties have agreed to use GWP-100 values from the IPCC AR5 or GWP-100 values from a subsequent IPCC Assessment Report to report aggregate emissions and removals of GHGs. In addition, parties may use other metrics to report supplemental information on aggregate emissions and removals of GHGs.]

Coast The land near to the sea. The term 'coastal' can refer to that land (e.g., as in 'coastal communities'), or to that part of the marine environment that is strongly influenced by land-based processes. Thus, coastal seas are generally shallow and near-shore. The landward and seaward limits of the coastal zone are not consistently defined, either scientifically or legally. Thus, coastal waters can either be considered as equivalent to territorial waters (extending 12 nautical miles/22.2 km from mean low water), or to the full Exclusive Economic Zone, or to shelf seas, with less than 200 m water depth.

Common era (CE) CE (Common Era) and BCE (Before the Common Era) are alternative names for AD (Anno Domini) and BC (Before Christ) in the Gregorian international standard calendar-year system. CE/BCE are preferred in an international context because they are neutral with respect to religion. The numbering of calendar

years is the same under both terminologies. The CE began in year AD 1 and extends to the present day.

Compatible emissions *Earth system models* that simulate the land and ocean *carbon cycle* can calculate *carbon dioxide (CO₂)* emissions that are compatible with a given atmospheric CO₂ concentration trajectory. The compatible emissions over a given period of time are equal to the increase of carbon over that same period of time in the sum of the three active *reservoirs*: the *atmosphere*, the land and the *ocean*.

Compound events See *Compound weather/climate events*.

Compound weather/climate events The terms ‘compound events’, ‘compound extremes’ and ‘compound extreme events’ are used interchangeably in the literature and this report and refer to the combination of multiple drivers and/or *hazards* that contributes to societal and/or environmental *risk* (Zscheischler et al., 2018).

Concentrations scenario See *Scenario*.

Confidence The robustness of a finding based on the type, amount, quality and consistency of *evidence* (e.g., mechanistic understanding, theory, data, models, expert judgement) and on the degree of *agreement* across multiple lines of evidence. In this report, confidence is expressed qualitatively (Mastrandrea et al., 2010).

Constant composition commitment See *Climate change commitment*.

Constant emissions commitment See *Climate change commitment*.

Convection Vertical motion driven by buoyancy forces arising from static instability, usually caused by near-surface cooling or increases in salinity in the case of the *ocean* and near-surface warming or cloud-top radiative cooling in the case of the *atmosphere*. In the atmosphere, convection gives rise to cumulus clouds and precipitation and is effective at both scavenging and vertically transporting chemical species. In the ocean, convection can carry surface waters to deep within the ocean.

Convection-permitting models See *Cloud-resolving models (CRMs)*.

Coral bleaching Loss of coral pigmentation through the loss of intracellular symbiotic algae (known as zooxanthellae) and/or loss of their pigments.

Coral reef An underwater *ecosystem* characterised by structure-building stony corals. Warm-water coral reefs occur in shallow seas, mostly in the tropics, with the corals (animals) containing algae (plants) that depend on light and relatively stable temperature conditions. Cold-water coral reefs occur throughout the world, mostly at water depths of 50–500 m. In both kinds of reef, living corals frequently grow on older, dead material, predominantly made of calcium carbonate (CaCO₃). Both warm- and cold-water coral reefs support high *biodiversity* of fish and other groups and are considered to be especially vulnerable to *climate change*.

Coupled Model Intercomparison Project (CMIP) A *climate* modelling activity from the World Climate Research Programme (WCRP), which coordinates and archives *climate model* simulations

based on shared model inputs by modelling groups from around the world. The CMIP Phase 3 (CMIP3) multi-model dataset includes projections using Special Report on Emissions Scenarios (SRES) scenarios. The CMIP Phase 5 (CMIP5) dataset includes projections using the *Representative Concentration Pathways (RCP)*. The CMIP6 phase involves a suite of common model experiments as well as an ensemble of CMIP-endorsed Model Intercomparison Projects (MIPs).

Cryosphere The components of the Earth system at and below the land and *ocean* surface that are frozen, including snow cover, *glaciers*, *ice sheets*, *ice shelves*, *icebergs*, *sea ice*, lake ice, river ice, *permafrost* and seasonally *frozen ground*.

Cumulative emissions The total amount of emissions released over a specified period of time. See also *Carbon budget* and *Transient climate response to cumulative CO₂ emissions (TCRE)* (under *Climate sensitivity*).

Dansgaard–Oeschger events (D–O events) Millennial-scale events first characterized in Greenland *ice cores* as abrupt warming from a cold *stadial* state to a warmer *interstadial* state, followed by a return to a cold stadial state (Dansgaard et al., 1993), and traced in the *ocean* via deposits of ice-rafted sand grains (Bond and Lotti, 1995). Named after Willi Dansgaard and Hans Oeschger by Bond and Lotti (1995). An example of a D–O event during the most recent *deglacial* transition is the Bølling–Allerød interstadial. Warm D–O events in Greenland are associated with cooling events in Antarctica (Blunier and Brook, 2001) through ocean *thermohaline circulation* (Stocker and Johnsen, 2003). See also *Bipolar seesaw (also interhemispheric seesaw, interhemispheric asymmetry, hemispheric asymmetry)*.

Data assimilation Mathematical method used to combine different sources of information in order to produce the best possible estimate of the state of a system. This information usually consists of observations of the system and a numerical model of the system evolution. Data assimilation techniques are used to create initial conditions for weather forecast models and to construct *reanalyses* describing the trajectory of the *climate system* over the time period covered by the observations.

Dead zones Extremely *hypoxic* (i.e., low-oxygen) areas in *oceans* and lakes, caused by excessive nutrient input from human activities coupled with other factors that deplete the oxygen required to support many marine organisms in bottom and near-bottom water.

Decadal predictability Refers to the notion of *predictability* of the *climate system* on a decadal time scale. See also *Climate prediction, Predictability* and *Decadal prediction*.

Decadal prediction A *climate prediction* on decadal time scales. See also *Predictability* and *Decadal predictability*.

Decadal variability See *Climate variability*.

Deep uncertainty See *Uncertainty*.

Deforestation Conversion of *forest* to non-forest. [Note: For a discussion of the term forest and related terms such as *afforestation, reforestation* and deforestation, see the 2006 IPCC Guidelines for National Greenhouse Gas Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention

on Climate Change (IPCC, 2006, 2019; UNFCCC, 2021a, b).] See also *Afforestation* and *Reforestation*.

Deglacial or deglaciation or glacial termination The period of transition from *glacial* conditions at the end of a glacial period to *interglacial* conditions characterized by a reduction in land ice volume. Gradual changes can be punctuated by *abrupt changes* linked to *stadial/interstadial* events and *bipolar seesaw* aspect. The last deglacial transition occurred between about 18,000 and 11,000 years ago. It encompasses rapid events such as *Meltwater Pulse 1A (MWP-1A)* and millennial-scale fluctuations such as the *Younger Dryas*. See also *Glacial–interglacial cycles* and *Ice age*.

Detection Detection of change is defined as the process of demonstrating that *climate* or a system affected by climate has changed in some defined statistical sense, without providing a reason for that change. An identified change is detected in observations if its *likelihood* of occurrence by chance due to *internal variability* alone is determined to be small, for example, <10%.

Detection and attribution See *Detection* and *Attribution*.

Diatoms Microscopic (2–200 µm) unicellular photosynthetic algae that live in surface waters of lakes, rivers and *oceans* and form shells of opal. In the global ocean, marine diatom species distribution is primarily driven by nutrient availability. On regional scales, their species distribution in ocean sediment cores can be related to past *sea surface temperatures* (Abrantes et al., 2013).

Dimensions of integration In IPCC AR6, concepts used to synthesize the knowledge of *climate change* across not just the physical sciences, but also across *impacts*, *adaptation* and *mitigation* research. The concept of ‘dimensions of integration’ includes (i) emission and *concentration scenarios* underlying the climate change *projections* assessed in this report, (ii) levels of projected global mean temperature change and (iii) total amounts of cumulative carbon emissions for projections.

Direct (aerosol) effect See *Aerosol–radiation interaction*.

Direct air capture (DAC) Chemical process by which a pure *carbon dioxide (CO₂)* stream is produced by capturing CO₂ from the ambient air. See also *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

Disaster A ‘serious disruption of the functioning of a community or a society at any scale due to hazardous events interacting with conditions of exposure, vulnerability and capacity, leading to one or more of the following: human, material, economic and environmental losses and impacts’ (UNGA, 2016). See also *Exposure*, *Hazard*, *Risk* and *Vulnerability*.

Discharge (of ice) See *Mass balance/budget (of glaciers or ice sheets)*.

Dissolved inorganic carbon The combined total of different types of non-organic carbon in (seawater) solution, comprising carbonate (CO₃²⁻), bicarbonate (HCO₃⁻), carbonic acid (H₂CO₃) and *carbon dioxide (CO₂)*.

Diurnal temperature range (DTR) The difference between the maximum and minimum temperature during a 24-hour period.

Dobson unit (DU) A unit to measure the total amount of *ozone* in a vertical column above the Earth’s surface (total column ozone). The number of Dobson units is the thickness in units of 10⁻⁵ m that the *ozone* column would occupy if compressed into a layer of uniform density at a pressure of 1013 hPa and a temperature of 0°C. One DU corresponds to a column of ozone containing 2.69 × 10²⁰ molecules per square metre. A typical value for the amount of ozone in a column of the Earth’s *atmosphere*, although very variable, is 300 DU.

Downscaling A method that derives local- to regional-scale information from larger-scale models or data analyses. Two main methods exist: dynamical downscaling and empirical/statistical downscaling. The dynamical method uses the output of *regional climate models*, global models with variable spatial *resolution*, or high-resolution global models. The empirical/statistical methods are based on observations and develop statistical relationships that link the large-scale atmospheric variables with local/regional climate variables. In all cases, the quality of the driving model remains an important limitation on quality of the downscaled information. The two methods can be combined, for example, applying empirical/statistical downscaling to the output of a regional climate model consisting of a dynamical downscaling of a global climate model.

Drought An exceptional period of water shortage for existing *ecosystems* and the human population (due to low rainfall, high temperature, and/or wind). See also *Plant evaporative stress*.

Agricultural and ecological drought

Depending on the affected biome: a period with abnormal *soil moisture* deficit, which results from combined shortage of precipitation and excess *evapotranspiration*, and during the growing season impinges on crop production or *ecosystem* function in general.

Hydrological drought

A period with large *runoff* and water deficits in rivers, lakes and reservoirs.

Meteorological drought

A period with an abnormal precipitation deficit.

Dynamic global vegetation model (DGVM) A model that simulates vegetation development and dynamics through space and time, as driven by *climate* and other environmental changes.

Dynamical downscaling See *Downscaling*.

Dynamical system A process or set of processes whose evolution in time is governed by a set of deterministic physical laws. The *climate system* is a dynamical system.

Early Eocene Climatic Optimum (EECO) The EECO is a period of geological time that occurred about 53 to 49 million years ago, during the Eocene Epoch. Continental positions at this time were somewhat different to present due to tectonic plate movements. Geological data indicate that the EECO was a period of relatively high atmospheric CO₂ concentrations (about 1150–2500 ppmv) and relative warmth (*global mean surface temperature* was about 10–18°C above the 1850–1900 reference), and polar *ice sheets* were absent.

Earth system model (ESM) A coupled *atmosphere–ocean general circulation model (AOGCM)* in which a representation of

the *carbon cycle* is included, allowing for interactive calculation of atmospheric *carbon dioxide* (CO₂) or *compatible emissions*. Additional components (e.g., atmospheric chemistry, *ice sheets*, dynamic vegetation, nitrogen cycle, but also urban or crop models) may be included. See also *Earth system model of intermediate complexity (EMIC)*.

Earth system model of intermediate complexity (EMIC) EMICs represent *climate* processes at a lower *resolution* or in a simpler, more idealized fashion than an *Earth system model (ESM)*.

Earth's energy budget encompasses the major energy flows of relevance for the *climate system*: the top-of-atmosphere energy budget; the surface energy budget; changes in the global energy inventory and internal flows of energy within the climate system that characterize the climate state.

Top-of-atmosphere energy budget

Comprises the energy fluxes associated with incoming *solar radiation*, reflected solar radiation and emitted thermal radiation. Typical units: W m⁻².

Surface energy budget

Comprises the exchanges of heat at the surface of the Earth associated with both radiative and non-radiative processes. Typical units: W m⁻².

Global energy inventory

Quantifies the excess energy absorbed or lost by the Earth system (*ocean*, land, *atmosphere* and *cryosphere*), mostly in the form of heat, associated with *radiative forcing* of the *climate*. Typical units: Joules.

Global energy budget

For a given time period, the global energy budget expresses the balance between change in the global energy inventory, the time-integrated *effective radiative forcing* and time-integrated *radiative response of the climate system*. Typical units: Joules.

See also *Earth's energy imbalance*.

Earth's energy imbalance The persistent and positive (downward) net top of atmosphere energy flux associated with greenhouse gas *forcing* of the *climate system*. See also *Earth's energy budget* and *Radiative response (of the climate system)*.

Earth system sensitivity See *Climate sensitivity*.

Effective equilibrium climate sensitivity See *Climate sensitivity*.

East Antarctic Ice Sheet (EAIS) See *Ice sheet*.

East Asian monsoon (EAsiaM) See *Global monsoon*.

Eastern boundary upwelling systems (EBUS) Eastern boundary upwelling systems (EBUS) are located at the eastern (landward) edges of major *ocean* basins in both hemispheres, where equatorward winds drive upwelling currents that bring cool, nutrient-rich (and often oxygen-poor) waters from the deep ocean to the surface near the coast.

Eastern Pacific El Niño See *El Niño–Southern Oscillation (ENSO)*.

Economic potential See *Mitigation potential*.

Ecosystem A functional unit consisting of living organisms, their non-living environment and the interactions within and between them. The components included in a given ecosystem and its spatial boundaries depend on the purpose for which the ecosystem is defined: in some cases, they are relatively sharp, while in others they are diffuse. Ecosystem boundaries can change over time. Ecosystems are nested within other ecosystems, and their scale can range from very small to the entire *biosphere*. In the current era, most ecosystems either contain people as key organisms or are influenced by the effects of human activities in their environment.

Effective radiative forcing (ERF) See *Radiative forcing*, *Aerosol effective radiative forcing (ERF_{ari+aci})* (under *Aerosol–radiation interaction*), *Effective radiative forcing (or effect) due to aerosol–cloud interactions (ERF_{aci})* (under *Aerosol–cloud interaction*) and *Effective radiative forcing (or effect) due to aerosol–radiation interactions (ERF_{ari})* (under *Aerosol–radiation interaction*).

Ekman transport The total transport resulting from a balance between the Coriolis force and the frictional stress due to the action of the wind on the *ocean* surface.

El Niño See *El Niño–Southern Oscillation (ENSO)*.

El Niño–Southern Oscillation (ENSO) The term El Niño was initially used to describe a warm-water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. It has since become identified with warming of the tropical Pacific Ocean east of the dateline. This oceanic event is associated with a fluctuation of a global-scale tropical and subtropical surface pressure pattern called the Southern Oscillation. This coupled *atmosphere–ocean* phenomenon, with preferred time scales of two to about seven years, is known as the El Niño–Southern Oscillation (ENSO). The warm and cold phases of ENSO are called El Niño and La Niña, respectively. ENSO is often measured by the surface pressure anomaly difference between Tahiti and Darwin and/or the *sea surface temperatures* in the central and eastern equatorial Pacific. This phenomenon has a great impact on the wind, sea surface temperature and precipitation patterns in the tropical Pacific. It has climatic effects throughout the Pacific region and in many other parts of the world through global *teleconnections*. See Section AIV.2.3 in Annex IV of the AR6 WGI report.

Central Pacific El Niño

An El Niño event in which *sea surface temperature* anomalies are stronger in the central equatorial Pacific than in the east. Also known as a Modoki El Niño event.

Eastern Pacific El Niño

An El Niño event in which *sea surface temperature* anomalies are largest in the eastern tropical Pacific.

Electromagnetic spectrum Wavelength, frequency or energy range of all electromagnetic radiation. In terms of *solar radiation*, the spectral irradiance is the power arriving at the Earth per unit area, per unit wavelength.

Elevation-dependent warming (EDW) Characteristic of many regions where mountains are located, in which past and/or future surface air temperature changes vary neither uniformly nor linearly with elevation. In many cases, warming is enhanced within or above a certain elevation range.

Emergence (of the climate signal) Emergence of a *climate change* signal or trend refers to when a change in *climate* (the ‘signal’) becomes larger than the amplitude of natural or internal variations (defining the ‘noise’). This concept is often expressed as a ‘signal-to-noise’ ratio and emergence occurs at a defined threshold of this ratio (e.g., $S/N > 1$ or 2). Emergence can refer to changes relative to a historical or modern baseline (usually at least 20 years long) and can also be expressed in terms of time (*time of emergence*) or in terms of a global warming level. Emergence is also used to refer to a time when we can expect to see a response to reducing *greenhouse gas (GHG)* emissions (emergence with respect to *mitigation*). Emergence can be estimated using observations and/or model simulations. See also *Time of emergence (ToE)*.

Emergent constraint An attempt to reduce the uncertainty in *climate projections*, using an ensemble of *Earth system models (ESMs)* to relate a specific feedback or future change to an observation of the past or current *climate* (typically some trend, variability or change in variability).

Emission factor/Emissions intensity A coefficient that quantifies the emissions or removals of a gas per unit activity. Emission factors are often based on a sample of measurement data, averaged to develop a representative rate of emission for a given activity level under a given set of operating conditions.

Emission pathways See *Pathways*.

Emissions See *Cumulative emissions*, *Anthropogenic emissions*, *Fossil fuel emissions*, *Non-CO₂ emissions and radiative forcing* and *Negative greenhouse gas emissions*. See also *Emissions scenario* (under *Scenario*), and *Emission pathways*.

Emulation Reproducing the behaviour of complex, process-based models (namely, *Earth system models, ESMs*) via simpler approaches, using either *emulators* or *simple climate models (SCMs)*. The computational efficiency of emulating approaches opens new analytical possibilities given that ESMs take a lot of computational resources for each simulation. See also *Emulators* and *Simple climate model (SCM)*.

Emulators A broad class of heavily parametrized models (‘simple climate models’), statistical methods like neural networks, genetic algorithms or other artificial intelligence approaches designed to reproduce the responses of more complex, process-based *Earth system models (ESMs)*. The main application of emulators is to extrapolate insights from ESMs and observational constraints to a larger set of *emission scenarios*. See also *Emulation* and *Simple climate model (SCM)*.

Energy balance model (EBM) An energy balance model is a simplified climate model that is typically used as an emulator of climate to analyse the energy budget of the Earth to compute changes in the *climate*. In its simplest form, there is no explicit spatial dimension, and the model then provides an estimate of the changes in globally averaged temperature computed from the changes in radiation. This zero-dimensional energy balance model can be extended to a one-dimensional or two-dimensional model if changes to the energy budget with respect to latitude, or both latitude and longitude, are explicitly considered.

Energy balance The difference between the total incoming and total outgoing energy. If this balance is positive, warming occurs; if it is negative, cooling occurs. Averaged over the globe and over long time periods, this balance must be zero. Because the *climate system* derives virtually all its energy from the Sun, zero balance implies that, globally, the absorbed *solar radiation*, that is, *incoming solar radiation* minus reflected *solar radiation* at the top of the *atmosphere* and *outgoing longwave radiation* emitted by the *climate system* are equal.

Energy budget (of the Earth) The Earth is a physical system with an energy budget that includes all gains of incoming energy and all losses of outgoing energy. The Earth’s energy budget is determined by measuring how much energy comes into the Earth system from the Sun, how much energy is lost to space, and accounting for the remainder on Earth and its *atmosphere*. *Solar radiation* is the dominant source of energy into the Earth system. Incoming solar energy may be scattered and reflected by clouds and *aerosols* or absorbed in the atmosphere. The transmitted radiation is then either absorbed or reflected at the Earth’s surface. The average *albedo* of the Earth is about 0.3, which means that 30% of the incident solar energy is reflected into space, while 70% is absorbed by the Earth. Radiant solar or shortwave energy is transformed into sensible heat, latent energy (involving different water states), potential energy, and kinetic energy before being emitted as *infrared radiation*. With the average surface temperature of the Earth of about 15°C (288 K), the main outgoing energy flux is in the infrared part of the spectrum. See also *Sensible heat flux* and *Latent heat flux*.

Enhanced weathering A proposed method to increase the natural rate of removal of *carbon dioxide (CO₂)* from the *atmosphere* using silicate and carbonate rocks. The active surface area of these minerals is increased by grinding, before they are actively added to soil, beaches or the open *ocean*. See also *Carbon dioxide removal (CDR)* and *Anthropogenic removals*.

Ensemble A collection of comparable datasets that reflect variations within the bounds of one or more sources of *uncertainty* and that, when averaged, can provide a more robust estimate of underlying behaviour. Ensemble techniques are used by the observational, *reanalysis* and modelling communities. See also *Climate simulation ensemble*.

Equilibrium and transient climate experiment An equilibrium climate experiment is a *climate model* experiment in which the model is allowed to fully adjust to a change in *radiative forcing*. Such experiments provide information on the difference between the initial and final states of the model, but not on the time-dependent response. If the forcing is allowed to evolve gradually according to a prescribed *emissions scenario*, the time-dependent response of a climate model may be analysed. Such an experiment is called a transient climate experiment.

Equilibrium climate sensitivity (ECS) See *Climate sensitivity*.

Equilibrium line The spatially averaged boundary at a given moment, usually chosen as the seasonal *mass budget* minimum at the end of summer, between the region on a *glacier* where there is a net annual loss of ice mass (ablation area) and that where there is a net annual gain (*accumulation* area). The altitude of this boundary is referred to as equilibrium line altitude (ELA).

Equivalent carbon dioxide (CO₂) emission See *CO₂ equivalent (CO₂-eq) emission*.

Eutrophication Over-enrichment of water by nutrients such as nitrogen and phosphorus. It is one of the leading causes of water quality impairment. The two most acute symptoms of eutrophication are *hypoxia* (or oxygen depletion) and harmful algal blooms.

Evaporation The physical process by which a liquid (e.g., water) becomes a gas (e.g., water vapour).

Evapotranspiration The combined processes through which water is transferred to the *atmosphere* from open water and ice surfaces, bare soil, and vegetation that make up the Earth's surface.

Potential evapotranspiration The potential rate of water loss from wet soils and from plant surfaces, without any limits imposed by the water supply.

Evidence Data and information used in the scientific process to establish findings. In this report, the degree of evidence reflects the amount, quality and consistency of scientific/technical information on which the Lead Authors are basing their findings. See also *Agreement, Confidence, Likelihood* and *Uncertainty*.

Exposure The presence of people; *livelihoods*; species or *ecosystems*; environmental functions, services, and resources; infrastructure; or economic, social, or cultural assets in places and settings that could be adversely affected.

Extended concentration pathways (ECPs) See *Representative concentration pathways (RCPs)* (under *Pathways*).

External forcing External forcing refers to a *forcing* agent outside the *climate system* causing a change in the climate system. Volcanic eruptions, solar variations and changes in Earth's orbit, as well as *anthropogenic* changes in the composition of the *atmosphere* or in *land use* are external forcings. See also *Orbital forcing*.

Extratropical cyclone (ETC) Any cyclonic-scale storm that is not a *tropical cyclone*. Usually refers to a mid- or high-latitude migratory storm system formed in regions of large horizontal temperature variations. Sometimes called extratropical storm or extratropical low.

Extratropical jets Extratropical jets are wind maxima in the upper *troposphere* marking zones of baroclinic instability. Anomalies in the position of these jets are often associated with storms, *blocking*, and weather extremes.

Extreme climate event See *Climate extreme (extreme weather or climate event)*.

Extreme coastal water level (ECWL) See *Extreme sea level (ESL)*.

Extreme sea level (ESL) The occurrence of an exceptionally low or high local sea surface height, arising from (a combination of) short-term phenomena (e.g., *storm surges*, tides and waves). *Relative sea level changes* affect extreme sea levels directly by shifting the mean water levels and indirectly by modulating the propagation of tides, waves and/or surges due to increased water depth. In addition, extreme sea levels can be influenced by changes in the frequency, tracks or strength of weather systems and storms, or due to anthropogenically induced changes such as the

modification of coastlines or dredging. In turn, changes in any or all of the contributions to extreme sea levels may lead to long-term relative sea level changes. Alternate expressions for ESL may be used depending on the processes resolved.

Extreme still water level (ESWL) refers to the combined contribution of relative sea level change, tides and storm-surges. Wind-waves also contribute to coastal sea level via three processes: infragravity waves (lower frequency gravity waves generated by the wind waves), wave setup (time-mean sea level elevation due to wave energy dissipation), and swash (vertical displacement up the shore-face induced by individual waves). Extreme total water level (ETWL) is the ESWL plus wave setup. When considering coastal impacts, swash is also important, and Extreme coastal water level (ECWL) is used. See also *Storm surge* and *Sea level change (sea level rise/sea level fall)*.

Extreme still water level (ESWL) See *Extreme sea level (ESL)*.

Extreme total water level (ETWL) See *Extreme sea level (ESL)*.

Extreme weather event An event that is rare at a particular place and time of year. Definitions of 'rare' vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th percentile of a probability density function estimated from observations. By definition, the characteristics of what is called extreme weather may vary from place to place in an absolute sense. See also *Climate extreme (extreme weather or climate event)*.

Extreme/heavy precipitation event An extreme/heavy precipitation event is an event that is of very high magnitude with a very rare occurrence at a particular place. Types of extreme precipitation may vary depending on its duration (hourly, daily or multi-days (e.g., 5 days)) though all of them qualitatively represent high magnitude. The intensity of such events may be defined with a block maxima approach such as annual maxima or with a peaks over threshold approach, such as rainfall above the 95th or 99th percentile at a particular place.

Faculae Bright patches on the Sun. The area covered by faculae is greater during periods of high *solar activity*.

Feedback See *Climate feedback*.

Fine-mode aerosol optical depth See *Aerosol optical depth (AOD)*.

Fingerprint The *climate* response pattern in space and/or time to a specific *forcing* is commonly referred to as a fingerprint. The spatial patterns of sea level response to melting of *glaciers* or *ice sheets* (or other changes in surface loading) are also referred to as fingerprints. Fingerprints are used to detect the presence of this response in observations and are typically estimated using forced *climate model* simulations. See also *Detection* and *attribution*.

Fire weather Weather conditions conducive to triggering and sustaining wildfires, usually based on a set of indicators and combinations of indicators including temperature, *soil moisture*, humidity, and wind. Fire weather does not include the presence or absence of fuel load.

Firn Snow that has survived at least one *ablation* season but has not been transformed to *glacier* ice. Its pore space is at least partially interconnected, allowing air and water to circulate. Firn densities typically are 400–830 kg m⁻³.

Fitness-for-purpose The suitability of a model (or other resource, such as a dataset or method) for a particular task, such as quantifying the contribution of increased *greenhouse gas* concentrations to recent changes in *global mean surface temperature* or projecting changes in *drought* frequency in a region under a given *scenario*. Assessment of a model's fitness-for-purpose can be informed both by how the model represents relevant physical processes and by how it scores on relevant performance metrics.

Flaring Open air burning of waste gases and volatile liquids, through a chimney, at oil wells or rigs, in refineries or chemical plants, and at landfills.

Flood The overflowing of the normal confines of a stream or other water body, or the accumulation of water over areas that are not normally submerged. Floods can be caused by unusually heavy rain, for example during storms and cyclones. Floods include river (fluvial) floods, flash floods, urban floods, rain (pluvial) floods, sewer floods, *coastal* floods and *glacial lake outburst floods (GLOFs)*.

Flux A movement (a flow) of matter (e.g., water vapour, particles), heat or energy from one place to another, or from one medium (e.g., land surface) to another (e.g., atmosphere).

Foraminifera Single-celled, sand-sized marine organisms (protists) that possess a hard test mainly composed of agglutinated walls (detrital grains glued together with organic cement) or calcium carbonate (predominantly calcite). They are used to reconstruct a range of (paleo)environmental variables such as salinity, temperature, oxygenation, oxygen isotope composition and organic and nutrient flux.

Forcing See *Radiative forcing*.

Forest A vegetation type dominated by trees. Many definitions of the term forest are in use throughout the world, reflecting wide differences in biogeophysical conditions, social structure and economics. [Note: For a discussion of the term forest in the context of National GHG inventories, see the 2006 IPCC Guidelines for National GHG Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019; UNFCCC, 2021a, b).] See also *Afforestation*, *Deforestation* and *Reforestation*.

Fossil fuel emissions Emissions of *greenhouse gases (GHGs)* (in particular *carbon dioxide (CO₂)*), other trace gases and *aerosols* resulting from the combustion of fuels from fossil carbon deposits such as oil, gas and coal.

Fossil fuels Carbon-based fuels from fossil hydrocarbon deposits, including coal, oil and natural gas.

Free atmosphere The atmospheric layer that is negligibly affected by friction against the Earth's surface, and which is above the *atmospheric boundary layer*.

Frozen ground Soil or rock in which part or all of the pore water consists of ice. See also *Active layer* and *Permafrost*.

General circulation The large-scale motions of the *atmosphere* and the *ocean* as a consequence of differential heating on a rotating Earth. General circulation contributes to the *energy balance* of the system through transport of heat and momentum.

General circulation model (GCM) A numerical representation of the *atmosphere–ocean–sea ice* system based on the physical, chemical and biological properties of its components, their interactions and feedback processes. General circulation models are used for weather forecasts, seasonal to *decadal prediction*, and *climate projections*. They are the basis of the more complex *Earth system models (ESMs)*. See also *Climate model*.

Geocentric sea level change See *Sea level change (sea level rise/sea level fall)*.

Geoid The equipotential surface having the same geopotential at each latitude and longitude around the world (geodesists denote this potential W0) that best approximates the mean sea level. It is the surface of reference for measurement of altitude. In practice, several variations of definitions of the geoid exist depending on the way the permanent tide (the zero-frequency gravitational tide due to the Sun and Moon) is considered in geodetic studies.

Geostrophic winds or currents A wind or current that is in balance with the horizontal pressure gradient and the Coriolis force, and thus is outside of the influence of friction. Thus, the wind or current is directly parallel to isobars and its speed is proportional to the horizontal pressure gradient.

Glacial isostatic adjustment (GIA) The ongoing changes in *gravity*, *rotation and viscoelastic solid Earth deformation (GRD)* in response to past changes in the distribution of ice and water on Earth's surface. On a time scale of decades to tens of millennia following mass redistribution, Earth's mantle flows viscously as it evolves toward isostatic equilibrium, causing solid Earth movement and *geoid* changes, which can result in regional-to-local sea level variations. See also *Sea level change (sea level rise/sea level fall)*.

Glacial lake outburst flood (GLOF)/Glacier lake outburst A sudden release of water from a glacier lake, including any of the following types – a glacier-dammed lake, a pro-glacial moraine-dammed lake or water that was stored within, under or on the *glacier*.

Glacial or glaciation A period characterized by the establishment of expanded *ice sheets* and *glaciers*, and associated with global mean sea level (GMSL) substantially lower than present; generally coincides with even-numbered *marine isotope stages*. Glacial intervals were interrupted by *interglacial* intervals. The Last Glacial Maximum (LGM) is a specific interval within the most recent glaciation, when ice sheets were near their global maximum volume (Clark et al., 2009; Gowan et al., 2021) and GMSL was nearly at its lowest level (Lambeck et al., 2014; Yokoyama et al., 2018). Local or regional glacial maxima may be diachronous, for example ranging from about 29,000 years ago and 16,000 years ago. For purposes of global synthesis, IPCC AR6 adopts a practical chronostratigraphic definition of LGM of 23,000–19,000 years BP (before 1950; chronozone level 1 of Mix et al., 2001). For modelling purposes, LGM is defined by the model time step nearest to the centre of this interval, 21,000 years ago (Kageyama et al., 2017). See also *Deglacial or deglaciation or glacial termination*, *Glacial–interglacial cycles*, *Ice age* and *Interglacial or interglaciation*.

Glacial termination See *Deglacial or deglaciation or glacial termination*.

Glacial–interglacial cycles Phase of the Earth’s history marked by large changes in continental ice volume and global sea level. See also *Glacial or glaciation*, *Deglacial or deglaciation or glacial termination*, *Interglacial or interglaciation* and *Ice age*.

Glaciated State of a surface that was covered by *glacier* ice in the past, but not at present. See also *Glacierized*.

Glacier A perennial mass of ice, and possibly firn and snow, originating on the land surface by accumulation and compaction of snow and showing evidence of past or present flow. A glacier typically gains mass by *accumulation* of snow and loses mass by *ablation*. Land ice masses of continental size (>50,000 km²) are referred to as *ice sheets* (Cogley et al., 2011).

Outlet glacier A *glacier*, usually between rock walls, that is part of, and drains, an *ice sheet*. See also *Ice stream*.

Glacierized A surface that is currently covered by *glacier* ice. See also *Glaciated*.

Global carbon budget See *Carbon budget*.

Global dimming Global dimming refers to the observed widespread reduction in the amount of *solar radiation* received at the Earth’s surface from the 1950s to the 1980s, with an increase in *anthropogenic* aerosol emissions appearing to have contributed. This was followed by a partial recovery since the 1990s (‘brightening’), particularly in industrialized areas, coincident with a reduction in anthropogenic *aerosol* emissions.

Global mean sea level (GMSL) change See *Sea level change (sea level rise/sea level fall)*.

Global mean surface air temperature (GSAT) Global average of near-surface air temperatures over land, *oceans* and *sea ice*. Changes in GSAT are often used as a measure of global temperature change in *climate models*. See also *Global mean surface temperature (GMST)*.

Global mean surface temperature (GMST) Estimated global average of near-surface air temperatures over land and *sea ice*, and *sea surface temperature (SST)* over ice-free *ocean* regions, with changes normally expressed as departures from a value over a specified *reference period*. See also *Global mean surface air temperature (GSAT)*.

Global monsoon The global monsoon (GM) is a global-scale solstitial mode that dominates the annual variation of tropical and sub-tropical precipitation and circulation. The GM domain is defined as the area where the annual range of precipitation (local summer minus winter mean precipitation rate) is greater than 2.5 mm day⁻¹, following on from the definition as in Kitoh et al. (2013). Further details on how the GM is defined, used and related to regional monsoons throughout the Report are provided by Annex V in the AR6 WGI report.

Australian and Maritime Continent monsoon (AusMCM)

The Australian–Maritime Continent monsoon (AusMCM) occurs during December–January–February, with the large-scale shift of the *Inter-tropical Convergence Zone* into the Southern Hemisphere and covering northern Australia and the Maritime Continent up to 10°N. The AusMCM is characterized by the seasonal reversal of prevailing easterly winds to westerly winds and the onset of periods of active

convection and heavy rainfall. Over northern Australia, the monsoon season generally lasts from December to March and is associated with west to north-westerly inflow of moist winds, producing convection and heavy precipitation. Over the Maritime Continent, the main rainy season south of the equator is centred on December to February with north-westerly monsoon flow at low levels. Further details on how AusMCM is defined and used throughout the Report are provided in Annex V.

East Asian monsoon (EAsiaM)

The East Asian monsoon (EAsiaM) is the seasonal reversal in wind and precipitation occurring over East Asia, including eastern China, Japan and the Korean peninsula. In contrast to the other monsoons it extends quite far north, out of the tropical belt, and it is largely influenced by subtropical systems and by disturbances from the mid-latitudes. The EAsiaM manifests during boreal summer with warm and wet southerly winds, but also during boreal winter with cold and dry northerly winds. In late April/early May, rainfall onsets in the central Indochina Peninsula, and in mid-June the rainy season arrives over East Asia with the formation of the Meiyu front along the Yangtze River valley, Changma in Korea and Baiu in Japan. In July, the monsoon advances up to North China, the Korean peninsula and central Japan. During boreal winter, strong north-westerlies manifest over north and north-east China, Korea and Japan, while strong north-easterlies arrive along the coast of East Asia. Further details on how EAsiaM is defined and used throughout the Report are provided in Annex V.

North American monsoon (NAmerM)

The North American monsoon (NAmerM) is a regional-scale atmospheric circulation system with increases in summer precipitation over northwestern Mexico and southwest United States. The monsoonal characteristics of the region include a pronounced annual maximum of precipitation in boreal summer (June–July–August) accompanied by a surface low pressure system and an upper-level anticyclone, although seasonal reversal of the surface winds is primarily limited to the northern Gulf of California. Further details on how NAmerM is defined and used throughout the Report are provided in Annex V.

South American monsoon (SAmerM)

The South American monsoon (SAmerM) is a regional circulation characterized by inflow of low-level winds from the Atlantic to South America, including Brazil, Peru, Bolivia and northern Argentina, associated with the development of surface pressure gradients (and intense precipitation) during austral summer (December–January–February). During September–October–November, areas of intense *convection* migrate from northwestern South America to the south. Associated with this regime, an upper-tropospheric anticyclone (a.k.a. the Bolivian High) forms over the Altiplano region during the monsoon onset. The SAmerM then retreats during March–April–May with a northeastward migration of the convection. Further details on how SAmerM is defined and used throughout the Report are provided in Annex V.

South and South East Asian monsoon (SAsiaM)

The South and South East Asian monsoon (SAsiaM) is characterized by pronounced seasonal reversals of wind and precipitation. The SAsiaM region extends across vast geographical areas and several countries, including India, Bangladesh, Nepal, Myanmar, Sri Lanka,

Pakistan, Thailand, Laos, Cambodia, Vietnam and the Philippines. The SAsiaM starts in late May/early June and progresses towards the northeast, ending in late September/early October. During the core monsoon season, maxima of SAsiaM precipitation are located over the west coast, north-east and central north India, Myanmar and Bangladesh, whereas minima are located over north-west and south-eastern India, western Pakistan, and south-eastern and northern Sri Lanka. Further details on how SAsiaM is defined and used throughout the Report are provided in Annex V.

West African monsoon (WAFriM)

The West African monsoon (WAFriM) is a seasonal reversal in wind and precipitation whose domain includes Benin, Burkina-Faso, northern Cameroon, Cape Verde, northern Central African Republic, Chad, Gambia, Ghana, Guinea, Guinea Bissau, Ivory Coast, Liberia, Mali, Mauritania, Niger, Nigeria, Senegal, Sierra Leone and Togo. The WAFriM is characterized by the northward progression from May to September of moist low-level south-westerlies from the Gulf of Guinea. In May and June, rainfall essentially remains along the Guinean coast with a maximum occurring near 5°N, followed by a sudden decrease of rainfall, marking the 'short dry season' in the Guinean coast and the monsoon onset in the Sahel. Then rainfall continues to progress northward up to about 18–20°N, with a maximum near 12°N in late August/September, until it retreats starting from October towards the Guinean coast for a second maximum. Further details on how WAFriM is defined and used throughout the Report are provided in Annex V.

Global surface temperature See *Global mean surface temperature (GMST)* and *Global mean surface air temperature (GSAT)*. See also *Global warming*.

Global warming Global warming refers to the increase in *global surface temperature* relative to a baseline *reference period*, averaging over a period sufficient to remove interannual variations (e.g., 20 or 30 years). A common choice for the baseline is 1850–1900 (the earliest period of reliable observations with sufficient geographic coverage), with more modern baselines used depending upon the application. See also *Climate change* and *Climate variability*.

Global warming potential (GWP) An index measuring the *radiative forcing* following an emission of a unit mass of a given substance, accumulated over a chosen time horizon, relative to that of the reference substance, *carbon dioxide (CO₂)*. The GWP thus represents the combined effect of the differing times these substances remain in the *atmosphere* and their effectiveness in causing radiative forcing. See also *Lifetime* and *Greenhouse gas emission metric*.

Gravitational, rotational and deformational (GRD) effects See *Sea level change (sea level rise/sea level fall)*.

Gravity Recovery and Climate Experiment (GRACE) A pair of satellites that measured the Earth's gravity field anomalies from 2002 to 2017. These fields have been used, among other things, to study mass changes of the polar *ice sheets* and *glaciers*.

Greenhouse effect The infrared radiative effect of all infrared-absorbing constituents in the *atmosphere*. *Greenhouse gases (GHGs)*, clouds, and some *aerosols* absorb *terrestrial radiation* emitted by the Earth's surface and elsewhere in the atmosphere. These substances emit *infrared radiation* in all directions, but, everything else being

equal, the net amount emitted to space is normally less than would have been emitted in the absence of these absorbers because of the decline of temperature with altitude in the *troposphere* and the consequent weakening of emission. An increase in the concentration of GHGs increases the magnitude of this effect; the difference is sometimes called the enhanced greenhouse effect. The change in a GHG concentration because of *anthropogenic emissions* contributes to an instantaneous radiative forcing. Earth's surface temperature and *troposphere* warm in response to this *forcing*, gradually restoring the radiative balance at the top of the atmosphere.

Greenhouse gas emission metric A simplified relationship used to quantify the effect of emitting a unit mass of a given *greenhouse gas* on a specified key measure of *climate change*. A relative GHG emission metric expresses the effect from one gas relative to the effect of emitting a unit mass of a reference GHG on the same measure of climate change. There are multiple emission metrics, and the most appropriate metric depends on the application. GHG emission metrics may differ with respect to (i) the key measure of climate change they consider, (ii) whether they consider climate outcomes for a specified point in time or integrated over a specified time horizon, (iii) the time horizon over which the metric is applied, (iv) whether they apply to a single emission pulse, emissions sustained over a period of time, or a combination of both, and (v) whether they consider the climate effect from an emission compared to the absence of that emission or compared to a reference emissions level or climate state.

Notes: Most relative GHG emission metrics (such as the *global warming potential (GWP)*, global temperature change potential (GTP), global damage potential, and GWP*) use *carbon dioxide (CO₂)* as the reference gas. Emissions of non-CO₂ gases, when expressed using such metrics, are often referred to as 'carbon dioxide equivalent' emissions. A metric that establishes equivalence regarding one key measure of the *climate system* response to emissions does not imply equivalence regarding other key measures. The choice of a metric, including its time horizon, should reflect the policy objectives for which the metric is applied.

Greenhouse gas neutrality Condition in which metric-weighted anthropogenic *greenhouse gas (GHG)* emissions associated with a subject are balanced by metric-weighted anthropogenic GHG removals. The subject can be an entity such as a country, an organization, a district or a commodity, or an activity such as a service or an event. GHG neutrality is often assessed over the life cycle, including indirect ('scope 3') emissions, but can also be limited to the emissions and removals, over a specified period, for which the subject has direct control, as determined by the relevant scheme. The quantification of GHG emissions and removals depends on the GHG emission metric chosen to compare emissions and removals of different gases, as well as the time horizon chosen for that metric.

Note 1: GHG neutrality and net zero GHG emissions are overlapping concepts. The concepts can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms greenhouse gas neutrality and net zero greenhouse gas emissions are equivalent. At sub-global scales, net zero greenhouse gas emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while greenhouse gas neutrality generally includes emissions and removals within and

beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant emissions and removals.

Note 2. Under the Paris Rulebook (Decision 18/CMA.1, annex, paragraph 37), parties have agreed to use GWP100 values from the IPCC AR5 or GWP100 values from a subsequent IPCC Assessment Report to report aggregate emissions and removals of GHGs. In addition, parties may use other metrics to report supplemental information on aggregate emissions and removals of GHGs.

Note 3: In some cases, achieving greenhouse gas neutrality may rely on the supplementary use of offsets to balance emissions that remain after actions by the reporting entity are taken into account.

See also *Carbon neutrality*, *Greenhouse gas emission metric* and *Net zero greenhouse gas emissions*.

Greenhouse gases (GHGs) Gaseous constituents of the *atmosphere*, both natural and *anthropogenic*, that absorb and emit radiation at specific wavelengths within the spectrum of radiation emitted by the Earth's surface, by the atmosphere itself, and by clouds. This property causes the *greenhouse effect*. Water vapour (H_2O), *carbon dioxide* (CO_2), *nitrous oxide* (N_2O), *methane* (CH_4) and *ozone* (O_3) are the primary GHGs in the Earth's atmosphere. Human-made GHGs include *sulphur hexafluoride* (SF_6), *hydrofluorocarbons* (HFCs), *chlorofluorocarbons* (CFCs) and perfluorocarbons (PFCs); several of these are also O_3 -depleting (and are regulated under the *Montreal Protocol*). See also *Well-mixed greenhouse gas*.

Greenland Ice Sheet (GrIS) See *Ice sheet*.

Gross Primary Production (GPP) See *Primary production*.

Ground-level ozone Atmospheric *ozone* (O_3) is formed naturally or from human-emitted *precursors* near Earth's surface, thus affecting human health, agriculture and *ecosystems*. Ozone is a *greenhouse gas* (GHG), but ground-level ozone, unlike stratospheric ozone, also directly affects organisms at the surface. Ground-level ozone is sometimes referred to as tropospheric ozone, although much of the *troposphere* is well above the surface and thus does not directly expose organisms at the surface.

Grounding line The junction between a *glacier* or *ice sheet* and an *ice shelf*; the place where ice starts to float. This junction normally occurs over a zone, rather than at a line.

Gyre Basin-scale *ocean* horizontal circulation pattern with slow flow circulating around the ocean basin, closed by a strong and narrow (100 to 200 km wide) boundary current on the western side. The subtropical gyres in each ocean are associated with high pressure in the centre of the gyres; the subpolar gyres are associated with low pressure.

Hadley cell See *Hadley circulation*.

Hadley circulation A direct, thermally driven overturning cell in the *atmosphere* consisting of poleward flow in the upper *troposphere*, subsiding air into the subtropical anticyclones, return flow as part of the trade winds near the surface, and with rising air near the equator in the so-called *Inter-tropical Convergence Zone*.

Halocarbons A collective term for the group of partially halogenated organic species, which includes the *chlorofluorocarbons* (CFCs), hydrochlorofluorocarbons (HCFCs), *hydrofluorocarbons* (HFCs), halons, methyl chloride and methyl bromide. Many of the halocarbons have large *global warming potentials*. The chlorine and bromine-containing halocarbons are also involved in the depletion of the *ozone layer*.

Halocline A layer in the oceanic water column in which salinity changes rapidly with depth. Generally, saltier water is denser and lies below less salty water. In some high-latitude *oceans* the surface waters may be colder than the deep waters, and the halocline is responsible for maintaining water column stability and isolating the surface waters from the deep waters.

Halosteric See *Sea level change (sea level rise/sea level fall)*.

Halosteric sea level change See *Sea level change (sea level rise/sea level fall)*.

Hazard The potential occurrence of a natural or human-induced physical event or trend that may cause loss of life, injury, or other health *impacts*, as well as damage and loss to property, infrastructure, *livelihoods*, service provision, *ecosystems* and environmental resources. See also *Impacts (consequences, outcomes)* and *Risk*.

Heat index A measure of how hot the air feels to the human body. The index is mainly based on surface air temperature and *relative humidity*; thus it reflects the combined effect of high temperature and humidity on human physiology and provides a relative indication of potential health risks.

Heat stress A range of conditions in, for example, terrestrial or aquatic organisms when the body absorbs excess heat during overexposure to high air or water temperatures or thermal radiation. In aquatic water-breathing animals, hypoxia and acidification can exacerbate *vulnerability* to heat. Heat stress in mammals (including humans) and birds, both in air, is exacerbated by a detrimental combination of ambient heat, high humidity and low wind speeds, causing regulation of body temperature to fail.

Heatwave A period of abnormally hot weather, often defined with reference to a relative temperature threshold, lasting from two days to months. Heatwaves and warm spells have various and, in some cases, overlapping definitions. See also *Marine heatwave*, *Blocking*, *Heat index* and *Heat stress*.

Heavy precipitation event See *Extreme/heavy precipitation event*.

Heinrich event Distinct layers of coarse-grained sediments comprised of ice-rafted debris identified across marine sediment cores in the North Atlantic. These sedimentary layers are closely associated with millennial-scale cooling events in the North Atlantic and a distinct pattern of global temperature and hydrological changes that are largely consistent with evidence for a slowdown, or even near-collapse, of the *Atlantic Meridional Overturning Circulation* (AMOC) during these times.

Heterotrophic respiration The conversion of organic matter to *carbon dioxide* (CO_2) by organisms other than autotrophs.

Holocene The current *interglacial* geological epoch, the second of two epochs within the *Quaternary* Period, the preceding being the *Pleistocene*. The International Commission on Stratigraphy (ICS) defines the start of the Holocene Epoch at 11,700 years before 2000 (Walker et al., 2019) spanning the interval from 11,700 yr to the present day. Together with the subadjacent Pleistocene, it comprises the Quaternary System/Period. The Holocene record contains diverse geomorphological, biological, climatological and archaeological evidence, within sequences that are often continuous and extremely well-preserved at decadal, annual and even seasonal resolution. As a consequence, the Holocene is perhaps the most intensively studied series/epoch within the entire Geological Time Scale. Yet until recently little attention had been paid to a formal subdivision of the Holocene. Here we describe an initiative by the Subcommission on Quaternary Stratigraphy (SQS. It encompasses the mid-Holocene (MH), the 1000-year-long interval centred at 6000 years before 1950; a period of long-standing focus for climate modelling, with enhanced seasonality in the Northern Hemisphere and decreased seasonality in the Southern Hemisphere. The early part of the Holocene is marked by the late stages of *deglaciation* of Pleistocene land ice, sea level rise, and the occurrence of warm phases that affected different regions at different times, often referred to as the 'Holocene Thermal Maximum'. In addition, the epoch includes the post-glacial interval, which began approximately 7000 years ago when the fundamental features of the modern *climate system* were essentially in place, as the influence of remnant Pleistocene *ice sheets* waned. See also *Anthropocene*.

Holocene Thermal Maximum (HTM) See *Holocene*.

Human influence on the climate system Human-driven activities that lead to changes in the *climate system* due to perturbations of the Earth's energy budget (also called anthropogenic *forcing*). Human influence results from emissions of *greenhouse gases*, *aerosols*, *ozone-depleting substances (ODSs)*, and *land-use change*. See also *Anthropogenic*, *Anthropogenic emissions* and *Anthropogenic removals*.

Human system Any system in which human organizations and institutions play a major role. Often, but not always, the term is synonymous with society or social system. Systems such as agricultural systems, urban systems, political systems, technological systems and economic systems are all human systems in the sense applied in this Report.

Hurricane See *Tropical cyclone*.

Hydroclimate Part of the *climate* pertaining to the hydrology of a *region*.

Hydrofluorocarbons (HFCs) A type of *greenhouse gas (GHG)*, HFCs are organic compounds that contain fluorine, carbon and hydrogen atoms and they are produced commercially as a substitute for *chlorofluorocarbons (CFCs)*. They are mainly used in refrigeration and semiconductor manufacturing.

Hydrological cycle The cycle in which water evaporates from the *ocean* and the land surface, is carried over the Earth in atmospheric circulation as water vapour, condenses to form clouds, precipitates over the ocean and land as rain or snow, which on land can be intercepted by trees and vegetation, potentially accumulating as snow or ice, provides runoff on the land surface, infiltrates into soils,

recharges groundwater, discharges into streams, and ultimately, flows into the oceans as rivers, polar *glaciers* and *ice sheets*, from which it will eventually evaporate again. The various systems involved in the hydrological cycle are usually referred to as hydrological systems.

Hydrological drought See *Drought*.

Hydrological sensitivity (η) The linear change in global mean precipitation per degree Celsius of *global mean surface air temperature (GSAT)* change once precipitation changes related to fast atmospheric and land surface adjustments to *radiative forcings* have occurred. Units are % per °C although it can also be calculated as W m⁻² per °C. See also *Apparent hydrological sensitivity (η_a)*.

Hydrosphere The component of the *climate system* comprising liquid surface and subterranean water, such as in *oceans*, seas, rivers, freshwater lakes, underground water, *wetlands*, etc.

Hypoxic Conditions of low dissolved oxygen in shallow water *ocean* and freshwater environments. There is no universal threshold for hypoxia. A value around 60 µmol kg⁻¹ has commonly been used for some estuarine systems, although this does not necessarily directly translate into biological impacts. Anoxic conditions occur where there is no oxygen present at all. See also *Eutrophication*.

Hypsometry The distribution of land or ice surface as a function of altitude.

Ice age An informal term for a geological period characterized by a long-term reduction in the temperature of the Earth's *climate*, resulting in the presence or expansion of *ice sheets* and *glaciers*. Among the Earth's ice ages is the current *Quaternary* Period, characterized by alternating *glacial* and *interglacial* intervals. See also *Deglacial or deglaciation or glacial termination* and *Glacial-interglacial cycles*.

Ice core A cylinder of ice drilled out of a *glacier* or *ice sheet* to determine the physical properties of the ice body and to gain information on past changes in *climate* and composition of the *atmosphere* that are preserved in the ice or in air trapped in the ice.

Ice sheet An ice body originating on land that covers an area of continental size, generally defined as covering >50,000 km², and that has formed over thousands of years through *accumulation* and compaction of snow. An ice sheet flows outward from a high central ice plateau with a small average surface slope. The margins usually slope more steeply, and most ice is *discharged* through fast-flowing ice streams or *outlet glaciers*, often into the sea or into *ice shelves* floating on the sea. There are only two ice sheets in the modern world, one on Greenland and one on Antarctica. The latter is divided into the East Antarctic Ice Sheet (EAIS), the West Antarctic Ice Sheet (WAIS) and the Antarctic Peninsula Ice Sheet. During *glacial* periods, there were other ice sheets.

Ice shelf A floating slab of ice originating from land of considerable thickness extending from the coast (usually of great horizontal extent with a very gently sloping surface), resulting from the flow of *ice sheets*, initially formed by the accumulation of snow, and often filling embayments in the coastline of an ice sheet. Nearly all ice shelves are in Antarctica, where most of the ice *discharged* into the *ocean* flows via ice shelves.

Ice stream A stream of ice with strongly enhanced flow that is part of an *ice sheet*. It is often separated from surrounding ice by strongly sheared, crevassed margins.

Ice–albedo feedback A *climate feedback* involving changes in the Earth's surface *albedo*. Snow and ice have an albedo much higher (up to ~0.8) than the average planetary albedo (~0.3). With increasing temperatures, it is anticipated that snow and ice extent will decrease, the Earth's overall albedo will decrease and more *solar radiation* will be absorbed, warming the Earth further.

Iceberg Large piece of freshwater ice broken off from a *glacier* or an *ice shelf* during *calving* and floating in open water (at least 5 m height above sea level). Smaller pieces of floating ice known as 'bergy bits' (less than 5 m above sea level) or 'growlers' (less than 2 m above sea level) can originate from glaciers or ice shelves, or from the breaking up of a large iceberg. Icebergs can also be classified by shape, most commonly being either tabular (steep sides and a flat top) or non-tabular (varying shapes, with domes and spires) (NOAA, 2021). In lakes, icebergs can originate by breaking off shelf ice, which forms through freezing of a lake surface.

Impacts The consequences of realized *risks* on natural and human systems, where risks result from the interactions of climate-related *hazards* (including extreme weather/climate events), *exposure*, and *vulnerability*. Impacts generally refer to effects on lives, *livelihoods*, health and well-being, *ecosystems* and species, economic, social and cultural assets, services (including ecosystem services), and infrastructure. Impacts may be referred to as consequences or outcomes and can be adverse or beneficial. See also *Adaptation*, *Exposure*, *Hazard*, *Vulnerability* and *Risk*.

Incoming solar radiation See *Insolation*.

Indian Ocean basin (IOB) mode A mode of interannual variability characterized by a temporal alternation of basin-wide warming and cooling of the Indian Ocean sea surface. It mostly develops in response to *El Niño–Southern Oscillation (ENSO)*, but often persists after ENSO's equatorial eastern Pacific signal has dissipated. The IOB affects atmospheric circulation, temperature, and precipitation in South, South East, and East Asia as well as Africa, and modulates *tropical cyclone* activity in the north-western Pacific. See Section AIV.2.4 in Annex IV of the AR6 WGI report. See also *Modes of climate variability* and *Indian Ocean Dipole (IOD)*.

Indian Ocean Dipole (IOD) A mode of interannual variability that features an east–west dipole of *sea surface temperature* anomalies in the tropical Indian Ocean. Its positive phase shows concurrent sea surface cooling off Sumatra and Java and warming off Somalia in the west, combined with anomalous surface easterlies along the equator, while the opposite anomalies are seen in the negative phase. The IOD typically develops in boreal summer and matures in boreal autumn and controls part of the rainfall interannual variability in Australia, South Eastern Asia and Eastern Africa. See Section AIV.2.4 in Annex IV of the AR6 WGI report. See also *Indian Ocean Basin (IOB) mode*.

Indirect aerosol effect See *Aerosol–cloud interaction*.

Indirect land-use change (iLUC) See *Land-use change (LUC)*.

Industrial revolution A period of rapid industrial growth with far-reaching social and economic consequences, beginning in Britain

during the second half of the 18th century and spreading to Europe and later to other countries including the United States. The invention of the steam engine was an important trigger of this development. The industrial revolution marks the beginning of a strong increase in the use of *fossil fuels*, initially coal, and hence emission of *carbon dioxide (CO₂)*.

Infrared radiation See *Terrestrial radiation*.

Initial condition ensemble (ICE) See *Climate simulation ensemble*.

Insolation The amount of *solar radiation* reaching the Earth by latitude and by season measured in W m⁻². Usually, insolation refers to the radiation arriving at the top of the *atmosphere*. Sometimes it is specified as referring to the radiation arriving at the Earth's surface. See also *Orbital forcing* and *Total solar irradiance (TSI)*.

Instantaneous radiative forcing (or effect) due to aerosol–cloud interactions (IRFaci) See *Aerosol–cloud interaction*.

Instantaneous radiative forcing (or effect) due to aerosol–radiation interactions (IRFari) See *Aerosol–radiation interaction*.

Integrated assessment model (IAM) Models that integrate knowledge from two or more domains into a single framework. They are one of the main tools for undertaking integrated assessments. One class of IAM used with respect to climate change *mitigation* may include representations of: multiple sectors of the economy, such as energy, *land use* and *land-use change*; interactions between sectors; the economy as a whole; associated *greenhouse gas (GHG)* emissions and *sinks*; and reduced representations of the *climate system*. This class of model is used to assess linkages between economic, social and technological development and the evolution of the climate system. Another class of IAM additionally includes representations of the costs associated with climate change *impacts*, but includes less detailed representations of economic systems. These can be used to assess impacts and mitigation in a cost–benefit framework and have been used to estimate the social cost of carbon.

Inter-decadal Pacific Oscillation (IPO) See *Pacific Decadal Variability (PDV)*.

Inter-tropical Convergence Zone (ITCZ) The Inter-tropical Convergence Zone is an equatorial zonal belt of low pressure, strong *convection* and heavy precipitation near the equator where the north-east trade winds meet the south-east trade winds. This band moves seasonally. See also *South Pacific Convergence Zone (SPCZ)*.

Interglacial or interglaciation A globally warm period lasting thousands of years between *glacial* periods within an *ice age*. Generally coincides with odd-numbered *marine isotope stages (MIS)* when mean sea level was close to present. The Last Interglacial (LIG) occurred between about 129 and 116 ka (thousand years) before present (defined as 1950) although the warm period started in some areas a few thousand years earlier. In terms of MIS, *interglaciations* are defined as the interval between the midpoint of the preceding termination and the onset of the next glaciation. The LIG coincides with MIS 5e. The present interglaciation, the *Holocene*, started at 11,700 years before 2000 CE, although global mean sea level did not approach its present position until roughly 7000 years ago. See also

Deglacial or deglaciation or glacial termination, Glacial-interglacial cycles, Glacial or glaciation and Ice age.

Internal climate variability See *Internal variability* (under *Climate variability*).

Interstadial or interstade A brief period of regional climatic warming during a *glacial* or *interglacial* interval, often characterized by transient glacial retreats. Interstadials are generally of short duration (hundreds to a few thousand years) compared to glacial or interglacial intervals (lasting many thousands to tens of thousands of years). One example of a regional interstadial event is based on millennial scale warming recorded by oxygen *isotope* ratios in Greenland *ice cores*, the so called “Greenland Interstadials” (Johnsen et al., 1992). See also *Stadial or stade*.

Irreversibility A perturbed state of a *dynamical system* is defined as irreversible on a given time scale if the recovery from this state due to natural processes takes substantially longer than the time scale of interest. See also *Tipping point*.

Isostatic or Isostasy Isostasy refers to the response of the Earth to changes in surface load. It includes the deformational and gravitational response. This response is elastic on short time scales, as in the Earth–*ocean* response to recent changes in mountain glaciation, or viscoelastic on longer time scales, as in the response to the last *deglaciation* following the *Last Glacial Maximum*.

Isotopes Atoms of the same chemical element that have the same the number of protons but differ in the number of neutrons. Some proton–neutron configurations are stable (stable isotopes), others are unstable undergoing spontaneous radioactive decay (radioisotopes). Most elements have more than one stable isotope. Isotopes can be used to trace transport processes or to study processes that change the isotopic ratio. Radioisotopes provide, in addition, time information that can be used for radiometric dating. See also ^{13}C and ^{14}C .

Key climate indicators See *Climate indicator*.

Kriging Kriging is a method of interpolation (normally spatial interpolation when used with atmospheric or oceanographic data) in which the interpolated values are estimated using a Gaussian process governed by prior covariances.

La Niña See *El Niño–Southern Oscillation (ENSO)*.

Land The terrestrial portion of the biosphere that comprises the natural resources (soil, near-surface air, vegetation and other biota, and water), the ecological processes, topography, and human settlements and infrastructure that operate within that system (UNCCD, 1994; FAO, 2007).

Land cover The biophysical coverage of *land* (e.g., bare soil, rocks, *forests*, buildings and roads or lakes). Land cover is often categorized in broad land-cover classes (e.g., deciduous forest, coniferous forest, mixed forest, grassland, bare ground). [Note: In some literature, land cover and *land use* are used interchangeably, but the two represent distinct classification systems. For example, the land cover class woodland can be under various land uses such as livestock grazing, recreation, conservation, or wood harvest.]

Land–cover change Change from one *land cover* class to another, due to change in *land use* or change in natural conditions (Pongratz et al., 2018). See also *Land-use change (LUC)*.

Land surface air temperature (LSAT) The near-surface air temperature over land, typically measured at 1.25–2 m above the ground using standard meteorological equipment.

Land use The total of arrangements, activities and inputs applied to a parcel of *land*. The term land use is also used in the sense of the social and economic purposes for which land is managed (e.g., grazing, timber extraction, conservation and city dwelling). In national *greenhouse gas (GHG)* inventories, land use is classified according to the IPCC land-use categories of forest land, cropland, grassland, wetlands, settlements, other lands (see the 2006 IPCC Guidelines for National GHG Inventories and their 2019 Refinement for details (IPCC, 2006, 2019)).

Land-use change (LUC) The change from one *land use* category to another. Note that in some scientific literature, land-use change encompasses changes in land-use categories as well as changes in land management. See also *Afforestation, Deforestation and Reforestation*.

Indirect land-use change (iLUC) Land-use change outside the area of focus that occurs as a consequence of change in use or management of land within the area of focus, such as through market or policy drivers. For example, if agricultural land is diverted to biofuel production, *forest* clearance may occur elsewhere to replace the former agricultural production. See *Land-use change (LUC)*.

Land water storage (LWS) Land water storage (LWS) includes all surface water, *soil moisture*, groundwater storage and snow, but excludes water stored in *glaciers* and *ice sheets*. Changes in LWS can be caused either by direct human intervention in the water cycle (e.g., storage of water in reservoirs by building dams in rivers, groundwater extraction from groundwater reservoirs for consumption and irrigation, or *deforestation*) or by *climate* variations (e.g., changes in the amount of water in endorheic lakes and *wetlands*, the canopy, the soil, the *permafrost* and the snowpack). Land water storage changes caused by climate variations may also be indirectly affected by *anthropogenic* influences. See also *Sea level change (sea level rise/sea level fall)*.

Lapse rate The rate of change of an atmospheric variable, usually temperature, with height. The lapse rate is considered positive when the variable decreases with height.

Large-scale The *climate system* involves process interactions from the micro- to the global-scale. Any threshold for defining ‘large-scale’ is arbitrary. Understanding of large-scale *climate variability* and change requires knowledge of both the response to external *forcings* and the role of *internal variability*. Many external forcings have substantial hemispheric or continental scale variations. *Modes of climate variability* are driven by *ocean*-basin-scale processes. Thus we define large-scale to include ocean-basin and continental scales as well as hemispheric and global scales.

Last deglacial transition See *Deglacial or deglaciation or glacial termination* and *Younger Dryas*.

Last Glacial Maximum (LGM) See *Glacial or glaciation*.

Last Interglacial (LIG) See *Interglacial or interglaciation*.

Last millennium The interval of the *Common Era (CE)* between 1001 and 2000 CE. Encompasses the Little Ice Age, a roughly defined period characterized by multiple expansions of mountain *glaciers* worldwide, the timing of which differs among regions but generally occurred between 1400 CE and 1900 CE. The last millennium also mostly encompasses the Medieval Warm Period (also called the Medieval Climate Anomaly), a roughly defined period of relatively warm conditions or other *climate* excursions such as extensive *drought*, the timing and magnitude of which differ among regions, but generally occurred between 900 and 1400 CE. Transient *climate model* experiments by the Paleoclimate Modelling Intercomparison Project (PMIP) for the last millennium extend from 850–1849 CE.

Latent heat flux The turbulent *flux* of heat from the Earth's surface to the *atmosphere* that is associated with *evaporation* or condensation of water vapour at the surface; a component of the surface energy budget. See also *Sensible heat flux*.

Lifetime Lifetime is a general term used for various time scales characterizing the rate of processes affecting the concentration of trace gases. The following lifetimes may be distinguished:

Response time or adjustment time (T_a)

Response time or adjustment time (T_a) is the time scale characterizing the decay of an instantaneous pulse input into the *reservoir*. The term adjustment time is also used to characterize the adjustment of the mass of a reservoir following a step change in the *source* strength. Half-life or decay constant is used to quantify a first-order exponential decay process. See *Response time or adjustment time* for a different definition pertinent to *climate* variations.

The term lifetime is sometimes used, for simplicity, as a surrogate for adjustment time.

In simple cases, where the global removal of the compound is directly proportional to the total mass of the reservoir, the adjustment time equals the *turnover time*: $T = T_a$. An example is CFC-11, which is removed from the *atmosphere* only by photochemical processes in the *stratosphere*. In more complicated cases, where several reservoirs are involved or where the removal is not proportional to the total mass, the equality $T = T_a$ no longer holds.

Carbon dioxide (CO_2) is an extreme example. Its turnover time is only about 4 years because of the rapid exchange between the atmosphere and the *ocean* and terrestrial biota. However, a large part of that CO_2 is returned to the atmosphere within a few years. The adjustment time of CO_2 in the atmosphere is determined from the rates of removal of carbon by a range of processes with time scales from months to hundreds of thousands of years. As a result, 15 to 40% of an emitted CO_2 pulse will remain in the atmosphere longer than 1,000 years, 10 to 25% will remain about ten thousand years, and the rest will be removed over several hundred thousand years.

In the case of *methane (CH_4)*, the adjustment time is different from the turnover time because the removal is mainly through a chemical reaction with the hydroxyl radical (OH), the concentration of which itself depends on the CH_4 concentration. Therefore, the CH_4 removal rate S is not proportional to its total mass M .

Turnover time (T) (also called global atmospheric lifetime) is the ratio of the mass M of a *reservoir* (e.g., a gaseous compound in the *atmosphere*) and the total rate of removal S from the *reservoir*: $T = M/S$. For each removal process, separate turnover times can be defined. In soil carbon biology, this is referred to as mean residence time.

Light-absorbing particles Light-absorbing particles (LAP), for example, *black carbon (BC)*, brown carbon and dust, are particles that absorb *solar radiation* and convert it into internal energy, thus raising the particle's temperature and emitting thermal-infrared radiation that is selectively absorbed by the surrounding medium. LAP affect the energy balance of the *atmosphere* and clouds, and when deposited on snow and ice, they reduce snow/ice albedo, increasing heating and accelerating melting. These particles have a warming effect on *climate*.

Likelihood The chance of a specific outcome occurring, where this might be estimated probabilistically. Likelihood is expressed in this report using a standard terminology (Mastrandrea et al., 2010). See also *Agreement*, *Confidence*, *Evidence* and *Uncertainty*.

Lithosphere The upper layer of the solid Earth, both continental and oceanic, which comprises all crustal rocks and the cold, mainly elastic part of the uppermost mantle. Volcanic activity, although part of the *lithosphere*, is not considered as part of the *climate system*, but acts as an *external forcing* factor.

Livelihood The resources used and the activities undertaken in order for people to live. Livelihoods are usually determined by the entitlements and assets to which people have access. Such assets can be categorized as human, social, natural, physical or financial.

Local sea level change See *Sea level change (sea level rise/sea level fall)*.

Long-lived greenhouse gases (LLGHGs) A set of *well-mixed greenhouse gases* with long atmospheric *lifetimes*. This set of compounds includes *carbon dioxide (CO_2)* and *nitrous oxide (N_2O)*, together with some halogenated compounds. They have a warming effect on *climate*. These compounds accumulate in the *atmosphere* at decadal to centennial time scales, and their effect on climate hence persists for decades to centuries after their emission. On time scales of decades to a century, already emitted emissions of long-lived climate forcers can only be abated by greenhouse gas removal.

Longwave radiation See *Terrestrial radiation*.

Low-likelihood, high impact outcomes Outcomes/events whose probability of occurrence is low or not well known (as in the context of *deep uncertainty*) but whose potential *impacts* on society and *ecosystems* could be high. To better inform *risk assessment* and decision-making, such low-*likelihood* outcomes are considered if they are associated with very large consequences and may therefore constitute material *risks*, even though those consequences do not necessarily represent the most likely outcome.

Madden-Julian Oscillation (MJO) The largest mode of tropical atmospheric intra-seasonal variability with typical periods ranging from 20 to 90 days. The MJO corresponds to planetary-scale disturbances of pressure, wind and deep *convection* moving predominantly eastward along the equator. As it progresses, the MJO

is associated with the temporal alternation of large-scale enhanced and suppressed rainfall, with maximum loading over the Indian and western Pacific oceans, although influences of the MJO can be tracked over the Atlantic/Africa in dynamical fields. See Section AIV.2.8 in Annex IV of the AR6 WGI report.

Maladaptive actions (Maladaptation) Actions that may lead to increased *risk* of adverse *climate*-related outcomes, including via increased *greenhouse gas (GHG)* emissions, increased *vulnerability* to *climate change*, or diminished welfare, now or in the future. Maladaptation is usually an unintended consequence.

Marine cloud brightening (MCB) See *Solar radiation modification (SRM)*.

Marine heatwave A period during which water temperature is abnormally warm for the time of the year relative to historical temperatures, with that extreme warmth persisting for days to months. The phenomenon can manifest in any place in the *ocean* and at scales of up to thousands of kilometres. See also *Heatwave*.

Marine ice cliff instability (MICI) A hypothetical mechanism of an ice cliff failure. In case a marine-terminated *ice sheet* loses its buttressing *ice shelf*, an ice cliff can be exposed. If the exposed ice cliff is tall enough (about 800 m of the total height, or about 100 m of the above-water part), the stresses at the cliff face exceed the strength of the ice, and the cliff fails structurally in repeated *calving* events. See also *Marine ice sheet instability (MISI)*.

Marine ice sheet instability (MISI) A mechanism of *irreversible* (on the decadal to centennial time scale) retreat of a *grounding line* for the marine-terminating *glaciers*, in case the glacier bed slopes towards the *ice sheet* interior. See also *Marine ice cliff instability (MICI)*.

Marine isotope stage (MIS) Geological periods of alternating *glacial* and *interglacial* conditions, each typically lasting tens of thousands of years as inferred from the oxygen *isotope* composition of microfossils from deep sea sediment cores. MIS numbers increase back in time from the present, which is MIS 1. Even-number MISs coincide with glacial periods, and odd-numbered MISs are interglacials.

Marine-based ice sheet An *ice sheet* containing a substantial region that rests on a bed lying below sea level and whose perimeter is in contact with the *ocean*. The best known example is the West Antarctic Ice Sheet.

Mass balance/budget (of glaciers or ice sheets) Difference between the mass input (*accumulation*) and the mass loss (*ablation*) of an ice body (e.g., a *glacier* or *ice sheet*) over a stated time period, which is often a year or a season. Surface mass balance refers to the difference between surface accumulation and surface ablation.

Ablation (of glaciers, ice sheets, or snow cover)

All processes that reduce the mass of a *glacier*, *ice sheet*, or *snow cover*. The main processes are melting, and for glaciers also *calving* (or, when the glacier nourishes an *ice shelf*, *discharge of ice* across the *grounding line*), but other processes such as sublimation and loss of wind-blown snow can also contribute to ablation. Ablation also refers to the mass lost by any of these processes.

Accumulation (of glaciers, ice sheets, or snow cover)

All processes that add to the mass of a *glacier*, an *ice sheet*, or *snow cover*. The main process of accumulation is snowfall. Accumulation also includes deposition of hoar, freezing rain, other types of solid precipitation, gain of wind-blown snow, avalanching, and basal accumulation (often beneath floating ice).

Discharge (of ice)

Rate of the flow of ice through a vertical section of a *glacier* perpendicular to the direction of the flow of ice. Often used to refer to the loss of mass at marine-terminating glacier fronts (mostly *calving* of *icebergs* and submarine melt), or to mass flowing across the *grounding line* of a floating *ice shelf*.

Mean sea level The surface level of the *ocean* at a particular point averaged over an extended period of time such as a month or year. Mean sea level is often used as a national datum to which heights on land are referred.

Megacity Urban agglomerations with 10 million inhabitants or more.

Meltwater Pulse 1A (MWP-1A) A particular interval of rapid global *sea level rise* between about 14,700 and 14,300 years ago, associated with the end of the last *ice age* and attributed to freshwater *flux* to the *ocean* from accelerated melting of *ice sheets* and *glaciers*. First defined based on oxygen *isotope* data (Duplessy et al., 1981), and later shown to be reflected by high rates of sea level rise (Fairbanks, 1989). See also *Deglacial or deglaciation or glacial termination*.

Meridional overturning circulation (MOC) Meridional (north–south) overturning circulation in the *ocean* quantified by zonal (east–west) sums of mass transports in depth or density layers. In the North Atlantic, away from the subpolar regions, the MOC (which is in principle an observable quantity) is often identified with the thermohaline circulation (THC), which is a conceptual and incomplete interpretation. The MOC is also driven by wind, and can also include shallower overturning cells such as occur in the upper ocean in the tropics and subtropics, in which warm (light) waters moving poleward are transformed to slightly denser waters and subducted equatorward at deeper levels.

Atlantic Meridional Overturning Circulation (AMOC)

The main current system in the South and North Atlantic Oceans. AMOC transports warm upper-*ocean* water northwards and cold, deep water southwards, as part of the global ocean circulation system. Changes in the strength of AMOC can affect other components of the *climate system*.

Meteorological drought See *Drought*.

Methane (CH₄) The greenhouse gas methane is the major component of natural gas and associated with all hydrocarbon fuels. Significant *anthropogenic emissions* also occur as a result of animal husbandry and paddy rice production. Methane is also produced naturally where organic matter decays under anaerobic conditions, such as in *wetlands*. Under future *global warming*, there is potential for increased methane emissions from thawing *permafrost*, *wetlands* and sub-sea gas hydrates. See also *Short-lived climate forcers (SLCFs)*.

Microclimate Local *climate* at or near the Earth's surface.

Microwave sounding unit (MSU) A microwave sounder on U.S. National Oceanic and Atmospheric Administration (NOAA) polar orbiter satellites that estimates the temperature of thick layers of the *atmosphere* by measuring the thermal emission of oxygen molecules from a complex of emission lines near 60 GHz. A series of nine MSUs began making this kind of measurement in late 1978. Beginning in mid-1998, a follow-on series of instruments, the Advanced Microwave Sounding Units (AMSUs), began operation.

Mid-Holocene (MH) See *Holocene*.

Mid-Pliocene Warm Period (MPWP) See *Pliocene*.

Mineralization/Remineralization The conversion of an element from its organic form to an inorganic form as a result of microbial decomposition. In nitrogen mineralization, organic nitrogen from decaying plant and animal residues (proteins, nucleic acids, amino sugars and urea) is converted to ammonia (NH₃) and ammonium (NH₄⁺) by biological activity.

Mitigation (of climate change) A human intervention to reduce emissions or enhance the *sinks* of *greenhouse gases*.

Mitigation pathways See *Pathways*.

Mitigation potential The quantity of net *greenhouse gas* emission reductions that can be achieved by a given *mitigation* option relative to specified emission baselines. [Note: Net greenhouse gas emission reductions is the sum of reduced emissions and/or enhanced *sinks*.] See also *Sequestration potential*.

Biogeophysical potential

The mitigation potential constrained by biological, geophysical and geochemical limits and thermodynamics, without taking into account technical, social, economic and/or environmental considerations.

Economic potential

The portion of the technical potential for which the social benefits exceed the social costs, taking into account a social discount rate and the value of externalities.

Technical potential

The mitigation potential constrained by biogeophysical limits as well as availability of technologies and practices. Quantification of technical potentials takes into account primarily technical considerations, but social, economic and/or environmental considerations are occasionally also included, if these represent strong barriers for the deployment of an option.

Mitigation scenario See *Scenario*.

Mixing ratio See *Mole fraction or mixing ratio*.

Model ensemble See *Climate simulation ensemble*. See also *Ensemble*.

Model initialization A *climate prediction* typically proceeds by integrating a *climate model* forward in time from an initial state that is intended to reflect the actual state of the *climate system*. Available observations of the climate system are assimilated into the model. Initialization is a complex process that is limited by available observations, observational errors and, depending on the procedure used, may be affected by *uncertainty* in the history of climate *forcing*. The initial conditions will contain errors that grow as the forecast

progresses, thereby limiting the time period over which the forecast will be useful.

Model spread The range or spread in results from *climate models*, such as those assembled for Coupled Model Intercomparison Project Phase 6 (CMIP6). Does not necessarily provide an exhaustive and formal estimate of the *uncertainty* in *feedbacks*, *forcing* or *projections* even when expressed numerically, for example, by computing a standard deviation of the models' responses. In order to quantify uncertainty, information from observations, physical constraints and expert judgement must be combined, using a statistical framework.

Modes of climate variability Recurrent space-time structures of *natural variability* of the *climate system* with intrinsic spatial patterns, seasonality and time scales. Modes can arise through the dynamical characteristics of the atmospheric circulation but also through coupling between the *ocean* and the *atmosphere*, with some interactions with land surfaces and *sea ice*. Many modes of variability are driven by internal climate processes and are a critical potential source of climate *predictability* on sub-seasonal to decadal time scales. See Annex IV of the AR6 WGI report. See also *Annular modes*, *Tropical Atlantic Variability (TAV)*, *Indian Ocean Dipole (IOD)*, *Indian Ocean Basin (IOB) mode*, *Pacific Decadal Variability (PDV)*, *Pacific Decadal Oscillation (PDO)* (under *Pacific Decadal Variability (PDV)*), *El Niño–Southern Oscillation (ENSO)*, *North Atlantic Oscillation (NAO)*, *Northern Annular Mode (NAM)* (under *Annular modes*), *Southern Annular Mode (SAM)* (under *Annular modes*), *Atlantic Meridional Mode (AMM)* (under *Tropical Atlantic Variability (TAV)*), *Atlantic Zonal Mode (AZM)* (under *Tropical Atlantic Variability (TAV)*), *Madden–Julian Oscillation (MJO)*, *Atlantic Multi-decadal Variability (AMV)* and *Inter-decadal Pacific Oscillation (IPO)* (under *Pacific Decadal Variability (PDV)*).

Mole fraction or mixing ratio Mole fraction, or mixing ratio, is the ratio of the number of moles of a constituent in a given volume to the total number of moles of all constituents in that volume. It is usually reported for dry air. Typical values for *well-mixed greenhouse gases* are in the order of μmol mol⁻¹ (parts per million: ppm), nmol mol⁻¹ (parts per billion: ppb), and fmol mol⁻¹ (parts per trillion: ppt). Mole fraction differs from volume mixing ratio, often expressed in ppmv, etc., by the corrections for non-ideality of gases. This correction is significant relative to measurement precision for many *greenhouse gases* (Schwartz and Warneck, 1995).

Monsoon See *Global monsoon*.

Montreal Protocol The Montreal Protocol on Substances that Deplete the Ozone Layer was adopted in Montreal in 1987, and subsequently adjusted and amended (including London (1990), Copenhagen (1992), Vienna (1995), Montreal (1997), Beijing (1999) and Kigali (2016)). It controls the consumption and production of chlorine- and bromine-containing chemicals that destroy *stratospheric ozone* (O₃), such as *chlorofluorocarbons (CFCs)*, methyl chloroform, carbon tetrachloride and many others. Since the Kigali Amendment in 2016, *hydrofluorocarbons (HFCs)*, which were used as alternatives to *ozone-depleting substances (ODSs)*, have been targeted for a phase-down due to their *climate* effect as *greenhouse gases (GHGs)*.

Multi-model ensemble (MME) See *Climate simulation ensemble*. See also *Ensemble*.

Narrative See *Storyline*. See also *Pathways*.

Natural systems The dynamic physical, physicochemical and biological components of the Earth system that would operate independently of human activities.

Natural variability See *Climate variability*.

Near-surface permafrost See *Permafrost*.

Negative greenhouse gas emissions Removal of *greenhouse gases (GHGs)* from the *atmosphere* by deliberate human activities, that is, in addition to the removal that would occur via natural *carbon cycle* or atmospheric chemistry processes. See also *Carbon dioxide removal (CDR)*, *Net negative greenhouse gas emissions*, *Net zero CO₂ emissions* and *Net zero greenhouse gas emissions*.

Net negative greenhouse gas emissions A situation of net negative greenhouse gas emissions is achieved when metric-weighted anthropogenic *greenhouse gas (GHG)* removals exceed metric-weighted anthropogenic GHG emissions. Where multiple GHG are involved, the quantification of net emissions depends on the metric chosen to compare emissions of different gases (such as *global warming potential*, global temperature change potential, and others, as well as the chosen time horizon). See also *Net zero CO₂ emissions*, *Net zero greenhouse gas emissions*, *Negative greenhouse gas emissions*, *Carbon dioxide removal (CDR)* and *Greenhouse gas emission metric*.

Net primary production (NPP) See *Primary production*.

Net zero CO₂ emissions Condition in which anthropogenic *carbon dioxide (CO₂)* emissions are balanced by anthropogenic CO₂ removals over a specified period.

Note: Carbon neutrality and net zero CO₂ emissions are overlapping concepts. The concepts can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms carbon neutrality and net zero CO₂ emissions are equivalent. At sub-global scales, net zero CO₂ emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while carbon neutrality generally includes emissions and removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant CO₂ emissions and removals.

See also *Net zero greenhouse gas emissions* and *Carbon neutrality*.

Net zero greenhouse gas emissions Condition in which metric-weighted anthropogenic *greenhouse gas (GHG)* emissions are balanced by metric-weighted anthropogenic GHG removals over a specified period. The quantification of net zero GHG emissions depends on the GHG emission metric chosen to compare emissions and removals of different gases, as well as the time horizon chosen for that metric.

Note 1: GHG neutrality and net zero GHG emissions are overlapping concepts. The concept of net zero GHG emissions can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms GHG neutrality and net zero GHG emissions are equivalent. At sub-global scales, net zero GHG

emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while GHG neutrality generally includes anthropogenic emissions and anthropogenic removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant emissions and removals.

Note 2: Under the Paris Rulebook (Decision 18/CMA.1, annex, paragraph 37), parties have agreed to use GWP100 values from the IPCC AR5 or GWP100 values from a subsequent IPCC Assessment Report to report aggregate emissions and removals of GHGs. In addition, parties may use other metrics to report supplemental information on aggregate emissions and removals of GHGs.

See also *Net zero CO₂ emissions*, *Greenhouse gas emission metric* and *Greenhouse gas neutrality*.

Nitrogen deposition Nitrogen deposition is defined as the nitrogen transferred from the *atmosphere* to the Earth's surface by the processes of wet deposition and dry deposition.

Nitrous oxide (N₂O) The main *anthropogenic* source of N₂O, a greenhouse gas (GHG), is agriculture (soil and animal manure management), but important contributions also come from sewage treatment, *fossil fuel* combustion, and chemical industrial processes. N₂O is also produced naturally from a wide variety of biological sources in soil and water, particularly microbial action in wet tropical *forests*.

Non-CO₂ emissions and radiative forcing Non-CO₂ emissions included in this report are all *anthropogenic emissions* other than *carbon dioxide (CO₂)* that result in *radiative forcing*. These include *short-lived climate forcers*, such as *methane (CH₄)*, some fluorinated gases, *ozone (O₃)* precursors, *aerosols* or aerosol *precursors*, such as *black carbon* and sulphur dioxide, respectively, as well as long-lived *greenhouse gases*, such as *nitrous oxide (N₂O)* or other fluorinated gases. The radiative forcing associated with non-CO₂ emissions and changes in surface *albedo* (e.g., resulting from *land-use change*) is referred to as non-CO₂ radiative forcing.

Non-linearity A process is called non-linear when there is no simple proportional relation between cause and effect. The *climate system* contains many such non-linear processes, resulting in a system with potentially very complex behaviour. Such complexity may lead to *abrupt climate change* and *tipping points*.

Non-methane volatile organic compounds (NMVOCs) See *Volatile organic compounds (VOCs)*.

Non-overshoot pathways See *Pathways*.

North American monsoon (NAmerM) See *Global monsoon*.

Northern Annular Mode (NAM) See *Annular modes*.

North Atlantic Oscillation (NAO) The leading mode of large-scale atmospheric variability in the North Atlantic basin characterized by alternating (see-saw) variations in sea level pressure or geopotential height between the Azores High in the subtropics and the Icelandic Low in the mid- to high latitudes, with some northward extension deep into the Arctic. It is associated with fluctuations in the strength and latitudinal position of the main westerly winds across

a vast North Atlantic–Europe domain, and thus with fluctuations in the embedded *extratropical cyclones* and associated frontal systems leading to strong *teleconnection* over the entire North Atlantic adjacent continents. The positive and negative phases of the NAO show similar characteristics described for the *Northern Annular Mode (NAM)*. See Section AIV.2.1 in Annex IV of the AR6 WGI report.

Northern polar vortex See *Stratospheric polar vortex*.

Ocean The interconnected body of saline water that covers 71% of the Earth’s surface, contains 97% of the Earth’s water and provides 99% of the Earth’s biologically habitable space. It includes the Arctic, Atlantic, Indian, Pacific and Southern Oceans, as well as their marginal seas and coastal waters.

Ocean acidification (OA) A reduction in the *pH* of the *ocean*, accompanied by other chemical changes (primarily in the levels of carbonate and bicarbonate ions), over an extended period, typically decades or longer, which is caused primarily by *uptake* of *carbon dioxide (CO₂)* from the *atmosphere*, but can also be caused by other chemical additions or subtractions from the ocean. *Anthropogenic* OA refers to the component of pH reduction that is caused by human activity (IPCC, 2011, p. 37).

Ocean alkalization/Ocean alkalinity enhancement A proposed *carbon dioxide removal (CDR)* method that involves deposition of alkaline minerals or their dissociation products at the *ocean* surface. This increases surface *total alkalinity*, and may thus increase ocean *carbon dioxide (CO₂)* uptake and ameliorate surface *ocean acidification*. See also *Anthropogenic removals*.

Ocean carbon cycle The ocean *carbon cycle* is the set of processes that exchange carbon between various *pools* within the *ocean*, as well as between the *atmosphere*, Earth’s interior, *cryosphere*, and the sea-floor. See also *Carbon cycle*.

Ocean deoxygenation The loss of oxygen in the *ocean*. It results from ocean warming, which reduces oxygen solubility and increases oxygen consumption and *stratification*, thereby reducing the mixing of oxygen into the ocean interior. Deoxygenation can also be exacerbated by the addition of excess nutrients in the *coastal* zone.

Ocean dynamic sea level change See *Sea level change (sea level rise/sea level fall)*.

Ocean fertilization A proposed *carbon dioxide removal (CDR)* method that relies on the deliberate increase of nutrient supply to the near-surface *ocean* with the aim of *sequestering* additional CO₂ from the *atmosphere* through biological production. Methods include direct addition of micro-nutrients or macro-nutrients. To be successful, the additional carbon needs to reach the deep ocean where it has the potential to be sequestered on climatically relevant time scales. See also *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

Ocean heat uptake efficiency This is a measure (W m⁻² °C⁻¹) of the rate at which heat storage by the global *ocean* increases as global surface temperature rises. It is a useful parameter for *climate change* simulations in which the *radiative forcing* is changing monotonically, when it can be compared with the *climate feedback parameter* to gauge the relative importance of radiative response and ocean heat *uptake* in determining the rate of *climate change*. It can be estimated

from such an experiment as the ratio of the rate of increase of ocean heat content to the surface temperature change.

Ocean stratification See *Stratification*.

Orbital forcing Orbital *forcing* is the influence of slow, systematic and predictable changes in orbital parameters (eccentricity, obliquity and precession of the equinox) on incoming *solar radiation (insolation)*, especially its latitudinal and seasonal distribution. It is an *external forcing* and a key driver of *glacial–interglacial cycles*.

Organic aerosol Component of the *aerosol* that consists of organic compounds, mainly carbon, hydrogen, oxygen and lesser amounts of other elements.

Outgoing longwave radiation Net outgoing radiation in the infrared part of the spectrum at the top of the *atmosphere*.

Outlet glacier See *Glacier*.

Overshoot pathways See *Pathways*.

Oxygen minimum zone (OMZ) The midwater layer (200–1000 m) in the open *ocean* in which oxygen saturation is the lowest in the ocean. The degree of oxygen depletion depends on the largely bacterial consumption of organic matter, and the distribution of the OMZs is influenced by large-scale ocean circulation. In coastal oceans, OMZs extend to the shelves and may also affect benthic *ecosystems*.

Ozone (O₃) The triatomic form of oxygen, and a gaseous *atmospheric* constituent. In the *troposphere*, O₃ is created both naturally and by photochemical reactions involving gases resulting from human activities (e.g., smog). Tropospheric O₃ acts as a *greenhouse gas (GHG)*. In the *stratosphere*, O₃ is created by the interaction between solar ultraviolet radiation and molecular oxygen (O₂). Stratospheric O₃ plays a dominant role in the stratospheric radiative balance. Its concentration is highest in the *ozone layer*. See also *Ground-level ozone*, *Ozone hole*, *Ozone-depleting substances (ODSs)*, *Ozonesonde* and *Short-lived climate forcers (SLCFs)*.

Ozone layer A layer of Earth’s *stratosphere* that absorbs most of the Sun’s ultraviolet radiation. It contains high concentrations of *ozone (O₃)* in relation to other parts of the *atmosphere*, although still small in relation to other gases in the *stratosphere*. The ozone layer contains less than 10 parts per million of ozone, while the average ozone concentration in Earth’s atmosphere as a whole is about 0.3 parts per million. The ozone layer is mainly found in the lower portion of the stratosphere, from approximately 15 to 35 kilometres (9.3 to 21.7 miles) above Earth, although its thickness varies seasonally and geographically. See also *Ozone hole* and *Ozone-depleting substances (ODSs)*.

Ozone-depleting substances (ODSs) Man-made gases that destroy *ozone (O₃)* once they reach the *ozone layer* in the *stratosphere*. Ozone-depleting substances include: *chlorofluorocarbons (CFCs)*, *hydrochlorofluorocarbons (HCFCs)*, *hydrobromofluorocarbons (HBFCs)*, *halons*, *methyl bromide*, *carbon tetrachloride* and *methyl chloroform*. They are used as refrigerants in commercial, home and vehicle air conditioners and refrigerators, foam blowing agents, components in electrical equipment, industrial solvents, solvents for cleaning (including dry cleaning), aerosol spray propellants and fumigants. See also *Ozone layer*, *Ozone (O₃)* and *Stratospheric ozone*.

Ozonesonde An ozonesonde is a radiosonde measuring *ozone* (O_3) concentrations. The radiosonde is usually carried on a weather balloon and transmits measured quantities by radio to a ground-based receiver.

Pacific Decadal Oscillation (PDO) See *Pacific Decadal Variability (PDV)*.

Pacific Decadal Variability (PDV) Coupled decadal-to-inter-decadal variability of the atmospheric circulation and underlying *ocean* that is typically observed over the entire Pacific Basin beyond the *El Niño–Southern Oscillation (ENSO)* time scale. In the AR6 WGI report, PDV encapsulates the *Pacific Decadal Oscillation (PDO)*, the South Pacific Decadal Oscillation (SPDO), tropical Pacific decadal variability (also called decadal ENSO), and the Inter-decadal Pacific Oscillation (IPO). Typically, the positive phase of the PDV is characterized by anomalously high *sea surface temperatures* in the central-eastern tropical Pacific that extend to the extratropical North and South Pacific along the American coasts, encircled to the west by cold sea surface *anomalies* in the mid-latitude North and South Pacific. The negative phase is accompanied by sea surface temperature anomalies of the opposite sign. Those sea surface temperature anomalies are linked to anomalies in atmospheric and oceanic circulation throughout the whole Pacific Basin. The PDV is associated with decadal modulations in the relative occurrence of El Niño and La Niña. See Section AIV.2.6 in Annex IV of the AR6 WGI report.

Inter-decadal Pacific Oscillation (IPO)

An equatorially symmetric pattern of *sea surface temperature* variability at decadal-to-inter-decadal time scales. While the *Pacific Decadal Oscillation (PDO)* and its South Pacific counterpart, the South Pacific Decadal Oscillation (SPDO), are considered as physically distinct modes, the tropical Pacific decadal–inter-decadal variability can drive both the PDO and SPDO, forming the IPO as a synchronized pan-Pacific variability. Its spatial pattern of sea surface temperature *anomalies* is similar to that of the *El Niño–Southern Oscillation (ENSO)*, but with a broader meridional extent in the tropical signal and more weights in the extratropics compared to the tropics. In the AR6 WGI report, it is encapsulated within the definition and description of *Pacific Decadal Variability (PDV)*. See also Section AIV.2.6 in Annex IV of the AR6 WGI report.

Pacific Decadal Oscillation (PDO)

The leading mode of variability obtained from decomposition in empirical orthogonal function of *sea surface temperature* over the North Pacific north of 20°N, and characterized by a strong decadal component. The positive phase of the PDO features a dipole of sea surface temperature *anomalies* in the North Pacific, with a cold lobe near the centre of the basin and extending westward along the Kuroshio, encircled by warmer conditions along the coast of North America and in the subtropics. A positive PDO is accompanied by an intensified Aleutian Low and an associated cyclonic circulation enhancement leading to *teleconnections* over the continents adjacent to the North Pacific. In the AR6 WGI report, the PDO is encapsulated within the definition and description of *Pacific Decadal Variability (PDV)*. See also Section AIV.2.6 in Annex IV of the AR6 WGI report.

Pacific–North American (PNA) pattern An atmospheric large-scale wave pattern featuring a sequence of tropospheric high and

low pressure *anomalies* stretching from the subtropical west Pacific to the east coast of North America.

Palaeocene–Eocene Thermal Maximum (PETM) The PETM is a transient event that occurred between 55.9 and 55.7 million years ago. Continental positions at this time were somewhat different to present due to tectonic plate movements. Geological data indicate that the PETM was characterised by a warming (*global mean surface temperature* rose to about 4°C–7°C warmer than the preceding mean state), and an increase in atmospheric CO₂ (from about 900 to about 2000 ppmv). In addition, ocean *pH* and oxygen content decreased; many deep-sea species went extinct and tropical *coral reefs* diminished.

Paleoclimate *Climate* during periods prior to the development of measuring instruments, including historic and geologic time, for which only *proxy* climate records are available.

Parameterization In *climate models*, this term refers to the technique of representing processes that cannot be explicitly resolved at the spatial or temporal *resolution* of the model (sub-grid scale processes) by relationships between model-resolved larger-scale variables and the area- or time-averaged effect of such sub-grid scale processes.

Pathways The temporal evolution of natural and/or human systems towards a future state. Pathway concepts range from sets of quantitative and qualitative *scenarios* or *narratives* of potential futures to solution-oriented decision-making processes to achieve desirable societal goals. Pathway approaches typically focus on biophysical, techno-economic, and/or socio-behavioural trajectories and involve various dynamics, goals, and actors across different scales. See also *Scenario* and *Scenario storyline* (under *Storyline*).

1.5°C pathway

A pathway of emissions of *greenhouse gases* and other climate forcers that provides an approximately one-in-two to two-in-three chance, given current knowledge of the climate response, of *global warming* either remaining below 1.5°C or returning to 1.5°C by around 2100 following an overshoot.

Emission pathways

Modelled trajectories of global *anthropogenic emissions* over the 21st century.

Mitigation pathways

A temporal evolution of a set of *mitigation scenario* features, such as *greenhouse gas (GHG)* emissions and socio-economic development.

Non-overshoot pathways

Pathways that stay below a specified concentration, *forcing*, or global warming level during a specified period of time (e.g., until 2100).

Overshoot pathways

Pathways that first exceed a specified concentration, *forcing*, or global warming level, and then return to or below that level again before the end of a specified period of time (e.g., before 2100). Sometimes the magnitude and *likelihood* of the overshoot is also characterized. The overshoot duration can vary from one pathway to the next, but in most overshoot pathways in the literature and referred to as overshoot pathways in the AR6, the overshoot occurs over a period of at least one decade and up to several decades.

Representative Concentration Pathways (RCPs)

Scenarios that include time series of *emissions* and concentrations of the full suite of *greenhouse gases (GHGs)* and *aerosols* and chemically active gases, as well as *land use/land cover* (Moss et al., 2010). The word representative signifies that each RCP provides only one of many possible scenarios that would lead to the specific *radiative forcing* characteristics. The term pathway emphasises that not only the long-term concentration levels are of interest, but also the trajectory taken over time to reach that outcome (Moss et al., 2010).

RCPs usually refer to the portion of the concentration pathway extending up to 2100, for which *integrated assessment models* produced corresponding *emission scenarios*. Extended concentration pathways describe extensions of the RCPs from 2100 to 2300 that were calculated using simple rules generated by stakeholder consultations, and do not represent fully consistent scenarios. Four RCPs produced from integrated assessment models were selected from the published literature and used in the Fifth IPCC Assessment, and are also used in this Assessment for comparison, spanning the range from approximately below 2°C warming to high (>4°C) warming best-estimates by the end of the 21st century: RCP2.6, RCP4.5 and RCP6.0 and RCP8.5.

- RCP2.6: One pathway where radiative forcing peaks at approximately 3 W m⁻² and then declines to be limited at 2.6 W m⁻² in 2100 (the corresponding Extended Concentration Pathway, or ECP, has constant emissions after 2100).
- RCP4.5 and RCP6.0: Two intermediate stabilization pathways in which radiative forcing is limited at approximately 4.5 W m⁻² and 6.0 W m⁻² in 2100 (the corresponding ECPs have constant concentrations after 2150).
- RCP8.5: One high pathway which leads to >8.5 W m⁻² in 2100 (the corresponding ECP has constant emissions after 2100 until 2150 and constant concentrations after 2250).

See also *Coupled Model Intercomparison Project (CMIP)* and *Shared Socio-economic Pathways (SSPs)* (under *Pathways*).

Shared Socio-economic Pathways (SSPs)

Shared Socio-economic Pathways (SSPs) have been developed to complement the *Representative Concentration Pathways (RCPs)*. By design, the RCP emission and concentration pathways were stripped of their association with a certain socio-economic development. Different levels of emissions and *climate change* along the dimension of the RCPs can hence be explored against the backdrop of different socio-economic development pathways (SSPs) on the other dimension in a matrix. This integrative SSP-RCP framework is now widely used in the climate *impact* and policy analysis literature, where *climate projections* obtained under the RCP scenarios are analysed against the backdrop of various SSPs. As several emissions updates were due, a new set of emissions scenarios was developed in conjunction with the SSPs. Hence, the abbreviation SSP is now used for two things: On the one hand SSP1, SSP2, ..., SSP5 are used to denote the five socio-economic scenario families. On the other hand, the abbreviations SSP1-1.9, SSP1-2.6, ..., SSP5-8.5 are used to denote the newly developed emissions scenarios that are the result of an SSP implementation

within an *integrated assessment model*. Those SSP scenarios are bare of climate policy assumption, but in combination with so-called shared policy assumptions (SPAs), various approximate *radiative forcing* levels of 1.9, 2.6, ..., or 8.5 W m⁻² are reached by the end of the century, respectively.

Pattern scaling Techniques used to represent the spatial variations in *climate* at a given increase in *global mean surface air temperature (GSAT)* are referred to as 'pattern scaling'.

Peat Soft, porous or compressed, sedimentary deposit of which a substantial portion is partly decomposed plant material with high water content in the natural state (up to about 90%).

Peatlands Peatland is a land where soils are dominated by *peat*.

Percentile A partition value in a population distribution that a given percentage of the data values are below or equal to. The 50th percentile corresponds to the median of the population. Percentiles are often used to estimate the extremes of a distribution. For example, the 90th (10th) percentile may be used to refer to the threshold for the upper (lower) extremes.

Permafrost Ground (soil or rock, and included ice and organic material) that remains at or below 0°C for at least two consecutive years (Harris et al., 1988). Note that permafrost is defined via temperature rather than ice content and, in some instances, may be ice-free.

Near-surface permafrost

Permafrost within about 3–4 m of the ground surface. The depth is not precise, but describes what commonly is highly relevant for people and *ecosystems*. Deeper permafrost is often progressively less ice-rich and responds more slowly to warming than near-surface permafrost. The presence or absence of near-surface permafrost is not the only significant metric of permafrost change, and deeper permafrost may persist when near-surface permafrost is absent.

Permafrost degradation

Decrease in the thickness and/or areal extent of permafrost.

Permafrost thaw

Progressive loss of ground ice in permafrost, usually due to input of heat. Thaw can occur over decades to centuries over the entire depth of permafrost ground, with impacts occurring while thaw progresses. During thaw, temperature fluctuations are subdued because energy is transferred by phase change between ice and water. After the transition from permafrost to non-permafrost, ground can be described as thawed.

Perturbed parameter ensemble See *Climate simulation ensemble*.

pH A dimensionless measure of the acidity of a dilute solution (e.g., seawater) based on the activity, or effective concentration, of hydrogen ions (H⁺) in the solution. pH is measured on a logarithmic scale where $\text{pH} = -\log_{10}(\text{H}^+)$. Thus, a pH decrease of 1 unit corresponds to a 10-fold increase in the acidity, or the activity of H⁺.

Phenology The relationship between biological phenomena that recur periodically (e.g., development stages, migration) and *climate* and seasonal changes.

Photosynthesis The production of carbohydrates in plants, algae and some bacteria using the energy of light. *Carbon dioxide (CO₂)* is used as the carbon source.

Physical climate storyline See *Storyline*.

Piacenzian warm period See *Pliocene*.

Plankton Free-floating organisms living in the upper layers of aquatic systems. Their distribution and migration are primarily determined by water currents. A distinction is made between phytoplankton, which depend on *photosynthesis* for their energy supply, and zooplankton, which feed on phytoplankton, other zooplankton, and bacterioplankton.

Plant evaporative stress Plant evaporative stress in both crops and natural vegetation can result from the combination of a high atmospheric evaporative demand and limited available water to supply this demand by means of *evapotranspiration*, further enhancing *agricultural and ecological drought*.

Pleistocene The Pleistocene Epoch is the earlier of two epochs in the *Quaternary* System, extending from 2.59 Ma to the beginning of the *Holocene* at approximately 11.7 ka.

Pliocene The Pliocene Epoch is the more recent of two epochs of the Neogene Period within the *Cenozoic Era*. It extends from 5.33 Ma to the beginning of the *Pleistocene* Epoch at 2.59 Ma. The Neogene Period precedes the current geological period, the *Quaternary* Period, which is one of several *ice ages* that have occurred during Earth's geological history. It encompasses the mid-Pliocene warm period (MPWP), also known as the Piacenzian warm period, which occurred from approximately 3.3 to 3.0 Ma. The MPWP, in turn, encompasses the *interglacial* episode, *marine isotope stage (MIS)* KM5c, which peaked at 3.205 Ma, when *orbital forcing* was similar to modern (Haywood et al., 2016).

Polar amplification Polar amplification describes the phenomenon where surface temperature change at high latitudes exceeds the global average surface temperature change. The terms Arctic amplification or Antarctic amplification are used when describing the phenomenon occurring at one of the poles.

Pollen analysis A technique of both relative dating and environmental *reconstruction*, consisting of the identification and counting of pollen types preserved in *peat*, lake sediments and other deposits.

Pool, carbon and nitrogen A *reservoir* in the Earth system where elements, such as carbon and nitrogen, reside in various chemical forms for a period of time. See also *Reservoir*, *Sequestration*, *Sequestration potential*, *Sink*, *Source* and *Uptake*.

Post-glacial period See *Holocene*.

Potential evapotranspiration See *Evapotranspiration*.

Pre-industrial (period) The multi-century period prior to the onset of large-scale industrial activity around 1750. The *reference period* 1850–1900 is used to approximate pre-industrial *global mean surface temperature (GMST)*. See also *Industrial revolution*.

Precipitable water The total amount of atmospheric water vapour in a vertical column of unit cross-sectional area. It is commonly

expressed in terms of the height of the water if completely condensed and collected in a vessel of the same unit cross section.

Precursors Atmospheric compounds that are not *greenhouse gases (GHGs)* or *aerosols*, but that have an effect on GHG or aerosol concentrations by taking part in physical or chemical processes regulating their production or destruction rates.

Predictability The extent to which future states of a system may be predicted based on knowledge of current and past states of the system. Because knowledge of the *climate system*'s past and current states is generally imperfect, as are the models that utilize this knowledge to produce a *climate prediction*, and because the *climate system* is inherently *non-linear* and *chaotic*, predictability of the climate system is inherently limited. Even with arbitrarily accurate models and observations, there may still be limits to the predictability of such a non-linear system (AMS, 2021). See also *Climate prediction* and *Prediction quality/skill*.

Prediction quality/skill Measures of the success of a prediction against observationally based information. No single measure can summarize all aspects of forecast quality, and a suite of *metrics* is considered. Metrics will differ for forecasts given in deterministic and probabilistic form. See also *Climate prediction* and *Predictability*.

Primary production The synthesis of organic compounds by plants and microbes, on land or in the *ocean*, primarily by *photosynthesis* using light and *carbon dioxide (CO₂)* as sources of energy and carbon respectively. It can also occur through chemosynthesis, using chemical energy, for example, in deep sea vents.

Gross primary production (GPP)

The total amount of carbon fixed by *photosynthesis* over a specified time period.

Net primary production (NPP)

The amount of carbon fixed by *photosynthesis* minus the amount lost by *respiration* over a specified time period.

Probability density function (PDF) A probability density function is a function that indicates the relative chances of occurrence of different outcomes of a variable. The function integrates to unity over the domain for which it is defined and has the property that the integral over a sub-domain equals the probability that the outcome of the variable lies within that sub-domain. For example, the probability that a temperature *anomaly* defined in a particular way is greater than zero is obtained from its PDF by integrating the PDF over all possible temperature anomalies greater than zero. Probability density functions that describe two or more variables simultaneously are similarly defined.

Process-based model Theoretical concepts and computational methods that represent and simulate the behaviour of real-world systems derived from a set of functional components and their interactions with each other and the system environment, through physical and mechanistic processes occurring over time.

Projection A potential future evolution of a quantity or set of quantities, often computed with the aid of a model. Unlike predictions, projections are conditional on assumptions concerning, for example, future socio-economic and technological developments that may

or may not be realized. See also *Climate projection*, *Pathways* and *Scenario*.

Proxy A proxy *climate indicator* is any biophysical property of materials formed during the past that is interpreted to represent some combination of climate-related variations back in time. Climate-related data derived in this way are referred to as proxy data, and time series of proxy data are proxy records. Examples of proxy types include pollen assemblages, *tree ring* widths, speleothem and coral geochemistry, and various data derived from marine sediments and *glacier* ice. Proxy data can be calibrated to provide quantitative *climate information*.

Proxy records See *Proxy*.

Quasi-Biennial Oscillation (QBO) A near-periodic oscillation of the equatorial zonal wind between easterlies and westerlies in the tropical *stratosphere* with a mean period of around 28 months. The alternating wind maxima descend from the base of the mesosphere down to the *tropopause* and are driven by wave energy that propagates up from the *troposphere*.

Quaternary The Quaternary Period is the last of three periods that make up the *Cenozoic Era* (66 Ma to present), extending from 2.58 Ma to the present, and includes the *Pleistocene* and *Holocene* Epochs.

Radiative forcing The change in the net, downward minus upward, radiative *flux* (expressed in W m^{-2}) due to a change in an external driver of *climate change*, such as a change in the concentration of *carbon dioxide (CO₂)*, the concentration of volcanic *aerosols* or the output of the Sun. The stratospherically adjusted radiative forcing is computed with all tropospheric properties held fixed at their unperturbed values, and after allowing for stratospheric temperatures, if perturbed, to readjust to radiative-dynamical equilibrium. Radiative forcing is called instantaneous if no change in stratospheric temperature is accounted for. The radiative forcing once both stratospheric and tropospheric adjustments are accounted for is termed the effective radiative forcing.

Radiative response (of the climate system) The net top-of-atmosphere radiative flux that opposes a change in *radiative forcing* as a result of *climate feedbacks*. Typical units: W m^{-2} . See also *Earth's energy budget* and *Climate feedback parameter*.

Rapid dynamical change (of glaciers or ice sheets) Changes in *glacier* or *ice sheet* mass controlled by changes in flow speed and *discharge* rather than by *accumulation* or *ablation*. This can result in a rate of mass change larger than that due to any imbalance between accumulation and ablation. Rapid dynamical change may be initiated by a climatic trigger, such as incursion of warm *ocean* water beneath an *ice shelf*, or thinning of a grounded tide-water terminus, which may lead to reactions within the glacier system that may result in rapid ice loss.

Reanalysis Reanalyses are created by processing past meteorological or oceanographic data using fixed state-of-the-art weather forecasting or *ocean* circulation models with *data assimilation* techniques. They are used to provide estimates of variables such as historical atmospheric temperature and wind or oceanographic temperature and currents, and other quantities. Using fixed data assimilation avoids effects from the changing analysis

system that occur in operational analyses. Although continuity is improved, global reanalyses still suffer from changing coverage and biases in the observing systems.

Reasons for concern (RFCs) Elements of a classification framework, first developed in the IPCC Third Assessment Report, which aims to facilitate judgements about what level of *climate change* may be dangerous (in the language of Article 2 of the UNFCCC; UNFCCC, 1992) by aggregating *risks* from various sectors, considering *hazards*, *exposures*, *vulnerabilities*, capacities to adapt, and the resulting *impacts*.

Reconstruction (of climate variable) Approach to reconstructing the past temporal and spatial characteristics of a *climate* variable from predictors. The predictors can be instrumental data if the reconstruction is used to infill missing data or *proxy* data if it is used to develop *paleoclimate* reconstructions. Various techniques have been developed for this purpose: linear multivariate regression-based methods and non-linear Bayesian and analogue methods.

Reference period A time period of interest, or a period over which some relevant statistics are calculated. A reference period can be used as a baseline period or as a comparison to a baseline period.

Baseline period

A time period against which differences are calculated (e.g., expressed as *anomalies* relative to a baseline).

Reference scenario See *Scenario*.

Reforestation Conversion to *forest* of land that has previously contained forests but that has been converted to some other use. [Note: For a discussion of the term forest and related terms such as *afforestation*, reforestation and *deforestation*, see the 2006 IPCC Guidelines for National Greenhouse Gas Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019; UNFCCC, 2021a, b).] See also *Afforestation*, *Deforestation*, *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

Region *Land* and/or *ocean* area characterized by specific geographical and/or climatological features. The *climate* of a region emerges from a multi-scale combination of its own features, remote influences from other regions, and global climate conditions.

Regional climate model (RCM) A *climate model* at higher *resolution* over a limited area. Such models are used in *downscaling* global *climate* results over specific regional domains.

Regional sea level change See *Sea level change (sea level rise/sea level fall)*.

Relative humidity The ratio of actual water vapour pressure to that at saturation with respect to liquid water or ice at the same temperature. See also *Specific humidity*.

Relative sea level (RSL) change See *Sea level change (sea level rise/sea level fall)*.

Remaining carbon budget See *Carbon budget*.

Representative Concentration Pathways (RCPs) See *Pathways*.

Reservoir A component or components of the *climate system* where a *greenhouse gas (GHG)* or a *precursor* of a greenhouse gas is stored (UNFCCC Article 1.7 (UNFCCC, 1992)). See also *Pool*, *carbon and nitrogen*, *Sequestration*, *Sequestration potential*, *Sink*, *Source* and *Uptake*.

Resilience The capacity of interconnected social, economic and ecological systems to cope with a hazardous event, trend or disturbance, responding or reorganizing in ways that maintain their essential function, identity and structure. Resilience is a positive attribute when it maintains capacity for *adaptation*, learning and/or transformation (Arctic Council, 2016). See also *Hazard*, *Risk* and *Vulnerability*.

Resolution In *climate models*, this term refers to the physical distance (metres or degrees) between each point on the grid used to compute the equations. Temporal resolution refers to the time step or time elapsed between each model computation of the equations.

Respiration The process whereby living organisms convert organic matter to *carbon dioxide (CO₂)*, releasing energy and consuming molecular oxygen.

Response time or adjustment time In the context of *climate* variations, the response time or adjustment time is the time needed for the *climate system* or its components to re-equilibrate to a new state, following a *forcing* resulting from external processes. It is very different for various components of the climate system. The response time of the *troposphere* is relatively short, from days to weeks, whereas the *stratosphere* reaches equilibrium on a time scale of typically a few months. Due to their large heat capacity, the *oceans* have a much longer response time: typically decades, but up to centuries or millennia. The response time of the strongly coupled surface–troposphere system is, therefore, slow compared to that of the stratosphere, and mainly determined by the oceans. The *biosphere* may respond quickly (e.g., to *droughts*), but also very slowly to imposed changes.

In the context of *lifetimes*, response time or adjustment time (T_a) is the time scale characterizing the decay of an instantaneous pulse input into the *reservoir*. See *Response time or adjustment time (T_a)* under *Lifetime*.

Return period An estimate of the average time interval between occurrences of an event (e.g., flood or extreme rainfall) of (or below/above) a defined size or intensity.

Return value The highest (or, alternatively, lowest) value of a given variable, on average occurring once in a given period of time (e.g., in 10 years).

Risk The potential for adverse consequences for human or ecological systems, recognizing the diversity of values and objectives associated with such systems. In the context of *climate change*, risks can arise from potential *impacts* of climate change as well as human responses to climate change. Relevant adverse consequences include those on lives, *livelihoods*, health and well-being, economic, social and cultural assets and investments, infrastructure, services (including ecosystem services), *ecosystems* and species.

In the context of climate change impacts, risks result from dynamic interactions between climate-related *hazards* with the *exposure*

and *vulnerability* of the affected human or ecological system to the hazards. Hazards, exposure and vulnerability may each be subject to uncertainty in terms of magnitude and *likelihood* of occurrence, and each may change over time and space due to socio-economic changes and human decision-making (see also *risk management*, *adaptation* and *mitigation*).

In the context of climate change responses, risks result from the potential for such responses not achieving the intended objective(s), or from potential trade-offs with, or negative side-effects on, other societal objectives, such as the Sustainable Development Goals (SDGs) (see also *risk trade-off*). Risks can arise, for example, from *uncertainty* in implementation, effectiveness or outcomes of climate policy, climate-related investments, technology development or adoption, and system transitions. See also *Hazard* and *Impacts (consequences, outcomes)*.

Risk assessment The qualitative and/or quantitative scientific estimation of *risks*. See also *Risk management* and *Risk perception*.

Risk framework A common framework for describing and assessing *risk* across all three Working Groups is adopted to promote clear and consistent communication of risks and to better inform *risk assessment* and decision-making related to *climate change*.

Risk management Plans, actions, strategies or policies to reduce the *likelihood* and/or magnitude of adverse potential consequences, based on assessed or perceived *risks*. See also *Risk assessment* and *Risk perception*.

Risk perception The subjective judgement that people make about the characteristics and severity of a *risk*. See also *Risk assessment* and *Risk management*.

Risk trade-off The change in the portfolio of *risks* that occurs when a countervailing risk is generated (knowingly or inadvertently) by an intervention to reduce the target risk (Wiener and Graham, 2009).

River discharge See *Streamflow*.

Rock glacier A debris landform (mass of rock fragments and finer material that contains either an ice core or an ice-cemented matrix) generated by a former or current gravity-driven creep of *permafrost* in mountain slopes (Harris et al., 1988; Giardino et al., 2011; IPA-RG, 2020). It is detectable in the landscape due to the occurrence of (i) a steep slope delimiting the terminal part, (ii) generally well-defined lateral margins in a continuation of the front, and (iii) transversal or longitudinal ridges and furrows (ridge and furrow topography). These are geomorphological indicators of the occurrence of permafrost conditions. Although it is an ice storage feature, it is not a type of *glacier* since it does not originate at the surface by the recrystallization of snow.

Runoff The flow of water over the surface or through the subsurface, which typically originates from the part of liquid precipitation and/or snow/ice melt that does not evaporate, transpire or refreeze, and returns to water bodies.

Sampling uncertainty See *Uncertainty*.

Scenario A plausible description of how the future may develop based on a coherent and internally consistent set of assumptions about key driving forces (e.g., rate of technological change (TC),

prices) and relationships. Note that scenarios are neither predictions nor forecasts, but are used to provide a view of the implications of developments and actions. See also [Pathways](#) and [Scenario storyline](#) (under [Storyline](#)).

Baseline scenario

See [Reference scenario](#) (under [Scenario](#)).

Concentrations scenario

A plausible representation of the future development of atmospheric concentrations of substances that are radiatively active (e.g., [greenhouse gases \(GHGs\)](#), [aerosols](#), tropospheric [ozone](#)), plus human-induced [land-cover changes](#) that can be radiatively active via [albedo](#) changes, and often used as input to a [climate model](#) to compute [climate projections](#).

Emissions scenario

A plausible representation of the future development of emissions of substances that are radiatively active (e.g., [greenhouse gases \(GHGs\)](#) or [aerosols](#)), plus human-induced [land-cover changes](#) that can be radiatively active via [albedo](#) changes, based on a coherent and internally consistent set of assumptions about driving forces (such as demographic and socio-economic development, technological change, energy and [land use](#)) and their key relationships. [Concentration scenarios](#), derived from emission scenarios, are often used as input to a [climate model](#) to compute [climate projections](#).

Mitigation scenario

A plausible description of the future that describes how the (studied) system responds to the implementation of [mitigation](#) policies and measures.

Reference scenario

Scenario used as starting or reference point for a comparison between two or more scenarios.

[Note 1: In many types of [climate change](#) research, reference scenarios reflect specific assumptions about patterns of socio-economic development and may represent futures that assume no climate policies or specified climate policies, for example those in place or planned at the time a study is carried out. Reference scenarios may also represent futures with limited or no climate [impacts](#) or [adaptation](#), to serve as a point of comparison for futures with impacts and adaptation. These are also referred to as baseline scenarios in the literature.

Note 2: Reference scenarios can also be climate policy or impact scenarios, which in that case are taken as a point of comparison to explore the implications of other features, for example, of delay, technological options, policy design and strategy or to explore the effects of additional impacts and adaptation beyond those represented in the reference scenario.

Note 3: The term business as usual scenario has been used to describe a scenario that assumes no additional policies beyond those currently in place and that patterns of socio-economic development are consistent with recent trends. The term is now used less frequently than in the past.

Note 4: In climate change [attribution](#) or impact attribution research, reference scenarios may refer to counterfactual historical scenarios

assuming no anthropogenic [greenhouse gas \(GHG\)](#) emissions (climate change attribution) or no climate change (impact attribution).]

Socio-economic scenario

A scenario that describes a plausible future in terms of population, gross domestic product (GDP), and other socio-economic factors relevant to understanding the implications of [climate change](#).

Scenario storyline

See [Storyline](#).

Sea ice Ice found at the sea surface that has originated from the freezing of seawater. Sea ice may be discontinuous pieces (ice floes) moved on the [ocean](#) surface by wind and currents (pack ice), or a motionless sheet attached to the [coast](#) (land-fast ice). Sea ice concentration is the fraction of the ocean covered by ice. Sea ice less than one year old is called first-year ice. Perennial ice is sea ice that survives at least one summer. It may be subdivided into second-year ice and multi-year ice, where multi-year ice has survived at least two summers.

Sea ice area (SIA)

Sea ice area is the area covered by sea ice. In contrast to [sea ice extent](#), it is a linear measure of sea ice coverage that does not depend on grid resolution.

Sea ice concentration

Sea ice concentration is the fraction of the [ocean](#) covered by ice.

Sea ice extent (SIE) Sea ice extent is calculated for gridded data products as the total area of all grid cells with [sea ice concentration](#) above a given threshold, usually 15 %. It hence is a grid-dependent, non-linear measure of sea ice coverage.

Sea level change (sea level rise/sea level fall) Change to the height of sea level, both globally and locally ([relative sea level change](#)) at seasonal, annual, or longer time scales due to (i) a change in [ocean](#) volume as a result of a change in the mass of water in the ocean (e.g., due to melt of [glaciers](#) and [ice sheets](#)), (ii) changes in ocean volume as a result of changes in ocean water density (e.g., expansion under warmer conditions), (iii) changes in the shape of the ocean basins and changes in the Earth's gravitational and rotational fields, and (iv) local subsidence or uplift of the land. [Global mean sea level \(GMSL\) change](#) resulting from change in the mass of the ocean is called barystatic. The amount of barystatic sea level change due to the addition or removal of a mass of water is called its [sea level equivalent \(SLE\)](#). Sea level changes, both globally and locally, resulting from changes in water density are called steric. Density changes induced by temperature changes only are called thermosteric, while density changes induced by salinity changes are called halosteric. Barystatic and steric sea level changes do not include the effect of changes in the shape of ocean basins induced by the change in the ocean mass and its distribution. See also [Vertical land motion \(VLM\)](#), [Land water storage](#), [Glacial isostatic adjustment \(GIA\)](#), [Extreme sea level \(ESL\)](#) and [Storm surge](#).

Geocentric sea level change

The change in local mean sea surface height with respect to the terrestrial reference frame; it is the sea level change observed with instruments from space. See also [Altimetry](#).

Global mean sea level (GMSL) change

The increase or decrease in the volume of the [ocean](#) divided by the ocean surface area. It is the sum of changes in ocean density through temperature changes (global mean [thermosteric sea level change](#)) and changes in the ocean mass as a result of changes in the [cryosphere](#) or [land water storage](#) (barystatic sea level change).

Gravitational, rotational and deformational (GRD) effects

Changes in Earth gravity, Earth rotation and viscoelastic solid Earth deformation (GRD) result from the redistribution of mass between terrestrial ice and water reservoirs and the [ocean](#). Contemporary terrestrial mass loss leads to elastic solid Earth uplift and a nearby relative sea level fall (for a single source of terrestrial mass loss this is within ~2000 km, for multiple sources the distance depends on the interaction of the different relative sea level patterns). Farther away (more than ~7000 km for a single source of terrestrial mass loss), relative sea level rises more than the global average, due (to first order) to gravitational effects. Earth deformation associated with adding water to the oceans and a shift of the Earth's rotation axis towards the source of terrestrial mass loss leads to second-order effects that increase spatial variability of the pattern globally. GRD effects due to the redistribution of ocean water within the ocean itself are referred to as self-attraction and loading effects.

Halosteric sea level change

Halosteric sea level change occurs as a result of salinity variations: higher salinity leads to higher density and decreases the volume per unit of mass. Although both processes can be relevant on regional to local scales, only thermosteric changes impact the [global mean sea level \(GMSL\) change](#), whereas the global mean halosteric change is negligible (Gregory et al., 2019).

Local sea level change

Change in sea level relative to a datum (such as present-day [mean sea level](#)) at spatial scales smaller than 10 km.

Ocean dynamic sea level change

Change in mean sea level relative to the [geoid](#) associated with circulation and density-driven changes in the [ocean](#). Ocean dynamic sea level change is regionally varying but by definition has a zero global mean and conventionally is inverse-barometer corrected (i.e., the effect of the hydrostatic depression of the sea surface by atmospheric pressure changes is removed). Changes in ocean currents occur due to variations in heating and cooling, variability in winds and changes in seasonally to annually averaged air temperature and humidity.

Regional sea level change

Change in sea level relative to a datum (such as present-day [mean sea level](#)) at spatial scales of about 100 km.

Relative sea level (RSL) change

The change in local mean sea surface height (SSH) relative to the local solid surface, that is, the sea floor, as measured by instruments that are fixed to the Earth's surface, such as [tide gauges](#). This reference frame is used when considering coastal [impacts](#), [hazards](#) and [adaptation](#) needs.

Steric sea level change

Steric sea level change is caused by changes in [ocean](#) density and is composed of [thermosteric sea level change](#) and [halosteric sea level change](#).

Thermosteric sea level change

Thermosteric sea level change (where thermosteric sea level rise may also be referred to as thermal expansion) occurs as a result of changes in [ocean](#) temperature: increasing temperature reduces ocean density and increases the volume per unit of mass.

Sea level equivalent (SLE) The SLE of a mass of water, ice, or water vapour is that mass, converted to a volume using a density of 1000 kg m^{-3} , and divided by the present-day [ocean](#) surface area of $3.625 \times 1000 \text{ m}^2$. Thus, 362.5 Gt of water mass added to the ocean correspond to 1 mm of global mean sea level rise.

Sea level rise (SLR) See [Sea level change \(sea level rise/sea level fall\)](#).

Sea surface temperature (SST) The subsurface bulk temperature in the top few metres of the [ocean](#), measured by ships, buoys and drifters. From ships, measurements of water samples in buckets were mostly switched in the 1940s to samples from engine intake water. Satellite measurements of skin temperature (uppermost layer; a fraction of a millimetre thick) in the infrared or the top centimetre or so in the microwave are also used, but must be adjusted to be compatible with the bulk temperature.

Semi-direct (aerosol) effect See [Aerosol–radiation interaction](#).

Semi-empirical model Model in which calculations are based on a combination of observed associations between variables and theoretical considerations relating variables through fundamental principles (e.g., conservation of energy). For example, in sea level studies, semi-empirical models refer specifically to transfer functions formulated to project future [global mean sea level \(GMSL\) change](#), or contributions to it, from future [global surface temperature](#) change or [radiative forcing](#).

Sensible heat flux The turbulent or conductive flux of heat from the Earth's surface to the [atmosphere](#) that is not associated with phase changes of water; a component of the surface energy budget. See also [Latent heat flux](#).

Sequestration The process of storing carbon in a carbon [pool](#). See also [Pool](#), [carbon and nitrogen](#), [Reservoir](#), [Sequestration potential](#), [Sink](#), [Source](#) and [Uptake](#).

Sequestration potential The quantity of [greenhouse gases](#) that can be removed from the [atmosphere](#) by [anthropogenic](#) enhancement of [sinks](#) and stored in a [pool](#). See [Mitigation potential](#) for different subcategories of sequestration potential. See also [Pool](#), [carbon and nitrogen](#), [Reservoir](#), [Sequestration](#), [Source](#) and [Uptake](#).

Shared policy assumptions (SPAs) See [Shared Socio-economic Pathways \(SSPs\)](#) (under [Pathways](#)).

Shared Socio-economic Pathways (SSPs) See [Pathways](#).

Short-lived climate forcers (SLCFs) A set of chemically reactive compounds with short (relative to [carbon dioxide \(CO₂\)](#)) atmospheric [lifetimes](#) (from hours to about two decades) but characterized by different physiochemical properties and environmental effects. Their emission or formation has a significant effect on [radiative forcing](#) over a period determined by their respective atmospheric lifetimes. Changes in their emissions can also induce long-term [climate](#) effects via, in particular, their interactions

with some biogeochemical cycles. SLCFs are classified as direct or indirect, with direct SLCFs exerting climate effects through their radiative forcing and indirect SLCFs being the *precursors* of other direct climate forcers. Direct SLCFs include *methane* (CH_4), *ozone* (O_3), primary *aerosols* and some halogenated species. Indirect SLCFs are precursors of ozone or secondary aerosols. SLCFs can be cooling or warming through interactions with radiation and clouds. They are also referred to as near-term climate forcers. Many SLCFs are also air pollutants. A subset of exclusively warming SLCFs is also referred to as short-lived climate pollutants (SLCPs), including methane, ozone, and *black carbon* (BC).

Short-lived climate pollutants (SLCP) See *Short-lived climate forcers (SLCFs)*.

Shortwave radiation See *Solar radiation*.

Significant wave height The average trough-to-crest height of the highest one-third of the wave heights (sea and swell) occurring in a particular time period.

Simple climate model (SCM) A broad class of lower-dimensional models of the *energy balance*, radiative transfer, *carbon cycle*, or a combination of such physical components. SCMs are also suitable for performing *emulations* of *climate*-mean variables of *Earth system models (ESMs)*, given that their structural flexibility can capture both the parametric and structural uncertainties across process-oriented ESM responses. They can also be used to test consistency across multiple lines of *evidence* with regard to *climate sensitivity* ranges, *transient climate responses (TCRs)*, *transient climate response to cumulative CO₂ emissions (TCREs)* and carbon cycle *feedbacks*. See also *Emulators* and *Earth system model of intermediate complexity (EMIC)*.

Sink Any process, activity or mechanism which removes a *greenhouse gas*, an *aerosol* or a *precursor* of a greenhouse gas from the *atmosphere* (UNFCCC Article 1.8 (UNFCCC, 1992)). See also *Pool, carbon and nitrogen, Reservoir, Sequestration, Sequestration potential, Source* and *Uptake*.

Small Island Developing States (SIDS) Small Island Developing States (SIDS), as recognized by the United Nations OHRLLS (UN Office of the High Representative for the Least Developed Countries, Landlocked Developing Countries and Small Island Developing States), are a distinct group of developing countries facing specific social, economic and environmental vulnerabilities (UN-OHRLLS, 2011). They were recognized as a special case both for their environment and development at the Rio Earth Summit in Brazil in 1992. Fifty-eight countries and territories are presently classified as SIDS by the UN OHRLLS, with 38 being UN member states and 20 being Non-UN Members or Associate Members of the Regional Commissions (UN-OHRLLS, 2018).

Snow cover Snow cover refers to all the snow that has accumulated on the ground at a given time (UNESCO/IASH/WMO, 1970).

Snow cover duration (SCD)

How long snow continuously remains on the land surface, or the period between snow-on and snow-off dates.

Snow cover extent (SCE)

The areal extent of snow covered ground.

Snow water equivalent (SWE)

The depth of liquid water that would result if a mass of snow melted completely.

Socio-economic scenario See *Scenario*.

Soil moisture Water stored in the soil in liquid or frozen form. Root-zone soil moisture is of most relevance for plant activity.

Soil temperature The temperature of the soil. This can be measured or modelled at multiple levels within the depth of the soil.

Solar activity General term collectively describing a variety of magnetic phenomena on the Sun such as *sunspots*, *faculae* (bright areas), and flares (emission of high-energy particles). It varies on time scales from minutes to millions of years. The *solar cycle*, with an average duration of 11 years, is an example of a quasi-regular change in solar activity.

Solar cycle (11-year) A quasi-regular modulation of *solar activity* with varying amplitude and a period of between 8 and 14 years.

Solar radiation Electromagnetic radiation emitted by the Sun with a spectrum close to that of a black body with a temperature of 5770 K. The radiation peaks in visible wavelengths. When compared to the *terrestrial radiation* it is often referred to as shortwave radiation. See also *Insolation* and *Total solar irradiance (TSI)*.

Solar radiation modification (SRM) Refers to a range of radiation modification measures not related to greenhouse gas (GHG) *mitigation* that seek to limit *global warming*. Most methods involve reducing the amount of incoming *solar radiation* reaching the surface, but others also act on the *longwave radiation* budget by reducing optical thickness and cloud lifetime.

Cirrus cloud thinning (CCT)

One of several radiation modification approaches to counter the warming caused by *greenhouse gases (GHGs)*. In this approach, it is proposed to reduce the amount of cirrus clouds by injecting ice nucleating substances in the upper *troposphere*. The reduction in cirrus clouds is expected to increase the amount of longwave cooling to space resulting in a planetary cooling. Although cirrus cloud thinning primarily affects the *longwave radiation* budget of our planet, it is often identified as one of the *solar radiation modification (SRM)* approaches in the literature.

Marine cloud brightening (MCB)

One of several solar radiation modification (SRM) approaches to increase the planetary *albedo*. In this approach, it is proposed to inject sea salt *aerosols* into persistent marine low clouds. This is expected to increase the cloud droplet concentration of these clouds and their reflectivity.

Stratospheric aerosol injection (SAI)

One of several solar radiation modification (SRM) approaches to increase the planetary *albedo*. In the approach, it is proposed to inject highly reflective *aerosols* such as sulphates into the lower *stratosphere*. This is expected to increase the fraction of *solar radiation* deflected to space resulting in a planetary cooling.

Solubility pump A physicochemical process that transports *dissolved inorganic carbon* from the *ocean*'s surface to its interior. The solubility pump is primarily driven by the solubility of *carbon dioxide (CO₂)* (with more CO₂ dissolving in colder water) and the large-scale, thermohaline patterns of ocean circulation.

Source Any process or activity which releases a *greenhouse gas*, an *aerosol* or a *precursor* of a greenhouse gas into the *atmosphere* (UNFCCC Article 1.9 (UNFCCC, 1992)). See also *Pool, carbon and nitrogen, Reservoir, Sequestration, Sequestration potential, Sink and Uptake*.

South American monsoon (SAmM) See *Global monsoon*.

South and Southeast Asian monsoon (SAsM) See *Global monsoon*.

Southern Annular Mode (SAM) See *Annular modes*.

South Pacific Convergence Zone (SPCZ) A band of low-level convergence, cloudiness and precipitation ranging from the west Pacific warm pool south-eastwards towards French Polynesia. It is one of the most significant features of subtropical Southern Hemisphere *climate*. It shares some characteristics with the *Intertropical Convergence Zone (ITCZ)*, but is more extratropical in nature, especially east of the International Date Line.

Southern Oscillation See *El Niño–Southern Oscillation (ENSO)*.

Specific humidity The specific humidity specifies the ratio of the mass of water vapour to the total mass of moist air. See also *Relative humidity*.

Stadial or stade A brief period of regional climatic cooling during a *glacial* or *interglacial* interval, often characterized by transient glacial advances. Stadials are generally of short duration (hundreds to a few thousand years) compared to glacial or interglacial intervals (lasting many thousands to tens of thousands of years). One example of a regional stadial event is based on millennial scale cooling recorded by oxygen *isotope* ratios in Greenland *ice cores*, the so called "Greenland Stadials" (Johnsen et al., 1992). See also *Interstadial or interstade*.

Statistical downscaling See *Downscaling*.

Steric sea level change See *Sea level change (sea level rise/sea level fall)*.

Storm surge The temporary increase, at a particular locality, in the height of the sea due to extreme meteorological conditions (low atmospheric pressure and/or strong winds). The storm surge is defined as being the excess above the level expected from the tidal variation alone at that time and place. See also *Sea level change (sea level rise/sea level fall)* and *Extreme sea level (ESL)*.

Storm tracks Originally, a term referring to the tracks of individual cyclonic weather systems, but now often generalized to refer to the main *regions* where the tracks of extratropical disturbances occur as sequences of low (cyclonic) and high (anticyclonic) pressure systems.

Storyline A way of making sense of a situation or a series of events through the construction of a set of explanatory elements. Usually, it is built on logical or causal reasoning. In *climate* research,

the term storyline is used both in connection to *scenarios* as related to a future trajectory of the climate and *human systems* or to a weather or climate event. In this context, storylines can be used to describe plural, conditional possible futures or explanations of a current situation, in contrast to single, definitive futures or explanations.

Physical climate storyline

A self-consistent and plausible unfolding of a physical trajectory of the *climate system*, or a weather or climate event, on time scales from hours to multiple decades (Shepherd et al., 2018). Through this, storylines explore, illustrate and communicate *uncertainties* in the *climate system* response to *forcing* and in *internal variability*.

Scenario storyline

A narrative description of a *scenario* (or family of scenarios), highlighting the main scenario characteristics, relationships between key driving forces and the dynamics of their evolution.

Stratification Process of forming of layers of (*ocean*) water with different properties such as salinity, density and temperature that act as barrier for water mixing. The strengthening of near-surface stratification generally results in warmer surface waters, decreased oxygen levels in deeper water, and intensification of *ocean acidification (OA)* in the upper ocean.

Stratosphere The highly stratified region of the atmosphere above the *tropopause*, extending to about 50 km altitude. See also *Troposphere*.

Stratospheric aerosol injection (SAI) See *Solar radiation modification (SRM)*.

Stratosphere–troposphere exchange (STE) *Stratosphere–troposphere* exchange (STE) is understood as the *flux* of air or trace constituents across the *tropopause*, including both directions: the stratosphere to troposphere transport (STT) and troposphere to stratosphere transport (TST). STE is one of the key factors controlling the budgets of *ozone*, water vapour and other substances in both the *troposphere* and the lower *stratosphere*.

Stratospheric ozone Stratospheric ozone describes the *ozone (O₃)* that resides in the *stratosphere*, the region of the *atmosphere* which exists between 10 and 50 kilometres above the surface of the earth. Ninety percent of total-column ozone resides in the stratosphere. See also *Ozone layer* and *Ozone-depleting substances (ODSs)*.

Stratospheric polar vortex A large-scale region of cold air poleward of approximately 60 degrees that is contained by a strong westerly jet from the *tropopause* (8–10 km) to the stratopause (50–60 km) and that forms in each hemisphere during the winter half-year. Planetary waves can temporarily disrupt the vortex, producing easterly winds and rapid warming over polar regions in the *stratosphere*, and leading to substantial weakening or breakdown of the vortex.

Stratospheric sounding unit (SSU) A three-channel infrared sounder on operational U.S. National Oceanic and Atmospheric Administration (NOAA) polar-orbiting satellites. The three channels are used to determine profiles of temperature in the *stratosphere* (AMS, 2021).

Streamflow Water flow within a river channel, for example, expressed in $\text{m}^3 \text{s}^{-1}$. A synonym for river discharge.

Subduction *Ocean* process in which surface waters enter the ocean interior from the surface mixed layer through Ekman pumping and lateral *advection*. The latter occurs when surface waters are advected to a region where the local surface layer is less dense and therefore must slide below the surface layer, usually with no change in density.

Sudden stratospheric warming (SSW) A phenomena of rapid warming in the *stratosphere* at high latitudes (sometimes more than 50°C in 1–2 days) that can cause breakdown of *stratospheric polar vortices*.

Sulphur hexafluoride (SF_6) SF_6 , a *greenhouse gas (GHG)*, is mainly used in heavy industry to insulate high-voltage equipment and to assist in the manufacturing of cable-cooling systems and semiconductors.

Sunspots Dark areas on the Sun where strong magnetic fields reduce the convection, causing a temperature reduction of about 1500 K compared to the surrounding regions. The number of sunspots is higher during periods of higher *solar activity* and varies in particular with the *solar cycle*.

Surface air temperature See *Land surface air temperature (LSAT)* and *Global mean surface air temperature (GSAT)*.

Surface mass balance (SMB) See *Mass balance/budget (of glaciers or ice sheets)*.

Surface temperature See *Global mean surface air temperature (GSAT)*, *Global mean surface temperature (GMST)*, *Land surface air temperature (LSAT)* and *Sea surface temperature (SST)*.

Surprises A class of *risk* that can be defined as low-*likelihood* but well-understood events and events that cannot be predicted with current understanding (see Section 1.4.4.3 in AR6 WGI Chapter 1).

Swash See *Extreme sea level (ESL)*.

Talik A layer or body of unfrozen ground in a *permafrost* area due to a local anomaly in thermal, hydrological, hydrogeological or hydrochemical conditions (IPA, 2005).

Technical potential See *Mitigation potential*.

Teleconnection Association between *climate* variables at widely separated, geographically fixed locations related to each other through physical processes and oceanic and/or atmospheric dynamical pathways. Teleconnections can be caused by several climate phenomena, such as Rossby wave-trains, mid-latitude jet and *storm track* displacements, fluctuations of the *Atlantic Meridional Overturning Circulation (AMOC)*, fluctuations of the *Walker circulation*, etc. They can be initiated by *modes of climate variability*, thus providing the development of remote climate *anomalies* at various temporal lags. See also *Teleconnection pattern*.

Teleconnection pattern Spatial structure of climate *anomalies* that are linked to each other through *teleconnection* processes or that are the *large-scale* fingerprint of *modes of climate variability*. Teleconnection patterns can be visualized using correlation and/or regression maps of *climate* variables with some *climate indices* (i.e.,

those derived from the temporal variation of the main modes of climate variability). They can also be obtained from principal component analysis, singular value decomposition/maximum covariance analysis, clustering based on spatial recurrence criteria, etc. See also Section Atlas.3.1 of the AR6 WGI report and *Teleconnection*.

Temperature overshoot Exceedance of a specified global warming level, followed by a decline to or below that level during a specified period of time (e.g., before 2100). Sometimes the magnitude and *likelihood* of the overshoot is also characterized. The overshoot duration can vary from one *pathway* to the next, but in most *overshoot pathways* in the literature and as referred to as overshoot pathways in the AR6, the overshoot occurs over a period of at least one decade and up to several decades. See also *Pathways*.

Terrestrial radiation Radiation emitted by the Earth's surface, the *atmosphere* and clouds. It is also known as thermal infrared or longwave radiation and is to be distinguished from the near-infrared radiation that is part of the solar spectrum. Infrared radiation, in general, has a distinctive range of wavelengths (spectrum) longer than the wavelength of the red light in the visible part of the spectrum. The spectrum of terrestrial radiation is almost entirely distinct from that of shortwave or *solar radiation* because of the difference in temperature between the Sun and the Earth–atmosphere system.

Thermal expansion See *Steric sea level change* (under *Sea level change (sea level rise/sea level fall)*).

Thermocline The layer of maximum vertical temperature gradient in the *ocean*, lying between the surface ocean and the abyssal ocean. In subtropical regions, its source waters are typically surface waters at higher latitudes that have subducted (see *Subduction*) and moved equatorward. At high latitudes, it is sometimes absent, replaced by a *halocline*, which is a layer of maximum vertical salinity gradient.

Thermohaline circulation (THC) See *Meridional overturning circulation (MOC)*.

Thermokarst Process by which characteristic landforms result from thawing of ice-rich *permafrost* or melting of massive ice (IPA, 2005).

Thermosteric See *Sea level change (sea level rise/sea level fall)*.

Tide gauge A device at a coastal or deep-sea location that continuously measures the level of the sea with respect to the adjacent land. Time averaging of the sea level so recorded gives the observed secular changes of the relative sea level.

Time of emergence (ToE) Time when a specific *anthropogenic* signal related to *climate change* is statistically detected to emerge from the background noise of natural *climate variability* in a *reference period*, for a specific *region* (Hawkins and Sutton, 2012). See also *Emergence (of the climate signal)*.

Tipping element A component of the Earth system that is susceptible to a *tipping point*.

Tipping point A critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly. See also *Tipping element*, *Irreversibility* and *Abrupt change*.

Total alkalinity Total Alkalinity (AT) is a measurable parameter of the seawater acid–base system which, when expressed in micromoles per kilogram of seawater, is a conservative variable both on mixing and for changes in temperature and/or pressure. Changes in total alkalinity in the [oceans](#) can result from a variety of biogeochemical processes that affect the acid–base composition of the seawater itself. However, its value is not affected by the exchange of [carbon dioxide](#) gas between seawater and the [atmosphere](#). Measurements of total alkalinity can thus be used to help study these biogeochemical processes and can also be used to help calculate the state of the seawater acid–base system. Total alkalinity is most commonly measured using an acidimetric titration technique that determines how much acid is required to titrate a seawater sample to a specified equivalence point.

Total carbon budget See [Carbon budget](#).

Total solar irradiance (TSI) The total amount of [solar radiation](#) in watts per square metre received outside the Earth's [atmosphere](#) on a surface normal to the incident radiation and at the Earth's mean distance from the Sun. Reliable measurements of solar radiation can only be made from space, and the precise record extends back only to 1978. Variations of a few tenths of a percent are common, usually associated with the passage of [sunspots](#) across the solar disk. The [solar cycle](#) variation of TSI is of the order of 0.1% (AMS, 2021). See also [Insolation](#).

Total water level See [Extreme sea level \(ESL\)](#).

Trace gas A minor constituent of the [atmosphere](#), next to nitrogen and oxygen that together make up 99% of all volume. The most important trace gases contributing to the [greenhouse effect](#) are [carbon dioxide](#) (CO₂), [ozone](#) (O₃), [methane](#) (CH₄), [nitrous oxide](#) (N₂O), perfluorocarbons (PFCs), [chlorofluorocarbons](#) (CFCs), [hydrofluorocarbons](#) (HFCs), [sulphur hexafluoride](#) (SF₆) and water vapour (H₂O).

Transient climate response (TCR) See [Climate sensitivity](#).

Transient climate response to cumulative CO₂ emissions (TCRE) See [Climate sensitivity](#).

Tree rings Concentric rings of secondary wood evident in a cross section of the stem of a woody plant. The difference between the dense, small-celled late wood of one season and the wide-celled early wood of the following spring enables the age of a tree to be estimated, and the ring widths or density can be related to [climate](#) parameters such as temperature and precipitation.

Tropical Atlantic modes See [Tropical Atlantic Variability \(TAV\)](#).

Tropical Atlantic Variability (TAV) A generic term to describe the [climate variability](#) of the tropical Atlantic which is dominated at interannual to decadal time scales by two main climate modes: the [Atlantic Zonal Mode \(AZM\)](#) and the [Atlantic Meridional Mode \(AMM\)](#). The Atlantic Zonal Mode, also commonly referred to as the Atlantic Niño or Atlantic equatorial mode, is associated with [sea surface temperature](#) anomalies near the equator, peaking in the eastern basin, while the Atlantic meridional mode is characterized by an inter-hemispheric gradient of sea surface temperature and wind anomalies. Both modes are associated with significant [teleconnections](#) over Africa and South America.

Atlantic Meridional Mode (AMM) The Atlantic Meridional Mode (AMM) refers to the interannual to [decadal variability](#) of the cross-equatorial [sea surface temperature](#) gradients and surface wind anomalies in the tropical Atlantic. It modulates the strength and latitudinal shifts of the [Inter-tropical Convergence Zone \(ITCZ\)](#), which impacts regional rainfall over Northeast Brazil and Atlantic [hurricane](#) activity. See Section AIV.2.5 in Annex IV of the AR6 WGI report.

Atlantic Zonal Mode (AZM) An equatorial coupled mode in the Atlantic similar to [El Niño–Southern Oscillation \(ENSO\)](#) in the Pacific, and therefore sometimes referred to as the Atlantic Niño. The AZM is associated with [sea surface temperature](#) anomalies near the equatorial Atlantic and rainfall disturbances over the African monsoon domain. Its variations are mostly observed in the interannual scale. It is called also Atlantic equatorial mode. See Section AIV.2.5 in Annex IV of the AR6 WGI report.

Tropical cyclone The general term for a strong, cyclonic-scale disturbance that originates over tropical [oceans](#). Distinguished from weaker systems (often named tropical disturbances or depressions) by exceeding a threshold wind speed. A tropical storm is a tropical cyclone with one-minute average surface winds between 18 and 32 m s⁻¹. Beyond 32 m s⁻¹, a tropical cyclone is called a hurricane, typhoon, or cyclone, depending on geographic location.

Tropopause The boundary between the [troposphere](#) and the [stratosphere](#). It ranges from 8–9 km at high latitudes to 15–16 km in the tropics.

Troposphere The lowest part of the [atmosphere](#), below the [tropopause](#), where clouds and weather phenomena occur. In the troposphere, temperatures generally decrease with height. See also [Stratosphere](#).

Tropospheric ozone See [Ozone \(O₃\)](#) and [Ground-level ozone](#).

Tundra A treeless biome characteristic of polar and alpine regions.

Turnover time (T) See [Lifetime](#).

Typhoon See [Tropical cyclone](#).

Typological domains See [Typological regions](#).

Typological regions Regions of the Earth that share one or more specific features (known as 'typologies'), such as geographic location (e.g., coastal), physical processes (e.g., [monsoons](#)), and biological (e.g., [coral reefs](#), tropical [forests](#)), geological (e.g., mountains) or [anthropogenic](#) (e.g., [megacities](#)) formation, and for which it is useful to consider the common [climate](#) features. Typological regions are smaller than climatic zones (e.g., a mountain region) and can be discontinuous (e.g., a group of megacities affected by the [urban heat island](#) effect, or monsoon regions).

Uncertainty A state of incomplete knowledge that can result from a lack of information or from disagreement about what is known or even knowable. It may have many types of sources, from imprecision in the data to ambiguously defined concepts or terminology, incomplete understanding of critical processes, or uncertain [projections](#) of human behaviour. Uncertainty can therefore be represented by quantitative measures (e.g., a [probability density function](#)) or by qualitative statements (e.g., reflecting the judgement

of a team of experts) (see Moss and Schneider, 2000; IPCC, 2004; Mastrandrea et al., 2010). See also [Confidence](#) and [Likelihood](#).

Deep uncertainty

A situation of deep uncertainty exists when experts or stakeholders do not know or cannot agree on: (1) appropriate conceptual models that describe relationships among key driving forces in a system; (2) the probability distributions used to represent uncertainty about key variables and parameters; and/or (3) how to weigh and value desirable alternative outcomes (Lempert et al., 2003).

Interpolation uncertainty

Uncertainty arising from a statistical or physical model-based interpolation of a field between available estimates to create a more spatio-temporally complete estimate.

Sampling uncertainty

Uncertainty arising from incomplete or uneven availability of measurements in either space or time or both.

Trend estimates uncertainty

Uncertainty arising from data fitting to a time-series with potential non-linear and autorogressive character.

United Nations Framework Convention on Climate Change (UNFCCC) The UNFCCC was adopted in May 1992 and opened for signature at the 1992 Earth Summit in Rio de Janeiro. It entered into force in March 1994 and as of September 2020 had 197 Parties (196 States and the European Union). The Convention's ultimate objective is the 'stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system' (UNFCCC, 1992). The provisions of the Convention are pursued and implemented by two further treaties: the Kyoto Protocol and the Paris Agreement.

Uptake The transfer of substances (such as carbon) or energy (e.g., heat) from one compartment of a system to another; for example, in the Earth system from the [atmosphere](#) to the [ocean](#) or to the land. See also [Pool, carbon and nitrogen, Reservoir, Sequestration, Sequestration potential, Sink](#) and [Source](#).

Upwelling region A region of an [ocean](#) where cold, typically nutrient-rich waters well up from the deep ocean.

Urban heat island (UHI) The relative warmth of a city compared with surrounding rural areas, associated with heat trapping due to the close proximity of tall buildings, the heat-absorbing properties of urban building materials, reduced ventilation, and heat generated directly from human activities. See also [Urbanization](#).

Urbanization In the WGI report, urbanization is used to mean the process of soil sealing with the change of natural [land cover](#) to built environment and urban areas, together with its associated [albedo](#) changes, and increased surface [runoff](#) and elevated warming. See also [Urban heat island \(UHI\)](#).

Ventilation The exchange of [ocean](#) properties with the atmospheric surface layer such that property concentrations are brought closer to equilibrium values with the [atmosphere](#) (AMS, 2021), and the processes that propagate these properties into the ocean interior.

Vertical land motion (VLM) The change in height of the land surface or the sea floor and can have several causes in addition to elastic deformation associated with contemporary changes in [gravity, rotation and viscoelastic solid Earth deformation \(GRD\)](#) and viscoelastic deformation associated with [glacial isostatic adjustment \(GIA\)](#). Subsidence (sinking of the land surface or sea floor) can, for instance, occur through compaction of alluvial sediments in deltaic regions, removal of fluids such as gas, oil, and water, or drainage of peatlands. Tectonic deformation of the Earth's crust can occur as a result of earthquakes and volcanic eruptions. See also [Sea level change \(sea level rise/sea level fall\)](#).

Very short-lived halogenated substances (VSLs) Very short-lived halogenated substances (VSLs) are considered to include source gases (very short-lived halogenated substances present in the [atmosphere](#) in the form they were emitted from natural and [anthropogenic](#) sources), halogenated product gases arising from source gas degradation, and other sources of [tropospheric](#) inorganic halogens. VSLs have tropospheric [lifetimes](#) of around 0.5 years or less.

Volatile organic compounds (VOCs) Important class of organic chemical air pollutants that are volatile at ambient air conditions. Other terms used to represent VOCs are hydrocarbons (HCs), reactive organic gases (ROGs) and non-methane volatile organic compounds (NMVOCs). NMVOCs are major contributors – together with nitrogen oxides (NO_x), and carbon monoxide (CO) – to the formation of photochemical oxidants such as [ozone \(O₃\)](#).

Biogenic volatile organic compounds (BVOCs)

Organic gas-phase compounds emitted from terrestrial and aquatic ecosystems that are critical in ecology and plant physiology, from abiotic and biotic stress functions to integrated components of metabolism. BVOCs are important in atmospheric chemistry as [precursors](#) for [ozone \(O₃\)](#) and secondary organic aerosol formation. Other terms used to represent BVOCs are hydrocarbons (HCs), reactive organic gases (ROGs) and non-methane volatile organic compounds (NMVOCs).

Vulnerability The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts and elements including sensitivity or susceptibility to harm and lack of capacity to cope and adapt. See also [Exposure, Hazard](#) and [Risk](#).

Walker circulation Direct thermally driven zonal overturning circulation in the [atmosphere](#) over the tropical Pacific Ocean, with rising air in the western and sinking air in the eastern Pacific.

Warm spell See [Heatwave](#).

Water cycle See [Hydrological cycle](#).

Water mass A body of [ocean](#) water with identifiable properties (temperature, salinity, density, chemical tracers) resulting from its unique formation process. Water masses are often identified through a vertical or horizontal extremum of a property such as salinity. North Pacific Intermediate Water (NPIW) and Antarctic Intermediate Water (AAIW) are examples of water masses.

Water security 'The capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality water for sustaining livelihoods, human well-being, and socio-

economic development, for ensuring protection against water-borne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability' (UN-Water, 2013).

Wave run-up See *Extreme sea level (ESL)*.

Wave setup See *Extreme sea level (ESL)*.

Weathering The gradual removal of atmospheric *carbon dioxide (CO₂)* through dissolution of silicate and carbonate rocks. Weathering may involve physical processes (mechanical weathering) or chemical activity (chemical weathering).

Well-mixed greenhouse gas A *greenhouse gas (GHG)* that has an atmospheric *lifetime* long enough (greater than several years) to be homogeneously mixed in the *troposphere*, and as such the global average mixing ratio can be determined from a network of surface observations. For many well-mixed greenhouse gases, measurements made in remote regions differ from the global mean by <15%.

West African monsoon (WAFriM) See *Global monsoon*.

West Antarctic Ice Sheet (WAIS) See *Ice sheet*.

Wetland Land that is covered or saturated by water for all or part of the year (e.g., *peatland*).

Younger Dryas The period from approximately 12.9 to 11.7 ka (thousand years before 1950), during the *last deglacial transition*, characterized by a temporary return to colder conditions in many locations, especially around the North Atlantic. See also *Stadial* and *Last deglacial transition*.

Zero emissions commitment See *Climate change commitment*.

20CR	20th Century Reanalysis	AO	Arctic Oscillation
A1B	Special Report on Emissions Scenarios A1B scenario	AOD	aerosol optical depth
AABW	Antarctic bottom water	AOGCM	atmosphere–ocean general circulation model
AAIW	Antarctic intermediate water	AP	Antarctic Peninsula
AAO	Antarctic Oscillation	AQ	air quality
abrupt4xCO2	Scenario with abrupt quadrupling of the atmospheric concentration of carbon dioxide	AR	atmospheric river
ACC	Antarctic Circumpolar Current	AR4	IPCC Fourth Assessment Report
ACCESS	Australian Community Climate and Earth System Simulator	AR5	IPCC Fifth Assessment Report
ACCMIP	Atmospheric Chemistry and Climate Model Intercomparison Project	AR6	IPCC Sixth Assessment Report
ACE	Accumulated Cyclone Energy	ARO	Arctic Ocean
AED	atmospheric evaporative demand	ARP	Arabian Peninsula
AerChemMIP	Aerosols and Chemistry Model Intercomparison Project	ARS	Arabian Sea
AeroCom	Aerosol Comparisons between Observations and Models project	ASE	Amundsen Sea Embayment
AERONET	Aerosol Robotic Network	AUS	Australasia
AEW	African Easterly Wave	AusMCM	Australian–Maritime Continent monsoon
AF	airborne fraction of CO ₂	AVHRR	Advanced Very High Resolution Radiometer
AFOLU	agriculture, forestry and other land use	AZM	Atlantic Zonal Modes
AFR	Africa	BC	black carbon
AGAGE	Advanced Global Atmospheric Gases Experiment	BCE	Before the Common Era
AGCM	atmospheric global climate model	BCP	biological carbon pump
AGFP	absolute global forcing potential	BE	Berkeley Earth
AGR/ECOL	agriculture and ecological droughts	BECCS	bioenergy with carbon capture and storage
AGTP	absolute global temperature change potential	BOB	Bay of Bengal
AGWP	absolute global warming potentials	BP	before the present
AIRS	Atmospheric Infrared Sounder	BrC	brown carbon
AIS	Antarctic Ice Sheet	BSISO	boreal summer intra-seasonal oscillation
ALL	all forcings	BU	bottom up
ALT	active layer thickness	BVOC	biogenic volatile organic compound
AMIP	Atmospheric Model Intercomparison Project	C3S	Copernicus Climate Change Service
AMM	Atlantic Meridional Mode	C4MIP	Coupled Climate Carbon Cycle Model Intercomparison Project
AMMA	African Monsoon Multidisciplinary Analyses	CAF	Central Africa
AMO	Atlantic Multi-decadal Oscillation	CAM	Central America
AMOC	Atlantic Meridional Overturning Circulation	CAMS	Copernicus Atmosphere Monitoring Service
AMSU	Advanced Microwave Sounding Unit	CanESM2	Canadian Earth System Model version 2
AMV	Atlantic Multi-decadal Variability	CanESM5	Canadian Earth System Model version 5
		CAPE	convective available potential energy
		CAR	Caribbean
		CAU	Central Australia
		CCM	chemistry–climate model

CCMI	Chemistry–Climate Modelling Initiative	CORDEX	Coordinated Regional Climate Downscaling Experiment
CCN	cloud condensation nuclei	COSMO	Consortium for Small-scale Modeling
CCS	carbon dioxide capture and storage	COVID-19	coronavirus disease of 2019
CCT	cirrus cloud thinning	CP	Central Pacific
CD	cooling degree days	CPM	convection-permitting model
CDD	consecutive dry days	CRA	climate risk and adaptation assessment
CDR	carbon dioxide removal	CRE	cloud radiative effect
CDRMIP	Carbon Dioxide Removal Model Intercomparison Project	CRM	cloud resolving model
CDW	Circumpolar Deep Water	CRU	Climate Research Unit
CE	Common Era	CRUTEM	Climatic Research Unit gridded global historical near-surface air temperature dataset
CEDS	Community Emissions Data System	CRUTS	Climatic Research Unit gridded time-series dataset
CERES	Clouds and the Earth’s Radiant Energy System	CSIRO	Commonwealth Scientific and Industrial Research Organisation
CESM	Community Earth System Model	DACCS	direct air carbon capture with carbon storage
CFCs	chlorofluorocarbons	DAMIP	Detection and Attribution Model Intercomparison Project
CFMIP	Cloud Feedback Model Intercomparison Project	DCPP	Decadal Climate Prediction Project
CFSR	Climate Forecast System Reanalysis	DECK	Diagnostic, Evaluation and Characterization of Klima
CGTP	combined global temperature change potential	DeepMIP	Deep-Time Model Intercomparison Project
CH₄	methane	DF	drought frequency
CICERO	Center for International Climate and Environment Research	DGVM	dynamic global vegetation model
CID	climatic impact-driver	DI	Drought Index
CISM2	Community Ice Sheet Model 2	DIC	dissolved inorganic carbon
CLLJ	Caribbean low-level jet	DJF	December–January–February
CLSAT	China Land Surface Air Temperature	DJFM	December–January–February–March
CMAP	NOAA Climate Prediction Center Merged Analysis of Precipitation	DMS	dimethyl sulphide
CMIP	Coupled Model Intercomparison Project	DTR	diurnal temperature range
CMIP3	Coupled Model Intercomparison Project Phase 3	DU	Dobson Units
CMIP5	Coupled Model Intercomparison Project Phase 5	EAIS	East Antarctic Ice Sheet
CMIP6	Coupled Model Intercomparison Project Phase 6	EAN	East Antarctica
CNA	Central North America	EO	Equatorial Atlantic Ocean
CNRM	Centre National de la Recherche Météorologique	EAS	East Asia
CO	carbon monoxide	EAsiaM	East Asian monsoon
CO₂	carbon dioxide	EASM	East Asian summer monsoon
CO₂-eq	carbon dioxide equivalent	EAU	Eastern Australia
COBE	Centennial in situ Observation-Based Estimates of Sea Surface Temperature	EAWM	East Asian winter monsoon
		EBAF	CERES Energy Balanced and Filled climate data record

EBM	Energy Balance Model	ESM	Earth system model
EBUS	Eastern boundary upwelling systems	ESMValTool	Earth System Model Evaluation Tool
ECMWF	European Centre for Medium-Range Weather Forecasts	ESRL	NOAA Earth System Research Laboratory
ECS	equilibrium climate sensitivity	ESWL	extreme still water levels
ECV	Essential Climate Variable	ET	evapotranspiration
ECWL	Extreme Coastal Water Level	ETC	extratropical cyclone
EDW	elevation-dependent warming	ETCCDI	Expert Team on Climate Change Detection and Indices
EECO	Early Eocene Climatic Optimum	ETWL	Extreme Total Water Level
EEU	Eastern Europe	EU	European Union
EgC	exagrams of carbon (1000 petagrams of carbon)	FaIR	Finite Amplitude Impulse Response simple climate model
EIO	Equatorial Indian Ocean	FAIR	Findable, Accessible, Interoperable and Reusable principles
EMIC	Earth models of intermediate complexity	FAPAR	fraction of absorbed photosynthetically active radiation
ENA	Eastern North America	FAR	IPCC First Assessment Report
ENSO	El Niño–Southern Oscillation	FD	frost days
EOF	empirical orthogonal function	FESOM	Finite Element Sea ice/Ice Shelf Ocean Model
EOV	Essential Ocean Variable	FFDI	Forest Fire Danger Index
EP	Eastern Pacific	FOLU	forestry and other land use
EPA	USA Environmental Protection Agency	fsST	fixed-sea surface temperature
EPO	Equatorial Pacific Ocean	GCM	general circulation model or global climate model
EqAmer	equatorial America	GCOS	Global Climate Observing System
ERA-Interim	ECMWF global reanalysis	GCP	Global Carbon Project
ERA20C	ECMWF 20th century reanalysis	GDD	growing degree days
ERA20CM	ECMWF 20th century atmospheric model ensemble	GDP	gross domestic product
ERA5	ECMWF global reanalysis (replaces ERA-Interim)	GeoMIP	Geoengineering Model Intercomparison Project
ERF	effective radiative forcing	GFCS	Global Framework for Climate Services
ERFaci	effective radiative forcing due to aerosol–cloud interactions	GFDL	NOAA Geophysical Fluid Dynamics Laboratory
ERFari	effective radiative forcing due to in aerosol–radiation interactions	GHCN	NOAA Global Historical Climatology Network
ERSST	Extended Reconstructed Sea Surface Temperature	GHCNd	NOAA Global Historical Climatology Network daily database
ESA	European Space Agency	GHCnv4	NOAA Global Historical Climatology Network monthly database version 4
ESA CCI	European Space Agency Climate Change Initiative	GHG	greenhouse gas
ESAF	East Southern Africa	GHM	global hydrological model
ESB	East Siberia	GIA	glacial isostatic adjustment
ESGF	Earth System Grid Federation	GIC	Greenland/Iceland

SO₂	sulphur dioxide	ThSL	thermsteric sea level
SO₄²⁻	sulphate	TIB	Tibetan Plateau
SOA	secondary organic aerosols	TNn	annual minimum daily minimum temperature
SOI	Southern Oscillation Index	TNx	annual maximum daily minimum temperature
SON	September–October–November	TOA	the net top-of-the-atmosphere
SOO	Southern Ocean	ToE	time of emergence
SO_x	sulphur oxides	TPI	tripole Index
SPCZ	South Pacific Convergence Zone	TRMM	Tropical Rainfall Measuring Mission
SPEI	Standardized Precipitation Evapotranspiration Index	TS	Technical Summary
SPI	Standardized Precipitation Index	TSI	total solar irradiance
SPM	Summary for Policymakers	UAH	University of Alabama in Huntsville
SPO	South Pacific Ocean or South Pole Observatory	UHI	urban heat island
SR1.5	IPCC Special Report on Global Warming of 1.5°C	UN	United Nations
SRCLL	IPCC Special Report on Climate Change and Land	UNEP	United Nations Environment Programme
SRES	IPCC Special Report on Emissions Scenarios	UNFCCC	United Nations Framework Convention on Climate Change
SREX	IPCC Special Report on Managing the Risk of Extreme Events and Disasters to Advance Climate Change Adaptation	UTLS	upper troposphere and lower stratosphere
SRI	Standardized Runoff Index	UV	ultraviolet
SRM	solar radiation modification	UVic ESCM	University of Victoria Earth System Climate Model
SROCC	IPCC Special Report on the Ocean and Cryosphere in a Changing Climate	VLM	vertical land motion
SSA	Southern South America	VOC	volatile organic compounds
		VPD	vapour pressure deficit
		VSLS	very short-lived halogenated species

Acronyms

WAF	Western Africa
WAfriM	West African monsoon
WAIS	West Antarctic Ice Sheet
WAN	West Antarctica
WBC	western boundary current
WBG	wet bulb globe temperature
WC	Walker circulation
WCA	West Central Asia
WCE	Western and Central Europe
WCRP	World Climate Research Programme
WG	IPCC Working Group
WHO	World Health Organization
WMGHG	well-mixed greenhouse gas
WMO	World Meteorological Organization
WNA	Western North America
WNP	Western North Pacific
WOA18	World Ocean Atlas 2018
WSAF	West Southern Africa
WSB	Wilkes Subglacial Basin
WUE	water-use efficiency
YJ	yottajoule, 10^{24} joules
ZEC	zero emissions commitment
ZJ	zettajoule, 10^{21} joules

AIX

Annex IX: Contributors to the IPCC WGI Sixth Assessment Report

This annex should be cited as:

IPCC, 2021: Annex IX: Contributors to the IPCC Working Group I Sixth Assessment Report. In *Climate Change 2021: The Physical Science Basis. Contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change* [Masson-Delmotte, V., P. Zhai, A. Pirani, S.L. Connors, C. Péan, S. Berger, N. Caud, Y. Chen, L. Goldfarb, M.I. Gomis, M. Huang, K. Leitzell, E. Lonnoy, J.B.R. Matthews, T.K. Maycock, T. Waterfield, O. Yelekçi, R. Yu, and B. Zhou (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 2267–2286.

AAS, Wenche

Norwegian Institute for Air Research (NILU)

Annex X: Expert Reviewers of the IPCC Sixth Assessment Report

This annex should be cited as:

IPCC, 2021: Annex X: Expert Reviewers of the IPCC Working Group I Sixth Assessment Report. In *Climate Change 2021: The Physical Science Basis. Contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change* [Masson-Delmotte, V., P. Zhai, A. Pirani, S.L. Connors, C. Péan, S. Berger, N. Caud, Y. Chen, L. Goldfarb, M.I. Gomis, M. Huang, K. Leitzell, E. Lonnoy, J.B.R. Matthews, T.K. Maycock, T. Waterfield, O. Yelekçi, R. Yu, and B. Zhou (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 2287–2338.

Index

This index should be cited as:

IPCC, 2021: Index. In: *Climate Change 2021: The Physical Science Basis*. Contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change [Masson-Delmotte, V., P. Zhai, A. Pirani, S.L. Connors, C. Péan, S. Berger, N. Caud, Y. Chen, L. Goldfarb, M.I. Gomis, M. Huang, K. Leitzell, E. Lonnoy, J.B.R. Matthews, T.K. Maycock, T. Waterfield, O. Yelekçi, R. Yu, and B. Zhou (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, pp. 2339–2391.

Note: * indicates the term also appears in the Glossary (Annex VII).

A

Abrupt climate change*. *See also* **Tipping points*/elements***

Atlantic Meridional Overturning Circulation collapse, 1148, 1214
biogeochemical cycle, 739
definition of, 202, 739
Earth system model projections, 741
forest dieback, 740
from solar radiation modification, 1059
from water cycle change, 1148
greening of Sahara and Sahel amplification, 1150
in Earth's history, 202
in water cycle, 1059, 1148, 1148–1151, 1151
potential irreversibility of, 633
simulation of, 979, 983, 1010
tipping point thresholds, 106, 630
water cycle changes, 1059

Absolute global forcing potential (AGFP), 1012

Absolute global temperature change potential (AGTP), 1013, 1015

Abundances. *See* **Atmospheric concentrations (abundances)**

Added value*, 1990

AerChemMIP multi-model ensemble

black carbon interaction adjustments, 950
climate–biogenic volatile organic compound feedback, 859
dimethyl sulphide feedback estimate, 858
global OH increase, 850
interactive gas and aerosol chemistry analysis, 852
lightning feedback parameter estimation, 859
nitrate aerosol inclusion in, 854
non-CO₂ parameter estimates, 860
perturbation lifetime for CH₄, 836
projections of atmosphere composition, 878
radiative forcing from emissions (1750–2019), 853
seasaltclimate feedback estimates, 858
surface ozone and particulate matter analysis, 861
 α estimation, 858

Aerosol–cloud interactions* (ERFaci)

alteration of cloud radiative properties, 951
AR5 assessment of, 825, 953
cirrus cloud thinning effects, 861
cooking and heating emissions effect, 866
direct interactions of, 852
effective radiative forcing (1750–2014), 926
effects on water clouds, 950
historical estimates of, 321–322
model-based evidence for, 953
observation-based evidence for, 951
overall assessment of, 953
quantification of forcing from, 951
satellite-based estimates of, 953
sea-spray feedback effects, 858
seeding and cloud-thinning effects, 860
sulphur dioxide emissions in, 820, 855

sulphur emissions from shipping, 872

Aerosol Comparison between Observations and Models project (AeroCom)

atmospheric short-lived climate forcers, 835
black carbon concentration estimates, 848
non-CO₂ parameter estimates, 860
present-day aerosol optical depth estimation, 844

Aerosol effective radiative forcing (ERFari+aci).

See also **Effective radiative forcing (ERF)**
direct and indirect components of, 852
distribution of (1850–2014), 852, 853
evolution of 20-year means of regional, 852
geographical variations in, 855
shortwave and longwave components of, 852
South–North gradient of, 819

Aerosol index (AI), 951

Aerosol optical depth (AOD)

changes in global mean, 845
change with anthropogenic emissions, 939
forcing of aerosol–radiation interactions, 844
global mean trend in (1850–2015), 844
industrial-era change in, 949
over mid-latitudes since 2000, 290
satellite-derived trends of, 309
simulation of regional trends, 844
spatially resolved trends of, 309
sub-micrometre aerosol contribution to, 290
trends in (2000–2009), 308

Aerosol–radiation interactions* (ERFari)

contribution to total forcing from, 926
direct and indirect effects of, 852
marine cloud brightening effects, 860
model-based evidence, 950
top-of-atmosphere adjustments, 948

Aerosols*. *See also* **Particulate matter (PM)**;

Secondary organic aerosols (SOA)

agricultural sources of, 866
ammonia reactions in, 842
AR5 findings for, 844
atmospheric effects of light-absorbing, 1078
carbonaceous, 847–848
chemistry and microphysical processes, 833
composition of, 823
contribution to sea level change, 481
effective radiative forcing (1750–2014), 926
effective radiative forcing (1995–2014), 852
effects in SSP scenarios, 30
effects of decrease in, 1557
for solar radiation modification, 860
from sea spray, 858
historical effective radiative forcing of, 819
in dimming and brightening, 939
indirect effects in forcing, 948
instantaneous and radiation interactions, 950–956
interactions with radiation, 949
mineral dust abundance in, 858
net effect on radiation budget, 311
ocean heat uptake effects of, 1229
particle size in anthropogenic, 309
particulate matter in, 844
precursor sulphur gases in formation of, 845
proxy records of, 308
radiative forcing effects of, 823

regional emissions of, 1373
response to humidity in clouds, 952
sea-salt aerosol interactions, 478
short-lived climate forcers in atmosphere, 819
surface air temperature response (1995–2014), 856
total aerosol effective radiative forcing, 954
water cycle changes from anthropogenic, 1076–1078

Afforestation*/reforestation*. *See also*

Deforestation*

biogenic volatile organic compound emissions, 831
for CO₂ removal, 621, 698, 762
for negative emissions, 1528
freshwater requirements of, 699
in temperate regions, 310
precipitation effects in tropics, 698
regional water cycle alteration with, 1076
surface albedo effects of, 956

Africa

2°C warming effects on, 135
air pollution sources in, 869
assessment of projections, 1969–1970
Atlas, 1967–1971
attribution for trends in, 1968–1969
carbon monoxide burden in, 841
climate features and previous findings, 1967
climatic features in variability in, 1967
climatic impact-driver change in, 1791–1797
climatic impact-driver indices change, 1792
coastal and ocean related hazards, 1796
coastal erosion changes, 1796
confidence in climatic impact-driver changes, 1797
drought changes and human contribution, 1624
drought duration projections, 1120
extreme daily precipitation in, 1558
findings in AR5 and SR1.5 assessments, 1968–1969
glacier, snow and ice changes in, 135
global runoff projections, 1119
groundwater projections in South-western Africa, 1123
heat and cold changes in, 1791–1792
heat stress threshold projections, 1793
heavy precipitation and flooding in, 135
heavy precipitation changes by warming level, 1619
heavy precipitation projections, 1565
hot and cold extreme projections, 1556
model performance assessment, 1969
oceanic influences on climate, 1971
particulate matter emission sources, 821
precipitation and temperature change (1961–2015), 1971
precipitation projections for, 1795
projections for warming, 613
rainfall projections through 21st century, 1971
regional precipitation changes for, 135
regional solar radiation projections, 1791
regional wind projections, 135
sea level changes in, 135
snow and ice projections for, 1795
summary of changes, 122, 135, 1971
surface ozone and particulate matter projections, 882

responses to a collapse of Atlantic Meridional Overturning Circulation, 1148
 river and pluvial flood event projections, 1518
 runoff, streamflow and flooding, 1086
 seasonal snow cover, 1090
 solar modification effects on, 1059
 streamflow and surface water deficits, 1572
 streamflow observations for detection and attribution, 456
 streamflow record evidence for deficits, 1574
 tropical forest effects of, 1851
 variability and extremes in, 1058
 wetlands and lakes, 1090

Water management

effects on land surface hydrology, 1143
 heavy precipitation and flood impacts on, 1783
 snow, glacier and ice-sheet indices use in, 1785
 snowpack changes and storage, 1221
 use of drought indices in, 1783

Water masses*

entry into glacial fjords, 1257
 formation in marginal sea areas, 1244
 heat storage in Southern and North Atlantic, 1214, 1225
 ice shelf penetration by, 1268
 ocean heat uptake circulation by, 1235
 redistribution of, 1246
 salinity changes and rate of formation, 1234
 salinity changes in, 1235
 subduction in Southern Hemisphere Mode Waters, 1231
 variability on Antarctic continental shelf, 1240
 warming in subduction regions, 1232

Water-use efficiency (WUE), 697, 722

Water vapour

and temperature lapse-rate feedbacks, 969
 attribution of tropospheric changes in, 451
 CMIP6 projections for, 1107
 contribution to global warming, 95
 increased atmospheric content of, 1526
 stratospheric increase with methane, 946
 transport of, 1080
 trends (1998–2019), 450

Wave-mean flow interaction, 2156

Waves

contribution to extreme sea level, 1310
 response to surface conditions, 1313
 wind-generated, 1221

Weather and climate extreme events in a changing climate

attribution of extremes, 1525, 1532, 1540
 changes in low-likelihood, high-impact extremes, 1534–1536
 compound events, 1598–1604
 concurrent meteorological conditions (July 2018), 1603
 confidence for changes at 2°C, 1529
 data and methods, 1536–1543
 data sources for studies of, 1537
 definition of extremes, 1536
 detection and attribution, 1552–1553
 droughts, 1518, 1570–1587
 extratropical storms, 1592–1594

extreme El Niño in 2015–2016, 1601–1602
 extreme precipitation changes, 1531
 extreme storms, 1583–1599
 extreme winds, 1597
 extremes in paleoclimate and instrumental records, 1538–1540
 floods, 1567–1571
 global and regional-scale emergence of changes, 1542
 global warming levels versus scenarios for end users, 1542–1545
 greenhouse gases and external forcing effects, 1522
 heavy precipitation and pluvial floods, 1518
 heavy precipitation events, 1557–1568
 hot and cold extremes projections, 1518
 impact of concomitant extremes, 1522
 large-scale circulation on changes, 1528
 low-likelihood, high-impact extremes, 1534–1535
 magnitude and probability changes, 1611
 mean fractional changes with warming, 1527
 Northern Annular Mode links with, 1105
 paleoclimate compared to instrumental records, 1538–1540
 projections for changes in extremes, 1533
 regional information on extremes, 1604–1607
 regional-scale processes and feedbacks in, 1528
 spatial and temporal scales of, 1522
 temperature and precipitation extremes (2018), 1603
 temperature anomalies time series, 1523
 temperature extremes, 1530, 1546–1558
 thermodynamic and dynamic changes in, 1526
 tropical cyclones, 1585
 warming effects on, 1761

Weather generators, 1391

Well-mixed greenhouse gases* (WMGHGs)

atmospheric burdens (2005–2011), 298
 atmospheric concentrations from ice cores, 301
 changes from pre-industrial levels, 676
 CO₂ trend (since 1958), 303
 concentration and effective radiative forcing changes, 68
 concentration changes (since 1850), 290
 concentrations in geological periods, 298–301
 forcing offset by aerosols, 310
 from human activities, 4
 glacial-interglacial fluctuations, 300
 growth rates, 303
 in human-induced climate change, 680
 methane concentrations (past 110 kyr), 301
 methane mixing ratio (2019), 303
 modern measurements of, 301
 N₂O fluctuations at glacial-interglacial transition, 301
 N₂O global surface mean trends, 303
 ozone and aerosol chemistry effects, 944
 plant function effects of, 1787
 pre-instrumental and instrumental mixing ratios, 2140
 present-day mole fractions for, 948
 summary of changes in, 303
