Caribbean (CAR)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (McLean et al., 2015; Angeles-Malaspina et al., 2018; Dunn et al., 2020)	Strong evidence of changes from observations that are in the direction of model-projected changes for the future. The magnitude of projected changes increases with global warming.	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (11.SM). Median increase of more than 1.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Chou et al., 2014a; Angeles-Malaspina et al., 2018)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). More than 2°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Chou et al., 2014a)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). More than 3.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Hall et al., 2013; Chou et al., 2014a; Angeles-Malaspina et al., 2018; Coppola et al., 2021b)
	Likely increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Medium confidence in a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
North-Western South America (NWS)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (Dereczynski et al., 2020; Dunn et al., 2020)	Robust evidence of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 1.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Chou et al., 2014a)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Chou et al., 2014a)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 2°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 4.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5/CMIP3 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Chou et al., 2014a; López-Franca et al., 2016; Coppola et al., 2021b)

Northern South America (NSA)	MET	Low confidence: Mixed trends between subregions, but some evidence of increased drought duration (Skansi et al., 2013; Marengo and Espinoza, 2016; Spinoni et al., 2019; Avila-Diaz et al., 2020; Dereczynski et al., 2020; Dunn et al., 2020)	Low confidence: Limited evidence	Medium confidence: Available evidence suggests drying (Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019; 11.SM)	Medium confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019; Spinoni et al., 2020; 11.SM)	High confidence: Increase in drought severity (Chou et al., 2014a; Duffy et al., 2015; Touma et al., 2015; Marengo and Espinoza, 2016; Spinoni et al., 2020; Coppola et al., 2021b; 11.SM)
	AGR ECOL	Low confidence: Mixed trends between subregions and different drought metrics, including soil moisture, PDSI-PM and SPEI-PM, but some evidence of decrease in drought severity (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Medium confidence: Increase in drying. Tendency towards increase in drought severity in total and surface soil moisture (11.SM; L. Xu et al., 2019) inconsistent trends in studies based on the SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Medium confidence: Increase. Tendency towards increase in drought severity in total soil moisture (11.SM), surface soil moisture (L. Xu et al., 2019) and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	High confidence: Increase in drought severity with different metrics and <i>high agreement</i> between studies (11.SM; Cook et al., 2014a, 2020; Dai et al., 2018; Lu et al., 2019; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Limited evidence. Available evidence suggests lack of signal (Marengo and Espinoza, 2016; Gudmundsson et al., 2021)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows mixed trends (Touma et al., 2015)	Low confidence: Limited evidence. Tendency to drying in two studies (Touma et al., 2015; Cook et al., 2020)	High confidence: Increase in drought severity (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)
South American Monsoon (SAM)	MET	Medium confidence: Increase in the frequency and severity of meteorological droughts based on SPI and CDD (Spinoni et al., 2019; Avila-Diaz et al., 2020; Dereczynski et al., 2020)	Low confidence: Limited evidence and recent droughts in 2010 were not attributed to anthropogenic climate change (Shiogama et al., 2013).	Medium confidence: Increase meteorological droughts (11.SM; Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019). Drying trends in CDD in CMIP6 and SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019) but divergent trends in an RCM driven by two GCMs (Chou et al., 2014a)	Medium confidence: Increase in meteorological droughts (Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019; 11.SM). Drying trend in CDD in CMIP6 and SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019) but divergent trends in an RCM driven by two GCMs (Chou et al., 2014a) and weak trends in CMIP5-based SPI projections (Spinoni et al., 2020)	High confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; Spinoni et al., 2020; Coppola et al., 2021b; 11.SM)
	AGR ECOL	Low confidence: Mixed trends depending on subregions and drought metrics, including soil moisture, PDSI-PM and SPEI-PM (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Medium confidence: Increase in agricultural and ecological droughts based on total column and surface soil moisture, (11.SM; L. Xu et al., 2019), and inconsistent signal with SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	High confidence: Increase in drought severity with different metrics (Naumann et al., 2018; L. Xu et al., 2019; Gu et al., 2020; 11.SM)	High confidence: Increase in drought severity with different metrics and <i>high agreement</i> between studies (11.SM (Cook et al., 2014a, 2020; Dai et al., 2018; Lu et al., 2019; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Limited evidence. Available evidence suggests lack of signal (Gudmundsson et al., 2021)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows mixed signal (Touma et al., 2015)	Low confidence: Limited evidence. Mixed signals (Touma et al., 2015) or tendency to drying (Cook et al., 2020)	High confidence: Increase in drought severity (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)

Region and Drought Type		Observed Trends	Human Contribution	Projections		
				+1.5°C	+2°C	+4°C
North-Eastern South America (NES)	MET	High confidence: Increase in drought duration (Marengo et al., 2017; Brito et al., 2018; Spinoni et al., 2019; Avila-Diaz et al., 2020; Dereczynski et al., 2020; Dunn et al., 2020)	Low confidence: Low confidence in human influence on meteorological drought in the region (Otto et al., 2015b; Martins et al., 2018)	Medium confidence: Increase of CDD (11.SM; Chou et al., 2014a) and SPI (Xu et al. 2019, Touma et al. 2015). Increase in CDD for change of +0.5°C in global warming based on CMIP5 (Wartenburger et al., 2017; SR1.5, Chapter 3)	Medium confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019; Spinoni et al., 2020; Chapter 11 Supplementary Material)	Medium confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; Spinoni et al., 2020; Coppola et al., 2021b; Chapter 11 Supplementary Material)
	AGR ECOL	Medium confidence: Increase in drought severity based on different drought metrics, including soil moisture, PDSI-PM and SPEI-PM (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Low confidence: Lack of signal based on different metrics, including total and surface column soil moisture (11.SM; L. Xu et al., 2019), and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Medium confidence: Increase. Dominant increase in drying with some inconsistencies between different drought metrics and models (Naumann et al., 2018; L. Xu et al., 2019; Gu et al., 2020; 11.SM)	Medium confidence: Increase in drought severity with different metrics and <i>high agreement</i> between different studies (11.SM; Cook et al., 2014a, 2020; Dai et al., 2018; Lu et al., 2019; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Limited evidence. One study shows an increase in drought severity (Gudmundsson et al., 2021).	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows a weak drying (Touma et al., 2015).	Low confidence: Limited evidence. Weak drying (Touma et al., 2015) or inconsistent trends (Cook et al., 2020)	Low confidence: Mixed signals among studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)
South-Western South America (SWS)	MET	Medium confidence: Increase in drought duration and severity (Skansi et al., 2013; Garreaud et al., 2017, 2020; Saurral et al., 2017; Boisier et al., 2018; Dereczynski et al., 2020; Dunn et al., 2020)	Medium confidence that human-induced climate change has contributed to long-term trends and Central Chile drought between 2010 and 2018 (Boisier et al., 2016; Garreaud et al., 2020)	Low confidence: Inconsistent trends. Increase in meteorological drought based on CDD in CMIP6 GCMs (11.SM, but inconsistent trends in SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019) and substantial model spread in Eta-RCM driven with two GCMs (Chou et al., 2014a)	Low confidence: Mixed trends between studies and models. Increase in meteorological drought based on CDD in CMIP6 GCMs (11.SM), but inconsistent trends in SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019) and substantial model spread in Eta-RCM driven with two GCMs (Chou et al., 2014a)	Medium confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; Spinoni et al., 2020)
	AGR ECOL	Low confidence: Mixed trends according to subregions and different drought metrics, including soil moisture, PDSI-PM and SPEI-PM (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Low confidence: Mixed trends based on different metrics, including decrease in total column and surface soil moisture in CMIP6 (11.SM), weak drying in total and surface soil moisture in CMIP5 (L. Xu et al., 2019), and weak signal based on the SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Medium confidence: Increase in drought severity based on total and surface soil moisture in CMIP6 (11.SM) and CMIP5 (L. Xu et al., 2019), and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	High confidence: Increase in drought severity with different metrics and <i>high agreement</i> between studies (11.SM; Cook et al., 2014a, 2020; Dai et al., 2018; Lu et al., 2019; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Limited evidence. General lack of signal in one study (Gudmundsson et al., 2021) but streamflow decrease in subregions in another study (Boisier et al. (2018)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows drying (Touma et al., 2015)	Low confidence: Limited evidence. Strong drying in (Cook et al., 2020); weak drying in (Touma et al., 2015)	High confidence: Increase in drought severity (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)

Region and Drought Type		Observed Trends	Human Contribution	Projections		
				+1.5°C	+2°C	+4°C
South-Eastern South America (SES)	MET	Low confidence: Mixed signals in observed trends depending on subregion (Saurral et al., 2017; Knutson and Zeng, 2018; Spinoni et al., 2019; Dereczynski et al., 2020; Dunn et al., 2020)	Low confidence: Limited evidence Wetting trend in models and observations in part of region in one study (Knutson and Zeng, 2018)	Low confidence: Inconsistent trends. Weak drying trend based on CDD CMIP6 (11.SM), inconsistent trend between models based on SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019) and lack of signal in study with one RCM driven by two GCMs (Chou et al., 2014a)	Low confidence: Mixed signals between studies and models (Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019; Spinoni et al., 2020; 11.SM)	Low confidence: Mixed signals between studies and models (Chou et al., 2014a; Touma et al., 2015; Spinoni et al., 2020; Coppola et al., 2021b; 11.SM)
	AGR ECOL	Low confidence: Mixed trends according to subregions and different drought metrics, including soil moisture, PDSI-PM and SPEI-PM (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Low confidence: Mixed trends based on different metrics, including lack of signal in total column soil moisture, (11.SM), weak drying with surface soil moisture (L. Xu et al., 2019) and wetting based on the SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Low confidence: Mixed signal in changes in drought severity with different metrics, (11.SM; Naumann et al., 2018; L. Xu et al., 2019; Gu et al., 2020)	Low confidence: Mixed signals. Inconsistent trends or lack of signal in total and surface soil moisture (11.SM; Dai et al., 2018; Lu et al., 2019; Cook et al., 2020); decreasing drought severity in PDSI and SPEI-PM (Cook et al., 2014a; Dai et al., 2018; Vicente-Serrano et al., 2020c)
	HYDR	Medium confidence: Decrease. Reduction of hydrological droughts (Dai and Zhao, 2017; Rivera and Penalba, 2018)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows mixed signal (Touma et al., 2015).	Low confidence: Limited evidence. Mixed signal (Touma et al., 2015) or wetting (Cook et al., 2020)	Low confidence: Mixed signal among studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)
Southern South America (SSA)	MET	Medium confidence: Increase in the frequency of droughts (Skansi et al., 2013; Spinoni et al., 2019; Dereczynski et al., 2020; Dunn et al., 2020)	Low confidence: Limited evidence	Low confidence: Lack of signal (11.SM; Chou et al., 2014a)	Medium confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; L. Xu et al., 2019; Spinoni et al., 2020; 11.SM)	Medium confidence: Increase in drought severity (Chou et al., 2014a; Touma et al., 2015; Spinoni et al., 2020; Coppola et al., 2021b; 11.SM)
	AGR ECOL	Low confidence: Mixed trends depending on subregions and drought metrics, including soil moisture, PDSI-PM and SPEI-PM (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Medium confidence: Increase in drought severity considering total column soil moisture, (11.SM), and surface soil moisture (L. Xu et al., 2019) and weak drying with the SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	High confidence: Increase in drought severity (Naumann et al., 2018; L. Xu et al., 2019; Gu et al., 2020; 11.SM)	High confidence: Increase in drought severity with different metrics and <i>high agreement</i> between studies (11.SM; Cook et al., 2014a, 2020; Dai et al., 2018; Lu et al., 2019; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Limited evidence and lack of signal (Gudmundsson et al., 2021)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows drying (Touma et al., 2015)	Low confidence: Limited evidence. Drying (Touma et al., 2015; Cook et al., 2020) or inconsistent trend (R. Zhai et al., 2020)	High confidence: Increase in drought severity (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)

Table 11.16 | Observed trends, human contribution to observed trends, and projected changes at 1.5°C, 2°C and 4°C of global warming for temperature extremes in Europe, subdivided by AR6 regions. See Sections 11.9.1 and 11.9.2 for details.

Increasing hot extremes, decreasing cold extremes			All		
Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
All Europe	All subregions show a <i>very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	<i>Robust evidence</i> of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Hu et al., 2020; Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021). Median increase of more than 1.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021). Median increase of more than 5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021)
	<i>Very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Human influence <i>very likely</i> contributed to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
Greenland/Iceland (GIC)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (Mernild et al., 2014; Sui et al., 2017; Dunn et al., 2020; Peña-Angulo et al., 2020a)	Strong evidence of changes from observations that are in the direction of model-projected changes for the future. The magnitude of projected changes increases with global warming	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 1°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Wehner et al., 2018b; Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 1.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Wehner et al., 2018b; Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 1°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Sillmann et al., 2013b; Cardell et al., 2020)

Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
Greenland/ Iceland (GIC) <i>continued</i>	<i>Very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	<i>Medium confidence</i> in a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
Mediterranean (MED) ⁷	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (El Kenawy et al., 2013; Peña-Angulo et al., 2020a) for Spain, Donat et al., 2013b, 2014a, 2016a; Acero et al., 2014; Filahi et al., 2016; Fioravanti et al., 2016; Ruml et al., 2017; Türkeş and Erlat, 2018; Driouech et al., 2021)	<i>Robust evidence</i> of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Sippel and Otto, 2014; Z. Wang et al., 2017a; Wilcox et al., 2018; Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Zollo et al., 2016; Weber et al., 2018; Cardoso et al., 2019)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 1°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Tomozeiu et al., 2014; Nastos and Kapsomenakis, 2015; Zollo et al., 2016; Abaurrea et al., 2018; Weber et al., 2018; Cardoso et al., 2019; Cardell et al., 2020; Coppola et al., 2021a)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 3.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Giorgi et al., 2014; Tomozeiu et al., 2014; Engelbrecht et al., 2015; Nastos and Kapsomenakis, 2015; Zollo et al., 2016; Cardoso et al., 2019; Cardell et al., 2020; Driouech et al., 2020; Coppola et al., 2021a)
	<i>Very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Human influence <i>likely</i> contributed to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Likely</i> (compared with the recent past (1995–2014)) <i>Very likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)

⁷ This region includes northern Africa and southern Europe.

Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
Western and Central Europe (WCE)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (Twardosz and Kossowska-Cezak, 2013; Shevchenko et al., 2014; Christidis et al., 2015; Scherrer et al., 2016; Dunn et al., 2020)	<i>Robust evidence</i> of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Dong et al., 2014, 2016a; Christidis et al., 2015; Sippel et al., 2016, 2017a, 2018; Z. Wang et al., 2017a; Cattiaux and Ribes, 2018; Leach et al., 2020; Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes (Lau and Nath, 2014; Lhotka et al., 2018)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 1.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 3°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes (Lau and Nath, 2014; Russo et al., 2015; Lhotka et al., 2018)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 5.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 6°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes (Lau and Nath, 2014; Lhotka et al., 2018)
	<i>Very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Human influence <i>likely</i> contributed to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
Eastern Europe (EEU)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (Donat et al., 2016a; P. Zhang et al., 2019; Dunn et al., 2020; Peña-Angulo et al., 2020a)	<i>Robust evidence</i> of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Sippel and Otto, 2014; Hauser et al., 2016; Z. Wang et al., 2017a; Leach et al., 2020; Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Wehner et al., 2018b; Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 1.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Wehner et al., 2018b; Khlebnikova et al., 2019b; Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 4.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 5.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Sillmann et al., 2013b; Khlebnikova et al., 2019b; Cardell et al., 2020)

Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
Eastern Europe (EEU) <i>continued</i>	<i>Very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Human influence <i>likely</i> contributed to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past (1995–2014)) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
Northern Europe (NEU)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (Matthes et al., 2015; Vikhamar-Schuler et al., 2016; Dunn et al., 2020)	<i>Robust evidence</i> of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Massey et al., 2012; Otto et al., 2012; King et al., 2015b; Z. Wang et al., 2017a; Christiansen et al., 2018; Roth et al., 2019; Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 1.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Laliberté et al., 2015; Forzieri et al., 2016; Dosio and Fischer, 2018; Jacob et al., 2018; Sigmond et al., 2018)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 1.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Laliberté et al., 2015; Forzieri et al., 2016; Dosio and Fischer, 2018; Jacob et al., 2018; Sigmond et al., 2018)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). 			Increasing heavy precipitation		
			All		
Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
All Europe	Significant intensification of heavy precipitation (Sun et al., 2021)	<i>Robust evidence</i> of a human contribution to the observed intensification of heavy precipitation (Paik et al., 2020)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021). Median increase larger than zero in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021). Median increase of more than 8% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021)
	<i>Likely</i> intensification of heavy precipitation	Human influence <i>likely</i> contributed to the observed intensification of heavy precipitation	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)
Greenland/Iceland (GIC)	Intensification of heavy precipitation (Peña-Angulo et al., 2020a)	<i>Limited evidence</i>	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 10% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity of heavy precipitation (Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 8% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 15% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity of heavy precipitation (Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 30% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 30% in annual Rx1day and Rx5day and 35% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and CORDEX simulations for an increase in the intensity of heavy precipitation (Cardell et al., 2020)
	<i>Medium confidence</i> in the intensification of heavy precipitation	<i>Low confidence</i>	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
Mediterranean (MED) ⁸	Lack of agreement on the evidence of trends (Casanueva et al., 2014; Donat et al., 2014a; de Lima et al., 2015; Gajić-Čapka et al., 2015; Rajczak and Schär, 2017; Jacob et al., 2018; Mathbout et al., 2018b; Ribes et al., 2019; Dunn et al., 2020; Peña-Angulo et al., 2020a; Coppola et al., 2021a; Sun et al., 2021)	<i>Limited evidence</i> (Añel et al., 2014)	CMIP6 models, CMIP5 models, and RCMs project inconsistent changes in the region (Zollo et al., 2016; Samuels et al., 2018; Cardell et al., 2020; Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and larger than 0 in annual Rx1day and Rx5day and less than -2% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Zollo et al., 2016; Samuels et al., 2018; Cardell et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 8% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 2% in annual Rx1day and Rx5day and less than -2% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Rajczak et al., 2013; Monjo et al., 2016; Zollo et al., 2016; Samuels et al., 2018; Trambly and Somot, 2018; Cardell et al., 2020; Dröuech et al., 2020; Coppola et al., 2021b)

⁸ This region includes northern Africa and southern Europe.

Greenland/Iceland (GIC) <i>continued</i>	AGR ECOL	Low confidence: Limited evidence , given limited number of studies and limited data (Walsh et al., 2020)	Low confidence: Limited evidence because of lack of studies	Low confidence: Limited evidence because of lack of studies (Walsh et al., 2020) and inconsistent changes in soil moisture in CMIP6 (11.SM)	Low confidence: Limited evidence because of lack of studies (Walsh et al., 2020) and inconsistent changes in soil moisture in CMIP6 (11.SM)	Low confidence: Limited evidence because of lack of studies (Walsh et al., 2020) and inconsistent changes in soil moisture in CMIP6 (11.SM)
	HYDR	Low confidence: Limited evidence given limited number of studies and limited data (Walsh et al., 2020)	Low confidence: Limited evidence because of lack of studies	Low confidence: Limited evidence because of lack of studies	Low confidence: Limited evidence because of lack of studies	Low confidence: Limited evidence because of lack of studies
Mediterranean (MED) ¹⁰	MET	Low confidence: Mixed signals. Observed land precipitation trends show pronounced variability within the region, with magnitude and sign of trends in the path century depending on time period (Donat et al., 2014a; Stagge et al., 2017; Mathbout et al., 2018a; Zittis, 2018). There is low confidence in an increase of drought frequency and severity based on SPI (Spinoni et al., 2015; Gudmundsson and Seneviratne, 2016; MedECC, 2020; Peña-Angulo et al., 2020a; Driouech et al., 2021; Vicente-Serrano et al., 2021)	Low confidence: Mixed signals. There are mixed signals within the region and low confidence in human influence on meteorological drought over MED (Kelley et al., 2015; Gudmundsson and Seneviratne, 2016; Knutson and Zeng, 2018; Wilcox et al., 2018)	Medium confidence: Increase. With medium confidence CMIP5 and CMIP6 show a decline in winter and summer total precipitation and increase in number of CDD (percentage precipitation change per degree of local warming is with high confidence larger in June–July–August (JJA) than December–January–February (DJF) (Interactive Atlas, Cardell et al., 2020; Li et al., 2021; 11.SM). Also weak increase in meteorological drought based on SPI (Touma et al., 2015; L. Xu et al., 2019)	Medium confidence: Increase. With medium confidence CMIP5 and CMIP6 show a decline in winter and summer total precipitation and increase in number of CDD (percentage precipitation change per degree of local warming is with high confidence larger in JJA than DJF) (Interactive Atlas, Cardell et al., 2020; Li et al., 2021; 11.SM). Also weak increase in meteorological drought based on SPI (Touma et al., 2015; L. Xu et al., 2019)	High confidence: Increase. With high confidence CMIP5 and CMIP6 (and EURO-CORDEX) show a decline in winter and summer total precipitation and increase in number of CDD. Drought intensity and frequency increase with high confidence , particularly in the southern Mediterranean (11.SM; Interactive Atlas; Samuels et al., 2018; Cardell et al., 2020; Cook et al., 2020; Driouech et al., 2020; Spinoni et al., 2020; Coppola et al., 2021a; Li et al., 2021)
	AGR ECOL	Medium confidence: Increase. Increases in probability and intensity of agricultural and ecological droughts based on soil moisture and water-balance deficits, but weaker signals in some studies (Greve et al., 2014; Hanel et al., 2018; García-Herrera et al., 2019; Moravec et al., 2019; Padrón et al., 2020; Markonis et al., 2021).	Medium confidence: of attribution of increasing trend in ecological and agricultural drought, based on soil moisture and water-balance metrics (Mariotti et al., 2015; García-Herrera et al., 2019; Marvel et al., 2019; Padrón et al., 2020) García-Herrera et al. (2019): Attribution of the 2016–2017 drought in southwestern Europe to climate change based on NCEP trends in soil moisture for weather analogues to 2016–2017 event	Medium confidence: Drought increase for pre-industrial and recent past baselines Recent past baseline: Decreasing soil water availability during drought events compared to 1971–2000, even when accounting for adaptation to mean conditions (Samaniego et al., 2018) Increasing drought duration and frequency compared to 1971–2000 (L. Xu et al., 2019)	High confidence: Drought increase for pre-industrial and recent past baselines Recent past baseline: Decreasing soil water availability during drought events compared to 1971–2000, even when accounting for adaptation to mean conditions; about twice larger signal compared to response at +1.5°C (Samaniego et al., 2018)	Very likely: Drought increase for pre-industrial and recent past baselines Recent past baseline: Based on projections at +3°C: Large decreasing soil water availability during drought events compared to 1971–2000, even when accounting for adaptation to mean conditions; more than three times larger signal compared to response at +1.5°C (Samaniego et al., 2018)

10 This region includes northern Africa and southern Europe.

Region and Drought Types		Observed Trends	Detection and Attribution; Event Attribution	Projections		
				+1.5°C	+2°C	+4°C
Mediterranean (MED) ¹¹ <i>continued</i>	AGR ECOL <i>cont.</i>	Also increases based on analyses using the Standardized Precipitation Evapotranspiration Index (SPEI) and the Palmer Drought Severity Index (PDSI). Increase of drought severity in South Europe (Dai and Zhao, 2017; Stagge et al., 2017; Spinoni et al., 2019), the Iberian Peninsula (Vicente-Serrano et al., 2014; González-Hidalgo et al., 2018)	Mariotti et al. (2015): Attributable trend to CC: Decrease in soil moisture in summer that agrees with CMIP5 models. However, no emergence yet in soil moisture or P–E at grid cell scale (see Cross-Chapter Box A.1. on Uncertainty)	Recent past baseline (continued): Increasing drought magnitude based on SPEI-PM compared to +0.6°C baseline, using simulations within single ESM driven with sea surface temperature and sea ice conditions of seven ESMs (Naumann et al., 2018) Pre-industrial baseline: Decrease in soil moisture during drought events in CMIP6 models at +1.5°C vs pre-industrial baseline (11.SM)	Recent past baseline (continued): Increasing drought duration and frequency compared to 1971–2000, with about twice larger signal compared to response at +1.5°C (L. Xu et al., 2019) Increasing drought magnitude based on SPEI-PM compared to +0.6°C baseline, using simulations within single ESM driven with sea surface temperature and sea ice conditions of seven ESMs (Naumann et al., 2018) Pre-industrial baseline: Decreases of surface and total soil moisture, in AMJJAS and ONDJFM half years (Cook et al., 2020) Decrease in soil moisture during drought events in CMIP6 models at +2°C vs pre-industrial baseline (11.SM)	Recent past baseline (continued): Based on projections at +3°C: About five-fold increase in drought magnitude based on SPEI-PM compared to +0.6°C baseline, using simulations within single ESM driven with sea surface temperature and sea ice conditions of seven ESMs (Naumann et al., 2018) Pre-industrial baseline: Strong decreases of surface and total soil moisture, in spring-summer (AMJJAS) and autumn-winter (ONDJFM) half years, with about twice larger response compared to +2°C (Cook et al., 2020) Very large decrease in soil moisture during drought events in CMIP6 models at +4°C vs pre-industrial baseline (11.SM)
		(Markonis et al., 2021): Increase in duration of agricultural droughts based on soil moisture deficits from 1901–2015 (García-Herrera et al., 2019): Increase in soil moisture anomalies for weather analogues to 2016/2017 drought events in 1985–2018 vs 1948–1984 (Padrón et al., 2020): Weak signals in water-balance (precipitation-evapotranspiration) deficits in the dry season (1985–2014) to (1902–1950) (Greve et al., 2014): Increase in water-balance (precipitation-evapotranspiration) deficits on annual scale, (1985–2005) to (1948–1968) (Hanel et al., 2018): Significant decrease in soil moisture in Southern Europe from 1766–2015 from hydrological model driven with reconstructed meteorological data				

11 This region includes northern Africa and southern Europe.

Region and Drought Types		Observed Trends	Detection and Attribution; Event Attribution	Projections		
				+1.5°C	+2°C	+4°C
Mediterranean (MED) ¹² <i>continued</i>	HYDR	High confidence: Increase in frequency and severity of hydrological droughts, particularly in northern part of the domain (Section 8.3.1.6; Lorenzo-Lacruz et al., 2013; Dai and Zhao, 2017; Gudmundsson et al., 2017, 2019, 2021)	Medium confidence: Increase. Model-based assessment shows with <i>medium confidence</i> a human fingerprint on increased hydrological drought, related to rising temperature and atmospheric demand (Gudmundsson et al., 2017, 2021) and recent events. There is <i>medium confidence</i> that change in land use and terrestrial water management contribute to trends in hydrological drought (Teuling et al., 2019; Vicente-Serrano et al., 2019)	Medium confidence: Increase in hydrological drought for pre-industrial and recent past baseline Recent past baseline: Forzieri et al. (2014): 20-year deficit volumes are projected to increase by 50% by the 2020s compared to 1961–1990 (based on simulations with LISFLOOD model driven by 12 RCM simulations with different GCM-RCM pairs; CMIP3 GCMs, A1B scenario). Frequency of hydrological droughts is projected to increase (Touma et al., 2015)	High confidence: Increase. Recent past baseline: Forzieri et al. (2014) [LISFLOOD simulations driven by 12 RCM-GCM pairs using CMIP3 GCMs]: Strong increase in the 20-year return level minimum flow and deficit volumes in 2050 in A1B scenario compared to 1961–1990 Roudier et al. (2016) [11 RCMs]: Increase in the severity of the low flows at +2°C compared to 1971–2000 conditions in the Iberian Peninsula, Southern France and Greece Schewe et al. (2014). Decrease between 30 and 50% of the annual runoff compared to 1980–2010 Touma et al. (2015): Increase in the frequency of hydrological droughts relative to 1961–2005 Pre-industrial baseline: Cook et al. (2020) [13 CMIP6 models and SSP1-2.6] Decrease in surface and total runoff, in both spring-summer (AMJJAS) and autumn–winter (ONDJFM) half years, with strongest decreases for total runoff in spring–summer half years	Very likely: Increase Recent past baseline: Forzieri et al. (2014) [LISFLOOD simulations driven by 12 RCM-GCM pairs using CMIP5 GCMs]: Strong increase in the 20-year return level minimum flow and deficit volumes in 2080 in A1B scenario compared to 1961–1990 Prudhomme et al. (2014) [five CMIP5 models driving seven global impact models. RCP8.5, 2070–2099] Strong increase (40–60%) of dry days compared to 1976–2005 Giuntoli et al. (2015) (five CMIP5 models driving six global hydrology models): 50–60% increase in frequency of days under low flow in 2066–2099 compared to 1972–2005. Strong signal-to-noise ratio in terms of model agreement, strongest hot spot globally Pre-industrial baseline: Cook et al. (2020) [13 CMIP6 models and SSP3-7.0. Very strong decrease (40–60%) of total runoff in spring-summer half-year in southern Europe. Also strong decreases (>20%) for total runoff in autumn–winter half-year, and for surface runoff in both half years (AMJJAS, ONDJFM)]
Western and Central Europe (WCE)	MET	Low confidence: Limited evidence in change in severity. Small and non-significant changes and some dependency on season and location. Small and non-significant changes in the frequency of dry spells (Zolina et al., 2013), CDD (Dunn et al., 2020), and in drought severity (SPI) (Orlowsky and Seneviratne, 2013; Stagge et al., 2017; Caloiero et al., 2018; Spinoni et al., 2019); but wet days decrease in summer (Gobiet et al., 2014)	Low confidence: No signal or varying signal depending on considered index (Gudmundsson and Seneviratne, 2016; Hauser et al., 2017)	Low confidence: Inconsistent signal in CDD in CMIP6 (11.SM) and in SPI in CMIP5 (Orlowsky and Seneviratne, 2013; Touma et al., 2015; L. Xu et al., 2019)	Low confidence: Inconsistent signal, but with weak tendency to drying in CDD in CMIP6 (11.SM) and SPI in CMIP5 (Orlowsky and Seneviratne, 2013; Touma et al., 2015; L. Xu et al., 2019)	Medium confidence: Increase based on CDD (11.SM). Also partial drying based on CMIP5 SPI, but strong geographical gradients and trends, in part not significant (Orlowsky and Seneviratne, 2013; Touma et al., 2015; Vicente-Serrano et al., 2020c). Summer decrease in wet days projected in Switzerland (Fischer et al., 2015)

12 This region includes northern Africa and southern Europe.

Region and Drought Types		Observed Trends	Detection and Attribution; Event Attribution	Projections		
				+1.5°C	+2°C	+4°C
Western and Central Europe (WCE) <i>continued</i>	AGR ECOL	Medium confidence: Increase. Dominant signal shows an increase in available studies based on soil moisture models and SPEI-PM (Greve et al., 2014; Trnka et al., 2015b; Hanel et al., 2018; Moravec et al., 2019; Spinoni et al., 2019; Padrón et al., 2020; Markonis et al., 2021), despite some conflicting trends in some subregions (Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence due to limited number of studies; one study suggests attribution of the 2017 drought event to climate change due to decreasing trends in soil moisture (García-Herrera et al., 2019)	Low confidence: Inconsistent signal in CMIP6 (11.SM) or weak (L. Xu et al., 2019) or insignificant signal (Samaniego et al., 2018), mostly in summer season. A bit stronger signal based on SPEI-PM projections (Naumann et al., 2018)	Medium confidence: Increase of drought frequency and severity based on some AGR and ECOL drought metrics, for surface soil moisture and SPEI-PM (11.SM; Naumann et al., 2018; Samaniego et al., 2018; L. Xu et al., 2019), mostly for summer season, but inconsistent trends for CMIP6 total soil moisture (Cook et al., 2020; 11.SM)	Medium confidence: Increase of drought frequency and severity based on some AGR and ECOL drought metrics, for CMIP6 surface soil moisture, root-zone soil moisture in hydrological models, and SPEI-PM (11.SM; Naumann et al., 2018; Samaniego et al., 2018; L. Xu et al., 2019; Cook et al., 2020), mostly in summer season, but inconsistent trends for CMIP6 total soil moisture (11.SM) despite projected drying in substantial fraction of domain, in particular over France (Cook et al., 2020)
	HYDR	Low confidence: Weak or insignificant trends (Stahl et al., 2010; Bard et al., 2015; Caillouet et al., 2017; Moravec et al., 2019; Vicente-Serrano et al., 2019; Gudmundsson et al., 2021)	Low confidence: Limited evidence because of lack of studies	Low confidence: No or weak changes; CORDEX simulations: no change in most of domain, slight wetting over the Alps (Forzieri et al., 2014; Touma et al., 2015; Marx et al., 2018)	Medium confidence: Increase in drying, mostly in western part of domain: summer season surface runoff compared to pre-industrial (Cook et al., 2020); annual discharge in substantial part of domain (Schewe et al., 2014); increase in duration and magnitude of low flows over France, decrease in eastern part of domain (Touma et al., 2015; Roudier et al., 2016); CORDEX simulations. drying in western and southeastern parts of domain, but wetting over the Alps (Forzieri et al., 2014; Marx et al., 2018)	Medium confidence: Increase based on several lines of evidence: Tendency towards drying but geographical variations (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)
Eastern Europe (EEU)	MET	Low confidence: Inconsistent or insignificant changes. Inconsistent or insignificant changes in CDD (Khlebnikova et al., 2019a; Dunn et al., 2020). No change or insignificant changes in SPI (Stagge et al., 2017; Caloiero et al., 2018; Spinoni et al., 2019)	Low confidence: Limited evidence because of lack of studies	Low confidence: Inconsistent changes. Inconsistent changes in CDD in CMIP6 (11.SM) and in SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019)	Low confidence: Inconsistent changes. Inconsistent changes in CDD in CMIP6 (11.SM) and in SPI in CMIP5 (Touma et al., 2015; L. Xu et al., 2019)	Low confidence: Inconsistent changes. Inconsistent CDD changes in CMIP6 (11.SM) and weak decrease in drying or inconsistent changes in SPI projections (Touma et al., 2015; Spinoni et al., 2020; Vicente-Serrano et al., 2020c)

Region and Drought Types		Observed Trends	Detection and Attribution; Event Attribution	Projections		
				+1.5°C	+2°C	+4°C
Eastern Europe (EEU) <i>continued</i>	AGR ECOL	Low confidence: Inconsistent or weak changes (Greve et al., 2014; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence because of lack of studies	Low confidence based on different metrics: Inconsistent trends in CMIP6 surface and total soil moisture (11.SM); weak trends in CMIP5 soil moisture (L. Xu et al., 2019) or SPEI-PM (Naumann et al., 2018) projections	Low confidence based on different metrics: Inconsistent trends in CMIP6 surface and total soil moisture (11.SM); weak trends in CMIP5 soil moisture (L. Xu et al., 2019) or SPEI-PM (Naumann et al., 2018) projections	Low confidence: Inconsistent trends based on different metrics: Slight wetting or inconsistent trends in total soil moisture (11.SM; Cook et al., 2020); slight drying in surface soil moisture (11.SM; Cook et al., 2020). Increasing drying of measures based on evaporative demand (Naumann et al., 2018)
	HYDR	Low confidence: Not enough data and limited studies (Gudmundsson et al., 2021)	Low confidence: Limited evidence because of lack of studies	Low confidence: Limited evidence. One study shows lack of signals (Touma et al., 2015)	Low confidence: Inconsistent changes. Some studies with increases in drought/decrease in runoff: (Forzieri et al., 2014) [11 RCMs forced with CMIP5 models and the LISFLOOD model]: Decrease in the 20-year return level minimum flow and deficit volumes; (Cook et al., 2020): decrease in summer surface runoff in CMIP6 models. Some studies with no change in HYDR drought or runoff: (Touma et al., 2015; Roudier et al., 2016) [11 RCMs]: No substantial changes in the severity of the low flows; (Schewe et al., 2014): No substantial changes in the annual runoff	Medium confidence: Weak increase. (Forzieri et al., 2014) [11 RCMs forced with CMIP5 models and the LISFLOOD model]: Decrease in the 20-year return level minimum flow and deficit. (Cook et al., 2020) [13 CMIP6 models and SSP3-7.0. Moderate decrease (20%) of total runoff in eastern Europe during the warm season. (Prudhomme et al., 2014) [five CMIP5 models and seven global impact models. RCP8.5] Small increase (10%) of dry days. (Giuntoli et al., 2015): Weak increase in probability of low flow but low signal-to-noise ratio
Northern Europe (NEU)	MET	Medium confidence: Decrease in intensity and frequency; but dependence on considered index, time frame and region, including negligible trends over shorter periods or some subregions (Orlowsky and Seneviratne, 2013; Stagge et al., 2017; Spinoni et al., 2019; Dunn et al., 2020)	Medium confidence: Human contribution to decrease (Gudmundsson and Seneviratne, 2016)	Medium confidence: Decrease of drought frequency and severity based on SPI indices (Touma et al., 2015; L. Xu et al., 2019), but unclear sign in CDD (11.SM)	Medium confidence: Decrease of drought frequency and severity based on SPI indices (Touma et al., 2015; L. Xu et al., 2019), but unclear sign in CDD (11.SM)	Medium confidence: Decrease of drought frequency and severity based on SPI indices (Touma et al., 2015; Spinoni et al., 2020; Vicente-Serrano et al., 2020c) but unclear sign and drying tendency in CDD (11.SM). Same assessment for pre-industrial and recent past baselines

Region and Drought Types		Observed Trends	Detection and Attribution; Event Attribution	Projections		
				+1.5°C	+2°C	+4°C
Northern Europe (NEU) <i>continued</i>	AGR ECOL	Low confidence: Overall weak signals and signs depend on considered season and index (Greve et al., 2014; Spinoni et al., 2019; Padrón et al., 2020; Markonis et al., 2021)	Low confidence: Limited evidence because of lack of studies	Low confidence: Inconsistent signal in CMIP6 total soil moisture at +1.5°C compared to pre-industrial baseline (11.SM). Overall inconsistency of signals between studies for different indices (e.g. total soil moisture, surface soil moisture, SPEI-PM) independently of global warming level (Naumann et al., 2018; L. Xu et al., 2019; Cook et al., 2020), but some spatial variations in trends and stronger signals in summer (Samaniego et al., 2018). Same assessment for pre-industrial and recent past baseline	Low confidence: Inconsistent signal in CMIP6 total soil moisture at +2°C compared to pre-industrial baseline (11.SM). Overall inconsistency of signals between studies for different indices (e.g. total soil moisture, surface soil moisture, SPEI-PM) independently of global warming level (Naumann et al., 2018; L. Xu et al., 2019; Cook et al., 2020); but some spatial variations in trends and stronger signals in summer and over Scandinavia compared to UK (Samaniego et al., 2018). Same assessment for pre-industrial and recent past baseline	Low confidence: Inconsistent signal in CMIP6 total soil moisture at +4°C compared to pre-industrial baseline (11.SM). Overall inconsistency of signals between studies for different indices (e.g. total soil moisture, surface soil moisture, SPEI-PM) independently of global warming level (Naumann et al., 2018; L. Xu et al., 2019; Cook et al., 2020; Vicente-Serrano et al., 2020c), but some spatial variations in trends and stronger signals in summer and over Scandinavia compared to UK (Samaniego et al., 2018). Same assessment for pre-industrial and recent past baseline
	HYDR	Medium confidence: Decrease in hydrological drought for overall region, but trends are weak, can be of different sign in sub-regions, and are dependent on time frame (Harrigan et al., 2018; Kay et al., 2018; Barker et al., 2019; Gudmundsson et al., 2019, 2021; Vicente-Serrano et al., 2019)	Low confidence: Limited evidence because of lack of studies	Low confidence: Weak and inconsistent signals. Slight increase in Scandinavia, slight decrease or no change in the UK (Forzieri et al., 2014; Touma et al., 2015; Marx et al., 2018)	Low confidence: Inconsistent changes, generally with drying in ESMs (CMIP5, CMIP6) and wetting in CORDEX (Forzieri et al., 2014; Touma et al., 2015; Roudier et al., 2016; Dai et al., 2018; Marx et al., 2018; Cook et al., 2020) Cook et al. (2020): Weak increase in hydrological drought (decrease in runoff) in summer in Scandinavia Roudier et al. (2016): Decrease in magnitude and duration of low-flows (wetting trend) Dai et al. (2018): CMIP5, RCP4.5, (2070–2099) – (1970–1999): slight drying trend, but lack of model agreement Forzieri et al. (2014), for 2050 compared to 1961–1990 baseline, CORDEX simulations: Decrease in magnitude of low flow in Scandinavia; no change in UK Marx et al. (2018), CORDEX simulations: slight wetting in Scandinavia	Medium confidence: Weak increase in hydrological drought in summer but low signal-to-noise ratio (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)

Table 11.19 | Observed trends, human contribution to observed trends, and projected changes at 1.5°C, 2°C and 4°C of global warming for temperature extremes in North America, subdivided by AR6 regions. See Sections 11.9.1 and 11.9.2 for details.

Increasing hot extremes, decreasing cold extremes			All		
Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
All North America	Most subregions show a <i>likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	<i>Robust evidence</i> of a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Seong et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021). Median increase of more than 1°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021). Median increase of more than 4.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021)
	<i>Very likely</i> increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Human influence <i>very likely</i> contributed to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
North Central America (NCA)	Significant increases in the intensity and frequency of hot extremes and significant decreases in the intensity and frequency of cold extremes (Martínez-Austria and Bandala, 2017; Montero-Martínez et al., 2018; García-Cueto et al., 2019; Dunn et al., 2020)	Strong evidence of changes from observations that are in the direction of model-projected changes for the future. The magnitude of projected changes increases with global warming	CMIP6 models project an increase in the intensity and frequency of TXx events and a decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 0.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 1.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Kharin et al., 2013; Sillmann et al., 2013b; Alexandru, 2018; Wehner et al., 2018b)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 1°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 2°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Kharin et al., 2013; Sillmann et al., 2013b; Alexandru, 2018; Wehner et al., 2018b)	CMIP6 models project a robust increase in the intensity and frequency of TXx events and a robust decrease in the intensity and frequency of TNn events (Li et al., 2021; 11.SM). Median increase of more than 3.5°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 4.5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Kharin et al., 2013; Sillmann et al., 2013b; Alexandru, 2018; Wehner et al., 2018b)

Median increase of more than 4°C in the 50-year TXx and TNn events compared to the 1°C warming level (Li et al., 2021) and more than 5°C in annual TXx and TNn compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes (Bennett and Walsh, 2015; G. Li et al., 2018; X. Zhang et al., 2019)
	Very likely increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	<i>High confidence</i> in a human contribution to the observed increase in the intensity and frequency of hot extremes and decrease in the intensity and frequency of cold extremes	Increase in the intensity and frequency of hot extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Increase in the intensity and frequency of hot extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial) Decrease in the intensity and frequency of cold extremes: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)

Table 11.20 | Observed trends, human contribution to observed trends, and projected changes at 1.5°C, 2°C and 4°C of global warming for heavy precipitation in North America, subdivided by AR6 regions. See Sections 11.9.1 and 11.9.3 for details.

Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
All North America	Significant intensification of heavy precipitation (Dunn et al., 2020; Sun et al., 2021)	<i>Robust evidence</i> of a human contribution to the observed intensification of heavy precipitation (Kirchmeier-Young and Zhang, 2020; Paik et al., 2020)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021). Median increase of more than 6% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021). Median increase of more than 15% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021)

Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
All North America <i>continued</i>	<i>Likely</i> intensification of heavy precipitation	Human influence <i>likely</i> contributed to the observed intensification of heavy precipitation	Intensification of heavy precipitation: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Virtually certain</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
North Central America (NCA)	Trends are generally not significant (Donat et al., 2016a; García-Cueto et al., 2019; Dunn et al., 2020; Sun et al., 2021)	Disagreement among studies (Hoerling et al., 2014; Eden et al., 2016; Pall et al., 2017)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 2% in annual Rx1day and Rx5day and 0% in annual Rx30day compared to pre-industrial (11.SM)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 4% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 4% in annual Rx1day and Rx5day and 0% in annual Rx30day compared to pre-industrial (11.SM)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 15% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 10% in annual Rx1day and Rx5day and 2% in annual Rx30day compared to pre-industrial (11.SM)
	<i>Low confidence</i>	<i>Low confidence</i>	Intensification of heavy precipitation: <i>Medium confidence</i> (compared with the recent past, 1995–2014) <i>High confidence</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)
Western North America (WNA)	Lack of agreement on the evidence of trends (Wu, 2015; Easterling et al., 2017; Dunn et al., 2020; Sun et al., 2021)	Evidence of a human contribution for some events (Easterling et al., 2017; Kirchmeier-Young and Zhang, 2020), but cannot be generalized	CMIP6 models project inconsistent changes in the region (Li et al., 2021)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 6% in annual Rx1day and Rx5day and 4% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Easterling et al., 2017)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 10% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 10% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Easterling et al., 2017)
	<i>Low confidence</i>	<i>Low confidence</i>	Intensification of heavy precipitation: <i>Low confidence</i> (compared with the recent past, 1995–2014) <i>Medium confidence</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Medium confidence</i> (compared with the recent past, 1995–2014) <i>High confidence</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)

Wang et al., 2018; Kirchmeier-Young and Zhang, 2020)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 4% in annual Rx1day and Rx5day and 2% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Easterling et al., 2017)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 4% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 6% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Easterling et al., 2017)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 10% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 10% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Knutson et al., 2015; Easterling et al., 2017; Kossin et al., 2017)
	<i>High confidence</i> in the intensification of heavy precipitation	<i>Medium confidence</i> in a human contribution to the intensification of heavy precipitation	Intensification of heavy precipitation: <i>Medium confidence</i> (compared with the recent past, 1995–2014) <i>High confidence</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)
Eastern North America (ENA)	Significant intensification of heavy precipitation (Wu, 2015; Easterling et al., 2017; Emanuel, 2017; Risser and Wehner, 2017; van Oldenborgh et al., 2017; Trenberth et al., 2018; S.-Y.S. Wang et al., 2018; Dunn et al., 2020; Sun et al., 2021), but a lack of a significant trend over Canada (Shephard et al., 2014; Mekis et al., 2015; Vincent et al., 2018)	Evidence of a human contribution for some events (Easterling et al., 2017; Teufel et al., 2019; Kirchmeier-Young and Zhang, 2020), but cannot be generalized	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 6% in annual Rx1day and Rx5day and 4% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Easterling et al., 2017; X. Zhang et al., 2019)	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 4% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 8% in annual Rx1day and Rx5day and 6% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Easterling et al., 2017; X. Zhang et al., 2019)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 15% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 15% in annual Rx1day and Rx5day and 10% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Knutson et al., 2015; Easterling et al., 2017; Kossin et al., 2017; X. Zhang et al., 2019)
	<i>High confidence</i> in the intensification of heavy precipitation	<i>Low confidence</i>	Intensification of heavy precipitation: <i>Medium confidence</i> (compared with the recent past, 1995–2014) <i>High confidence</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Very likely</i> (compared with the recent past, 1995–2014) <i>Extremely likely</i> (compared with pre-industrial)

Region	Observed Trends	Detection and Attribution; Event Attribution	Projections		
			1.5°C	2°C	4°C
North-East North America (NEN)	<i>Limited evidence</i> (Shephard et al., 2014; Mekis et al., 2015; Vincent et al., 2018)	Evidence of a human contribution for some events (Szeto et al., 2015), but cannot be generalized	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 8% in annual Rx1day and Rx5day and 6% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (X. Zhang et al., 2019)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 6% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 10% in annual Rx1day and Rx5day and 8% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (X. Zhang et al., 2019)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 20% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 20% in annual Rx1day and Rx5day and 15% in annual Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (X. Zhang et al., 2019)
	<i>Low confidence</i>	<i>Low confidence</i>	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)
North-West North America (NWN)	Lack of agreement on the evidence of trends (Shephard et al., 2014; Mekis et al., 2015; Vincent et al., 2018; Dunn et al., 2020; Sun et al., 2021)	Evidence of a human contribution for some events (Teufel et al., 2017; Kirchmeier-Young and Zhang, 2020), but cannot be generalized	CMIP6 models project an increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 2% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 6% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Bennett and Walsh, 2015; X. Zhang et al., 2019)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 6% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 10% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Bennett and Walsh, 2015; X. Zhang et al., 2019)	CMIP6 models project a robust increase in the intensity and frequency of heavy precipitation (Li et al., 2021; 11.SM). Median increase of more than 20% in the 50-year Rx1day and Rx5day events compared to the 1°C warming level (Li et al., 2021) and more than 20% in annual Rx1day, Rx5day, and Rx30day compared to pre-industrial (11.SM) Additional evidence from CMIP5 and RCM simulations for an increase in the intensity of heavy precipitation (Bennett and Walsh, 2015; X. Zhang et al., 2019)
	<i>Low confidence</i>	<i>Low confidence</i>	Intensification of heavy precipitation: <i>High confidence</i> (compared with the recent past, 1995–2014) <i>Likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Likely</i> (compared with the recent past, 1995–2014) <i>Very likely</i> (compared with pre-industrial)	Intensification of heavy precipitation: <i>Extremely likely</i> (compared with the recent past, 1995–2014) <i>Virtually certain</i> (compared with pre-industrial)

Table 11.21 | Observed trends, human contribution to observed trends, and projected changes at 1.5°C, 2°C and 4°C of global warming for meteorological droughts (MET), agricultural and ecological droughts (AGR/ECOL), and hydrological droughts (HYDR) in North America, subdivided by AR6 regions.
See Sections 11.9.1 and 11.9.4 for details.

Fact		Virtually certain		Extremely likely		Very likely		Likely		High confidence		Medium confidence		Low confidence	
Increasing drought														Decreasing drought	
Fact		Virtually certain		Extremely likely		Very likely		Likely		High confidence		Medium confidence		All	
Region and Drought Type		Observed Trends		Human Contribution		Projections									
						+1.5°C		+2°C		+4°C					
North Central America (NCA)	MET	Low confidence: Inconsistent changes in the duration and frequency of droughts, (Spinoni et al., 2019; Dunn et al., 2020)		Low confidence: No signal in precipitation (Funk et al., 2014; Swain et al., 2014; Wang and Schubert, 2014)		Low confidence: Limited evidence. Evidence suggests tendency towards drying (L. Xu et al., 2019; 11.SM)		Medium confidence: Increase in drought duration (L. Xu et al., 2019; Spinoni et al., 2020; 11.SM) L. Xu et al. (2019): Strong drying signal for meteorological drought duration using SPI at 2°C compared to recent past Spinoni et al. (2020): for RCP4.5 compared to recent past: SPI-based drying trends in CORDEX GCMs, but inconsistent signals in CORDEX RCMs		High confidence: Increase in meteorological drought severity in the majority of models (Sillmann et al., 2013b; Touma et al., 2015; Escalante-Sandoval and Nuñez-Garcia, 2017; Spinoni et al., 2020; 11.SM)					
	AGR ECOL	Limited evidence: No signal in the duration and severity of droughts based on soil moisture, PDSI and SPEI and conflicting trend depending of the subregion (Greve et al., 2014; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)		Low confidence: Limited evidence		Limited evidence: Mixed signal between the different drought metrics, including total column soil moisture, (11.SM), surface soil moisture (L. Xu et al., 2019) and a weak drying by SPEI-PM (Naumann et al., 2018; Gu et al., 2020)		Medium confidence: Increase of drought severity. This is consistent between the different drought metrics including total column soil moisture, (11.SM), surface soil moisture (L. Xu et al., 2019) and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)		Likely: Increase of drought severity. This is consistent between the different drought metrics including total column soil moisture, (11.SM), surface soil moisture (Dai et al., 2018; Lu et al., 2019), PDSI (Dai et al., 2018) and SPEI-PM (Cook et al., 2014a; Vicente-Serrano et al., 2020c)					
	HYDR	Low confidence: Limited evidence		Low confidence: Limited evidence		Low confidence: Limited evidence. One study shows inconsistent trends (Touma et al., 2015)		Low confidence: Limited evidence. Inconsistent trends in available studies (Touma et al., 2015; Cook et al., 2020; R. Zhai et al., 2020)		Low confidence: Mixed signal among studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020), but slight stronger tendency towards drying					
Western North America (WNA)	MET	Low confidence: Inconsistent trends depending on subregion (Swain and Hayhoe, 2015; Wehner et al., 2017; Spinoni et al., 2019; Dunn et al., 2020)		Low confidence: Limited evidence		Low confidence: Limited evidence and inconsistent trends depending on models and seasons (Swain and Hayhoe, 2015; L. Xu et al., 2019; 11.SM)		Low confidence: Limited evidence and inconsistent trends depending on models and seasons (Swain and Hayhoe, 2015; L. Xu et al., 2019; Spinoni et al., 2020)		Low confidence: Mixed signal among models, seasons, and studies (Swain and Hayhoe, 2015; Touma et al., 2015; Spinoni et al., 2020; 11.SM), with tendency towards drying in the spring and wetting in summer (Swain and Hayhoe, 2015)					

Region and Drought Type		Observed Trends	Human Contribution	Projections		
				+1.5°C	+2°C	+4°C
Western North America (WNA) <i>continued</i>	AGR ECOL	Medium confidence: Increase. Dominant increase but some inconsistent trends based on soil moisture, water-balance estimates, PDSI and SPEI, but some inconsistent trends depending study, index and the subregion (Greve et al., 2014; Griffin and Anchukaitis, 2014; Williams et al., 2015, 2020; Ahmadalipour and Moradkhani, 2017; Dai and Zhao, 2017; Spinoni et al., 2019; Padrón et al., 2020)	Medium confidence: Human contribution to observed trend. Williams et al. (2020) concluded human-induced climate change contributed to the strong soil moisture deficits recorded in the last two decades in Western North America through VPD (and AED) increases associated with higher air temperatures and lower air humidity. Williams et al. (2015) and Griffin and Anchukaitis (2014) concluded that increased AED has had an increased contribution to drought severity over the last decades, and played a dominant role in the intensification of the 2012–2014 drought in California.	Limited evidence: Inconsistent signal between models, with weak tendency to increased drying in total and surface soil moisture (L. Xu et al., 2019; 11.SM) and the SPEI-PM (Naumann et al., 2018; Gu et al., 2020). Weak soil moisture drying projection for California (Louise et al., 2018)	Medium confidence: Increase of drought severity. There are differences depending on metrics and models, with weak median drying and substantial inter-model spread for total soil moisture (Cook et al., 2020; 11.SM) and larger drying for surface soil moisture (L. Xu et al., 2019; Cook et al., 2020; 11.SM) and SPEI-PM (Naumann et al., 2018; Gu et al., 2020). Stronger soil moisture drying in southern part of domain (Cook et al., 2020)	Medium confidence: Increase of drought severity. There are differences depending on metrics and models, with weak drying in total column soil moisture (Cook et al., 2020; 11.SM), and substantial drying with surface soil moisture (Dai et al., 2018; Lu et al., 2019; Cook et al., 2020; 11.SM), PDSI (Dai et al., 2018) and SPEI-PM (Cook et al., 2014a; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Mixed signal between different time frames and subregions (Poshtiri and Pal, 2016; Gudmundsson et al., 2019, 2021; Dudley et al., 2020). Strong spatial variability in the recent trends of low flows in the region (Poshtiri and Pal, 2016) but dominant increase of hydrological drought in California and in the Colorado basin (M. Xiao et al., 2018; Milly and Dunne, 2020)	Low confidence: Mixed signal for overall region in observations. But evidence that temperature increase has been the main driver of increased hydrological drought in California and in the Colorado basin (Shukla et al., 2015; Udall and Overpeck, 2017; M. Xiao et al., 2018; Milly and Dunne, 2020)	Low confidence: Limited evidence. One study shows drying (Touma et al., 2015)	Medium confidence: Increase in hydrological drought (more intense low flows, less runoff and more frequent hydrological droughts) (Touma et al., 2015; Cook et al., 2020; R. Zhai et al., 2020) Particularly strong evidence of increasing hydrological droughts in regions dependent on snow pack reservoirs (Wehner et al., 2017; Ackerly et al., 2018; Rhoades et al., 2018)	Medium confidence: Increase in hydrological droughts (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020) Particularly strong evidence of increasing hydrological droughts in regions dependent on snow pack reservoirs (Wehner et al., 2017; Ackerly et al., 2018; Rhoades et al., 2018)
Central North America (CNA)	MET	Medium confidence: Decrease in the duration and frequency of meteorological droughts (Wehner et al., 2017; Spinoni et al., 2019; Dunn et al., 2020)	Low confidence: Limited evidence (Rupp et al., 2013; Easterling et al., 2017)	Low confidence: Limited evidence and inconsistent trends (L. Xu et al., 2019; 11.SM)	Low confidence: Mixed signal among different models (Sillmann et al., 2013b; Spinoni et al., 2020; 11.SM)	Low confidence: Mixed signal among different models (Sillmann et al., 2013b; Touma et al., 2015; Spinoni et al., 2020; 11.SM); drying trend in spring and summer (Swain and Hayhoe, 2015)

Region and Drought Type		Observed Trends	Human Contribution	Projections		
				+1.5°C	+2°C	+4°C
Central North America (CNA) <i>continued</i>	AGR ECOL	Low confidence: Mixed signal based on soil moisture, water-balance estimates, PDSI and SPEI and conflicting trend depending of the subregion (Greve et al., 2014; Dai and Zhao, 2017; Seager et al., 2019; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence. Human influence on surface soil moisture deficits due to increased evapotranspiration caused by higher temperatures (Easterling et al., 2017)	Medium confidence: Increase in drought. Dominant signal shows drought increase based on total and surface soil moisture (L. Xu et al., 2019; 11.SM) and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Medium confidence: Increase in drought severity or frequency. Changes are consistent between different drought metrics, including total column soil moisture, (11.SM; Cook et al., 2020), surface soil moisture (L. Xu et al., 2019) and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	High confidence: Increase of drought severity. Changes are consistent between different drought metrics, including total column soil moisture, (11.SM; Cook et al., 2020), surface soil moisture (Dai et al., 2018; Lu et al., 2019; Cook et al., 2020), PDSI (Dai et al., 2018), and SPEI-PM (Cook et al., 2014a; Feng et al., 2017; Vicente-Serrano et al., 2020c)
	HYDR	Low confidence: Mixed signal. No signal in changes (Mo and Lettenmaier, 2018; Dudley et al., 2020; Gudmundsson et al., 2021). Poshtiri and Pal (2016) show strong spatial variability in the recent trends of low flows, although there is an increase of hydrological droughts in the Missouri (Martin et al., 2020; Woodhouse and Wise, 2020) and in the Colorado basins (M. Xiao et al., 2018; Milly and Dunne, 2020). A wetting trend is shown in Dai and Zhao (2017)	Low confidence: Inconsistent trends in observations. Two studies suggest that temperature increase has been the main driver of increased hydrological drought in the Missouri basin (Martin et al., 2020; Woodhouse and Wise, 2020)	Low confidence: Limited evidence. One study shows drying (Touma et al., 2015)	Low confidence: Limited evidence and inconsistent trends (Touma et al., 2015; Cook et al., 2020; R. Zhai et al., 2020)	Low confidence: Mixed signals among studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)
Eastern North America (ENA)	MET	Low confidence: Inconsistent trends depending on the region (Wehner et al., 2017; Spinoni et al., 2019; Dunn et al., 2020)	Low confidence: Limited evidence (Easterling et al., 2017)	Low confidence: Limited evidence and inconsistent trends (L. Xu et al., 2019; 11.SM)	Low confidence: Limited evidence (L. Xu et al., 2019; Spinoni et al., 2020; 11.SM)	Medium confidence: Increase in drought severity in the majority of models, but weaker or inconsistent trends in part of region (Sillmann et al., 2013b; Touma et al., 2015; Spinoni et al., 2020; 11.SM)
	AGR ECOL	Low confidence: Mixed signals. Inconsistent trends depending on metric, subregion, time frame and studies, based on soil moisture, water-balance estimates, PDSI, and SPEI (Greve et al., 2014; Dai and Zhao, 2017; Park Williams et al., 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence. Human influence on surface soil moisture deficits due to increased evapotranspiration caused by higher temperatures (Easterling et al., 2017)	Low confidence: Inconsistent trends between models, metrics and studies based on total and surface soil moisture (L. Xu et al., 2019; 11.SM) and SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Low confidence: Inconsistent trends between models, metrics and studies based on total and surface soil moisture (L. Xu et al., 2019; Cook et al., 2020; 11.SM), and SPEI-PM (Naumann et al., 2018; Gu et al., 2020), but with stronger tendency towards drying	Medium confidence: Increase of drought severity. Consistent signal between different drought metrics, including total column soil moisture, (11.SM; Cook et al., 2020), surface soil moisture (Dai et al., 2018; Lu et al., 2019), PDSI (Dai et al., 2018) and SPEI-PM (Cook et al., 2014a; Vicente-Serrano et al., 2020c)

Region and Drought Type		Observed Trends	Human Contribution	Projections		
				+1.5°C	+2°C	+4°C
Eastern North America (ENA) <i>continued</i>	HYDR	Low confidence: Limited evidence. Decrease in low flows from 1971–2020, but not since 1950 (Gudmundsson et al., 2019, 2021). Poshtiri and Pal (2016) and Dudley et al. (2020) show strong spatial variability in the recent trends of low flows in the region	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows lack of signal (Touma et al., 2015).	Low confidence: Limited evidence and inconsistent trends (Touma et al., 2015; Cook et al., 2020; R. Zhai et al., 2020)	Low confidence: Mixed signal among models and studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020)
North-East North America (NEN)	MET	Low confidence: No or limited signal in duration and frequency of droughts (Bonsal et al., 2019; Dunn et al., 2020)	Low confidence: Limited evidence	Low confidence: Limited evidence. Available evidence suggest decrease in meteorological drought (L. Xu et al., 2019; 11.SM)	Medium confidence: Decrease in meteorological drought (Sillmann et al., 2013b; L. Xu et al., 2019; Spinoni et al., 2020; 11.SM)	Medium confidence: Decrease in meteorological drought (Touma et al., 2015; Spinoni et al., 2020; Vicente-Serrano et al., 2020c; 11.SM)
	AGR ECOL	Low confidence: Mixed signals between different drought metrics and strong spatial differences (Greve et al., 2014; Dai and Zhao, 2017; Padrón et al., 2020)	Low confidence: Limited evidence	Low confidence: Mixed signals between different models and metrics. Substantial inter-model variations and weak drying trend in soil moisture (L. Xu et al., 2019; 11.SM) and slight decrease in drought severity in SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Low confidence: Mixed signals between different models and drought metrics. Substantial inter-model spread for total column soil moisture, with overall weak or no change (11.SM; Cook et al., 2020), slight drying in surface soil moisture (L. Xu et al., 2019; 11.SM) and tendency to wetting trend in SPEI-PM (Naumann et al., 2018; Gu et al., 2020)	Low confidence: Mixed signals between models and different drought metrics, including total column soil moisture, which shows inconsistent changes (11.SM; Cook et al., 2020), surface soil moisture, which suggest drying (Dai et al., 2018; Lu et al., 2019; Cook et al., 2020; 11.SM), and PDSI (Dai et al., 2018) and SPEI-PM (Cook et al., 2014a; Vicente-Serrano et al., 2020c), which shows a tendency for wetting trend
	HYDR	Low confidence: Limited evidence. Inconsistent trends in one study (Dai and Zhao, 2017)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows inconsistent signals (Touma et al., 2015)	Low confidence: Inconsistent trends and limited evidence. Available studies suggest inconsistent trends in low flow (R. Zhai et al., 2020) and the SRI (Touma et al., 2015), and seasonally inconsistent trends in runoff, with decrease in summer and increase in winter (Cook et al., 2020)	Low confidence: Mixed signals among studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020). Some evidence (<i>medium confidence</i>) for strong seasonality of trends, with decrease in summer and increase in winter (Giuntoli et al., 2015; Cook et al., 2020)
North-West North America (NWN)	MET	Low confidence: Mixed signals with conflicting trends depending on the region (Bonsal et al., 2019; Spinoni et al., 2019; Dunn et al., 2020)	Low confidence: Limited evidence	Low confidence: Limited and inconsistent evidence. Some evidence points to decrease in meteorological drought severity or intensity based on SPI (L. Xu et al., 2019) and CDD (11.SM)	Medium confidence: Decrease in meteorological drought severity or intensity (Sillmann et al., 2013b; L. Xu et al., 2019; Spinoni et al., 2020; 11.SM)	Medium confidence: Decrease in meteorological drought severity in the majority of models (Sillmann et al., 2013b; Swain and Hayhoe, 2015; Touma et al., 2015; Spinoni et al., 2020; 11.SM)

Region and Drought Type		Observed Trends	Human Contribution	Projections		
				+1.5°C	+2°C	+4°C
North-West North America (NWN) <i>continued</i>	AGR ECOL	Low confidence: No signal or inconsistent signals in the duration and severity of droughts based on soil moisture, PDSI and SPEI and conflicting trends depending of the subregion (Greve et al., 2014; Dai and Zhao, 2017; Park Williams et al., 2017; Spinoni et al., 2019; Padrón et al., 2020)	Low confidence: Limited evidence	Limited evidence: Mixed signals in changes in drought severity. Inconsistent changes between models in CMIP6 and CMIP5 total and surface soil moisture (L. Xu et al., 2019; 11.SM); SPEI-PM also suggests inconsistent changes in drought severity (Naumann et al., 2018; Gu et al., 2020)	Low confidence: Mixed signals between different models, drought metrics and studies, including total and surface soil moisture, as well as SPEI-PM (11.SM; Naumann et al., 2018; L. Xu et al., 2019; Cook et al., 2020; Gu et al., 2020)	Low confidence: Mixed signals between different models and drought metrics, including total and surface soil moisture, PDSI and SPEI-PM (11.SM; Cook et al., 2014a, 2020; Dai et al., 2018; Lu et al., 2019; Vicente-Serrano et al., 2020c), with slight larger tendency towards wetting
	HYDR	Low confidence: Limited evidence. Regionally inconsistent trends in one study (Dai and Zhao, 2017)	Low confidence: Limited evidence	Low confidence: Limited evidence. One study shows lack of signals (Touma et al., 2015)	Low confidence: Limited evidence and inconsistent signals in available studies (Touma et al., 2015; Cook et al., 2020; R. Zhai et al., 2020)	Low confidence: Mixed signals among studies (Prudhomme et al., 2014; Giuntoli et al., 2015; Touma et al., 2015; Cook et al., 2020), but slight stronger tendency towards wetting

Appendix 11.A

Scaling of regional annual minimum temperature (TNn)

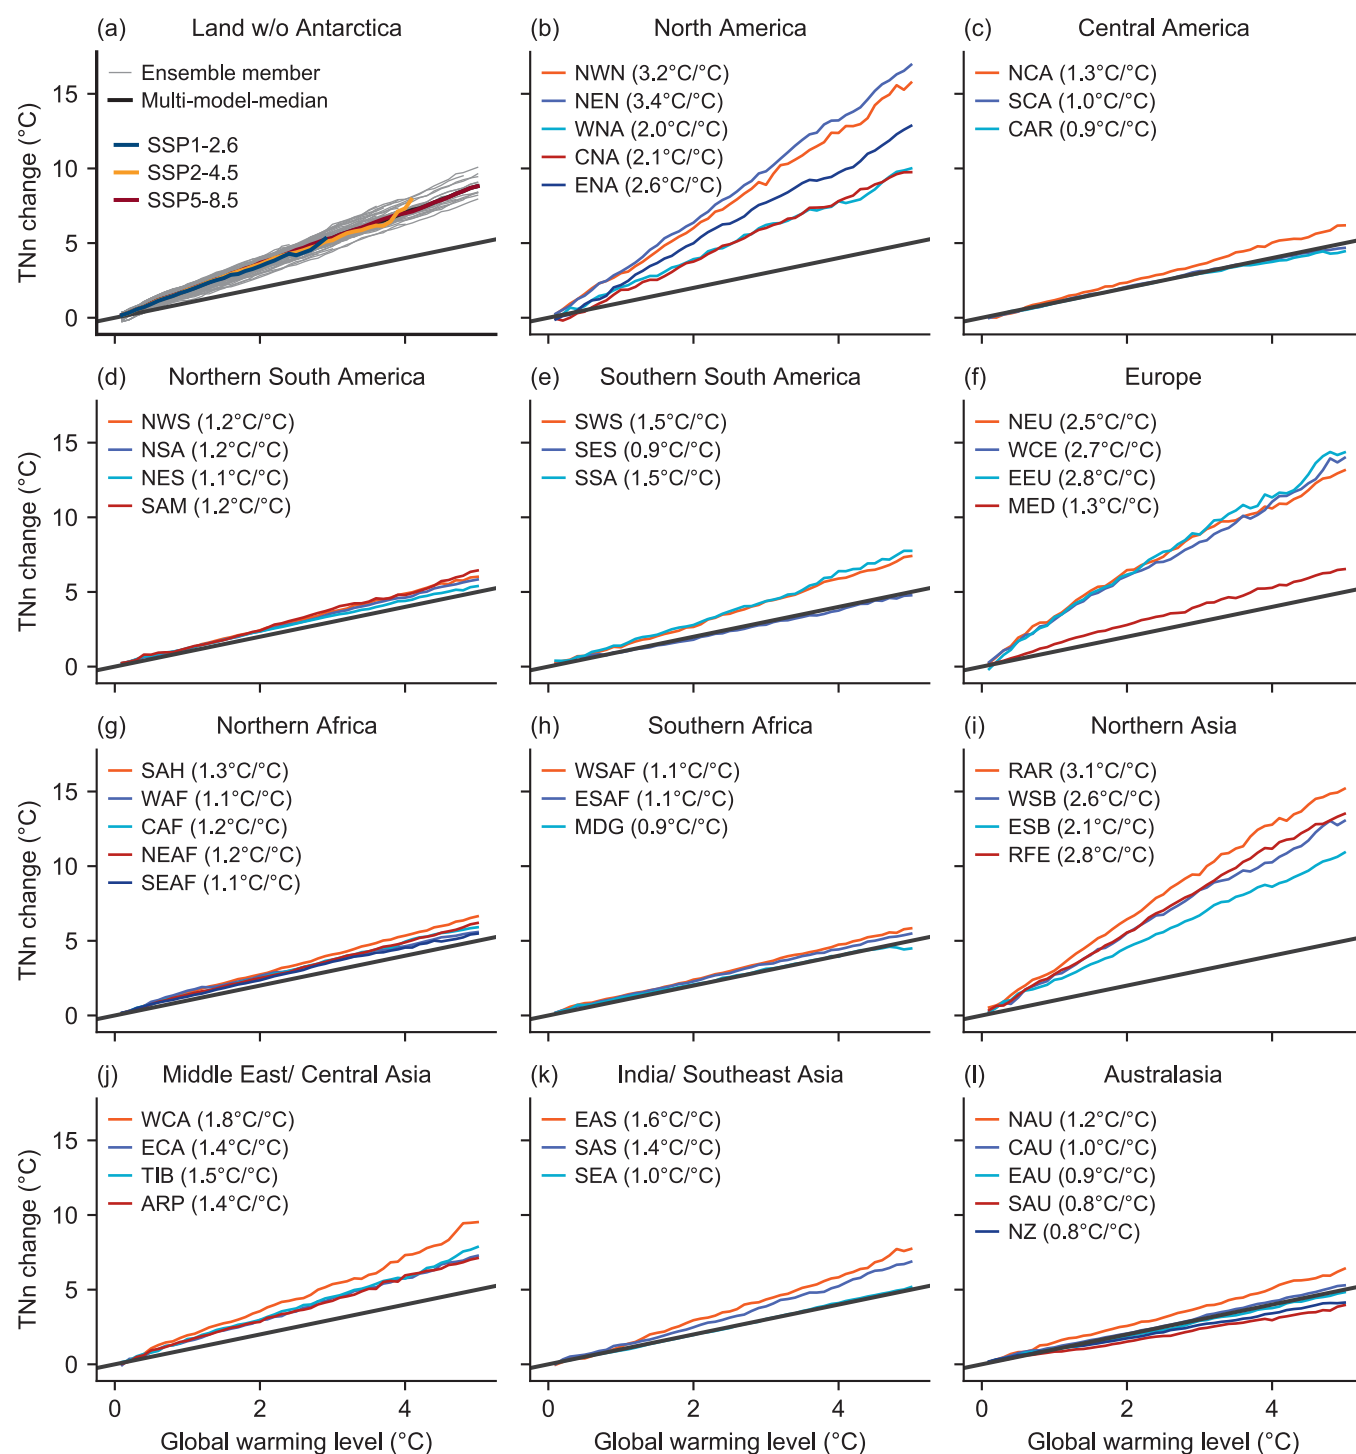

Figure 11.A.1 | As Figure 11.3 but for the annual minimum temperature (TNn).

Table 11.A.1 | Common drought metrics, associated drought types, drought indices, general description and associated references.

Drought Metric	Associated Drought Type	Drought Indices	Comments	Representative References
Precipitation deficit	Referred to as 'meteorological drought'	Standardized Precipitation Index (SPI), Consecutive dry days (CDD), Precipitation deciles and percentiles	SPI is defined for given time scales in order to identify precipitation deficits over different periods. The SPI shows flexibility to account for different time scales by summing precipitation over k months, termed accumulation periods. CDD is usually based on daily precipitation records. 'Dry-spell length' is another commonly used term. The number of dry days (NDD) is also used in some publications.	Donat et al. (2013b); Orłowsky and Seneviratne (2013); Sillmann et al. (2013a); Spinoni et al. (2014); Kingston et al. (2015); Stagge et al. (2017); Coppola et al. (2021b)
Excess atmospheric evaporative demand (AED)	Driver for agricultural and ecological drought, together with precipitation through its impact on evapotranspiration (ET) and vegetation stress under soil moisture deficits	Potential evaporation anomalies, Evaporative Demand Drought Index (EDDI)	AED can be measured locally by means of evaporation pans. Physically-based models (e.g., Penman–Monteith) using all aerodynamic and radiative drivers from observations produce robust estimates of the observed magnitude and variability of the evaporative demand. Empirical estimates based on air temperature are affected by more uncertainties (Section 11.6.1.2), especially when applied to climate change projections. AED is an upper bound for actual ET but also induces additional vegetation stress under dry conditions (Section 11.6.1.2).	Hobbins et al. (2012, 2016); Sheffield et al. (2012); Wang et al. (2012); McEvoy et al. (2016); Roberts et al. (2018); Stephens et al. (2018); Z. Sun et al. (2018); Vicente-Serrano et al. (2020a)
Soil moisture deficits	Usually referred to as 'agricultural drought'. Also relevant for ecological droughts	Soil moisture anomalies (SMA), Standardized Soil Moisture Index (SSMI)	Networks of ground-based soil moisture measurements are available in different regions, but are very sparse and cover very short periods. Surface soil moisture can be monitored from satellites, but only since the 1980s at the earliest. Physically based land surface models compute soil moisture using meteorological variables (precipitation, radiation, wind, temperature, humidity) as input.	Dorigo et al. (2011, 2015, 2017); Orłowsky and Seneviratne (2013); Seneviratne et al. (2013); AghaKouchak (2014); Sohrabi et al. (2015); Zhao and Dai (2015); Stillman et al. (2016); Yuan and Quiring (2017); Berg and Sheffield (2018); Hanel et al. (2018); Samaniego et al. (2018); Ford and Quiring (2019); Moravec et al. (2019); Seager et al., (2019)
Streamflow and surface water deficits	Usually referred to as 'hydrological drought'	Standardized Runoff Index (SRI), Standardized Streamflow Index (SSI), threshold level methods, Standardized Groundwater Index (SGI)	Usually based on monthly records of hydrological variables (e.g., streamflow, groundwater, reservoir storages), although daily streamflow is also used using threshold level methods. Observational data is available but not in all regions.	Bloomfield and Marchant (2013); Van Lanen et al. (2013); Wada et al. (2013); Forzieri et al. (2014); Prudhomme et al. (2014); Schewe et al. (2014); Van Loon (2015); Van Loon and Laaha (2015); Gosling et al. (2017)
Atmospheric-based drought indices	Metrics of drought severity based on meteorological variables, combining precipitation and AED as drivers	Standardized Precipitation Evapotranspiration Index (SPEI), Palmer Drought Severity Index (PDSI)	These drought indices are generated using precipitation and AED. The quality of the outputs depend on the method used to determine the AED. They are widely used for drought monitoring and early warning. These indices are not intended to be a soil moisture or water-balance proxy.	Dai, (2013); Beguería et al. (2014); Cook et al. (2014a); Mitchell et al. (2014); Stagge et al. (2015); Vicente-Serrano et al. (2015); Dai et al. (2018); Mukherjee et al. (2018a); Yang et al. (2020)

Table 11.A.2 | Synthesis table summarising assessments presented in Tables 11.4–11.21 for hot extremes (HOT EXT.), heavy precipitation (HEAVY PRECIP.), agriculture and ecological droughts (AGR./ECOL. DROUGHT), and hydrological droughts (HYDR. DROUGHT). It shows the direction of change and level of confidence in the observed trends (column OBS.), human contribution to observed trends (ATTR.), and projected changes at 1.5°C, 2°C and 4°C of global warming for each AR6 region. Projections are shown for two different baseline periods: 1850–1900 (pre-industrial) and 1995–2014 (modern or recent past) – see Section 1.4.1 for more details. Direction of change is represented by an upward arrow (increase) and a downward arrow (decrease). Level of confidence is reported for LOW: *low*, MED.: *medium*, HIGH: *high*; levels of likelihood (only in cases of *high confidence*) include: L: *likely*, VL: *very likely*, EL: *extremely likely*, VC: *virtual certain*. See Section 11.9, Tables 11.4–11.21 for details. Dark orange shading highlights *high confidence* (also including *likely*, *very likely*, *extremely likely* and *virtually certain* changes) increases in hot temperature extremes, agricultural and ecological drought, or hydrological droughts. Yellow indicates *medium confidence* increases in these extremes, and blue shadings indicate decreases in these extremes. *High confidence* increases in heavy precipitation are highlighted in dark blue, while *medium confidence* increases are highlighted in light blue. No assessment for changes in drought with respect to the 1995–2014 baseline is provided, which is why the respective cells are empty.

Executive Summary

Climate change information is increasingly available and robust at regional scale for impacts and risk assessment. Climate services and vulnerability, impacts and adaptation studies require regional scale multi-decadal climate observations and projections. Since the IPCC Fifth Assessment Report (AR5), the increased availability of coordinated ensemble regional climate model projections and improvements in the level of sophistication and resolution of global and regional climate models, completed by attribution and sectoral vulnerability studies, have enabled the investigation of past and future evolution of a range of climatic quantities that are relevant to socio-economic sectors and natural systems. Chapter 12 consolidates core physical knowledge from preceding AR6 Working Group I (WGI) chapters and post-AR5 climate impact assessment literature to assess the spatio-temporal evolution of the climatic conditions that may lead to regional scale impacts and risks (following the sectoral classes adopted by AR6 WGII) in the world's regions (presented in Chapter 1). {12.1}

The climatic impact-driver (CID) framework adopted in Chapter 12 allows for assessment of changing climate conditions that are relevant for regional impacts and risk assessment. CIDs are physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems and are thus a priority for climate information provision. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral or a mixture of each across interacting system elements, regions and society sectors. Each sector is affected by multiple CIDs and each CID affects multiple sectors. A CID can be measured by indices to represent related tolerance thresholds. {12.1–12.3}

The current climate in most regions is already different from the climate of the early or mid-20th century with respect to several CIDs. Climate change has already altered CID profiles and resulted in shifts in the magnitude, frequency, duration, seasonality and spatial extent of associated indices (*high confidence*). Changes in temperature-related CIDs such as mean temperatures, growing season length, extreme heat and frost have already occurred and many of these changes have been attributed to human activities (*medium confidence*). Mean temperatures and heat extremes have emerged above natural variability in all land regions (*high confidence*). In tropical regions, recent past temperature distributions have already shifted to a range different to that of the early 20th century (*high confidence*). Ocean acidification and deoxygenation have already emerged over most of the global open ocean, as has reduction in Arctic sea ice (*high confidence*). Using CID index distributions and event probabilities accurately in both current and future risk assessments requires accounting for the climate change-induced shifts in distributions that have already occurred. {12.4, 12.5}

Several impact-relevant changes have not yet emerged from the natural variability but will emerge sooner or later in this century depending on the emissions scenario (*high confidence*). Increasing precipitation is projected to emerge before the middle of the century in the high latitudes of the Northern

Hemisphere (*high confidence*). Decreasing precipitation will emerge in a very few regions (Mediterranean, Southern Africa, south-western Australia) (*medium confidence*) by mid-century (*medium confidence*). The anthropogenic forced signal in near-coast relative sea level rise will emerge by mid-century RCP8.5 in all regions with coasts, except in the West Antarctic region where emergence is projected to occur before 2100 (*medium confidence*). The signal of ocean acidification in the surface ocean is projected to emerge before 2050 in every ocean basin (*high confidence*). However, there is *limited evidence* of drought trends emerging above natural variability in the 21st century. {12.5}

Every region of the world will experience concurrent changes in multiple CIDs by mid-century (*high confidence*), challenging the resilience and adaptation capacity of the region. Changes in heat, cold, snow and ice, coastal, oceanic, and CO₂ at surface CIDs are projected with *high confidence* in most regions, indicating worldwide challenges, while additional region-specific changes are projected in other CIDs that may lead to more regional challenges. *High confidence* increases in some of the drought, aridity and fire weather CIDs will challenge, for example, agriculture, forestry, water systems, health and ecosystems in Southern Africa, the Mediterranean, North Central America, Western North America, the Amazon regions, South-Western South America, and Australia. *High confidence* changes in snow, ice and pluvial or river flooding will pose challenges for, for example, energy production, river transportation, ecosystems, infrastructure and winter tourism in North America, Arctic regions, Andes regions, Europe, Siberia, Central, South and East Asia, Southern Australia and New Zealand. Only a few CIDs are projected to change with *high confidence* in the Sahara, Madagascar, Arabian Peninsula, Western Africa and Small Islands; however, the *lower confidence* levels for CID changes in these regions can originate from knowledge gaps or model uncertainties, and does not necessarily mean that these regions have relatively low risk. {12.5}

Worldwide changes in heat, cold, snow and ice, coastal, oceanic and CO₂-related CIDs will continue over the 21st century, albeit with regionally varying rates of change, regardless of the climate scenario (*high confidence*). In all regions there is *high confidence* that, by 2050, mean temperature and heat extremes will increase, and there is *high confidence* that sea surface temperature will increase in all oceanic regions except the North Atlantic. Apart from a few regions with substantial land uplift, relative sea level rise is *very likely to virtually certain* (depending on the region) to continue in the 21st century, contributing to increased coastal flooding in most low-lying coastal areas (*high confidence*) and coastal erosion along most sandy coasts (*high confidence*), while ocean acidification is *virtually certain* to increase. It is *virtually certain* that atmospheric CO₂ at the surface will increase in all emissions scenarios until net zero emissions are achieved. Glaciers will continue to shrink and permafrost to thaw in all regions where they are present (*high confidence*). These changes will lead to climate states with no recent analogue that are of particular importance for specific regions such as tropical forests or biodiversity hotspots. {12.4}

A wide range of region-specific CID changes relative to recent past are expected with *high or medium confidence*, by 2050 and beyond. Most of these changes concern CIDs related to the water cycle

and storms. Agricultural and ecological drought changes are generally of *higher confidence* than hydrological drought changes, with increases projected in North and Southern Africa, Madagascar, Southern and Eastern Australia, some regions of Central and South America, Mediterranean Europe, Western North America and North Central America (*medium to high confidence*). Fire weather conditions will increase by 2050 under RCP4.5 or above in several regions in Africa, Australia, several regions of South America, Mediterranean Europe, and North America (*medium to high confidence*). Extreme precipitation and pluvial flooding will increase in many regions around the world (*high confidence*). Increases in river flooding are also expected in Western and Central Europe and in polar regions (*high confidence*), most of Asia, Australasia, North America, the South American Monsoon region and South-Eastern South America (*medium confidence*). Mean winds are projected to slightly decrease by 2050 over much of Europe, Asia and Western North America, and increase in many parts of South America except Patagonia, West and South Africa and the eastern Mediterranean (*medium confidence*). Extratropical storms are expected to have a decreasing frequency but increasing intensity over the Mediterranean, increasing intensity over most of North America, and an increase in both intensity and frequency over most of Europe (*medium confidence*). Enhanced convective conditions are expected in North America (*medium confidence*). Tropical cyclones are expected to increase in intensity despite a decrease in frequency in most tropical regions (*medium confidence*). Climate change will modify multiple CIDs over Small Islands in all ocean basins, most notably those related to heat, aridity and droughts, tropical cyclones and coastal impacts. {12.4}

The level of confidence in the projected direction of change in CIDs and the intensity of the signal depend on mitigation efforts over the 21st century, as reflected by the differences between end-century projections for different climate scenarios. Dangerous humid heat thresholds, such as the US National Oceanic and Atmospheric Administration Heat Index (NOAA HI) of 41°C, will be exceeded much more frequently under the SSP5-8.5 scenario than under SSP1-2.6 and will affect many more regions (*high confidence*). In many tropical regions, the number of days per year where an HI of 41°C is exceeded will increase by more than 100 days relative to the recent past under SSP5-8.5, while this increase will be limited to less than 50 days under SSP1-2.6 (*high confidence*). The number of days per year where temperature exceeds 35°C will increase by more than 150 days in many tropical areas, such as the Amazon basin and South East Asia under SSP5-8.5, while it is expected to increase by less than two months in these areas under SSP1-2.6 (except for the Amazon Basin). There is *high confidence* that sandy shorelines will retreat in most regions of the world, in the absence of additional sediment sources or physical barriers to shoreline retreat. The total length of sandy shorelines around the world that are projected to retreat by more than 100 m by the end of the century is about 35% greater under RCP8.5 (about 130,000 km) compared to that under RCP 4.5 (about 95,000 km). The frequency of the present-day 1-in-100 year extreme sea level event (represented here by extreme total water level) is also projected to increase substantially in most regions (*high confidence*). In a globally averaged sense, the 1-in-100 year extreme sea level is projected to become an event that

occurs multiple times per year under RCP8.5, while under RCP4.5 it is projected to become a one-in-five-year event, representing at least a five fold increase from RCP4.5 to RCP8.5. {12.4, 12.5}

There is *low confidence* in past and future changes of several CIDs. In nearly all regions there is *low confidence* in changes in hail, ice storms, severe storms, dust storms, heavy snowfall and avalanches, although this does not indicate that these CIDs will not be affected by climate change. For such CIDs, observations are short term or lack homogeneity, and models often do not have sufficient resolution or accurate parametrization to adequately simulate them over climate change time scales. {12.4}

Many global- and regional-scale CIDs have a direct relation to global warming levels (GWLs) and can thus inform the hazard component of 'Representative Key Risks' and 'Reasons for Concern' assessed by AR6 WGII. These include both mean and extreme heat, cold, wet and dry hazards; cryospheric hazards (snow cover, ice extent, permafrost); and oceanic hazards (marine heatwaves) (*high confidence*). For some of these, a quantitative relation can be drawn (*high confidence*). For example, with each degree of global surface air temperature (GSAT) warming, the magnitude and intensity of many heat extremes show a linear change, while some changes in frequency of threshold exceedances are exponential: Arctic temperatures warm about twice as fast as GSAT; global sea surface temperatures increase by about 80% of GSAT change; Northern Hemisphere spring snow cover decreases by about 8% per 1°C. For other hazards (e.g., ice-sheet behaviour, glacier mass loss, global mean sea level rise, coastal floods and coastal erosion) the time and/or scenario dimensions remain critical and a simple relation with GWLs cannot be drawn (*high confidence*), but still quantitative estimates assuming specific time frames and/or stabilized GWLs can be derived (*medium confidence*). Model uncertainty challenges the link between specific GWLs and tipping points and irreversible behaviour, but their occurrence cannot be excluded and their chances increase with warming levels (*medium confidence*). {CCB 12.1}

Since AR5, climate change information produced in climate service contexts has increased significantly due to scientific, technological advancements and growing user demand (*very high confidence*). Climate services involve the provision of climate information in such a way as to assist decision-making. These services include appropriate engagement from users and providers, are based on scientifically credible information and expertise, have an effective access mechanism, and respond to user needs. Climate services are being developed across regions, sectors, time scales and target users. {12.6}

Climate services are growing rapidly and are highly diverse in their practices and products (*very high confidence*). The decision-making context, level of user engagement and co-production between scientists, practitioners and intended users are important determinants of the type of climate service developed and its utility supporting adaptation, mitigation and risk management decisions. User needs and decision-making contexts are very diverse and there is no universal approach to climate services. {12.6}

Realization of the full potential of climate services is often hindered by limited resources for the co-design and co-production process, including sustained engagement between scientists, service providers and users (*high confidence*). Further challenges relate to climate services development, provision of climate services, generation of climate service products, communication with users, and evaluation of the quality and socio-economic value of climate services. The development of climate services often uncovers and presents new research challenges to the scientific community. {12.6}

12.1 Framing

Climate change is already resulting in significant societal and environmental impacts and will induce major socio-economic damages in the future (AR5 WGII). The society, at large, benefits from information related to climate change risks, which enables the development of options to protect lives, preserve nature, build resilience and prevent avoidable loss and damage. Climate change can also lead to beneficial conditions that can be taken into account in adaptation strategies.

This chapter assesses climate change information relevant for regional impact and for risk assessment. It complements other WGI chapters that focus on the physical processes determining changes in the climate system and on methods for estimating regional changes.

Impacts of climate change are driven not only by changes in climate conditions, but also by changes in exposure and vulnerability (Cross-Chapter Box 1.3). This chapter concentrates on drivers of impacts that are of climatic origin (see also the IPCC Special Report on Global Warming of 1.5°C (SR1.5, IPCC, 2018), and Section 1.3.2 in this Report), referred to in WGI as ‘climatic impact-drivers’ (CIDs). CIDs are physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions. However, this chapter largely focuses on drivers commonly connected to hazards, and adopts the IPCC risk framework (Cross-Chapter Box 1.3) since the main objective of the United Nations Framework Convention on Climate Change (UNFCCC) is to ‘prevent dangerous anthropogenic interference with the climate system’ (Article 2).

In some cases, risk assessments may require climate information beyond the CIDs identified in this chapter, with further impacts or risk modelling often driven by historical climate forcing datasets (e.g., Ruane et al., 2021) and full climate scenario time series (e.g., Lange, 2019) produced using methods described in Chapter 10. Chapter 12 focuses on the assessment of a finite number of drivers and how they are projected to evolve with climate change, in order to inform impact and risk assessments.

This chapter is new in IPCC WGI assessment reports, in that it represents a contribution to the ‘IPCC risk framework’. Within this framework, climate-related impacts and risks are determined through an interplay between the occurrence of climate hazards and their consequences depending on the exposure of the affected human or natural system and its vulnerability to the hazardous conditions. In Chapter 12, we are assessing climatic impact-drivers that could lead to hazards or to opportunities, from the literature and model results since AR5. This will particularly support the assessment of key risks related to climate change by WGII (Chapter 16). Despite the fact that impacts may also be induced by climate adaptation and mitigation policies themselves, as well as by socio-economic trends, changes in vulnerability or exposure, and external geophysical hazards such as volcanoes, the focus here is only on climatic impacts and risks induced by shifts in physical climate phenomena that directly influence human and ecological systems (Cross-chapter Box 1.3).

This chapter follows the terminology associated with the framing introduced in Chapter 1 (Cross-Chapter Box 1.2) and as found in Annex VII: Glossary. The highlighted terms below are introduced and used extensively in this chapter:

- **Indices for climatic impact-drivers:** numerically computable indices using one or a combination of climate variables designed to measure the intensity of the climatic impact-driver, or the probability of exceedance of a threshold. For instance, an index of heat inducing human health stress is the Heat Index (HI) that combines temperature and relative humidity (e.g., Burkart et al., 2011; Lin et al., 2012; Kent et al., 2014) and is used by the NOAA for issuing heat warnings.
- **Thresholds for climatic impact-drivers:** an identified index value beyond which a climatic impact-driver interacts with vulnerability or exposure to create, increase or reduce an impact, risk or opportunity. Thresholds can be used to measure various aspects of the climatic impact-driver (magnitude or intensity, duration, frequency, timing, and spatial extent of threshold exceedance). For instance, a threshold of daily maximum temperature above 35°C is considered critical for maize pollination and production (e.g., Schauburger et al., 2017; Tesfaye et al., 2017).

The approach adopted here is consistent with the UN Sendai Framework for Disaster Risk Reduction 2015–2030, which aims to face disaster consequences (including but not limited to climate disasters) and reduce risks in natural, managed and built environments (Aitsi-Selmi et al., 2015; UNISDR, 2015). The classification of climatic impact-drivers in this chapter is largely consistent with the classification of hazards used in the Sendai Framework. However, the UNISDR hazard list spans a wider range of hazards inducing damage to society, including hazards that are not directly related to climate (such as volcanoes and earthquakes), which are excluded from the assessment herein. Furthermore, the UNISDR classification of hazards does not include mean climatic conditions, which are also discussed as climatic impact-drivers in this chapter. The first priority mentioned in the Sendai Framework is understanding disaster risk as a necessary step for action. Facilitating such an understanding is a clear goal of this chapter.

The chapter adopts a regional perspective (continental regions as defined in Chapter 1 and used in WGII; see Figure 1.18) on climatic impact-drivers to support decision-making across a wide audience of global and regional stakeholders in addition to governments (e.g., civil society organizations, public and private sectors, academia). While the focus here is on future changes, it also describes current levels and observed trends of CIDs as an important point of reference for informing adaptation strategies.

Figure 12.1 summarizes the rationale behind Chapter 12 as the linkage (also referred to as a ‘handshake’) between WGI and WGII, illustrating how the changing profile of risk may be informed by an assessment of climatic impact-drivers, aligning WGI findings on physical climate change with WGII needs. The implementation of mitigation policy shifts may modulate hazard probability changes (i.e., by reducing emissions to limit global warming) as well as regional vulnerability and exposure. The assessment herein is organized around regional climatic impact-drivers, but also relates key indices and thresholds to increasing

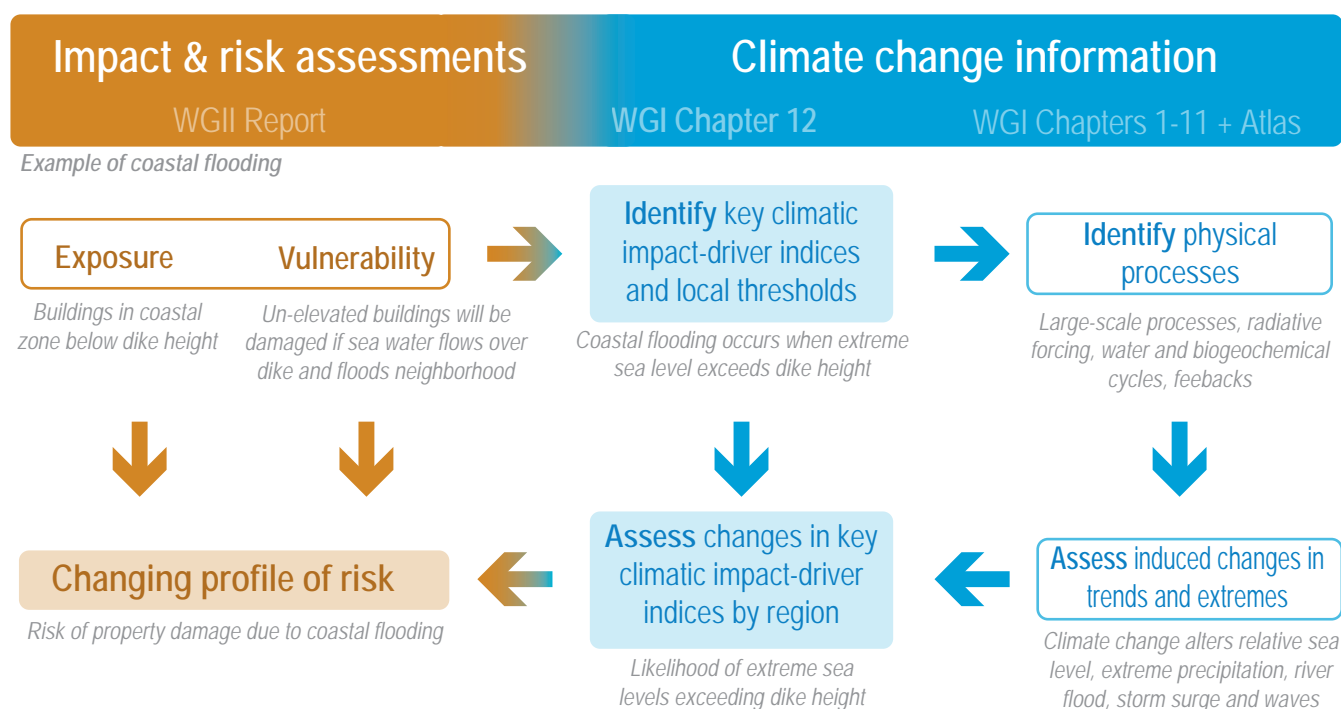

Figure 12.1 | Schematic diagram showing the use of climate change information (AR6 WGI chapters) for typical impacts or risk assessment (AR6 WGII chapters) and the role of Chapter 12, via an illustration of the assessment of property damage or loss in a particular region when extreme sea level exceeds dike height.

global drivers (such as mean surface warming) as a contribution to the assessment of 'Reasons for Concern' in WGII (O'Neill et al., 2017).

The narrative of Chapter 12 is illustrated in Figure 12.2. First, Section 12.2 defines a range of climatic impact-driver categories that are relevant for regional and sectoral impacts. Next, Section 12.3 identifies climatic impact-drivers and their relevant indices that are frequently used in the context of climate impacts in the WGII focus sectors (AR6 WGII Chapters 2–8). The assessment of changes in regional-scale climatic impact-drivers is then developed within Section 12.4 by continent, following the structure of the WGII assessment report regional chapters (AR6 WGII Chapters 9–15), and adding the polar regions, open/deep ocean and other specific zones corresponding to the WGII Cross-Chapter Papers. Section 12.5 then presents a global perspective (both bottom-up and top-down) on the change of regional climatic impact-drivers, including an assessment of the 'emergence' of climatic impact-drivers. Section 12.6 discusses how climate information is used in 'climate services', which encompasses a range of activities bridging climate science and its use for adaptation and mitigation decision-making (see also AR6 WGII Chapter 17). The chapter concludes with final remarks in Section 12.7.

The chapter includes two Cross-Chapter Boxes. Cross-Chapter Box 12.1 connects climatic impact-drivers to global climate drivers and levels of warming as an element of the 'Reasons for Concern' framework (AR6 WGII Chapter 16). An additional Cross-Chapter Box, including three case studies from Europe, Asia and Africa, describes how climate services draw upon and apply regional climate information to support stakeholder decisions (Cross-Chapter Box 12.2).

12.2 Methodological Approach

This section details the methodological approach followed in Chapter 12 and discusses the underlying rationale for the assessments presented herein. Scientific literature on vulnerability, impacts, and adaptation (as typically assessed in IPCC WGII) is examined to identify relevant climatic impact-drivers (CIDs) that contribute to sectoral risks and opportunities. Projected changes in corresponding CID indices are then derived from existing literature on changes in the physical climate system, results of other AR6 WGI chapters, and direct calculations based on climate projections from several model ensembles.

The classification of climatic impact-drivers, the ways that they change (e.g., their magnitude or intensity, duration, frequency, timing and spatial extent) is described in this section. It is emphasized that this chapter assesses literature relating only to physical climatic impact-drivers, not their impacts on human systems or the environment. Thus, here we do not consider indicators including exposure or vulnerability as assessed by WGII, although the selection of climatic impact-drivers is informed by literature feeding into WGII.

Chapter 12 assesses climate change information relevant for regional impact and for risk assessment in the seven main sectors corresponding to Chapters 2–8 of the WGII Assessment Report:

- Terrestrial and freshwater ecosystems and their services (WGII Chapter 2);
- Ocean and coastal ecosystems and their services (WGII Chapter 3);

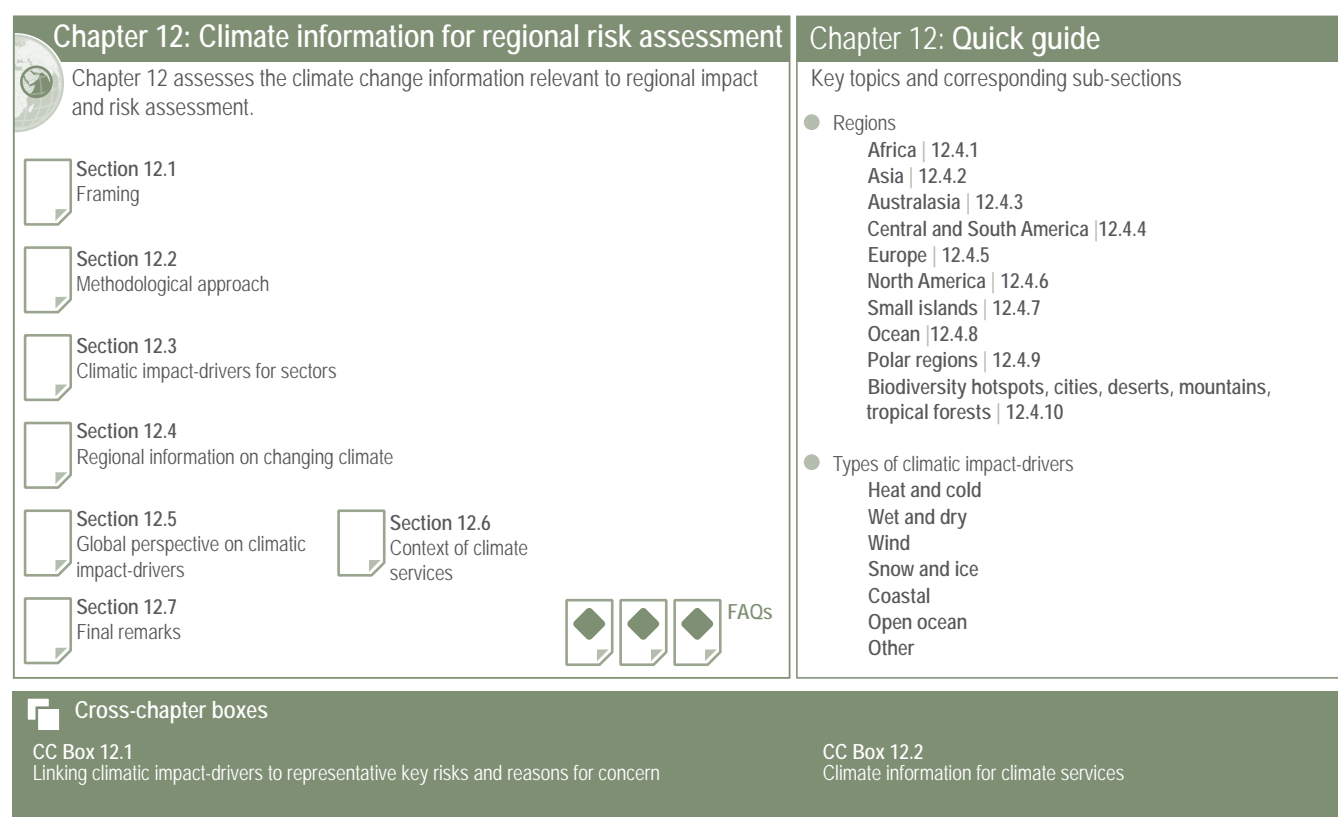

Figure 12.2 | Visual guide to Chapter 12.

- Water (WGII Chapter 4);
- Food, fibre and other ecosystem products (WGII Chapter 5);
- Cities, settlements and key infrastructure (WGII Chapter 6);
- Health, well-being and the changing structure of communities (WGII Chapter 7);
- Poverty, livelihoods and sustainable development (WGII Chapter 8).

Many of these sectors also include assets affected by climate change that are important for recreation and tourism, including elements of ecosystems services, health and well-being, communities, livelihoods and sustainable development (see also Chapter 1 on the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES), and the IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems (SRCL; Hurlbert et al., 2019; IPCC, 2019c)).

CIDs can be captured in seven main types: heat and cold; wet and dry; wind; snow and ice; coastal; oceanic and other. Table 12.1 provides an overview of the seven CID types and the CID categories associated with each type. The type 'Other' comprises additional CIDs that are not encompassed within the other six CID types, including air pollution weather (e.g., meteorological conditions that favour high concentrations of surface ozone, particulate matter or other air pollutants), near-surface atmospheric CO₂ concentrations, and mean radiation forcing at the surface (which are, for example, relevant for plant growth). Icebergs, fog and lightning are also noted in this chapter but are not broadly assessed across all subsections. In addition, there

can be changes in impacts associated with earthquakes that interact with climate variables and climate change, such as liquefaction (e.g., Yasuhara et al., 2012) during earthquakes, or earthquakes caused by snow and water changes (Amos et al., 2014; Johnson et al., 2017), which are secondary effects on geophysical hazards that are not further assessed in this chapter. The characteristics and physical description of the climate phenomena or essential climate variables associated with each of these CID categories are assessed and described in previous Chapters 2–11 or Chapter 12 directly as indicated in Table 12.1. The CID categories are further mapped on to different sectors in Section 12.3 (Table 12.2).

Potential changes in the seasonality of CIDs or the length and characteristics of seasons (e.g., changes in growing season length or pollen season) are also important as they may shift the timing of many CIDs with broad implications for sectors and regional stakeholders (Wanders and Wada, 2015; Cassou and Cattiaux, 2016; Hansen and Sato, 2016; Brönnimann et al., 2018; Marelle et al., 2018; Unterberger et al., 2018; Kuriqi et al., 2020). Episodic CIDs characterize impact-relevant conditions persisting from short to long time frames but eventually returning to normal conditions.

In some situations, phenomena causing severe impacts go well beyond a single extreme event or a single climate variable, and can include interaction of climatic conditions, such as sea level rise and storm surge (Wahl et al., 2015), precipitation in combination with strong winds (Martius et al., 2016) or flooding quickly followed by a heatwave (S.S.-Y. Wang et al., 2019; see also Section 10.5.2.4). Such

Table 12.1 | Overview of the main climatic impact-driver (CID) types and related CID categories with a short description and their link to other chapters where the underlying climatic phenomenon and its associated essential climate variables are assessed and described.

CID Type	CID Category	Brief Description	Physical Description of Phenomena
Heat and Cold	Mean air temperature	Mean surface air temperature and its diurnal and seasonal cycles.	Chapters 2, 3, 4 and Atlas
	Extreme heat	Episodic high surface air temperature events potentially exacerbated by humidity.	Chapter 11
	Cold spell	Episodic cold surface air temperature events potentially exacerbated by wind.	Chapter 11
	Frost	Freeze and thaw events near the land surface and their seasonality.	Chapter 12
Wet and Dry	Mean precipitation	Mean precipitation and its diurnal and seasonal cycles.	Chapters 2, 8 and Atlas
	River flood	Episodic high water levels in streams and rivers driven by basin runoff and the expected seasonal cycle of flooding.	Chapters 8 and 11
	Heavy precipitation and pluvial flood	High rates of precipitation and resulting episodic, localized flooding of streams and flat lands.	Chapter 11
	Landslide	Ground and atmospheric conditions that lead to geological mass movements, including landslide, mudslide and rockfall.	Chapter 12
	Aridity	Mean conditions of precipitation and evapotranspiration compared to potential atmospheric and surface water demand, resulting in low mean surface water, low soil moisture and/or low relative humidity.	Chapters 8, 11 and Atlas
	Hydrological drought	Episodic combination of runoff deficit and evaporative demand that affects surface water or groundwater availability.	Chapters 8 and 11
	Agricultural and ecological drought	Episodic combination of soil moisture supply deficit and atmospheric demand requirements that challenges the vegetation's ability to meet its water needs for transpiration and growth. <i>Note: 'agricultural' vs. 'ecological' term depends on affected biome.</i>	Chapters 8 and 11
	Fire weather	Weather conditions conducive to triggering and sustaining wildfires, usually based on a set of indicators and combinations of indicators including temperature, soil moisture, humidity and wind. Fire weather does not include the presence or absence of fuel load. <i>Note: distinct from wildfire occurrence and area burned.</i>	Chapters 11 and 12
Wind	Mean wind speed	Mean wind speeds and transport patterns and their diurnal and seasonal cycles.	Chapters 2 and 12
	Severe wind storm	Episodic severe storms including extratropical cyclone wind storms, thunderstorms, wind gusts, derechos and tornadoes.	Chapters 11 and 12
	Tropical cyclone	Strong, rotating storm originating over tropical oceans accompanied by high winds, rainfall and storm surges.	Chapter 11
	Sand and dust storm	Storms causing the transport of soil and fine dust particles.	Chapters 8 and 12
Snow and Ice	Snow, glacier and ice sheet	Snowpack seasonality and characteristics of glaciers and ice sheets including calving events and meltwater.	Chapters 2, 9 and Atlas
	Permafrost	Permanently frozen deep soil layers, their ice characteristics, and the characteristics of seasonally frozen soils above.	Chapters 2 and 9
	Lake, river and sea ice	The seasonality and characteristics of ice formations on the ocean and freshwater bodies of water.	Chapters 2 and 9
	Heavy snowfall and ice storm	High snowfall and ice storm events including freezing rain and rain-on-snow conditions.	Chapters 11 and 12
	Hail	Storms producing solid hailstones.	Chapters 11 and 12
	Snow avalanche	Cryospheric mass movements and the conditions of collapsing snowpack.	Chapter 12
Coastal	Relative sea level	The local mean sea surface height relative to the local solid surface.	Chapter 9
	Coastal flood	Flooding driven by episodic high coastal water levels that result from a combination of relative sea level rise, tides, storm surge and wave setup.	Chapters 9 and 12
	Coastal erosion	Long term or episodic change in shoreline position caused by relative sea level rise, nearshore currents, waves and storm surge.	Chapter 12
Open Ocean	Mean ocean temperature	Mean temperature profile of ocean through the seasons, including heat content at different depths and associated stratification.	Chapters 2 and 9
	Marine heatwave	Episodic extreme ocean temperatures.	Chapters 9 and 12
	Ocean acidity	Profile of ocean water pH levels and accompanying concentrations of carbonate and bicarbonate ions.	Chapter 5
	Ocean salinity	Profile of ocean salinity and associated seasonal stratification. <i>Note: distinct from salinization of freshwater resources.</i>	Chapters 2 and 5
	Dissolved oxygen	Profile of ocean water dissolved oxygen and episodic low oxygen events.	Chapter 5
Other	Air pollution weather	Atmospheric conditions that increase the likelihood of high particulate matter or ozone concentrations or chemical processes generating air pollutants. <i>Note: distinct from aerosol emissions or air pollution concentrations themselves.</i>	Chapter 6
	Atmospheric CO ₂ at surface	Concentration of atmospheric carbon dioxide (CO ₂) at the surface. <i>Note: distinct from overall radiative effect of CO₂ as greenhouse gas.</i>	Chapter 5
	Radiation at surface	Balance of net shortwave, longwave and ultraviolet radiation at the Earth's surface and their diurnal and seasonal patterns.	Chapter 7

compound events, particularly in the context of climate extremes, are assessed in Section 11.8. A combination of non-extreme climatic impact-drivers in time or space can also lead to severe impacts (Cutter, 2018).

Several climatic impact-drivers are reliant on many factors beyond their associated primary climatic phenomenon. For example, river flooding is heavily dependent on river management and engineering and could also be affected by tidal water levels due to sea level rise and/or storm surge. Coastal flooding could be affected by coastal protection structures, port and harbour structures, as well as river flows (on inlet-interrupted coasts). Coastal erosion could be influenced by coastal protection measures as well as fluvial sediment supply to the coast. Furthermore, air pollution weather is not the only or dominant driver, for instance, of surface ozone pollution, but precursor emissions from anthropogenic sources can play a significant role (Section 6.5). Chapter 12 focuses only on the influence of the atmospheric, land and oceanic conditions associated with the climatic impact-drivers and the confidence in the direction of CID changes given here does not take into account existing or potential future adaptation measures, unless otherwise stated.

For each CID category there can be a range of indices that capture the sector- or application-relevant characteristics of a climatic impact-driver as described in Sections 12.3 and 12.4. Indices for climatic impact-drivers that are based on absolute or percentile thresholds (e.g., daily maximum temperature above 35°C) can be affected by biases in climate model simulations, such as local or regional deviations of a simulated climate variable from observed values (Sillmann et al., 2014; Dosio, 2016). Where sensible (i.e., where reliable observational data are available and a climate model that fits for the desired purpose), the output of climate model simulations can be bias-adjusted, potentially involving advanced methods to account for multiple variables and extreme value statistics as assessed in detail in Cross-Chapter Box 10.2. Yet, there is no general agreement about which bias adjustment methods to apply, as artefacts can arise both from the climate model and from the bias adjustment method, and the number of available methods has considerably grown in recent years (for a detailed discussion of available methods and their performance see Sections 10.3.1.3.2 and 10.3.3.7.2, and Cross-Chapter Box 10.2). The WGI Interactive Atlas illustrates original and bias-adjusted CIDs (see Atlas.1.4.5).

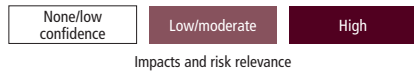

A global perspective on climatic impact-drivers is provided in Section 12.5.1. Section 12.5.2 focuses on assessing evidence for the emergence (Section 1.4.2.2) of an anthropogenic climate change signal on the change in CIDs beyond natural climate variability, based on the literature assessed in other chapters and additional literature, at both global and regional scales. The process of generating user-relevant regional climate information in the context of co-production and climate services is assessed in Sections 10.5, 12.6, Box 10.2 and Cross-Chapter Boxes 10.3 and 12.2. Cross-Chapter Box 12.1 provides a global perspective on climatic impact-drivers related to their evolution for different GWLs (Section 1.6).

12.3 Climatic Impact-drivers for Sectors

Climate change becomes relevant for regional impact management and for risk assessment when changes in mean conditions or episodic events affect natural and societal assets (system components with socio-economic, cultural or intrinsic value) positively or negatively (Table 12.2). Decision makers, policymakers, risk managers and engineers therefore benefit from climate information that tracks key trends and exceedance of thresholds that represent crucial challenges for natural and human systems. While useful indices can vary widely for a given sector and precise tolerance threshold values are often unknown, common metrics, categories and progressions of threshold levels allow experts to recognize coherent messages concerning altered regional impacts and risk profiles under climate change.

This section surveys the links between CIDs and affected sectors; not to perform specific climate change impact or risk assessments (see AR6 WGII), but to describe key indices (among many) that quantify these links as guidance for stakeholders seeking applicable climate information. This survey builds on the work of the World Meteorological Organization Expert Team on Sector-Specific Climate Indices (ET-SCI) and previous IPCC assessments, notably AR5 WGII (Birkmann et al., 2014; IPCC, 2014a) and IPCC Special Reports (IPCC, 2018, 2019b, c) that have assessed climate hazards affecting sectors but is organized from a CID perspective drawing also upon recent summaries of sectoral hazards (Mora et al., 2018; ICOMOS, 2019; Yokohata et al., 2019). Impacts, risks and opportunities are rarely attributable to a single CID index or threshold, but climate shifts that push conditions outside of expected conditions and beyond tolerance levels are indicative of impact, risk or benefit given vulnerability and exposure. Focus is on direct sectoral connections of a CID (Hallegatte and Przyluski, 2010) rather than cascading or secondary effects (e.g., water-borne diseases following a flood, mental health challenges following a severe storm, or the effects of drought on poverty), as these are strongly affected by exposure, vulnerability and response, as discussed in the WGII Report.

Table 12.2 presents a summary of Section 12.3 connections between CIDs as defined in Table 12.1 and key sectoral assets, utilizing the WGII organization of sectors (corresponding to WGII Chapters 2–8). Colours are shown for connections with at least *medium confidence* as assessed from sectoral impacts and risk literature, with relevance assessed according to the prominence of that specific CID/asset connection in analyses of current and future impacts and risk. Within each sector there is a multitude of specific sectoral systems that may be affected by CID increases and decreases, with consequences further distinguished by region, background climate and socio-economic or ecological context of the affected asset. Our aim is therefore to recognize important drivers and the common attributes of change within each CID that scientists and practitioners monitor to understand current and future challenges for important asset groups, thereby pointing to the climate information that needs to be tailored and analysed for impacts and for risk assessment (Section 12.6). Additional effects whereby CIDs affect each other (across Table 12.2 columns) are discussed as climatic phenomena within WGI. The ways sectoral assets affect each other (across Table 12.2 rows) are described throughout WGII, for example with information about the

[illegible]

		Climatic Impact-driver																																
		Heat and Cold				Wet and Dry							Wind				Snow and Ice					Coastal		Open Ocean					Other

Poverty, Livelihoods and Sustainable Development (WGII Chapter 8)	Housing stock ^b																																	
	Farmland ^b																																	
	Livestock mortality ^b																																	
	Indigenous traditions																																	

^a The Recreation and tourism asset category includes outdoor exercise and the tourism industry (including ecosystem services) assessed in many WGII chapters.

^b This asset category is distinguished by the threat of a full loss of key investments and living environments rather than a recoverable damage or loss of productivity or profit.

None/low confidence	Low/moderate	High
---------------------	--------------	------

Impacts and risk relevance

suitability of future climate zones and climate velocity challenges for a given asset potentially drawing from multiple CIDs and associated system tolerance thresholds (Hamann et al., 2015). Some broad connections indicated as *low confidence* may be under-represented in the literature or could be acute under specific circumstances.

12.3.1 Heat and Cold

12.3.1.1 Mean Air Temperature

Information about increasing mean annual and seasonal air temperature is relevant in the determination of suitable species range for terrestrial, freshwater and intertidal species (Thomas et al., 2004; Elith et al., 2010; Hincapie and Caicedo, 2013; Cooper, 2014; Krist et al., 2014; Lindner et al., 2014; Saintilan et al., 2014; Lenoir and Svenning, 2015; Myers-Smith et al., 2015; Urban, 2015; Thorne et al., 2017). Ocean ecosystems are affected by the ocean temperature CID (described in Section 12.3.6.1). Species redistribution and extinction studies also need information about climate velocity, a comparison of the pace of warming to geographical temperature gradients that indicates the rate at which a species would have to move to maintain its climatological temperature (Thomas et al., 2004; Loarie et al., 2009; Dobrowski et al., 2013; Burrows et al., 2014; Dobrowski and Parks, 2016; Sittaro et al., 2017) with some studies incorporating additional variables beyond temperature (Hamann et al., 2015). Many freshwater ecosystems are strongly constrained by stream and lake temperatures (Scheurer et al., 2009; Comte and Grenouillet, 2013; Contador et al., 2014; Knouft and Ficklin, 2017). Warmer and more stratified lake temperatures are more conducive to cyanobacteria blooms with implications for ecosystem health and water resource quality (Whitehead et al., 2009; Moss et al., 2011; Jones and Brett, 2014; Chapra et al., 2017; Shatwell et al., 2019). Consideration of nighttime and daytime temperature trends also elucidates different biophysical effects on vegetation (Peng et al., 2013). Changes in the seasonal timing caused by warming trends are critical to species ranges and ecosystem function (Pearce-Higgins et al., 2015; Hughes et al., 2017b), and indices that characterize the onset of spring shed light on plant emergence and development (Ault et al., 2015).

Mean air temperature dictates many aspects of crop cultivation, livestock production, agroforestry and output from freshwater aquaculture and fisheries, as well as the potential for food contamination. Mean warming alters suitable cultivation zones for crop species (Bragança et al., 2016; Gendron St-Marseille et al., 2019; IPCC, 2019c) and tree species (Hanewinkel et al., 2013; Fei et al., 2017). Crop and ecosystem service productivity often responds directly to mean temperatures, although this is dependent on farming systems (Bassu et al., 2014; Challinor et al., 2014; Lobell and Tebaldi, 2014; Rosenzweig et al., 2014; Asseng et al., 2015; Li et al., 2015; Fleisher et al., 2017; Zhao et al., 2017; Smith and Fazil, 2019). Many studies relate plant development (phenology), insect generation cycles and pest outbreaks to growing degree days, an aggregation of daily thermal units above a threshold (e.g., $T_{\text{mean}} > 5^{\circ}\text{C}$) that accelerates with warmer conditions (Hof and Svahlin, 2016; Ruosteenoja et al., 2016; Tripathi et al., 2016). Many plants respond to changes in nighttime temperatures that affect respiration and transpiration rates (Narayanan et al., 2015; X. Chen et al., 2019), and warming of the soil column is also relevant to

determine plant sprouting (Grotjahn, 2021). A number of indices have been developed to represent the length of the viable local growing season, including a count of days where $T_{\text{max}} > 5^{\circ}\text{C}$ (Mueller et al., 2015) or the period between a year's first and last set of five consecutive days with a weighted $T_{\text{mean}} \geq 10^{\circ}\text{C}$ (G. Li et al., 2018). Warmer conditions and altered seasonality modify the range and metabolism of some pollinators, pests, diseases and weeds (Wolfe et al., 2008; Bebbler, 2015; Aljaryian and Kumar, 2016; IPBES, 2016; Ramesh et al., 2017; Deutsch et al., 2018; Nyangiwe et al., 2018) and may reduce the effectiveness of winter storage for farmers and caching species (Sutton et al., 2016).

Warming raises accumulated seasonal heat indices used in livestock production, especially when humidity is high (Key et al., 2014; Lallo et al., 2018), determines aquaculture suitability and is important for wild fish species migration (Tripathi et al., 2016; Brander et al., 2017). Agricultural planners may also calculate how overall warming trends alter the accumulation of vernalization units or chilling hours for agricultural or horticultural crops (often accumulated temperature deficit below a given daily or hourly threshold; Dennis and Peacock, 2009; Luedeling, 2012; Tripathi et al., 2016; Grotjahn, 2021). Warming in the post-harvest is also important for the determination of spoilage and waste (Stathers et al., 2013) as well as food-borne diseases (Kovats et al., 2004; Mbow et al., 2019).

Warming affects road degradation rates (Chinowsky and Arndt, 2012; Espinet et al., 2016) and warming rates inform designs for long-term energy efficiency of buildings (Kavelage et al., 2014). Mean temperature drives seasonal energy demand, often expressed using winter heating degree days (the accumulated deficit of daily temperatures below a 'comfortable' indoor temperature, e.g., 15.5°C) and summer cooling degree days (the accumulated excess of temperature above a 'comfortable' level, e.g., 18°C ; Spinoni et al., 2015; Arnell et al., 2019). Energy resources may also need information on warming trends to determine suitable zones and overall productivity for biofuels and solar panels, the efficiency of which decreases with higher temperatures (Schaeffer et al., 2012; Wild et al., 2015; Solaun and Cerdá, 2019).

Health impacts and risk studies compare seasonal temperature conditions to limiting thresholds to understand range shifts and incubation rates for pathogens, disease vectors and zoonotic hosts (e.g., mosquitoes, ticks; Caminade et al., 2012, 2014; Eisen and Moore, 2013; Lima et al., 2016; Ogden, 2017; Monaghan et al., 2018) and warming of surface ocean and lake waters conducive to bacterial outbreaks (Baker-Austin et al., 2013; Jacobs et al., 2015; Vezzulli et al., 2015). Warmer conditions can also affect tourism (Kovács et al., 2017) and impact human health by lengthening the allergy season and increasing pollen concentration (Hamaoui-Laguel et al., 2015; Kinney et al., 2015a; Lake et al., 2017; Upperman et al., 2017; Sapkota et al., 2019; Ziska et al., 2019).

12.3.1.2 Extreme Heat

Impacts and risk assessments utilize a large variety of indices and approaches tailored to evaluate heat impacts on human health (Sanderson et al., 2017; C. Gao et al., 2018; McGregor and Vanos, 2018; Staiger et al., 2019; J. Zhu et al., 2019; Schwingshackl et al., 2021). A mixture of simple and complex heat stress indices often combine

extreme temperatures and high humidity to capture human health challenges (Aström et al., 2013; Chow et al., 2016; Dahl et al., 2017a; Im et al., 2017; Coffel et al., 2018; J. Li et al., 2018; Vanos et al., 2020). Different optimum temperatures and extreme heat thresholds based on local distributions are needed to reflect acclimation of different locations and populations (Hajat et al., 2014; WHO, 2014; Kinney et al., 2015b; Russo et al., 2015; Petitti et al., 2016; Dosio, 2017; Cheng et al., 2018; Lay et al., 2018; Schwingshackl et al., 2021). Hot and humid heat episodes can be deadly (Mora et al., 2017), are associated with elevated hospital intake (Goldie et al., 2017) and lower safety and productivity of outdoor labourers (Dunne et al., 2013; Graff Zivin and Neidell, 2014; Kjellstrom et al., 2016; Pal and Eltahir, 2016; Y. Zhao et al., 2016; Mora et al., 2017; Watts et al., 2018; Orlov et al., 2019). Elevated nighttime temperatures prevent the human body from experiencing relief from heat stress (Zhang et al., 2012) and can be tracked over extended periods of sequential day and night heat extremes (Murage et al., 2017; Mukherjee and Mishra, 2018). Extreme heat also exacerbates asthma, respiratory difficulties and response to airborne allergens such as hay fever (Upperman et al., 2017). Extreme heat affects outdoor exercise such as the use of bike-share facilities (Heaney et al., 2019; Vanos et al., 2020). Large-scale recreational and sporting events such as marathons and tennis tournaments monitor heat extremes when determining the viability of host cities (Smith et al., 2016, 2018).

Short-term exposure of crops to temperatures beyond a critical temperature threshold can lead to lower yields and above a limiting temperature threshold, crops may fail altogether (Schlenker and Roberts, 2009; Lobell et al., 2012, 2013; Gourdji et al., 2013; Deryng et al., 2014; Schaubberger et al., 2017; Tesfaye et al., 2017; Vogel et al., 2019). The exact level of these thresholds depends on species, cultivar and farm management (Hatfield and Prueger, 2015; Hatfield et al., 2015; Bisbis et al., 2018; Grotjahn, 2021). The timing of heatwaves is particularly important, as extreme heat is more damaging during critical phenological stages (Teixeira et al., 2013; Eyshi Rezaei et al., 2015; Fontana et al., 2015; B. Wang et al., 2017; Mäkinen et al., 2018). Extreme canopy temperatures, rather than 2 m air temperatures, may be a more robust biophysical indicator of heat impacts on crop production (Siebert et al., 2017). Heat stress indices based upon temperature and humidity determine livestock productivity as well as conception and mortality rates (Key et al., 2014; Dash et al., 2016; Pragna et al., 2016; Rojas-Downing et al., 2017).

Heat extremes factor in mortality, morbidity and the range of some thermally sensitive ecosystem species (Smith and Nagy, 2015; Ratnayake et al., 2019; Thomsen et al., 2019). Combined heat and drought stress can reduce forest and grassland primary productivity (Ciais et al., 2005; De Boeck et al., 2018) and even cause tree mortality at higher extremes (Teskey et al., 2015).

Extreme heat events raise temperatures in buildings and cities already warmed by the urban heat island effect (Gaffin et al., 2012; Oleson et al., 2018; Zhao et al., 2018; Mauree et al., 2019; Box 10.3) and can induce disruptions in critical infrastructure networks (Chapman et al., 2013). Heat affects transportation infrastructure by warping roads and airport runways (Chinowsky and Arndt, 2012) or buckling railways (Dobney et al., 2010; Dépoues, 2017; Chinowsky et al., 2019), and high temperatures reduce air density leading to aircraft take-off

weight restrictions (Coffel et al., 2017; Palko, 2017; T. Zhou et al., 2018). Heat extremes increase peak cooling demand and challenge transmission and transformer capacity (Sathaye et al., 2013; Russo et al., 2016; Craig et al., 2018; X. Gao et al., 2018) and may cause transmission lines to sag or fail (Gupta et al., 2012). Thermal and nuclear electricity plants may be challenged when using warmer river waters for cooling or when mixing waste waters back into waterways without causing ecosystem impacts (Kopytko and Perkins, 2011; van Vliet et al., 2016; Tobin et al., 2018). Extreme temperature can also reduce photovoltaic panel efficiency (Jerez et al., 2015).

12.3.1.3 Cold Spells

The magnitude and timing (relative to developmental stages) of cold extremes (such as the typical coldest day of the year) set limits in the range of species habitat for ecosystems as well as for agricultural and forest pests (Osland et al., 2013; Cavanaugh et al., 2014; Parker and Abatzoglou, 2016; Brunner et al., 2018; Unterberger et al., 2018). Cold air outbreaks can lead to chilling injuries for crops (even above 0°C) and may kill outdoor livestock (particularly young animals; Mader et al., 2010; Liu et al., 2013; Grotjahn, 2021), but are often necessary for crop chill requirements (Dennis and Peacock, 2009).

Increases in human mortality can occur on exceptionally cold days (e.g., <1st percentile of temperatures in winter) although thresholds and human-perceived temperatures linked to wind speed (i.e., 'wind chill') vary geographically due to acclimatization (Li et al., 2013; Gao et al., 2015; J. Li et al., 2018; J. Zhu et al., 2019). The timing of 'unseasonal' cold spells also affect human health (Kinney et al., 2015b). Extreme cold can increase heat and electricity demand (Stuivenvold-Allen and Wang, 2019), cause water pipes to burst, and mechanically alter roads, railroads and buildings (Underwood et al., 2017).

12.3.1.4 Frost

Frost ($T_{\min} < 0^{\circ}\text{C}$) is a natural and fundamental aspect of many ecosystems, with more extreme conditions defined as ice (or icing) days ($T_{\max} < 0^{\circ}\text{C}$) (L.A. Vincent et al., 2018). Agricultural systems planning (e.g., planting calendars, seed selection or the opportunity to double-crop) requires information about the start and end of the frost-free season (Wypych et al., 2017; Wolfe et al., 2018). Crops and wild plants can be directly damaged by frost, but hard or killing frosts (at a threshold several degrees below freezing) can kill crops or lower harvest quality depending on duration (which relates to soil temperature penetration) and plant developmental stage (Crimp et al., 2016a; Cradock-Henry, 2017; G. Li et al., 2018; Mäkinen et al., 2018; Grotjahn, 2021). Earlier disappearance of snow cover reduces natural insulation that protects plants and burrowing animals from hard frost damages (Trnka et al., 2014; Mäkinen et al., 2018). In some cases an early season warm spell may reduce plant hardiness or induce fruit tree flowering that exposes plants to devastating subsequent frost impacts (Hufkens et al., 2012; Hatfield et al., 2014; Tripathi et al., 2016; Brunner et al., 2018; DeGaetano, 2018; Unterberger et al., 2018; Wolfe et al., 2018). Shifts in the seasonality of frozen soils also affect groundwater recharge and surface streamflow for water resource applications, particularly when peak precipitation is shifted to a season that no longer has frozen soils (Jyrkama and Sykes, 2007).

Figure 12.3 | Conceptual illustration of representative climatic impact-driver thresholds showing how graduating thresholds affect successive sectoral assets and lead to potentially more acute hazards as conditions become more extreme (exact values are not shown as these must be tailored to reflect diverse vulnerabilities of regional assets). Representative threshold definitions (T = instantaneous temperature; \bar{T} = mean temperature): **Cities and Infrastructures:** T_{trans} = temperature at which energy transmission lines efficiency reduced; $T_{aircraft}$ = temperature at which aircraft become weight-restricted for takeoff; $T_{hotroads}$ = temperature above which roads begin to warp; T_{stream} = temperature at which streams are not capable of adequately cooling thermal plants; CDD_{min} = minimum temperature for calculating cooling degree days; HDD_{max} = maximum temperature for calculating heating degree days; T_{ice} = temperature at which ice threatens transportation; $\bar{T}_{permafrost}$ = mean seasonal temperature above which permafrost thaws at critical depths; $T_{coldroads}$ = temperature below which road asphalt performance suffers. **Health:** T_{deadly} = temperature above which prolonged exposure may be deadly (often combined with humidity for heat indices); T_{severe} = temperature above which prolonged exposure may cause elevated morbidity; \bar{T}_{blooms} = mean temperature for harmful algal or cyanobacteria blooms; T_{danger} = level of dangerous cold temperatures (often combined with wind for chill indices); $\bar{T}_{overwinter}$ = temperature below which disease vector species cannot survive winter. **Ecosystems** (CID indices for air and ocean temperature): T_{hotlim} and $T_{coldlim}$ = limiting hot and cold temperatures for a given species range; T_{frost} = frost threshold; \bar{T}_{max} and \bar{T}_{min} = maximum and minimum suitable annual mean temperatures for a given species; T_{crit} = critical temperature above which a given species is stressed. **Agriculture:** T_{hotlim} = temperature above which a crop or livestock species dies; $T_{hotpest}$ = maximum (or 'lethal') temperature above which an agricultural pest/disease/weed cannot survive; T_{crit} = temperature at which productivity for a given crop is depressed; \bar{T}_{opt} = optimal mean temperature for a given plant's productivity; GDD_{min} = threshold temperature for growing degree days determining plant development; T_{chill} = temperature below which chilling units are accumulated; T_{frost} = temperature below which frost occurs; T_{hfrost} = temperature below which a hard frost threatens crops or livestock; $T_{coldpest}$ = minimum winter temperature below which a given agricultural pest cannot survive; $T_{coldlim}$ = minimum temperature below which a given crop cannot survive.

Regional information about the spring and autumn seasonal periods in which freeze-thaw cycles are common (such as the dates of first spring thaw and last spring frost, or the number of days where $T_{max} > 0^{\circ}\text{C}$ and $T_{min} < 0^{\circ}\text{C}$) are particularly useful in estimating the rate of potential road and building damage or determining seasonal truck weight restrictions (Kvande and Lisø, 2009; Chinowsky and Arndt, 2012; Palko, 2017; Daniel et al., 2018). The altitude of the freezing level also identifies portions of mountain slopes where freeze/thaw transitions or changes in snowpack condition can influence landslide and snow avalanche hazards (Coe et al., 2018). The geographical distribution of frost is also a determining factor in the range of vectors for human diseases such as malaria (X. Zhao et al., 2016; Smith et al., 2020).

Figure 12.3 illustrates how successive heat and cold hazards can potentially affect important natural and human systems, with climatic pressures reaching new sectoral assets or becoming increasingly severe as conditions become more extreme. While the precise value of any CID threshold may depend strongly on local environmental and system characteristics, there are common patterns and interdependencies in the types of thresholds encountered. Changes in the regional profile of CIDs can thus substantially alter threshold exceedance likelihoods.

12.3.2 Wet and Dry

12.3.2.1 Mean Precipitation

Changes in mean precipitation alter total water resources and long-term surface, snowpack and groundwater reservoirs (Schewe et al., 2014). Annual and seasonal wet trends can alter the suitable geographic range of species, with implications for biodiversity and vector-borne diseases (Knouft and Ficklin, 2017; Smith et al., 2020). The rate at which higher total streamflow increases river erosion and changes sediment loading is relevant for fish breeding (Scheurer et al., 2009), the location of riverine salt fronts that affect coastal agriculture and ecosystems (Chun et al., 2018; Vu et al., 2018), coastal freshwater stratification (Baker-Austin et al., 2013; Bell et al., 2013), and the accretion of sediment in estuaries and beaches (Syvitski and Milliman, 2007). Wetter conditions may shift tourist appeal (Kovács et al., 2017) and alter the pace of degradation for paved and especially unpaved roads (Chinowsky and Arndt, 2012).

Many agricultural systems require minimum rainfall totals or rely upon irrigation (Mbow et al., 2019). The length of the wet season helps determine the potential for multiple cropping seasons, but inconsistency of wet season arrival times poses challenges for farm management (Waha et al., 2020). Wetter growing season conditions increase the chance of waterlogging, which can delay planting or damage planted seeds (Rosenzweig et al., 2002; Ben-Ari et al., 2018; Mäkinen et al., 2018; Wolfe et al., 2018; Kolberg et al., 2019; Grotjahn, 2021). Tomasek et al. (2017) calculated 'workable days' for agricultural machinery around planting and harvest time set in part by limits in soil moisture saturation below which farmers can utilize critical machinery with less rutting or soil compaction. Wetter conditions may also increase canopy moisture that is conducive to crop pathogens (Garrett et al., 2006; Kilroy, 2015; Grotjahn, 2021).

12.3.2.2 River Flood

A large variety of climate indices and models are utilized to understand how river flooding affects both natural or built environments with highly variable hazard thresholds, given unique local topography and engineered defences such as dams and polders (Arnell and Gosling, 2016; Ekström et al., 2018). Key transportation routes, built infrastructure and agricultural lands are threatened when floods exceed design standards commonly based around flood magnitudes of a given historic return period (e.g., 1-in-100-year flood event), an annual exceedance probability or precipitation intensity-duration-frequency relationships with key indices (e.g., 10-day cumulative precipitation) related to catchment size and properties (Hirabayashi et al., 2013; Arnell and Lloyd-Hughes, 2014; Kundzewicz et al., 2014; Arnell and Gosling, 2016; Dikanski et al., 2016; Gosling and Arnell, 2016; Forzieri et al., 2017; Fluixá-Sanmartín et al., 2018; Koks et al., 2019). Floods and high-flow events can scour river beds and elevate silt loads, reducing water quality and accelerating deposition in estuaries and reservoirs (Khan et al., 2018; Parasiewicz et al., 2019). Floods can knock down, drown or wash away crops and livestock, and partially submerged plants can have yield reduction depending on water turbidity and their development stage (Ruane et al., 2013; Shrestha et al., 2019). Basin snowpack properties may also be important during heavy rain events, as rain-on-snow events can lead to rapid acceleration of flood stages that threaten wildlife and society (Hansen et al., 2014).

12.3.2.3 Heavy Precipitation and Pluvial Flood

Heavy downpours can lead to pluvial flooding in cities, roadways, farmland, subway tunnels and buildings (particularly those with basements; Grahn and Nyberg, 2017; Palko, 2017; Pregnolato et al., 2017; Orr et al., 2018). Heavy precipitation may overwhelm city transportation and storm water drainage systems, which are typically designed using intensity-duration-frequency information such as the return periods for 1-, 6- or 24-hour rainfall totals (Kermanshah et al., 2017; Depietri and McPhearson, 2018; Rosenzweig et al., 2018; Courty et al., 2019). Heavy rain events can directly cause leaf loss and damage, or knock over crops, also driving pollutant entrainment and erosion hazards in terrestrial ecosystems and farmland, with downstream ramifications for water quality (Hatfield et al., 2014; Segura et al., 2014; Li and Fang, 2016; Chhetri et al., 2019). The proportion of total precipitation that falls in heavy events also affects the percentage that is retained in the soil column, altering groundwater recharge and deep soil moisture content for agricultural use (Fishman, 2016; Lesk et al., 2020).

12.3.2.4 Landslide

Landslides, mudslides, rockfalls and other mass movements can lead to fatalities, destroy infrastructure and housing stock, and block critical transportation routes. Climate models cannot resolve these complex slope failure processes (nor triggering mechanisms such as earthquakes), so most studies rely on proxies or conditions conducive to slope failure (Gariano and Guzzetti, 2016; Ho et al., 2017). Common indices include precipitation intensity-duration thresholds (Brunetti et al., 2010; Khan et al., 2012; Melchiorre and Frattini, 2012) and

thresholds related to antecedent wet periods and extreme rainfall intensities (Alvioli et al., 2018; Monsieurs et al., 2019). Landslides and rockfalls may also be exacerbated by permafrost thaw and receding glaciers in polar and mountain areas (Cook et al., 2016; Haeberli et al., 2017; Patton et al., 2019).

12.3.2.5 Aridity

Aridity indices may track long-term changes in precipitation, evapotranspiration demand, surface water, groundwater or soil moisture (Sherwood and Fu, 2014; Herrera-Pantoja and Hiscock, 2015; B.I. Cook et al., 2020). Changes in soil moisture and surface water can shift the rate of carbon uptake by ecosystems (Humphrey et al., 2018) and alter suitable climate zones for wild species and agricultural cultivation (Feng and Fu, 2013; Garcia et al., 2014; Huang et al., 2016a; Schlaepfer et al., 2017; Fatemi et al., 2018; IPCC, 2019c) as well as the prevalence of related pests and pathogen-carrying vectors (Paritsis and Veblen, 2011; Smith et al., 2020). Water table depth, in relation to rooting depth, is also important for farms and forests under dry conditions (Feng et al., 2006). A reduction in water availability (via aridity or hydrological drought) challenges water supplies needed for municipal, industrial, agriculture and hydropower use (Schaeffer et al., 2012; Arnell and Lloyd-Hughes, 2014; Schewe et al., 2014; Gosling and Arnell, 2016; van Vliet et al., 2016).

12.3.2.6 Hydrological Drought

Water managers often utilize a variety of hydrological drought indices and hydrological models to characterize water resources, low flow conditions and the potential for irrigation (Wanders and Wada, 2015; Mukherjee et al., 2018). Low flow volume and intermittency thresholds can indicate reductions in dissolved oxygen, more concentrated pollutants, and higher stream temperatures relevant for ecosystems, water resource quality and thermal power plant cooling (Feeley et al., 2008; Döll and Schmied, 2012; Schaeffer et al., 2012; Prudhomme et al., 2014; van Vliet et al., 2016). Low water levels may also restrict waterway navigation for commerce and recreation (Forzieri et al., 2018).

12.3.2.7 Agricultural and Ecological Drought

Agricultural and ecological drought indices relate to the ability of plants to meet growth and transpiration needs (Table 11.3; Zargar et al., 2011; Lobell et al., 2015; Pedro-Monzonis et al., 2015; Bachmair et al., 2016; Wehner et al., 2017; Naumann et al., 2018) and the timing and duration of droughts can lead to substantially different impacts (Peña-Gallardo et al., 2019). Drought stress for agriculture and ecosystems is difficult to directly observe, and therefore scientists use a variety of drought indices (Table 11.3), proxy information about changes in precipitation supply and reference evapotranspiration demand, the ratio of actual/potential evapotranspiration or a deficit in available soil water content, particularly at rooting level (Park Williams et al., 2013; Trnka et al., 2014; C.D. Allen et al., 2015; Svoboda and Fuchs, 2017; Mäkinen et al., 2018; Otkin et al., 2018). Severe water stress can lead to crop failure, in particular when droughts persist for an extended period or occur during key plant developmental stages (Hatfield et al., 2014; Jolly et al., 2015; Leng and Hall, 2019). Projections

of high wind speed and low humidity (even for just a portion of the day) can also inform studies examining fruit desiccation and rice cracking (Grotjahn, 2021). Drought also raises disease infection rates for West Nile virus (Paull et al., 2017), and the alternation of dry and wet spells induces swelling and shrinkage of clay soils that can lead to sinkholes and destabilize buildings (Hadji et al., 2014).

12.3.2.8 Fire Weather

Complex fire weather indices shed light on conditions that increase the likelihood of wildfire and shifts in the fire season (Flannigan et al., 2013; Bedia et al., 2015; Jolly et al., 2015; Harvey, 2016; Littell et al., 2016; Westerling, 2016; Abatzoglou et al., 2019), which pose particularly acute challenges for indigenous communities (Christianson and McGee, 2019). Projection of future lightning frequency provides information on an important natural triggering mechanism, particularly when coupled with long-term warming and drying trends (Romps et al., 2014; Jin et al., 2015; Veraverbeke et al., 2017). Fuel aridity metrics also help determine vegetative fuel desiccation and therefore the ignitability, flammability and spread of fires when they occur (Abatzoglou and Williams, 2016). The presence of snow cover can influence the length of the fire season and the penetration of fire danger into new portions of the Arctic tundra (Young et al., 2017; Abatzoglou et al., 2019). Data on the changing characteristics of local wind circulations like the Santa Ana in California shed light on future intensity and spread patterns for fires (Jin et al., 2015). Fires also produce smoke plumes that reduce air and water quality (via deposition), adversely affecting health, visibility and water resources both near and far downwind (Dennekamp and Abramson, 2011; McKenzie et al., 2014; Dreessen et al., 2016; Liu et al., 2016; Martin, 2016).

12.3.3 Wind

12.3.3.1 Mean Wind Speed

Changes in the speed and direction of prevailing winds can alter the profile of seed dispersal, windblown pest and disease vectors, animal activities, and dust or pollen dispersal affecting ecosystems, agriculture and human health (Reid and Gamble, 2009; Bullock et al., 2012; Hellberg and Chu, 2016; Nourani et al., 2017). Seasonal winds influence algal blooms, ecosystems and fisheries via lake mixing, ocean currents and coastal upwelling (Bakun et al., 2015; Townhill et al., 2018; Woolway et al., 2020). Changes to wind density also modify a region's wind and wave renewable energy endowment (Schaeffer et al., 2012; Sierra et al., 2017; Craig et al., 2018; Devis et al., 2018; Tobin et al., 2018; Yalaw et al., 2020). D. Li et al. (2020) and Karnauskas et al. (2018a) evaluated wind thresholds at turbine height (about 80–100 m above ground) including periods outside of cut-in ($2.5\text{--}3\text{ m s}^{-1}$) and cut-out (about 25 m s^{-1}) levels beyond which given turbines could not operate.

12.3.3.2 Severe Wind Storm

High winds associated with severe storms can destroy trees and houses, break plant stems and knock fruits, nuts and grains to the

ground, with tolerance thresholds depending on crop species and developmental stage (Seidl et al., 2017; Lai, 2018; Elsner et al., 2019; Grotjahn, 2021). Severe storms particularly threaten energy infrastructure, with maximum wind speed associated with treefall and breaking of above-ground electrical transmission lines (Ward, 2013; Nik et al., 2020). The profile of heavy wind gusts is also required in the design of skyscrapers (C.-H. Wang et al., 2013) and bridges (Mondoro et al., 2018). Severe storms are difficult to simulate at the relatively coarse spatial scales of Earth system models, thus scientists often project changes by noting areas with increased convective available potential energy (CAPE) and strong low-level wind shear as these are conducive to tornado formation (Diffenbaugh et al., 2013; Tippet et al., 2016; Glazer et al., 2021).

12.3.3.3 Tropical Cyclone

Tropical cyclones and severe coastal storms can deliver wind, water and coastal hazards with the potential for widespread mortality and damages to cities, housing, transportation and energy infrastructure, ecosystems and agricultural lands (Burkett, 2011; NASEM, 2012; Bell et al., 2013; Wehof et al., 2014; Ward et al., 2016; Cheal et al., 2017; Godoi et al., 2018; Koks et al., 2019; Pinnegar et al., 2019). Storm planning is often tied to the Saffir–Simpson scale related to peak sustained wind speed (Izaguirre et al., 2021), with several indices focusing on storms' overall power and energy, size and translation speed to anticipate destructive potential (Knutson et al., 2015; Wang and Toumi, 2016; Parker et al., 2018; Hassanzadeh et al., 2020).

12.3.3.4 Sand and Dust Storm

Sand and dust storms erode soils, damage crops and induce problems for health, transportation, mechanical equipment and built infrastructure corresponding to the magnitude and duration of high winds and particulate matter concentrations (Goudie, 2014; O'Loingsigh et al., 2014; Crooks et al., 2016; Barreau et al., 2017; Bhattachan et al., 2018; Al Ameri et al., 2019; Middleton et al., 2019). Dust events may be represented as the number of dust hours per year and by particulate matter (PM) concentrations (Leys et al., 2011; Spickett et al., 2011; Hand et al., 2016). Photovoltaic panels can lose energy production efficiency with dust accumulation (Patt et al., 2013; Javed et al., 2017). It is also useful to track dust storm deposition of nutrients necessary for coral and tropical forest systems, but they may also feed algal blooms harming lake and coastal ecosystems, health and recreation (Jickells et al., 2005; Hallegraeff et al., 2014; Gabric et al., 2016). Dust storms also cause air pollution and redistribute the soil-based fungus associated with Valley fever (Barreau et al., 2017; Coopersmith et al., 2017; Tong et al., 2017; Gorris et al., 2018).

12.3.4 Snow and Ice

Cryospheric changes are a focus of Chapter 9 and were central to the recent IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC; IPCC, 2019b). Here we focus on the ways that scientists use snow and ice CIDs to understand current and future societal impacts and risks.

12.3.4.1 Snow, Glacier and Ice Sheet

A large number of indices have been used in water resource and ecosystem studies to track changes in snow under current and future climate conditions, including measurements of the snow water equivalent at key seasonal dates, the fraction of precipitation falling as snow, the first and last days of snow cover, and cold season temperatures (Mills et al., 2013; Pierce and Cayan, 2013; Berghuijs et al., 2014; Klos et al., 2014; Musselman et al., 2017; Rhoades et al., 2018). Impact studies also examine shifts in seasonal streamflow for snow-fed river basins (Mote et al., 2005; Pederson et al., 2011; Beniston and Stoffel, 2014; Coppola et al., 2014b, 2018; Fyfe et al., 2017; Islam et al., 2017; Knouft and Ficklin, 2017) as well as the geographic extent of snow cover and the depth of frosts when snow cover's natural insulation is absent (Scheurer et al., 2009; Millar and Stephenson, 2015). Studies examining the impact of snow changes on winter recreation and transportation have used thresholds of about 30 cm snow depth or snow water equivalent >10 cm to determine the length of the season for alpine and cross-country skiing and snowmobiling (Damm et al., 2017; Wobus et al., 2017b; Spandre et al., 2019; Steiger et al., 2019; Abegg et al., 2021). Changes in snow quality also affect recreational activities (Rutty et al., 2017), and artificial snowmaking can augment recreational snowpack depending on the number of suitable snowmaking hours (e.g., where wet bulb globe temperature (WBGT) $<-2.2^{\circ}\text{C}$; Wobus et al., 2017b). Local detail may also be provided by tracking the seasonal rain–snow transition line across space and elevation (Berghuijs et al., 2014) (Pierce and Cayan, 2013; Berghuijs et al., 2014; Klos et al., 2014; Musselman et al., 2017).

Change in ice sheet and glacier spatial extent and surface mass balance is relevant for polar and high mountain ecosystems and downstream assets that rely on glacial water resources (J.R. Lee et al., 2017; Milner et al., 2017; Huss and Hock, 2018; Schaeffli et al., 2019). The loss of glaciers reduces the thermal consistency of cold streams suitable for some freshwater species (Giersch et al., 2017), and parks and recreation areas may lose appeal as glaciers and seasonal snow cover retreat (Gonzalez et al., 2018; Wang and Zhou, 2019). Rapid glacial retreat can lead to glacial lakes and outburst floods that endanger downstream communities (Carrivick and Tweed, 2016; Cook et al., 2016; Harrison et al., 2018).

12.3.4.2 Permafrost

Changes in permafrost temperature, extent and active layer thickness are metrics that track how permafrost thaw below, for example, roads, airstrips, rails and building foundations in high-latitude and mountain regions may destabilize settlements and critical infrastructure (Pendakur, 2016; Derksen et al., 2018; Duvillard et al., 2019; Olsson et al., 2019; Streletskiy et al., 2019). Warmer conditions can also affect ecosystems, built infrastructure and water resources through thawing of especially ice-rich permafrost ($\geq 20\%$ ice content) and by thawing of ice wedges (Shiklomanov et al., 2017; Hjort et al., 2018), creation of thermokarst ponds and increased subsurface drainage for polar and high-mountain wetlands (Walvoord and Kurylyk, 2016; Farquharson et al., 2019) and the release of water pollutants such as mercury (Burkett, 2011; Schaeffer et al., 2012; Schuster et al., 2018).

12.3.4.3 Lake, River and Sea Ice

Reductions in the duration of thick sea, lake and river ice influence ecosystems as well as ice fishing, hunting, dog sledding and snowmobiling, which are recreation activities for some but vital aspects of many traditional indigenous communities (Durkalec et al., 2015; AMAP, 2017; Baztan et al., 2017; Arp et al., 2018; Rokaya et al., 2018; Knoll et al., 2019; Meredith et al., 2019; Sharma et al., 2019). The seasonal extent of thin ice and iceberg density also determines the viability of shipping lanes and seasonal roads (Valsson and Ulfarsson, 2011; Pizzolato et al., 2016; AMAP, 2017; Mullan et al., 2017; Sturm et al., 2017), oil and gas exploration timing (Schaeffer et al., 2012) and the seasonality of phytoplankton blooms (Oziel et al., 2017). Sea ice is a critical aspect of some ecosystems and fisheries (Massom and Stammerjohn, 2010; Jenouvrier et al., 2014; Bindoff et al., 2019; Meredith et al., 2019). Various definitions of 'ice free' Arctic Ocean conditions can be tailored to represent transportation needs, including thresholds of ice coverage ($<5\%$ or $<30\%$ or <1 million km^2) in September or over a four-month period (Laliberté et al., 2016; Jahn, 2018).

12.3.4.4 Heavy Snowfall and Ice Storm

Heavy snowfall is a substantial concern for cities, settlements and key transportation and energy infrastructure (Ward, 2013; Palko, 2017; Janoski et al., 2018; Collins et al., 2019). Heavy snowfall can interfere with transportation (Herring et al., 2018) and cause a loss of both work and school days depending on local snow removal infrastructure. Freezing rain and ice storms can be treacherous for road and air travel (Tamerius et al., 2016), and can knock down power and telecommunication lines if ice accumulation is high (Degelia et al., 2016). Rain-on-snow events can create a solid barrier that hinders wildlife and livestock grazing that is important to indigenous communities (Forbes et al., 2016). Shifts in the frequency, seasonal timing and regions susceptible to ice storms alter risks for agriculture and infrastructure (Lambert and Hansen, 2011; Klima and Morgan, 2015; Ning and Bradley, 2015; Groisman et al., 2016).

12.3.4.5 Hail

Information on the changing frequency and size distribution of hail can help stakeholders build resilience for agriculture, vehicles, transportation infrastructure and buildings, solar panels and wild species that see critical damage at particular hail size thresholds (Dessens et al., 2007; Webb et al., 2009; Patt et al., 2013; Fiss et al., 2019). Most climate models do not directly resolve hail and therefore studies often examine proxies associated with severe mesoscale storms (Tippett et al., 2015; Prein and Holland, 2018), although some regional studies now utilize hail-resolving models (Mahoney et al., 2012; Brimelow et al., 2017).

12.3.4.6 Snow Avalanche

Information about the changing frequency and seasonal timing of snow avalanches is important to assess threats to transportation routes, infrastructure, recreational skiing and people living in alpine communities (Lazar and Williams, 2008; Mock et al., 2017; Ballesteros-Cánovas et al., 2018; Hock et al., 2019). Like landslides and other mass movements, snow avalanches are not directly resolved by

climate models and are thus tracked using proxy climate information describing snow avalanche susceptibility, particularly the snow water equivalent, and triggering mechanisms such as warm spells, high winds, rain-on-snow and heavy precipitation (Hock et al., 2019). The quality of snow also provides insight into avalanche hazards (Mock et al., 2017), with the seasonal altitude of wet snowpack (>0.5% liquid water by volume) particularly important in determining characteristics of potential avalanches (Castebrunet et al., 2014).

12.3.5 Coastal

The SROCC included in-depth discussions of threats facing the world's coastlines (IPCC, 2019b) and Section 9.6 provides further discussion on coastal processes. Here we note major connections between coastal CIDs and ecosystem and societal assets near coastlines.

12.3.5.1 Relative Sea Level

Sea level rise hazards for coastal ecosystems, infrastructure, farmland, cities and settlements in a particular region are often driven by regional changes in relative sea level (RSL) that account for land uplift or subsidence and thus represent local asset vulnerability better than global mean sea level (Box 9.1; Hallegatte et al., 2013; Hinkel et al., 2013; McInnes et al., 2016; Weatherdon et al., 2016; Brown et al., 2018; IPCC, 2019b; Rasoulkhani et al., 2020). Vertical land motion (i.e., land subsidence) caused by local fluid (gas or groundwater) extraction can also have a large influence on relative sea levels (Minderhoud et al., 2020). Several indices have been suggested to signify coastal inundation, including a threshold when the local land elevation falls below the local mean higher high water (MHHW) that is close to the 'high tide' level (Kulp and Strauss, 2019) or a threshold when flooding occurs about once every two weeks (Sweet and Park, 2014; Dahl et al., 2017b). RSL rise (or RSLR) can drive increased inland penetration of above-ground and subterranean salt water fronts (i.e., salinity intrusion) affecting coastal ecosystems, agriculture and water resources (Ferguson and Gleeson, 2012; Kirwan and Megonigal, 2013; Rotzoll and Fletcher, 2013; Chen et al., 2016; Colombani et al., 2016; Holding et al., 2016; Sawyer et al., 2016; Mohammed and Scholz, 2018). The rate of RSLR can determine the survival and net pressure on niche coastal ecosystems such as mangroves, tidal flats, sea grasses and coral reefs (Hubbard et al., 2008; Craft et al., 2009; Bell et al., 2013; Kirwan and Megonigal, 2013; Alongi, 2015; Ellison, 2015; Lovelock et al., 2015; Ward et al., 2016; Lee et al., 2018).

12.3.5.2 Coastal Flood

Episodic coastal flooding of coastal communities, farmland, buildings, transportation routes, industry and other infrastructure is caused by extreme total water levels (ETWL), which is the combination of RSL, tides, storm surge and high wave setup at the shoreline (Vitousek et al., 2017; Melet et al., 2018; Vousdoukas et al., 2018, 2020a; Koks et al., 2019; Kirezci et al., 2020). Coastal settlement and infrastructure design often uses coastal flooding metrics such as the ETWL frequency distribution or the 100-year average return interval storm tide (storm surge + high tide) level (McInnes et al., 2016; Mills et al., 2016; Walsh et al., 2016b; Zheng et al., 2017). The duration

of floods that overtop coastal protection, due to extreme coastal water levels (ECWL), is important for port and harbour operations and coastal energy infrastructure thresholds (Bilskie et al., 2016; Camus et al., 2017). Frequent inundation by salt water can also have significant impacts on water resources, crops, aquaculture and transportation systems due to corrosion and undercutting of coastal roads, bridges and rails (Zimmerman and Faris, 2010; N. Ahmed et al., 2019; Gopalakrishnan et al., 2019).

12.3.5.3 Coastal Erosion

Effective management of coastal ecosystems, cities, settlements, beaches and infrastructure requires information about coastal erosion driven by storm surge, waves and sea level rise (Dawson et al., 2009; Hinkel et al., 2013; Harley et al., 2017; Mentaschi et al., 2017). Coastal erosion is generally accompanied by shoreline retreat, which can occur as a gradual process (e.g., due to sea level rise) or as an episodic event due to storm surge and/or extreme waves, especially when combined with high tide (Ranasinghe, 2016). The most commonly used shoreline retreat index is the magnitude of shoreline retreat by a pre-determined planning horizon such as 50 or 100 years into the future. Commonly used metrics for episodic coastal erosion include the beach erosion volume due to the 100-year recurrence storm wave height, the full exceedance probability distribution of coastal erosion volume (Li et al., 2014a; Pender et al., 2015; Ranasinghe and Callaghan, 2017) and the cumulative storm energy and storm power index (Godoi et al., 2018). The destruction or overtopping of barrier islands may lead to irreversible changes in the physical system as well as in coastal ecosystems (Carrasco et al., 2016; Zinnert et al., 2019). Shoreline position change rates along inlet-interrupted coasts may also be affected by changes in river flows and fluvial sediment supply (Hinkel et al., 2013; Bamunawala et al., 2018; Ranasinghe et al., 2019). Permafrost thaw and Arctic sea ice decline also reduce natural coastal protection from wave erosion for communities and industry (Forbes, 2011; Melvin et al., 2017).

12.3.6 Oceanic

Oceanic changes and impacts were a substantial focus of SROCC (IPCC, 2019b). Chapter 9 of this Report assesses changes in ocean processes, and here we note major connections used by scientists to understand how oceanic CIDs affect ecosystems and society.

12.3.6.1 Mean Ocean Temperature

Shifts in thermal zones affect the suitability of fisheries and marine and coastal species habitat and migration routes (Hoegh-Guldberg and Bruno, 2010; Doney et al., 2012; Burrows et al., 2014; Urban, 2015; Hixson and Arts, 2016; Tripathi et al., 2016; N. Ahmed et al., 2019; Bindoff et al., 2019). Intertidal species are particularly dependent on suitable conditions for both air and sea surface temperatures (Monaco and McQuaid, 2019). The structure of ocean warming also affects the intensity of upper-ocean stratification and the timing and strength of coastal upwelling (driven also by mean wind changes), which alters the vertical transport of oxygen- and nutrient-rich waters affecting fishery and marine ecosystem productivity (D. Wang et al., 2015).

12.3.6.2 Marine Heatwave

Marine heatwaves (MHW) push water temperatures above key thresholds and have been associated with coral bleaching episodes, species shifts and harmful algal blooms that can disrupt ecosystems, tourism and human health (Box 9.2; Wernberg et al., 2016; Arias-Ortiz et al., 2018; Oliver et al., 2018; Frölicher, 2019; Smale et al., 2019; Sully et al., 2019). The duration and return period of marine heatwaves provide insight into aggregate stresses on marine species, fisheries and ecosystems, with various indices gauging cumulative intensity or the number of days, weeks or months exceeding critical thresholds (Frieler et al., 2013; Frölicher et al., 2018; Hughes et al., 2018b; Cheung and Frölicher, 2020). Hobday et al. (2016) defined marine heatwaves as the exceedance of the 90th percentile of the sea surface temperature (SST) distribution on a given Julian day during five or more consecutive days, while Box 9.2, Figure 1 shows MHW as an exceedance of 99th-percentile 11-day de-seasonalized SSTs. The return period of marine heatwaves is also critical in determining a coral system's ability to recover before the next event (Hughes et al., 2018a).

12.3.6.3 Ocean Acidity

Uptake of atmospheric CO₂ and subsequent increases in dissolved CO₂ lowers ocean pH and can reduce carbonate ion concentrations below critical calcium carbonate saturation thresholds for marine and aquatic organisms growth, reproduction and/or survival, with extended implications for marine ecosystems including fisheries (Bell et al., 2013; Kroeker et al., 2013; Barange et al., 2014; Dutkiewicz et al., 2015; Ekstrom et al., 2015; Gattuso et al., 2015; Mathis et al., 2015a; Nagelkerken and Connell, 2015; Behrenfeld et al., 2016; Nagelkerken and Munday, 2016; Tripathi et al., 2016; Jiang et al., 2018; Weiss et al., 2018; N. Ahmed et al., 2019; Bindoff et al., 2019). Lower pH may provide more favourable conditions for toxic algal blooms (Riebesell et al., 2018) and can interact with hypoxic zones to impact ecosystems (Gobler and Baumann, 2016; Cai et al., 2017).

12.3.6.4 Ocean Salinity

Changes in currents, sea ice brine rejection and net freshwater flux in the ocean can alter salinity with effects on mixed layer structure, density stratification and the vertical movement of nutrients and marine organisms (Freeland, 2013; Haumann et al., 2016).

12.3.6.5 Dissolved Oxygen

Ocean warming and increased stratification decrease the oxygen content of the ocean (Griffiths et al., 2017; Schmidtke et al., 2017; Bindoff et al., 2019), lead to an expansion of oxygen minimum zones in the open ocean (Stramma et al., 2012; Zhang et al., 2013) and exacerbate the creation of anoxic 'dead zones' in the coastal oceans (Breitburg et al., 2018). Such a decline (characterized by successive dissolved oxygen concentration thresholds) could affect a wide range of marine organisms and reduce marine habitats (Chan et al., 2008; Vaquer-Sunyer and Duarte, 2008; Hoegh-Guldberg and Bruno, 2010; Altieri and Gedan, 2015; Breitburg et al., 2018) and can also lead to further local acidification (Zhang and Gao, 2016; Laurent et al., 2017).

12.3.7 Other Climatic Impact-drivers

12.3.7.1 Air Pollution Weather

Although future air pollution will be strongly driven by air quality policies, anthropogenically-driven changes to temperature, humidity, precipitation and synoptic patterns have the potential to affect the emissions, production, concentration and transport of particulate matter (e.g., from dust, fires, pollen) and gaseous pollutants such as sulphur dioxide, tropospheric ozone and nitrogen dioxide (Section 6.5) with resulting impacts on human health, agriculture and ecosystems (Ren et al., 2011; Fiore et al., 2015; Kinney et al., 2015a; Tian et al., 2016; Orru et al., 2017; Emberson et al., 2018; Hayes et al., 2020). Information about conditions leading to poor air quality is also important for visibility in natural parks and tourist locations (Yue et al., 2013; Val Martin et al., 2015), as well as the efficiency of solar photovoltaic panels (Sweerts et al., 2019). Relevant information about conditions favouring air pollution includes tracking warmer conditions that accelerate ozone formation (Peel et al., 2013; Schnell et al., 2016) and the frequency and duration of stagnant air events (Horton et al., 2014; Fann et al., 2015; Lelieveld et al., 2015; Vautard et al., 2018), although no regional index has proven sufficient to capture regional changes or acute events (Kerr and Waugh, 2018; Schnell et al., 2018). By contrast, precipitation and moister air tend to reduce pollution (Section 6.5).

12.3.7.2 Atmospheric Carbon Dioxide at Surface

Carbon dioxide (CO₂) is a well-mixed greenhouse gas with global repercussions on Earth's energy balance; however, atmospheric CO₂ concentration changes at the land surface also affect plant functions within ecosystems and agriculture (see also Chapter 5). High CO₂ concentration can increase photosynthesis rates and primary production within natural ecosystems (Norby et al., 2010; Ratliff et al., 2015; Zhu et al., 2016) and agricultural crops (Hatfield et al., 2011; Leakey et al., 2012; Bell et al., 2013; Glenn et al., 2014; Nagelkerken and Connell, 2015; Behrenfeld et al., 2016; Deryng et al., 2016; Kimball, 2016). High CO₂ concentration affects total biomass and plant sugar content important to bioenergy production (Schaeffer et al., 2012), but also helps some pests and weeds flourish (Hamilton et al., 2005; Wolfe et al., 2008; Valerio et al., 2013; Korres et al., 2016; Stinson et al., 2016; Ramesh et al., 2017), while potentially shifting the effectiveness of herbicides (Varanasi et al., 2016; Refatti et al., 2019). Higher CO₂ concentration reduces transpiration losses during drought conditions (Cammarano et al., 2016; Deryng et al., 2016; Swann et al., 2016; Durand et al., 2018), which also changes the energy balance within the plant canopy (Webber et al., 2017). Higher CO₂ reduces the nutritional density of crops and forage lands (Loladze, 2014; Müller et al., 2014; Myers et al., 2014, 2017; X. Li et al., 2016; M.A. Lee et al., 2017; Smith and Myers, 2018; Zhu et al., 2018; Beach et al., 2019) and can increase the production of toxins (Ziska et al., 2007) and allergenic pollen (Schmidt, 2016).

12.3.7.3 Radiation at Surface

Changes in surface solar and longwave radiation fluxes alter photosynthesis rates and potential evapotranspiration for natural ecosystems and food, fibre and energy crops (Mäkinen et al., 2018);

changes in radiation fluxes can also shift solar energy resources (Schaeffer et al., 2012; Jerez et al., 2015; Wild et al., 2015; Fant et al., 2016; Craig et al., 2018). Plants and aquatic systems particularly respond to changes in photosynthetically active radiation (PAR) and the fraction of diffuse radiation (Proctor et al., 2018; Ren et al., 2018; Ryu et al., 2018). Increases in ultraviolet radiation can also detrimentally affect ecosystems and human health (Barnes et al., 2019).

12.3.7.4 Additional Relevant Climatic Impact-drivers

Additional CIDs may be relevant for regional studies but are not the focus of assessment in this Report. For example, information about changes in the frequency and seasonal timing of fog helps anticipate airport delays and cool beach days, and is also important for water delivery and retention in coastal ecological and agricultural systems (Torregrosa et al., 2014).

Threats to many sectoral assets and associated systems may also be compounded when multiple hazards occur simultaneously in the same place, affect multiple regions at the same time, or occur in a sequence that may amplify overall impact (Section 11.8; IPCC, 2012; Clarke et al., 2018; Zscheischler et al., 2018; Raymond et al., 2020). There is emerging literature on many connected extremes and their associated hazards (e.g., climatic conditions that could drive multi-breadbasket failures; Trnka et al., 2019; Kornhuber et al., 2020), but a full accounting is not practical here especially considering the many possible CID combinations and the need to assess how exposed systems would be vulnerable to compound CIDs (assessed in WGII). Table 12.2 is once again instructive here in considering hazard-related storylines, as the multiple CIDs affecting a given sectoral asset (assessing across a row of Table 12.2) point to potentially dangerous hazard combinations. Similarly, change in a single CID has the potential to affect multiple sectoral assets (assessing down a column of Table 12.2) in a manner with broader systemic implications (AR6 WGII).

Recent literature defines CID indices to represent trends and thresholds that influence sectoral assets, albeit with considerable variation owing to the unique characteristics of regional and sectoral assets. Indices include direct information about the CID's profile (magnitude, frequency, duration, timing, spatial extent) or utilize atmospheric conditions as a proxy for CIDs that are more difficult to directly observe or simulate. Each sector is affected by multiple CIDs, and each CID affects multiple sectors. Assets within the same sector may require different or tailored indices even for the same CID. These indices may be defined to capture graduated thresholds associated with tipping points or inflection points in a particular sectoral vulnerability, with commonalities in the types of processes these thresholds represent even as their precise magnitude may vary by specific sectoral system and asset.

12.4 Regional Information on Changing Climate

This section describes the historical and projected changes in commonly used indices and thresholds associated with the main climatic impact-drivers (Sections 12.2 and 12.3) at the scale of AR6 regions

described in Figure 1.18a. The section is organised by continents (Sections 12.4.1–12.4.6) with a specific assessment for Small Islands (Section 12.4.7), open and deep ocean (Section 12.4.8), and polar regions (Section 12.4.9) as defined in Chapter 1 (Figure 1.18c). In addition, CID indices and thresholds relevant to 'specific zones', as defined in AR6 WGII Cross-Chapter Papers, are assessed in Section 12.4.10 except for the Mediterranean, which is addressed both under Africa and Europe (Sections 12.4.1 and 12.4.5) and is a focus in Section 10.6.4.

Regional assessment method and tables: In each section herein (Sections 12.4.1–12.4.10), we assess changes in sector-relevant CIDs following the main CID categories defined in Section 12.2 through commonly used indices and thresholds relevant for sectors described in 12.3. Sections 12.4.1–12.4.9 each include a summary qualitative CID assessment table (Tables 12.3–12.11) showing the confidence levels associated with the direction of projected CID changes (i.e., increasing or decreasing) for the mid-century period (2041–2060) relative to the recent past, for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above (RCP6.0, RCP8.5, SSP3-7.0, SSP5-8.5, SRES A2), which approximately encompasses GWLs of 2.0°C to 2.4°C (as best estimate; see Chapter 4, Table 4.5). For scenarios RCP2.6, SSP1-2.6 or SSP1-1.9, the signal may have lower confidence levels in some cases due to smaller overall changes, embedded in a similar internal variability, and to the availability of relatively few studies that account for these scenarios. Nevertheless, CID changes under these lower emissions scenarios are included in the text whenever information is available. For each cell in Tables 12.3–12.11, literature is assessed, aided by global Figure 12.4 or regional Figures 12.5–12.10. Confidence in projections is established considering evidence emerging from observations, attribution and projections, as explained in Cross-Chapter Box 10.3 while considering the amount of evidence and agreement across models and studies and model generations.

The confidence levels associated with the directions of projected CID changes are synthesized assessments based on literature that may utilize different indices and baseline periods or projections by GWLs. For extreme heat, cold spell, heavy precipitation and drought CIDs that are assessed in Chapter 11, here we draw projections from the 2°C GWL tables in Section 11.9. In some cases, more details are needed in order to emphasize one aspect of projected CID change. For instance, the change in a CID may be different for intensity, duration, frequency; or there can be strong sub-regional or seasonal signals; or different CID indices may have conflicting signals. A footnote is added in such cases, but a confidence level for a direction of projected change is given based on the Section 12.3 assessment of aspects of regional CID change that are most relevant for impacts and for risks. As an example, tropical cyclones are increasing in intensity but decreasing in frequency in some regions. Here, in assessing the confidence of the direction of projected change in the Tropical cyclone CID (i.e., the colour of the table cell), we assign more weight to the 'intensity' rather than the 'frequency', corresponding to the higher relevance of the intensity of major tropical cyclones for risk assessment. Low confidence of changes, arising from lack of evidence, strong spatial or seasonal heterogeneity, or lack of agreement, are represented by colour-less cells, and, for the sake of simplicity, only two categories of confidence are given: *medium confidence* and *high confidence* (and higher). In addition, CID assessment tables also indicate observed

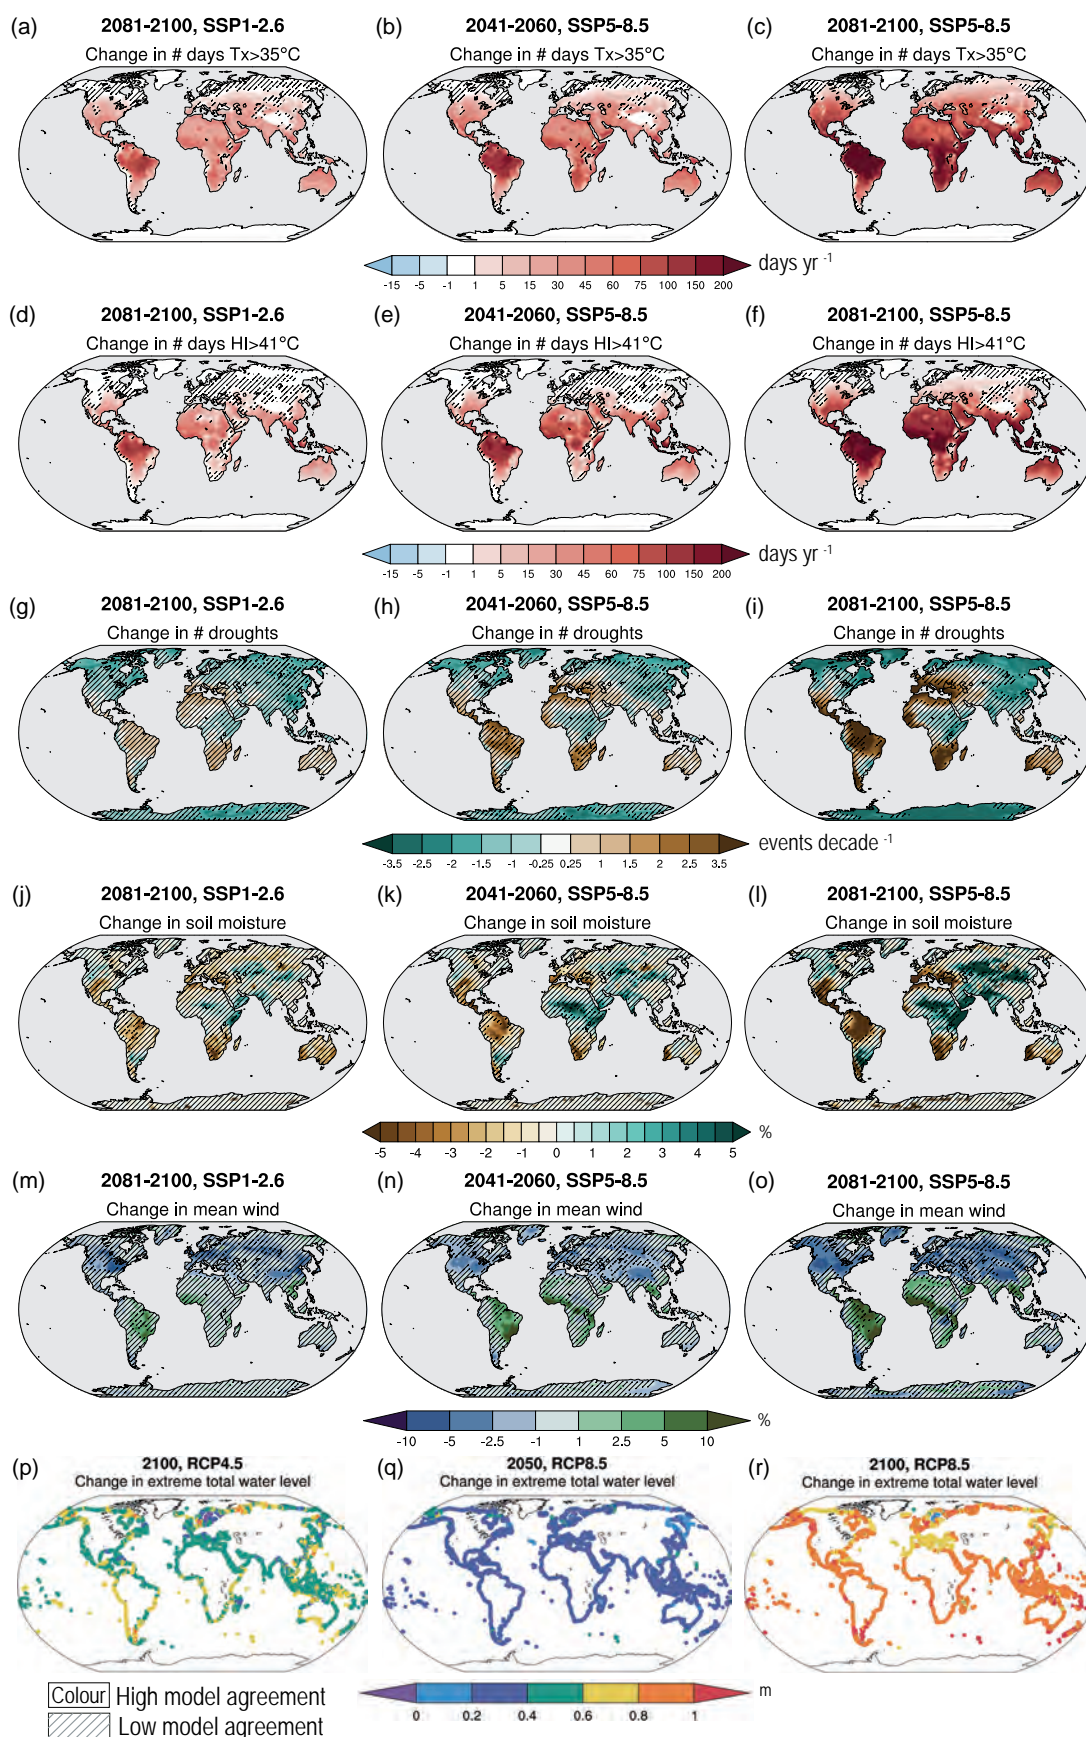

Figure 12.4 | Median projected changes in selected climatic impact-driver indices based on CMIP6 models.

Figure 12.4 (continued): (a–c) Mean number of days per year with maximum temperature exceeding 35°C; (d–f) mean number of days per year with the NOAA Heat Index (HI) exceeding 41°C; (g–i) number of negative precipitation anomaly events per decade using the six-month Standardized Precipitation Index; (j–l) mean soil moisture (%) and (m–o) mean wind speed (%). (p–r) shows change in extreme sea level (1-in-100-year return period total water level from Vousdoukas et al. (2018)'s CMIP5 based dataset; metres). Left-hand column is for SSP1-2.6, 2081–2100; middle column is for SSP5-8.5 2041–2060; and right-hand column SSP5-8.5, 2081–2100, all expressed as changes relative to 1995–2014. Exception is extreme total water level which is for (p) RCP4.5 2100, (q) RCP8.5 2050 and (r) RCP8.5 2100, each relative to 1980–2014. Bias correction is applied to daily maximum temperature and HI data (Atlas.1.4.5). Uncertainty is represented using the simple approach: no overlay indicates regions with high model agreement, where $\geq 80\%$ of models agree on the sign (direction) of change; diagonal lines indicate regions with low model agreement, where $< 80\%$ of models agree on the sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. See Annex VI for details of indices. Figures 12.SM.1–12.SM.6 show regionally averaged values of these indices for the AR6 WGI Reference Regions for various model ensembles, scenarios, time horizons and global warming levels. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

or projected emergence of the CID change signal from the natural interannual variability if assessed with at least *medium confidence* in Section 12.5.2, using as a basis a criterion of $S/N > 1$, noise being defined as the interannual variability. The time of emergence (ToE) is given as either: (i) already emerged in the historical period, or (ii) emerging by 2050 at least for RCP8.5/SSP5-8.5, or (iii) emerging after 2050 but before 2100 at least for scenarios RCP8.5 or SSP5-8.5. Table cells that do not include emergence information are indicative of 'low confidence of emergence in the 21st century', which includes situations where assessment indicates emergence will not occur before 2100 or that evidence is not available or insufficient for a confidence assessment of time of emergence.

Figures: The assessment of changes in CIDs is based on literature, physical understanding (Chapters 2–11), and global and regional climate projections of indices and thresholds presented in the Atlas, as well as in the global and regional figures in Section 12.4 (Figures 12.4–12.10) showing the future evolution of nine key CID indices/thresholds used in this assessment (see also Cross-Chapter Box 10.3). The figure indices and impact-relevant thresholds are described in Annex VI: Climatic Impact-drivers and Extreme Indices.

Figure 12.4 shows changes in six CID indices. These global maps are derived from Coupled Model Intercomparison Project Phase 6 (CMIP6) simulations for different time periods and scenarios (except for extreme total water level where CMIP Phase 5 (CMIP5) is used). The uncertainty due to climate models, time, scenarios and regional downscaling is illustrated in Supplementary Material SM.12.1 to SM.12.6, which show the distribution of the spatial average of the index among models over each land region for CMIP5, CMIP6 and Coordinated Regional Climate Downscaling Experiment (CORDEX) ensembles for the recent past, mid- and end-21st century, and for GWLs of +1.5°C, +2°C and +4°C. The hatching in the figure covers areas where less than 80% of models agree on the sign of change.

Further regional detail is provided for the remaining indices in each continental section in the form of continental maps accompanied by regional box plots displaying changes calculated for AR6 region averages, and the associated regionally averaged uncertainty.

Climatic impact-drivers changing in a globally coherent way: For the sake of conciseness, assessments pertaining to ocean acidity and the 'Other' CID type in Sections 12.2 and 12.3 are not provided per region in Sections 12.4.1–12.4.9 but are summarized here, given the globally coherent way in which they change.

Ocean acidity: Observations show increasing ocean acidification (*robust evidence, high agreement*), and it is *virtually certain* that

future ocean acidification will increase given future increases in greenhouse gases (Section 5.4). Areas below calcium carbonate saturation thresholds expanded from the 1990s to 2010 and Meredith et al. (2019) indicated that both the Southern and Arctic Oceans will experience year-round under-saturation conditions by 2100 under RCP8.5. The vertical level of the aragonite saturation horizon off the Pacific coast of North America has risen towards the surface by 30–50 m since pre-industrial times (Mathis et al., 2015b; Feely et al., 2016). In a study of US coastlines, Ekstrom et al. (2015) mapped out the projected year when aragonite saturation state drops below 1.5 (a sublethal threshold for bivalve mollusc larvae), finding hazardous conditions before 2030 from northern Oregon to Alaska and before 2100 for the Pacific coast and Atlantic coastline north of New Jersey. Mathis et al. (2015a) found that surface waters in the Beaufort Sea have already dropped below aragonite saturation thresholds, projecting further declines and the Chukchi Sea also dropping below saturation by about 2030.

Air pollution weather: The effect of climate change on air quality is assessed in Section 6.5 with limitations for local planning explained in Section 6.1.3, and only a brief summary is given here. Section 6.5 notes that climate change will have a small burden on particulate matter (PM) pollution (*medium confidence*) while the main controlling factor in determining future concentrations will be future emissions policy for PM and their precursors (*high confidence*). Surface ozone is sensitive to temperature and water vapour changes, but future levels depend on precursor emissions. Although there is *low confidence* in precise regional changes (Section 6.5), climate change will generally introduce a surface ozone (O_3) penalty (increasing concentrations with increasing warming levels) over regions with high anthropogenic and/or natural ozone precursor emissions, while in less polluted regions higher temperatures and humidity favour destruction of ozone (Schnell et al., 2016). There is *low confidence* in changes to future stagnation events given the lack of robust projections of related atmospheric conditions, such as future atmospheric blocking events (Sections 3.3.3 and 8.4.2). The response of regional air pollution to climate change will also be affected by other CIDs like fire weather, as well as by ecosystem responses such as shifts in emissions by vegetation (Fiore et al., 2015). Section 6.5 assessed *medium confidence* that climate-driven changes to meteorological conditions generally favour extreme air pollution episodes in heavily polluted environments, but noted strong regional and metric dependencies. Given the dominant influence of future air quality policies, uncertainties around stagnation or blocking events, and the potential contrasting regional changes of conditions favouring ozone and PM formation, accumulation and destruction, cells in Tables 12.3–12.11 for air pollution weather are marked as *low confidence*, and the reader is referred to Section 6.5 for further details.

Atmospheric CO₂ at surface: Observations show rising atmospheric CO₂ concentrations at the surface over all Earth regions (*robust evidence, high agreement*) (Sections 2.2 and 5.1.1), and it is *virtually certain* that surface atmospheric CO₂ concentrations will continue to increase without substantial changes to emissions (Section 5.4).

Radiation at surface: Radiation has undergone decadal variations in past observations, which are mostly responding to the so-called dimming and brightening phenomenon driven by the increase and decrease of aerosols. Over the last two decades or so, brightening continues in Europe and North America and dimming stabilizes over South and East Asia and increases in some other areas (Section 7.2.2.3). Future regional shortwave radiation projections depend mostly on cloud trends, aerosol and water vapour trends, and stratospheric ozone when considering UV radiation. Over Africa in 2050 and beyond, there is *medium confidence* that radiation will increase in North and South Africa and decrease over the Sahara, North Eastern Africa and Western Africa (Wild et al., 2015, 2017; Soares et al., 2019; C. Tang et al., 2019; Sawadogo et al., 2020, 2021). Over Asia, the CMIP5 multi-model mean response shows that solar radiation will decrease in South Asia and increase in East Asia (*medium confidence*) by the mid-century RCP8.5 (Wild et al., 2015, 2017; Ruosteenoja et al., 2019b). Projected solar resources show an increasing trend throughout the 21st century in East Asia under RCP2.6 and RCP8.5 scenarios in CMIP5 simulations (*medium confidence*) (Wild et al., 2015; F. Zhang et al., 2018; Shiogama et al., 2020). More sunshine is projected over Australia in winter and spring by the end of the century (*medium confidence*) with the increases in Southern Australia exceeding 10% (CSIRO and BOM, 2015; Wild et al., 2015). In Central and South America, there is *medium confidence* of increasing solar radiation over the Amazon basin and the northern part of South America (*medium confidence*) (Wild et al., 2015, 2017; de Jong et al., 2019). There is *low confidence* for an increase in surface radiation in central Europe, owing in particular to disagreement in cloud cover across global and regional models (Jerez et al., 2015; Bartók et al., 2017; Craig et al., 2018), as well as water vapour. The treatment of aerosol appears to be key in explaining these differences (Boé, 2016; Undorf et al., 2018; Boé et al., 2020; Gutiérrez et al., 2020). Regional and global studies, however, indicate that there is *medium confidence* in increasing radiation over southern Europe and decreasing radiation over Northern Europe. Increasing radiation trends are also found over southern and eastern USA, and decreasing trends over North-Western North America (Wild et al., 2015; Losada Carreño et al., 2020), despite large differences between responses from regional climate models (RCMs) and general circulation models (GCMs) over southern and eastern USA (*low confidence*), where, as for Central Europe, the role of aerosols appears important (Chen, 2021). Over polar regions there is *medium confidence* of a decrease in radiation due to increasing moisture in the atmosphere and clouds (Wild et al., 2015).

12.4.1 Africa

Previous IPCC assessments results are summarized in Atlas.4.1.1 For the purpose of this assessment the Africa region has been divided in nine sub-regions of which eight – Sahara (SAH), Western Africa

(WAF), Central Africa (CAF), North Eastern Africa (NEAF), South Eastern Africa (SEAF), West Southern Africa (WSAF), East Southern Africa (ESAF) and Madagascar (MDG) – are the official AR6 regions (Figure Atlas.2) and one – North Africa – is used in this assessment to indicate the African portion of the Mediterranean region.

Quite a large body of new literature is now available for the African climate as a result of regionally downscaled CORDEX Africa outputs, in particular, providing projections of both the mean climate (Mariotti et al., 2014; Nikulin et al., 2018; Dosio et al., 2019; Teichmann et al., 2021) and extreme climate phenomena (Giorgi et al., 2014; Nikulin et al., 2018; Dosio et al., 2019; Coppola et al., 2021b). CORDEX Africa simulations are assessed in the Atlas, which finds reasonable skill in mean temperature and precipitation as well as important features of regional climate (e.g., timing of monsoon onset in West Africa) although lower performance in Central Africa.

12.4.1.1 Heat and Cold

Mean air temperature: The African continent has experienced increased warming since the beginning of the 20th century in regions where measurements allow a sufficient homogeneous observation coverage to estimate trends (*high confidence*) (Figure Atlas.11). This warming is *very likely* attributable to human influence (Chapter 3 and Atlas.4.2) at continental scale. Mean annual temperatures have increased at a high rate since the mid-20th century, reaching 0.2°C–0.5°C per decade in some regions such as north, north-eastern, west and south-western Africa (*high confidence*) (Atlas.4.2 and Figure Atlas.11).

It is *very likely* that temperatures will increase in all future emissions scenarios and all regions of Africa (Atlas.4.4). By the end of the century under RCP8.5 or SSP5-8.5, all African regions will *very likely* experience a warming larger than 3°C except Central Africa, where warming is *very likely* expected above 2.5°C, while under RCP2.6 or SSP1-2.6, the warming remains *very likely* limited to below 2°C (Figure Atlas.12). A *very likely* warming with ranges between 0.5°C and 2.5°C is projected by the mid-century for all scenarios depending on the region (*high confidence*). Mean temperatures for all regions are projected to increase with increasing global warming (*virtually certain*) (Figure Atlas.12).

Extreme heat: Warm extremes have increased in most of the regions (*high confidence*), NEAF, SEAF and MDG (*medium confidence*) and with *low confidence* in CAF (Table 11.4). Despite the increasing mean temperature, there is *low confidence (limited evidence)* that Africa has experienced increased extreme heat stress trend for agriculture or human health in the last two decades of the 20th century in a few regions such as West Africa, South Africa and North Africa considering the period from 1973 to 2012 (Knutson and Ploshay, 2016).

A substantial increase in heatwave magnitude and frequency over most of the Africa domain is projected for even 2°C global warming (*high confidence*) (Sections 11.3 and 11.9, and Table 11.4), with potential effects on health and agriculture. The number of days with maximum temperature exceeding 35°C is projected to increase (Coppola et al., 2021b) in the range of 50–100 days by 2050 under

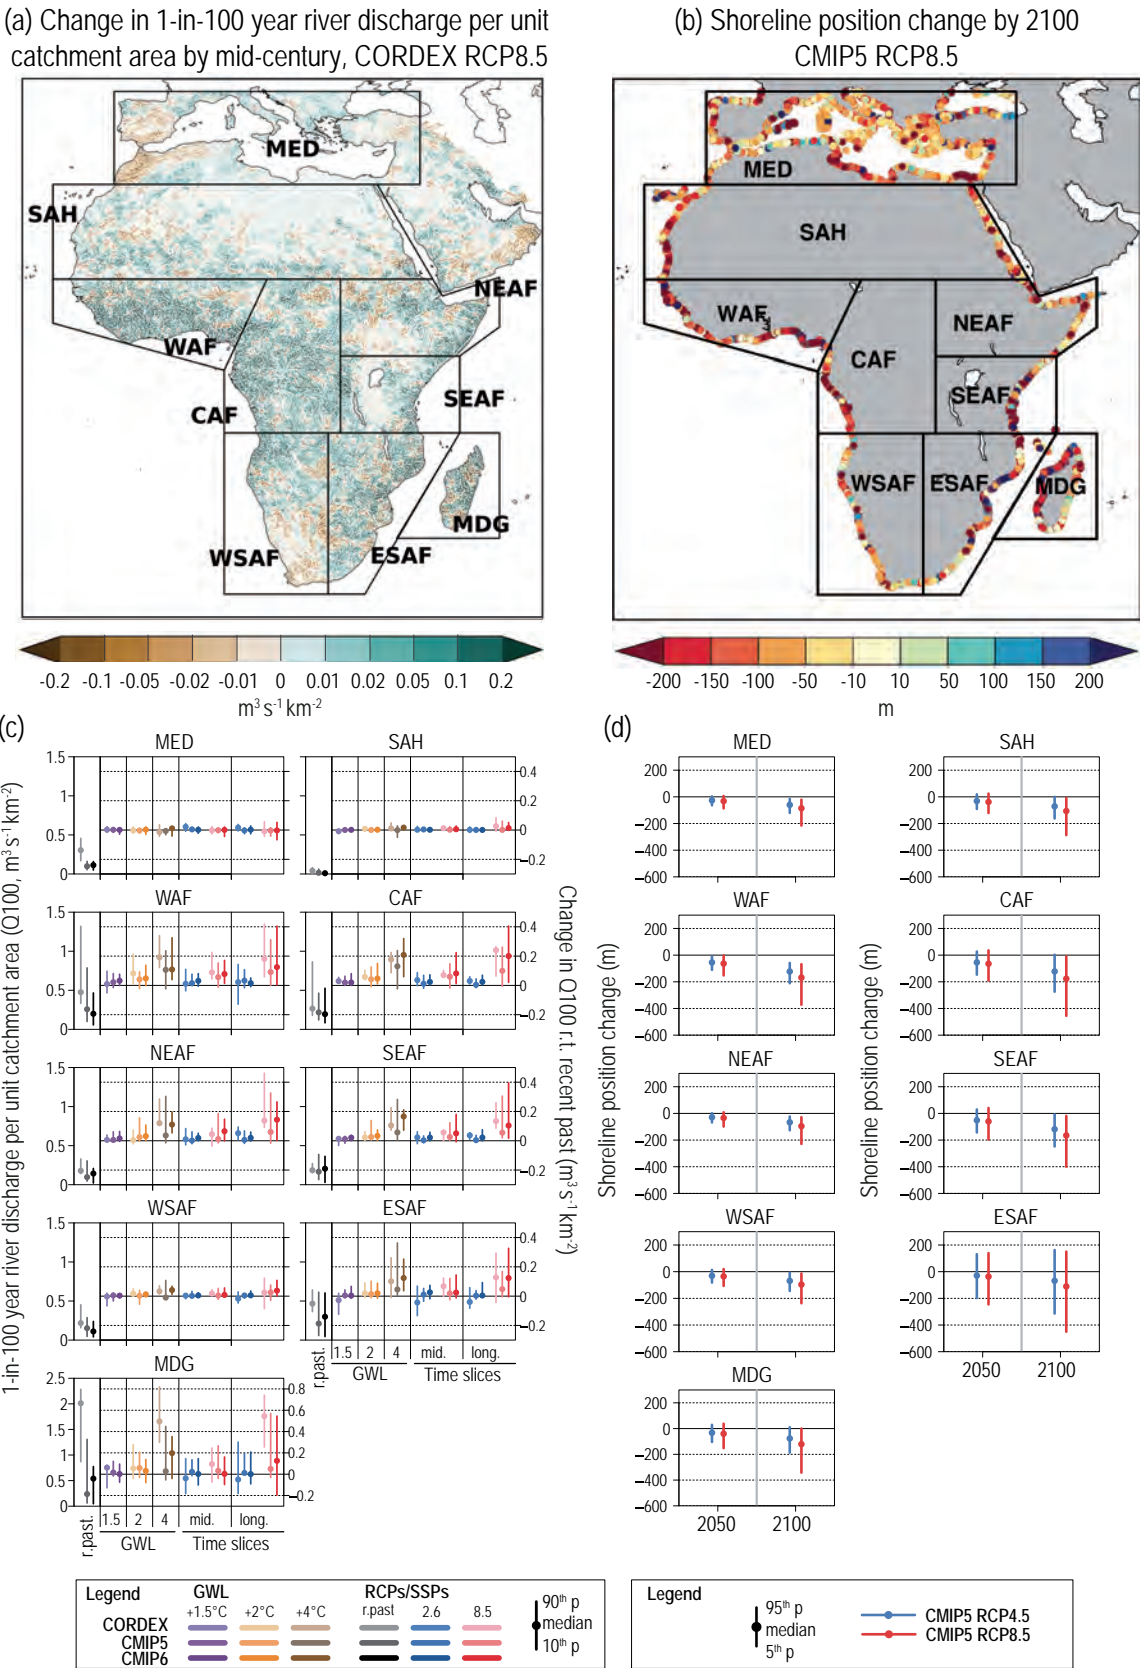

Figure 12.5 | Projected changes in selected climatic impact-driver indices for Africa.

Figure 12.5 (continued): (a) Mean change in 1-in-100-year river discharge per unit catchment area (Q_{100} , $m^3 s^{-1} km^{-2}$) from CORDEX-Africa models for 2041–2060 relative to 1995–2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 for RCP8.5 (metres; negative values indicate shoreline retreat) from the CMIP5-based dataset presented by Vousdoukas et al. (2020b). (c) Bar plots for Q_{100} ($m^3 s^{-1} km^{-2}$) averaged over land areas for the AR6 WGI Reference Regions (defined in Chapter 1). The left-hand column within each panel (associated with the left-hand y-axis) shows the ‘recent past’ (1995–2014) Q_{100} absolute values in grey shades. The other columns (associated with the right-hand y-axis) show the Q_{100} changes relative to the recent past values for two time periods (‘mid’ 2041–2060 and ‘long’ 2081–2100) and for three global warming levels (GWs, defined relative to the pre-industrial period 1850–1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10–90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5-based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al. (2020b). Dots indicate regional mean change estimates and bars show the 5–95th percentile range of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

SSP5-8.5 in WAF, ESAF and WSAF and NEAF (*high confidence*) (Figure 12.4b). Under SSP1-2.6, the change in the number of exceedance days remains limited to about 40–50 days per year at the end of the century in these regions, while it increases by 150 days or more in WAF, CAF for SSP5-8.5 (Figure 12.4a,c; Figure 12.SM.1).

Mortality-related heat stress levels and deadly temperatures are *very likely* to become more frequent in the future in RCP8.5/SSP5-8.5 and RCP4.5/SSP2-4.5 and for a 2°C global warming (Mora et al., 2017; Nangombe et al., 2018; Sylla et al., 2018a; Rohat et al., 2019; Q. Sun et al., 2019). In particular the equatorial regions where heat is combined with higher humidity levels, but also North Africa, the Sahel and Southern Africa (Figure 12.4d–f) are among the regions with the largest increases of heat stress (Zhao et al., 2015; Ahmadelipour and Moradkhani, 2018; Coffel et al., 2018). Mitigation scenarios make a large difference in frequency of exceedance of high heat stress indices thresholds (e.g., HI > 41°C) by the end of the century (Figure 12.4d–f; Schwingshackl et al., 2021). In West Africa and Central Africa, under SSP5-8.5, the expected number of days per year with HI > 41°C will increase by around 200 days while in SSP1-2.6 such exceedances are expected to increase by less than 50 days per year (Figure 12.4; Figure 12.SM.2).

Cold spell and frost: Africa experiences cold events and frost days that can affect agriculture, infrastructure, health and ecosystems, especially in Southern and North Africa, which have marked cold seasons and mountainous areas. Cold spells have *likely* decreased in frequency over subtropical areas. In particular, in North and Southern Africa, the frequency of cold events has *likely* decreased in the last few decades (Sections 11.3 and 11.9). There is a *high confidence* that cold spells and low target temperatures will decrease in future climates under all scenarios in West, Central and East Africa. Heating degree days will have a substantial decrease by the end of the century for up to about one month under RCP8.5 in North and Southern Africa (*high confidence*) (Coppola et al., 2021b).

There is *high confidence* that extreme heat has increased in frequency and intensity in most African regions. Heatwaves and deadly heat stress and the frequency of exceedance of hot temperature thresholds (e.g., 35°C) will drastically increase by the end of the century (*high confidence*) under SSP5-8.5, but limited increases are expected in SSP1-2.6. Dangerous heat stress thresholds (HI > 41°C) are projected to be crossed more than 200 days more in West and Central Africa under SSP5-8.5, while this increase remains limited to a few tens of days more for SSP1-2.6. Cold spells and frost days are projected to occur less frequently in all scenarios.

12.4.1.2 Wet and Dry

Mean precipitation: Since the mid-20th century, precipitation trends have varied in Africa but notable drying trends are found in eastern, central and north-eastern parts of Southern Africa, Central Africa and in the Horn of Africa (Atlas.4.2).

There is *high confidence* in projected mean precipitation decreases in North Africa and West Southern Africa and *medium confidence* in East Southern Africa by the end of the 21st century (Dosio et al., 2019; Gebrechorkos et al., 2019; Teichmann et al., 2021; Atlas.4.5). The Western Africa region features a gradient in which precipitation decreases in the west and increases in the east and increase is also projected over Eastern Africa (*medium confidence*) (Atlas.4.5), with trends in Western Africa affecting the boreal summer monsoon (Chen et al., 2020). Increasing precipitation for 1.5°C and 2°C GWs are found in central and eastern Sahel with *low confidence* and the wet signal is getting stronger and more extended for a 3°C and 4°C warmer world (Atlas.4.4).

A change in monsoon seasonality is also reported in Western Africa and Sahel (*low confidence*) with a forward shift in time (later onset and end; Section 8.2; Mariotti et al., 2011; Seth et al., 2013; Ashfaq et al., 2021). This shift has been associated with a precipitation decrease during the monsoon season attributed to a decrease of African easterly wave activity in the 6–9-day regime (Mariotti et al., 2014) and a soil precipitation feedback reported in Mariotti et al. (2011).

River flood: Generally in Africa from 1990 through 2014, annual flood frequencies have fluctuated and there is *medium confidence* in an upward trend in flood events occurrences (C.-J. Li et al., 2016). In particular, over Western Africa, upward trends in hydrological extremes such as maximum peak discharge have *likely* occurred during the last few decades (i.e., after 1980) and have caused increased flood events in riparian countries of rivers such as Niger, Senegal and Volta (*high confidence*) (Nka et al., 2015; Aich et al., 2016a; Wilcox et al., 2018; Trambly et al., 2020). In Southern Africa, trends in flood occurrences were decreasing prior to 1980 and increasing afterwards (*medium confidence*) (Trambly et al., 2020).

Under future climate scenarios, the extreme river discharge as characterized by the 30-year return period of 5-day average peak flow is projected to increase by the end of the century for RCP8.5 (more than 10% relative to the 1971–2000 period) for most of the tropical African river basins (Dankers et al., 2014) and a consistent increase of flood magnitude is projected across humid tropical Africa by 2050

for the A1B scenario (*medium confidence*) (Figure 12.5; Arnell and Gosling, 2013). Specifically, in Western Africa there is not a univocal pattern of change for future projections (Roudier et al., 2014); However, under RCP8.5, there is *medium confidence* of a projected increase of 20-year flood magnitudes by 2050 in countries within the Niger River basin (Aich et al., 2016b) and *low confidence (limited evidence)* of an increase in extreme peak flows and their duration in countries of the Volta River basin by 2050 and 2090 (Jin et al., 2018). A significant median change of flood magnitude for the Gambia River (−4.5%) and for the Sessandra (+14.4%) and Niger (+6.1%) are projected under several scenarios between mid- and end-of-century (Roudier et al., 2014). In East Africa, extreme flows are projected to increase for regions within the Blue Nile basin with *low confidence (limited evidence)* (Aich et al., 2014). However, uncertainty due to the climate scenario dominates the projection of extreme flows (Aich et al., 2014; Krysanova et al., 2017) for the Blue Nile and Niger River basins. Averaged over the African continent for different levels of global warming, the present-day 100-year return period flood levels will have a return period of 40 years in 1.5°C and 2°C (Alfieri et al., 2017) and 21 years for 4°C warmer climate (Hirabayashi et al., 2013; Alfieri et al., 2017).

Heavy precipitation and pluvial flood: Chapter 11 found that heavy precipitation intensity and frequency has *likely* increased over West and East Southern Africa but there is no evidence due to a lack of studies that any significant trend is observed in any other region. In addition, East Africa has experienced strong precipitation variability and intense wet spells leading to widespread pluvial flooding events hitting most countries including Ethiopia, Somalia, Kenya and Tanzania (*medium confidence*). Finally, with respect to Southern Africa, heavy precipitations events have increased in frequency (*medium confidence*).

In West Africa and Central Africa, there is *high confidence* that the intensity of extreme precipitation will increase in a future climate under both RCP4.5 and RCP8.5 scenarios and 1.5°C and 2°C GWLs threatening widespread flood occurrences before, during and after the mature monsoon season (Chapter 11). Extreme precipitation intensity is also increasing in several other regions, such as SAH, NEAF, SEAF, ESAF and MDG (*high confidence*) for 2°C GWL and higher (Chapter 11).

Landslides: There is an increase in reported landslides in WAF, CAF, NEAF and SEAF in the past decades but with *limited evidence* of significant trends (Gariano and Guzzetti, 2016; Haque et al., 2019). There is *low confidence (limited evidence)* of a future increase in landslides in central-eastern Africa, and literature is largely missing to assess this important hazard (Gariano and Guzzetti, 2016).

Aridity: Section 11.9 assesses *medium confidence* in observed long-term declines of soil moisture and aridity indices in several African regions (NAF, WAF). Trends in East Africa are not definitive given uncertain balances between precipitation and potential evaporation (Kew et al., 2021). Projected declines in precipitation and soil moisture trends indicate *high confidence* in increased aridity over the 21st century in NAF, WSAF and ESAF but *low confidence* elsewhere in Africa (Section 11.9; see also Figure 12.4j–l; Gizaw and

Gan, 2017). A growing number of studies provide further regional context on expanding aridity in several places in East and West Africa, respectively (Sylla et al., 2016a; Liu et al., 2018b; Haile et al., 2020).

Hydrological drought: Section 11.9 noted observed decreases in hydrological drought over the Mediterranean (*high confidence*) and diminished summer river flows in West Africa (*medium confidence*). Recent regional modelling studies project substantial increases in hydrological drought affecting major West African river basins under 1.5°C and 2°C GWLs and RCP4.5 and RCP8.5 scenarios (Oguntunde et al. 2018, 2020; Sylla et al., 2018b); however, there remains *low confidence* in future projections given disagreement with global model runoff projections (e.g., B.I. Cook et al., 2020). There is *high confidence* that a 2°C GWL would see an increase in hydrological droughts in the Mediterranean region, and *medium confidence* in increasing hydrological drought conditions in the Southern Africa regions (Section 11.9).

Agricultural and ecological drought: Farmers and food security experts in East Africa have noted spatial extensions in seasonal agricultural droughts in recent decades (Elagib, 2014), but it is difficult to disentangle these trends from climate variability. In Ethiopia, past severe agricultural drought conditions in the northern regions are moderately common events in recent years (Zeleeke et al., 2017). In Southern Africa, the number of ‘flash’ droughts (with rapid onset and durations from a few days to couple of months) have increased by 220% between 1961 and 2016 as a result of anthropogenic warming (Yuan et al., 2018). Section 11.9 notes *medium confidence* increases in agricultural and ecological drought trends in North, Western and Central Africa as well as both Southern Africa regions. The most striking drought is the Western Cape drought in 2015–2018, a prolonged drought that resulted in acute water shortages (Wolski, 2018; Burls et al., 2019; Section 10.6.2). Anthropogenic climate change caused a threefold increase in the probability of such a drought to occur (Chapters 10 and 11; Botai et al., 2017; Otto et al., 2018). Section 11.9 assesses increases in agricultural and ecological drought at 2°C GWL for North Africa and West Southern Africa (*high confidence*) and for East Southern Africa and Madagascar (*medium confidence*), with confidence generally rising for higher emissions scenarios (Sylla et al., 2016b; Zhao and Dai, 2017; Diedhiou et al., 2018; Abiodun et al., 2019; Todzo et al., 2020; Coppola et al., 2021b). Liu et al. (2018b) identified the Southern Africa region as the drought ‘hottest spot’ in Africa in 1.5°C and 2°C global warming scenarios.

Fire weather: There is *low confidence (low agreement)* in recent reductions in fire activity given soil moisture increases in some regions and substantial land use changes (Andela et al., 2017; Forkel et al., 2019; Zubkova et al., 2019). Days prone to fire conditions are going to increase in all extratropical Africa until the end of the century and fire weather indices are projected to largely increase in North and Southern Africa, where increasing aridity trends occur (*high confidence*), with an emerging signal well before the middle of the century where drought and heat increase will combine (Chapter 11; Engelbrecht et al., 2015; Abatzoglou et al., 2019). There is *low confidence (limited evidence)* of fire weather changes for other African regions.

Total precipitation is projected to decrease in the northernmost (*high confidence*) and southernmost regions of Africa (*medium confidence*), with West and East Africa regions each having a west-to-east pattern of decreasing-to-increasing precipitation (*medium confidence*). Most African regions will undergo an increase in heavy precipitation that can lead to pluvial floods (*high confidence*), even as increasing dry climatic impact-drivers (aridity, hydrological, agricultural and ecological droughts, fire weather) are generally projected in the North Africa and Southern African regions (*high confidence*) and western portions of West Africa (*medium confidence*).

12.4.1.3 Wind

Mean wind speed: Decreasing trends in wind speeds have occurred in many parts of Africa (*low confidence* due to observations with limited homogeneity) (McVicar et al., 2012; AR5 WGI). There is *high confidence* in climate change-induced future decreasing mean wind, wind energy potential and strong winds in North Africa and Mediterranean regions as a consequence of the poleward shift of the Hadley cell (Karnauskas et al., 2018a; Kjellström et al., 2018; Sivakumar and Lucio, 2018; Tobin et al., 2018; Jung and Schindler, 2019) in the RCP4.5 and RCP8.5 scenarios by the middle of the century or beyond, and for a GWL of 2°C or higher. Over Western Africa and Southern Africa a future significant increase in wind speeds and wind energy potential is expected (*medium confidence*) (Figure 12.4m–o; Karnauskas et al., 2018a; Jung and Schindler, 2019).

Severe wind storm: A limited number of studies allow an assessment of past trends in wind storms. In West Africa and specifically in the Sahel band, more intense storms have occurred since the 1980s (*low confidence, limited evidence*). A persistent and large increase of frequency of Sahelian mesoscale convective storms has been found in several studies (Panthou et al., 2014; C.M. Taylor et al., 2017), with consequences for extreme rainfalls, and potentially extreme winds (*low confidence, limited evidence*). There is *low confidence* of a general increasing trend in extreme winds across Western, Central, Eastern and Southern Africa in a majority of regions by the middle of the century even in high-end scenarios. The frequency of Mediterranean wind storms reaching North Africa, including Medicanes, is projected to decrease, but their intensities are projected to increase, by the mid-century and beyond under SRES A1B, SRES A2 and RCP8.5 (*medium confidence*) (Chapter 11; Cavicchia et al., 2014; Walsh et al., 2014; Tous et al., 2016; Romera et al., 2017; Romero and Emanuel, 2017; González-Alemán et al., 2019).

Tropical cyclone: In the South Indian Ocean, an increase in Category 5 cyclones has been observed in recent decades (Fitchett, 2018) as in other basins (Section 11.7). However, there is a projected decrease in the frequency of tropical cyclones making landfall over Madagascar, South Eastern Africa and East Southern Africa in a 1°C, 2°C and 3°C warmer world (*medium confidence*) (Malherbe et al., 2013; Roberts et al., 2015, 2020; Muthige et al., 2018; Knutson et al., 2020). There is *medium confidence* in general increasing intensities for cyclones in such studies for African regions.

Sand and dust storm: North Africa and the Sahel, and to a lesser extent Southern Africa, are prone to dust storms, having consequences on health (Querol et al., 2019), transmission of infectious diseases (Agier et al., 2013; Wu et al., 2016), and solar power generation and related maintenance costs. There is *limited evidence* and *low agreement* of secular 20th century trends in wind speeds or dust emissions (limited length of data records, large variability). Dust variations are controlled by changes in surface winds, precipitation and vegetation, which in turn are modulated at multiple time scales by dominant modes of internal climate variability (Chapter 10). In North Africa, wind variability explains both the observed high concentrations between the 1970s and 1980s and lower concentrations thereafter (Ridley et al., 2014; Evan et al., 2016). Yet, the effect of vegetation changes may not be negligible (Pu and Ginoux, 2017, 2018).

Changes to the frequency and intensity of dust storms also remain largely uncertain due to uncertainty in future regional wind and precipitation as the climate warms, CO₂ fertilization effects on vegetation (Huang et al., 2017), and anthropogenic land use and land-cover change due to land management and invasive species (Ginoux et al., 2012; Webb and Pierre, 2018). Dust loadings and related air pollution hazards (from fine particles that affect health) are projected to generally decrease in many regions of the Sahara and Sahel due to the changing winds (Evan et al., 2016) and slightly increase over the Guinea coast and West Africa (*low confidence*) (Ji et al., 2018).

In summary, there is *high confidence* of a decrease in mean wind speed and wind energy potential in North Africa and *medium confidence* of an increase in Southern and Western Africa, by the middle of the century regardless of climate scenario or global warming level equal or superior to 2°C, *high confidence* of a decrease in frequency of cyclones landing in SEAF, ESAF and MDG, and *low confidence* of a general increase in wind storms in most African regions located south of the Sahel. The evolution of dust storms remains largely uncertain.

12.4.1.4 Snow and Ice

Snow and glacier: African glaciers are located in East Africa and more specifically on Mount Kenya, the Rwenzori Mountains and Mount Kilimanjaro, with glaciers reducing substantially in each region (*high confidence*) (Taylor et al., 2006; Cullen et al., 2013; Chen et al., 2018; Prinz et al., 2018; Wang and Zhou, 2019). Observation and future projection of African glacier mass changes are assessed in Section 9.5.1 within the low-latitude glacier region, which is one of the regions with the largest mass loss even under low-emissions scenarios (assessment of this region is dominated by glaciers in the South American Andes, however) (*high confidence*). Glaciers in the low-latitude region will lose $67 \pm 42\%$, $86 \pm 24\%$ and $94 \pm 13\%$ of their mass by the end of the century for RCP2.6, RCP4.5 and RCP8.5 scenarios respectively (Marzeion et al., 2020). Cullen et al. (2013) calculated that even imbalances between the Mount Kilimanjaro glaciers and present-day climate would be enough to eliminate the mountain's glaciers by 2060. Snow water equivalent and snow cover season duration also decline in the East African mountains, Ethiopian Highlands and Atlas Mountains with climate change (*high confidence*) (López-Moreno et al., 2017).

In conclusion, there is *high confidence* that African snow and glaciers have very significantly decreased in the last decades and that this trend will continue over the 21st century.

12.4.1.5 Coastal and Oceanic

Relative sea level: Around Africa, from 1900 to 2018, a new tide gauge-based reconstruction finds a regional mean RSL change of 2.07 [1.36 to 2.77] mm yr⁻¹ in the South Atlantic and 1.33 [0.80 to 1.86] mm yr⁻¹ in the Indian Ocean (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). For the period 1993–2018, these RSLR rates, based on satellite altimetry, increased to 3.45 [3.04 to 3.86] mm yr⁻¹ and 3.65 [3.23 to 4.08] mm yr⁻¹ respectively (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5).

Relative sea level rise is *virtually certain* to continue in the oceans around Africa. Regional mean RSLR projections for the oceans around Africa range from 0.4–0.5 m under SSP1-2.6 to 0.8–0.9 m under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), which is within the range of projected GMSL change (Section 9.6.3.3). These RSLR projections may, however, be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

Coastal flood: The present-day 1-in-100-year extreme total water level is between 0.1 and 1.2 m around Africa, with values around 1 m or above along the south-west, south-east and central east coasts (Vousdoukas et al., 2018).

Extreme total water level (ETWL) magnitude and occurrence frequency are expected to increase throughout the region (*high confidence*) (Figure 12.4p–r and Figure 12.SM.6). Across the continent, the 5th–95th percentile range of the 1-in-100-year ETWL is projected to increase (relative to 1980–2014) by 7–36 cm and by 14–42 cm by 2050 under RCP4.5 and RCP8.5 respectively. By 2100, this range is projected to be 28–86 cm and 43–190 cm under RCP4.5 and RCP8.5 respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). In terms of ETWL occurrence frequencies, the present-day 1-in-100-year ETWL is projected to have median return periods of around 1-in-10-years to 1-in-20-years by 2050 and 1-in-1-year to 1-in-5-years by 2100 in southern and North Africa and occur more than once per year by 2050 and 2100 in most of East and West Africa under RCP4.5 (Vousdoukas et al., 2018). The present-day 1-in-50-year ETWL is projected to occur around three times a year by 2100 with an SLR of 1 m in Africa (Vitousek et al., 2017).

Coastal erosion: Shoreline retreat rates up to 1 m yr⁻¹ have been observed around the continent during 1984–2015, except in ESAF, which has experienced a shoreline progradation rate of 0.1 m/r over the same period (Luijendijk et al., 2018; Mentaschi et al., 2018). Mentaschi et al. (2018) report a coastal area losses of 160 km² and 460 km² over a 30-year period (1984–2015) along the Atlantic and Indian Ocean coasts of the continent. At the more regional level, in Ghana along the Gulf of Guinea about 79% of the shoreline

was found to be retreating while 21% was found to be stable or prograding over the period 1974–1996 (Addo and Addo, 2016).

Projections indicate that a vast majority of sandy coasts in the region will experience shoreline retreat throughout the 21st century (*high confidence*), while parts of the ESAF and western MDG coastline are projected to prograde over the 21st century, if present ambient trends continue. Median shoreline change projections (CMIP5), relative to 2010, presented by Vousdoukas et al. (2020b) show that, under RCP4.5, shorelines in Africa will retreat by between 30 m (SAH, NEAF, WSAF, ESAF, MDG) and 55 m (WAF, CAF), by mid-century. By the same period but under RCP8.5, the median shoreline retreat is projected to be between 35 m (SAH, NEAF, WSAF, ESAF) and 65 m (WAF, CAF). By 2100, more than 100 m of median retreat is projected in WAF, CAF and SEAF under RCP4.5, while under RCP8.5, more than 100 m of shoreline retreat is projected in all regions except NEAF and WSAF. Under RCP8.5 especially, the projected retreat by 2100 is greater than 150 m in WAF and CAF. The total length of sandy coasts in Africa that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 13,000 km and 17,000 km respectively, an increase of approximately 33%.

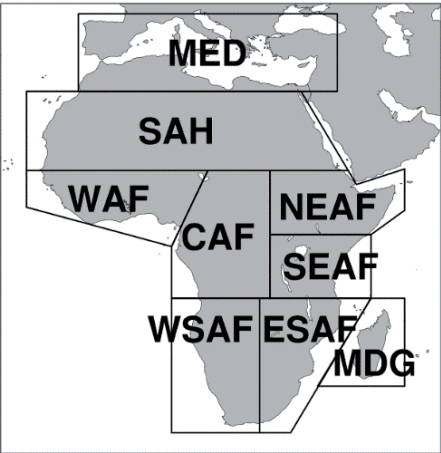

Marine heatwave (MHW): From 1982 to 2016, the coastal oceans of Africa have experienced on average 2–3 MHWs per year, with the coastal oceans around the southern half of the continent experiencing on average 2.5–3 MHWs per year. The average duration was between 5 and 15 days (Oliver et al., 2018). Changes over the 20th century, derived from MHW proxies, show an increase in frequency between 0.5 and 2 MHWs per decade over the region, especially off the Horn of Africa; an increase in intensity per event around Southern Africa; and an increase in MHW duration along the North African coastlines (Oliver et al., 2018).

There is *high confidence* that MHWs will increase around Africa. Mean SST, a common proxy for MHWs, is projected to increase by 1°C (2°C) around Africa by 2100, with a hotspot of around 2°C (5°C) along the coastlines of South Africa under RCP4.5 (RCP8.5; Interactive Atlas). Under global warming conditions, MHW intensity and duration will increase in the coastal zones of all sub-regions of Africa (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Australasia by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

In general, there is *high confidence* that most coastal- and ocean-related hazards in Africa will increase over the 21st century. Relative sea level rise is *virtually certain* to continue around Africa, contributing to increased coastal flooding in low-lying areas (*high confidence*) and shoreline retreat along most sandy coasts (*high confidence*). Marine heatwaves are also expected to increase around the region over the 21st century (*high confidence*).

The assessed direction of change in CIDs for Africa and associated confidence levels are illustrated in Table 12.3. No relevant literature could be found for permafrost and hail, although these phenomena may be relevant in parts of the continent.

Table 12.3 | Summary of confidence in direction of projected change in climatic impact-drivers in Africa, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2.

 Region	Climatic Impact-driver																												
	Heat and Cold				Wet and Dry								Wind			Snow and Ice					Coastal and Oceanic				Other				
	Mean air temperature	Extreme heat	Cold spell	Frost	Mean precipitation	River flood	Heavy precipitation and pluvial flood	Landslide	Aridity	Hydrological drought	Agricultural and ecological drought	Fire weather	Mean wind speed	Severe wind storm	Tropical cyclone	Sand and dust storm	Snow, glacier and ice sheet	Permafrost	Lake, river and sea ice	Heavy snowfall and ice storm	Hail	Snow avalanche	Relative sea level	Coastal flood	Coastal erosion	Marine heatwave	Ocean acidity	Air pollution weather	Atmospheric CO ₂ at surface

1. Contrasted regional signal: drying in western portions and wetting in eastern portions.

2. Likely increase over the Ethiopian Highlands.

3. Medium confidence of decrease in frequency and increase in intensity.

4. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.

5. Substantial parts of the ESAF and MDG coasts are projected to prograde if present-day ambient shoreline change rates continue.

^a North Africa is not an official region of IPCC AR6, but assessment here is based upon the African portions of the Mediterranean region.

● Already emerged in the historical period (*medium to high confidence*)

● Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

● Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant

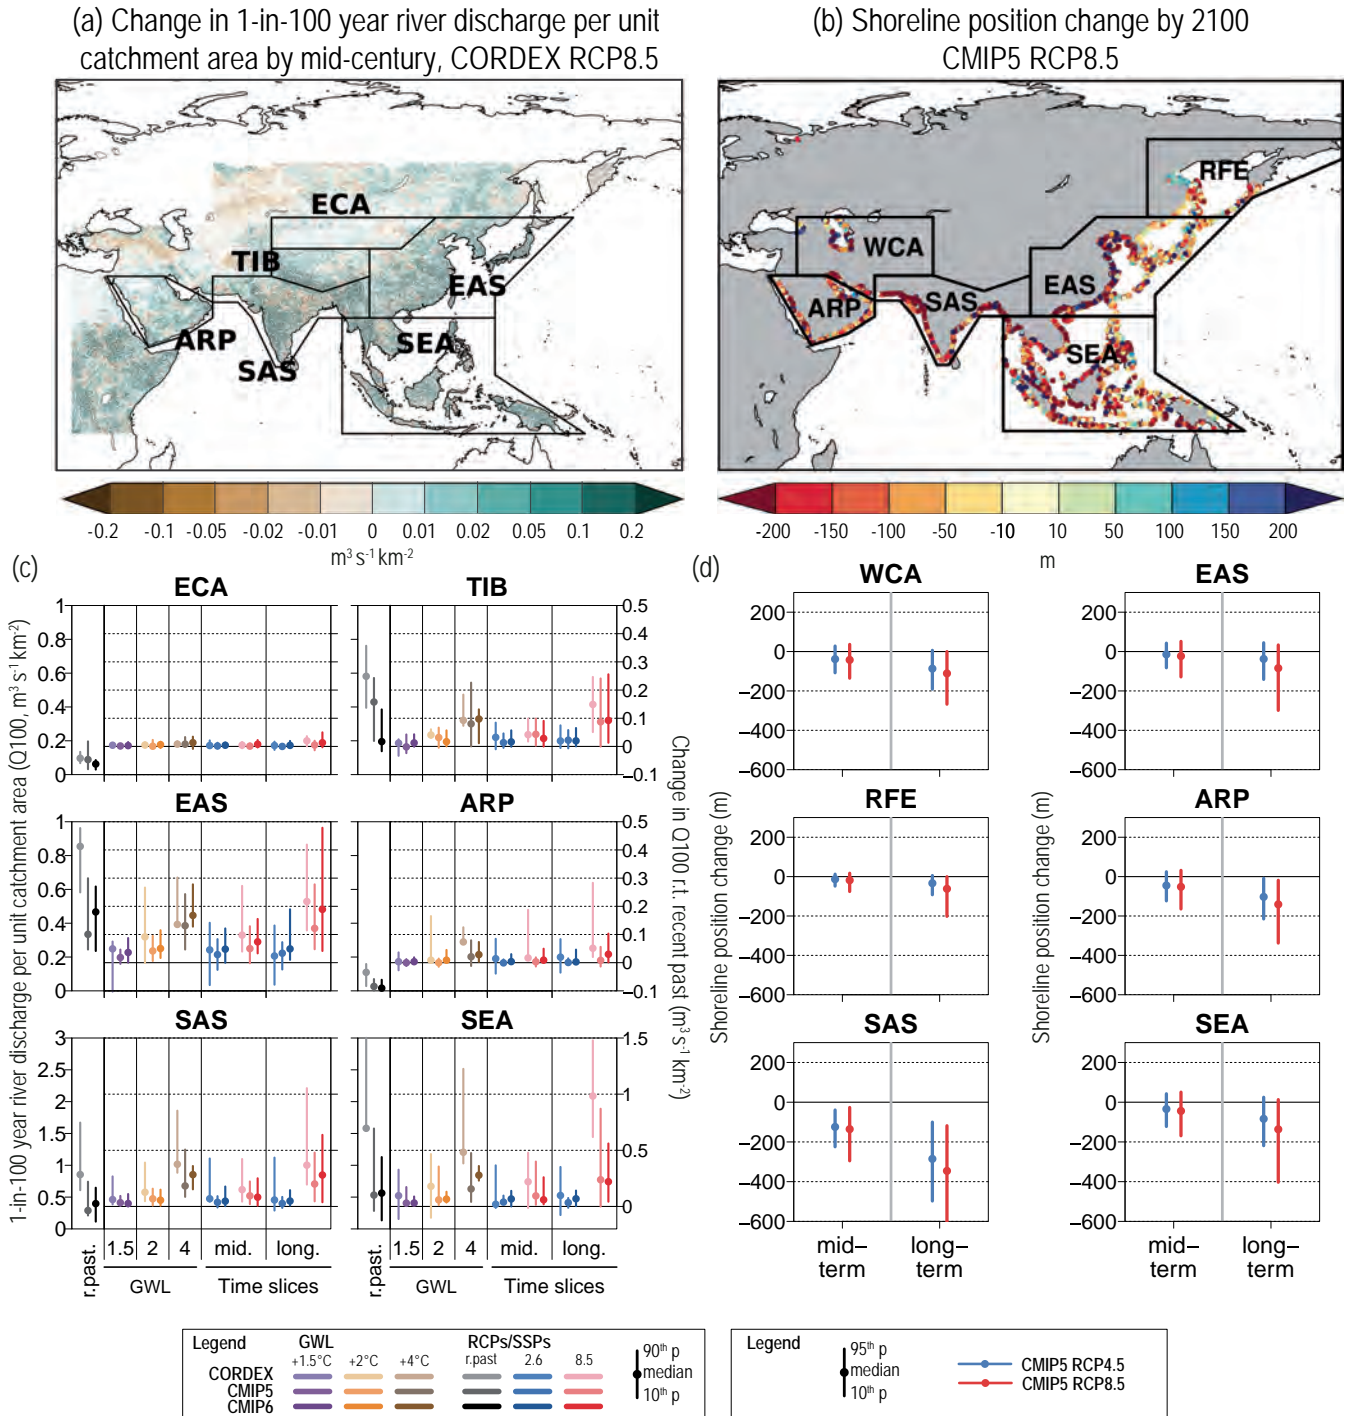

Figure 12.6 | Projected changes in selected climatic impact-driver indices for Asia. (a) Mean change in 1-in-100-year river discharge per unit catchment area (Q_{100} , $\text{m}^3 \text{s}^{-1} \text{km}^{-2}$) from CORDEX models for the West, South East and East Asia domains for 2041–2060 relative to 1995–2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 for RCP8.5 (metres; negative values indicate shoreline retreat) from the CMIP5-based dataset presented by Vousdoukas et al. (2020b). (c) Bar plots for Q_{100} ($\text{m}^3 \text{s}^{-1} \text{km}^{-2}$) averaged over land areas for the AR6 WGI Reference Regions (defined in Chapter 1). The left-hand column within each panel (associated with the left-hand y-axis) shows the ‘recent past’ (1995–2014) Q_{100} absolute values in grey shades. The other columns (associated with the right-hand y-axis) show the Q_{100} changes relative to the recent past values for two time periods (‘mid’ 2041–2060 and ‘long’ 2081–2100) and for three global warming levels (defined relative to the pre-industrial period 1850–1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10–90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5-based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al. (2020b). Dots indicate regional mean change estimates and bars show the 5–95th percentile range of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

12.4.2 Asia

According to the region definitions given in Chapter 1, Asia is divided into 11 regions: the Arabian Peninsula (ARP), Western Central Asia (WCA), West Siberia (WSB), East Siberia (ESB), the Russian Far East (RFE), East Asia (EAS), East Central Asia (ECA), the Tibetan Plateau (TIB), South Asia (SAS), South East Asia (SEA) and the Russian Arctic Region (RAR). CID changes in RAR are assessed in the Polar Region section (Section 12.4.9). As assessed in previous IPCC Reports, major concerns in Asia are associated particularly with droughts and floods in all regions, heat extremes in SAS and EAS, sand-dust storms in WCA, tropical cyclones in SEA and EAS, snow cover and glacier changes in ECA and the Hindu Kush Himalaya (HKH) region, and sea ice and permafrost thawing in northern Asia.

Since AR5, a large body of new literature is now available relevant to climate change in Asia, which includes projections of both mean climate and extreme climate phenomena from global and regional ensembles of climate simulations such as CMIP6 and CORDEX (Chapter 10 and the Atlas). Literature has also considerably grown on several climate topics relevant to Asia such as the mountain climate (Chapter 3 of the SROCC), and the novel regional assessments such as the Hindu Kush Himalaya Assessment (Wester et al., 2019). Figure 12.6 shows the regional changes in indices related to floods, and coastal erosion over Asia, which are assessed on a regional basis along with other climatic impact-driver indices below.

12.4.2.1 Heat and Cold

Mean air temperature: A long-term warming trend in annual mean surface temperature has been observed across Asia during 1960–2015, and the warming accelerated after the 1970s (*high confidence*) (Davi et al., 2015; Aich et al., 2017; Cheong et al., 2018; S. Dong et al., 2018; IPCC, 2018; Krishnan et al., 2019; M. Zhang et al., 2019). Records also indicate a higher rate of warming in minimum temperatures than maximum temperatures in Asia, leading to more frequent warm nights and warm days, and less frequent cold days and cold nights (*high confidence*) (Supari et al., 2017; Akperov et al., 2018; Cheong et al., 2018; Rahimi et al., 2018; Khan et al., 2019a; L. Li et al., 2019; M. Zhang et al., 2019).

Projections show continued warming over Asia in the future with contrasted regional patterns across the continent (*high confidence*) (Figure 4.19). For RCP8.5/SSP5-8.5 at the end of the century, the mean estimated warming exceeds 5°C in WSB, ESB and RFE and 7°C in some parts (*high confidence*). In most areas of ARP and WCA, 5°C is exceeded (Ozturk et al., 2017), but EAS, SAS and SEA have a lower projected warming of less than 5°C (Basha et al., 2017; C. Lu et al., 2019; Almazroui et al., 2020; Atlas.5). Under SSP1-2.6, the warming remains limited to 2°C in most areas except Arctic regions, where it exceeds 2°C (Figure 4.19).

Extreme heat: There is increased evidence and *high confidence* of more frequent heat extremes in the recent decades than in previous ones in most of Asia (Acar Deniz and Gönençgil, 2015; Rohini et al., 2016; Mishra et al., 2017; You et al., 2017; Imada et al., 2018; Khan et al., 2019b; Krishnan et al., 2019; Rahimi et al., 2019; Yin et al., 2019;

Chapter 11) due to the effects of anthropogenic global warming, El Niño and urbanization (Luo and Lau, 2017; Thirumalai et al., 2017; Imada et al., 2019; Y. Sun et al., 2019; Zhou et al., 2019). But there is *medium confidence* of heat extremes increasing in frequency in many parts of India (Rohini et al., 2016; Mazdiyasnani et al., 2017; van Oldenborgh et al., 2018; Sen Roy, 2019; Kumar et al., 2020) partly due to the alleviation of anthropogenic warming by increased air pollution with aerosols and expanding irrigation (van Oldenborgh et al., 2018; Thiery et al., 2020).

Extreme heat events are *very likely* to become more intense and/or more frequent in SAS, WCA, ARP, EAS, and SEA by the end of 21st century, especially under RCP6.0 and RCP8.5 (Figure 12.4a–c and Chapter 11; Lelieveld et al., 2016; Pal and Eltahir, 2016; Guo et al., 2017; Mishra et al., 2017; Dosio et al., 2018; Lin et al., 2018; Nasim et al., 2018; Shin et al., 2018; Hong et al., 2019; Su and Dong, 2019; Khan et al., 2020; Kumar et al., 2020). The exceedance of the dangerous heat stress 41°C threshold of the HI is expected to increase by about 250 days in SEA and by 50–150 days in SAS, WCA, ARP and EAS for SSP5-8.5 at the end of the century (Figure 12.4d–f and Figure 12.SM.2). Under SSP1-2.6, the increase would be restricted to less than 30 days in many of these regions except SEA, where the number of exceedance days increases by about 100 days in some areas. Such increases are already present in the middle of the century (Figure 12.4d–f; Schwingshackl et al., 2021). In these regions, the increase in number of days with exceedance of 35°C of high heat stress is also expected to increase substantially for the mid-century under SSP5-8.5 (typically by 10–50 days except in Arctic and Siberian regions), and by more than 60 days in areas of SEA, and a large difference is found between low- and high-end scenarios in the end of the century (*high confidence*) (Figure 12.4b). Over WSB, ESB and RFE also, an increase of extreme heat durations and frequency is expected in all scenarios (*high confidence*) (Kattsov et al., 2017; Khlebnikova et al., 2019b).

Cold spell and frost: Cold spells intensity and frequency, as well as the number of frost days, in most Asian regions have been decreasing since the beginning of the 20th century (*high confidence*) (Chapter 11; Sheikh et al., 2015; Donat et al., 2016; Erlat and Türkeş, 2016; S. Dong et al., 2018; Liao et al., 2018, 2020; Lu et al., 2018; van Oldenborgh et al., 2019), except for the central Eurasian regions, where there was a cooling trend during 1995–2014, which is linked to sea ice loss in the Barents–Kara Seas (*medium confidence*) (Atlas.5.2; Wegmann et al., 2018; Blackport et al., 2019; Mori et al., 2019).

It is *very likely* that cold spells will have a decreasing frequency in all future scenarios across Asian regions (J. Guo et al., 2018; Sui et al., 2018; L. Li et al., 2019), as well as frost days (L. Wang et al., 2017; Fallah-Ghalhari et al., 2019) except in tropical Asia (Chapter 11).

In Asia, temperatures have warmed during the last century (*high confidence*). Extreme heat episodes have become more frequent in most regions (*high confidence*), and are *very likely* to increase in all regions of Asia under all warming scenarios during this century. Dangerous heat stress thresholds such as HI > 41°C will be crossed much more often (typically 50–150 days per year more than the recent past) in many southern Asia regions at the end of the century under SSP5-8.5

while these numbers should remain limited to a few tens under SSP1-2.6 (*high confidence*). It is *very likely* that cold spells and frost days will decrease in frequency in all future scenarios across Asian regions during the century.

12.4.2.2 Wet and Dry

Mean precipitation: The most prominent features about changes in precipitation over Asia (1901–2010) are the increasing precipitation trends across higher latitudes, along with some scattered smaller regions of detectable increases and decreases (Knutson and Zeng, 2018); however, spatial variability remains high (W. Wang et al., 2015; Limsakul and Singhruck, 2016; Supari et al., 2017; Rahimi et al., 2018, 2019; Sein et al., 2018; Kumar et al., 2019; H. Wang et al., 2019; see Atlas.5) (*medium confidence*).

Mean precipitation is *likely* to increase in most areas of northern (WSB, ESB, RFE), southern (ECA, TIB, SAS) and East Asia (EAS) in different scenarios (*high confidence*) (Huang et al., 2014; Xu et al., 2017; Kusunoki, 2018; Mandapaka and Lo, 2018; Luo et al., 2019; Wu et al., 2019; X. Zhu et al., 2019; Almazroui et al., 2020; Jiang et al., 2020; Rai et al., 2020; see Atlas.5). Monsoon circulation will also increase seasonal contrasts, with SAS seeing wetter wet seasons and drier dry seasons (Atlas.5.3). Higher uncertainty between CMIP5 and CMIP6 as well as spatial differences lend *low confidence* to model projections in ARP and WCA (Atlas.5.5), with large seasonal differences (Zhu et al., 2020) and some models projecting decreases in precipitation in Central Asia (Ozturk et al., 2017), Pakistan (Nabeel and Athar, 2020) and SEA (Supari et al., 2020).

River flood: Flood risk has grown in many places in China from 1961 to 2017 (Kundzewicz et al., 2019) (*low confidence*). In SAS, the numbers of flood events and human fatalities have increased in India during 1978–2006 (Singh and Kumar, 2013), whereas the average country-wide inundation depth has been decreasing during 2002–2010 in Bangladesh, attributed to improved flood management (*low confidence*) (Sciance and Nooner, 2018).

Given the increase of heavy precipitation in most Asian regions, the river flood frequency and intensities will change consequently in Asia. Over China floods will increase with different levels under different warming scenarios (*medium confidence*) (Lin et al., 2018; Kundzewicz et al., 2019; Liang et al., 2019; Gu et al., 2020). Monsoon floods will be more intense in SAS (*medium confidence*) (Nowreen et al., 2015; Babur et al., 2016; Mohammed et al., 2018). The total flood damage will increase greatly in river basins in SEA countries under the conditions of climate change and rapid urbanization in the near future (Dahal et al., 2018; Kefi et al., 2020). A changing snowmelt regime in the mountains may contribute to a shift of spring floods to earlier periods in Central Asia in future (*medium confidence*) (Reyer et al., 2017b). The annual maximum river discharge can almost double by the mid-21st century in major Siberian rivers, and annual maximum flood area is projected to increase across Siberia mostly by 2–5% relative to the baseline period (1990–1999) under RCP8.5 scenario (*medium confidence*) (Shkolnik et al., 2018).

Heavy precipitation and pluvial flood: Pluvial floods are driven by extreme precipitation and land use. Observed changes in extreme

precipitation vary considerably by region (Chapter 11). Heavy precipitation is *very likely* to become more intense and frequent in all areas of Asia except in ARP (*medium confidence*) for a 2°C GWL or higher (Chapter 11).

Landslide: The majority of non-seismic fatal landslide events were triggered by rainfall, and Asia is the dominant geographical area of landslide distribution (Froude and Petley, 2018). Floods and landslides are the most frequently occurring natural hazards in the eastern Himalayas and hilly regions, particularly caused by torrential rain during the monsoon season (Gaire et al., 2015; Syed and Al Amin, 2016). They accounted for nearly half of the events recorded in the countries of the HKH region (Vaidya et al., 2019). Intense monsoon rainfall in northern India and western Nepal in 2013, which led to landslides and one of the worst floods in history, has been linked to increased loading of GHG and aerosols (Cho et al., 2016). Due to an increase of heavy precipitation and permafrost thawing, an increase in landslides is expected in some areas of Asia, such as northern Taiwan (China), some South Korean mountains, Himalayan mountains, and permafrost territories of Siberia, and the increase is expected to be the greatest over areas covered by current glaciers and glacial lakes (*medium confidence, medium evidence*) (Kim et al., 2015; Kharuk et al., 2016; C.-W. Chen et al., 2019; Kirschbaum et al., 2020).

Aridity: Aridity in West Central Asia and parts of South Asia increased in recent decades (*medium confidence*), as documented in Afghanistan (Qutbudin et al., 2019), Iran (Zarei et al., 2016; Zolfaghari et al., 2016; Pour et al., 2020), most parts of Pakistan (K. Ahmed et al., 2018, 2019), and many parts of India (Roxy et al., 2015; Mallya et al., 2016; Matin and Behera, 2017; Ramarao et al., 2019). Some spatial and seasonal differences within these regions remain, with Ambika and Mishra (2020) noting significant aridity declines over the Indo-Gangetic Plain in India during 1979–2018 due in part to the effect of irrigation, and Araghi et al. (2018) found that many parts of Iran show no significant trends in aridity. There was a drying tendency in the dry season and significant wetting in the wet season in the Philippines during 1951–2010 (Villafuerte et al., 2014), and slight wetting in Vietnam during 1980–2017 (Stojanovic et al., 2020) (*low confidence*). In EAS there is *low confidence* of broad aridity changes, as the frequency of droughts have increased (especially in spring) along a strip extending from south-west China to the western part of north-east China; however, there is no evidence of a significant increase in drought severity over China as a whole and many parts in the arid north-west China got wetter during 1961–2012 (W. Wang et al., 2015; Zhai et al., 2017; H. Wang et al., 2019; Zhang and Shen, 2019). In Siberia, the number of dry days has decreased for much of the region, but increased in its southern parts (Khlebnikova et al., 2019a).

The counteracting factors of projected increases in precipitation and temperature across most of Asia (Section 11.9 and Atlas.5) leads to *low confidence (limited evidence, inconsistent trends)* for broad, long-term aridity changes with *medium confidence* only for aridity increases in West Central Asia and East Asia. A growing number of studies highlight the potential for more localized aridity trends, including projection ensembles indicating significant increase in aridity and more frequent and intense droughts in most parts of

China (Y. Li et al., 2019; Yao et al., 2020) and India under RCP4.5 and RCP8.5 for the 2020–2100 period (Gupta and Jain, 2018; Bisht et al., 2019; Preethi et al., 2019).

Hydrological drought: Section 11.9 indicates that *limited evidence* and inconsistent regional trends gives *low confidence* to observed and projected changes in hydrological drought in all Asian regions at a 2°C GWL (approximately mid-century), although West Central Asia hydrological droughts increase at the 4°C GWL (approximately end-of-century under higher emissions scenarios) (*medium confidence*). Human activities such as reservoir operation and water abstraction have had a profound effect on low river flow characteristics and drought impacts in many Asian regions (Kazemzadeh and Malekian, 2016; Yang et al., 2020b). There was no observed overall long-term change of both meteorological droughts and hydrological droughts over India during 1870–2018 (Mishra, 2020), but there were strong trends towards drying of soil moisture in north-central India (Ganeshi et al., 2020) and intensified droughts in north-west India, parts of Peninsular India, and Myanmar (Malik et al., 2016). The frequency of water scarcity connected with hydrological droughts has increased significantly in southern Russia since the beginning of the 21st century (Frolova et al., 2017). Higher future temperatures are expected to alter the seasonal profile of hydrologic droughts given reduced summer snowmelt (*medium confidence*) downstream of mountains such as the Himalayas and the Tibetan Plateau (Sorg et al., 2014). Several studies project more severe future hydrological drought in the Weihe River basin in northern China (Yuan et al., 2016; Sun and Zhou, 2020).

Agricultural and ecological drought: Section 11.9 assesses *medium confidence* in observed increases to agricultural and ecological droughts in West Central Asia, East Central Asia, and East Asia. Persistent droughts were the main factor for grassland degradation and desertification in Central Asia in the early 21st century (G. Zhang et al., 2018; Emadodin et al., 2019). Compound meteorological drought and heat events, which lead to water stress conditions for agricultural and ecological systems, have become more frequent, widespread and persistent in China especially since the late 1990s (Yu and Zhai, 2020). There were more agricultural droughts in northern China than in southern China, and the intensity of agricultural drought increased during 1951–2018 (Zhao et al., 2021).

Studies examining a 2°C GWL give *low confidence* for projected broad changes to agricultural and ecological drought across all Asia regions, although at 4°C GWL agricultural and ecological drought increases are projected for West Central Asia and East Asia along with a decrease in South Asia (*medium confidence*) (Section 11.9). Summer temperature increase will enhance evapotranspiration, facilitating ecological and agricultural drought over Central Asia towards the latter half of this century (Chapter 11; see also Figure 12.4 for soil moisture and DF indices; Ozturk et al., 2017; Reyer et al., 2017b; Senatore et al., 2019). However, broader changes in droughts could not be determined in Asia due to the mixture of total precipitation signals together with temperature increase patterns (Section 11.9 and Atlas.5).

Fire weather: Under the global warming scenario of 2°C, the magnitude of length and frequency of fire seasons are projected to increase with strong effects in India, China and Russia (*medium*

confidence) (Q. Sun et al., 2019). Abatzoglou et al. (2019) found that higher fire weather conditions due to climate change emerge in the first part of the 21st century in South China, WCA as well as in boreal areas of Siberia and RFE. The potential burned areas in five Central Asian countries (Kazakhstan, Kyrgyzstan, Tajikistan, Uzbekistan and Turkmenistan) will increase by 2–8% in the 2030s and 3–13% in the 2080s compared with the baseline (*medium confidence*) (1971–2000; Zong et al., 2020).

In conclusion, there is *medium confidence* that extreme precipitation, mean precipitation and river floods will increase across most Asian regions. There is *low confidence* for projected changes in aridity and drought given overall increases in precipitation and regional inconsistencies, with medium increases for West Central Asia and East Asia especially beyond the middle of the century and global warming levels beyond 2°C. Fire weather seasons are projected to lengthen and intensify particularly in the northern regions (*medium confidence*).

12.4.2.3 Wind

Mean wind speed: There is *high confidence* of the slowdown in terrestrial near-surface wind speed (SWS) in Asia by approximately -0.1 m s^{-1} per decade since the 1950s based on observations and reanalysis data, with the significant decreases in Central Asia among the highest in the world followed by EAS and SAS (J. Wu et al., 2018; Tian et al., 2019; R. Zhang et al., 2019). But a short-term strengthening in SWS was observed during the winter since 2000 in eastern China (*medium confidence*) (Zeng et al., 2019; Zha et al., 2019).

There is *medium confidence* of future declining mean SWS in Asia, except in SAS and SEA, as global projections indicate a decreasing trend in all climate scenarios for most of northern Asia, TIB and East Asia by the mid-century (Karnauskas et al., 2018a; Fedotova, 2019; Jung and Schindler, 2019; Ohba, 2019; J. Wu et al., 2020; Zha et al., 2020; Figure 12.4m–o), with negative effects on wind energy potential. Decreases in North Asia are generally modest, not exceeding 10% for the mid-century and 20% for the end of century for the RCP8.5 and RCP4.5 scenarios (Figure 12.4m–o).

Severe wind storms: Consistent with the general mean decreasing surface winds, there is *medium confidence* that strong winds declined faster than weak winds in the past few decades in Asia in general (Vautard et al., 2010; Tian et al., 2019), but evidence is lacking for spatial patterns. There is *low confidence* that extra-tropical cyclones will decline in number in future climate scenarios over WCA, TIB, WSB and ESB, and intensify over the Arctic regions as a result of the poleward shift of storm tracks (Basu et al., 2018; Chapter 11). There is *limited evidence* for projection of changes in severe winds occurring in convective storms in Asia.

Tropical cyclone: There was an increase in the number and intensification rate of intense tropical cyclones (TC), such as Category 4–5 (wind speeds $>58 \text{ m s}^{-1}$), in the Western North Pacific (WNP) and Bay of Bengal since the mid-1980s (*medium confidence*) (Section 11.7; Kim et al., 2016; Mei and Xie, 2016; Walsh et al., 2016a; Knutson et al., 2019). There is *medium confidence* that

there has been a significant north-westward shift in TC tracks and a poleward shift in the average latitude where TCs reach their peak intensity in the WNP since the 1980s (Knutson et al., 2019; J. Sun et al., 2019; Lee et al., 2020), increasing exposure to TC passage and more destructive landfall over eastern China, Japan, and Korea in the last few decades (Kossin et al., 2016; Li et al., 2017; Altman et al., 2018; Liu and Chan, 2019), and decreasing exposure in the region of SAS and southern China (Cinco et al., 2016; Kossin et al., 2016; see Chapter 11). However, while the analysis shows fewer typhoons, more extreme TCs have affected the Philippines (*low confidence*) (Takagi and Esteban, 2016). The frequency and duration of tropical cyclones has significantly increased over time over the Arabian Sea and insignificantly decreased over the Bay of Bengal during 1977–2018 (*low confidence*) (Fan et al., 2020).

There is *medium confidence* that future TC numbers will decrease but the maximum TC wind intensities will increase in the western Pacific as elsewhere (Chapter 11, see Figure 11.24; Choi et al., 2019; Cha et al., 2020; Knutson et al., 2020). The simulations for the late 21st century for the RCP8.5 scenario yield considerably more TCs in the WNP that exceed 49.4 m s^{-1} (Category 3) intensity (McLay et al., 2019). There is *medium confidence* that the average location of the maximum wind will migrate poleward (see Chapter 11), and TC translation speeds at the higher latitudes would decrease (Yamaguchi et al., 2020). As a consequence, the intensity of TCs affecting the Japan Islands would increase in the future under the RCP8.5 scenario (Yoshida et al., 2017), whereas the frequency of TCs affecting the Philippine region and Vietnam is projected to decrease (Kieu-Thi et al., 2016; C. Wang et al., 2017; Gallo et al., 2019) (*medium confidence*).

Sand and dust storm: The Asia-Pacific region contributes 26.8 per cent to global dust emissions as of 2012 (UNESCAP, 2018). In West Asia, the frequency of dust events has increased markedly in some areas (east and north-east of Saudi Arabia, north-west of Iraq and east of Syria) from 1980 to the present (Nabavi et al., 2016; Alobaidi et al., 2017). This marked dust increase has been associated with drought conditions in the Fertile Crescent (Notaro et al., 2015; Yu et al., 2015), *likely* amplified by anthropogenic warming (Kelley et al., 2015; Chapter 10). Dust storm frequency in most regions of northern China show a decreasing trend since the 1960s due to the decrease in surface wind speed (*medium confidence*) (Guan et al., 2017).

While dust activity has decreased greatly over EAS, current climate models are unable to reproduce the trends (Guan et al., 2015, 2017; Zha et al., 2017; C. Wu et al., 2018). Thus, there is *limited evidence* for future trends of sand and dust storms in Asia.

In conclusion, surface wind speeds have been decreasing in Asia (*high confidence*), but there is a large uncertainty in future trends. There is *medium confidence* that mean wind speeds will decrease in Central and northern Asia, and that tropical cyclones will have decreasing frequency and increasing intensity overall.

12.4.2.4 Snow and Ice

Snow: There is no significant interannual trend of total snow cover from 2000 to 2016 over Eurasia (X. Wang et al., 2017a; Sun et al., 2020).

Observations do show significant changes in the seasonal timing of Eurasian snow cover extent (especially for earlier spring snowmelt) since the 1970s, with seasonal changes expected to continue in the future (*high confidence*) (Yeo et al., 2017; Zhong et al., 2021). By 2100, snowline elevations are projected to rise between 400 and 900 m (4.4 to 10.0 m yr^{-1}) in the Indus, Ganges and Brahmaputra basins under the RCP8.5 scenario (Viste and Sorteberg, 2015).

Glacier: Observation and future projection of glacier mass changes in Asia are assessed in Section 9.5.1 grouped in three main regions: northern Asia, High Mountains of Asia, and Caucasus and Middle East. All regions show continuing decline in glacier mass and area in the coming century (*high confidence*). Under RCP2.6 the pace of glacier loss slows, but glacier losses increase in RCP8.5 and peak in the mid to late 21st century. GlacierMIP projections indicate that glaciers in the High Mountains of Asia lose $42 \pm 25\%$, $56 \pm 24\%$ and $71 \pm 21\%$ of their 2015 mass by the end of the century for RCP2.6, RCP4.5 and RCP8.5 scenarios respectively. Under the same scenarios, glaciers in North Asia would lose $57 \pm 40\%$, $72 \pm 38\%$ and $85 \pm 30\%$ of their mass, and glaciers in the Caucasus and the Middle East would lose $68 \pm 32\%$, $83 \pm 19\%$ and $94 \pm 13\%$ of their mass (see also Kraaijenbrink et al., 2017; Rounce et al., 2020).

Although enhanced meltwater from snow and glaciers largely offsets hydrological drought-like conditions (Pritchard, 2019), this effect is unsustainable and may reverse as these cryospheric buffers disappear (*medium confidence*) (Gan et al., 2015; W. Dong et al., 2018; Huss and Hock, 2018). In the Himalayas and the TIB region higher temperatures will lead to higher glacier melt rates and significant glacier shrinkage and a summer runoff decrease (*medium confidence*) (Sorg et al., 2014). Glacier runoff in the Asian high mountains will increase up to mid-century, and after that runoff might decrease due to the loss of glacier storage (*medium confidence*) (Lutz et al., 2014; Huss and Hock, 2018; Rounce et al., 2020).

Compared with the 1990s, the number of lakes in TIB in the 2010s decreased by 2%, whereas total lake area expanded by 25% (S. Wang et al., 2020) due to the joint effect of precipitation increase and glacier retreat. Many new lakes are predicted to form as a consequence of continued glacier retreat in the Himalaya-Karakoram region (Linsbauer et al., 2016). As many of these lakes will develop at the immediate foot of steep icy peaks with degrading permafrost and decreasing slope stability, the risk of glacier lake outburst floods and floods from landslides into moraine-dammed lakes is increasing in Asian high mountains (*high confidence*) (Haeberli et al., 2017; Kapitsa et al., 2017; Bajracharya et al., 2018; Narama et al., 2018; S. Wang et al., 2020).

Permafrost: Permafrost is thawing in Asia (*high confidence*). Temperatures in the cold continuous permafrost of north-eastern East Siberia rose from the 1980s up to 2017, and the active layer thicknesses in Siberia and Russian Far East generally increased from late 1990s to 2017 (Romanovsky et al., 2018). The change in mean annual ground temperature for northern Siberia is about $+0.1$ to $+0.3^\circ\text{C}$ per decade since 2000 (Romanovsky et al., 2018). Ground temperature in the permafrost regions of TIB (taking 40% of TIB currently) increased (0.02 – 0.26°C per decade for different

boreholes) during 1980 to 2018, and the active layer thickened at a rate of 19.5 cm per decade (L. Zhao et al., 2020). There is *high confidence* that permafrost in Asian high mountains will continue to thaw and the active layer thickness will increase (Bolch et al., 2019). The permafrost area is projected to decline by 13.4–27.7% and 60–90% in TIB (L. Zhao et al., 2020) and $32\% \pm 11\%$ and $76\% \pm 12\%$ in Russia (Guo and Wang, 2016) by the end of the 21st century under the RCP2.6 and RCP8.5 scenarios respectively (*high confidence*).

Lake and river ice: Lake ice cover duration got shorter in many lakes in TIB (Yao et al., 2016; Cai et al., 2019; Guo et al., 2020) and some other areas such as north-west China (Cai et al., 2020) and north-east China (Yang et al., 2019) in the last two decades (*high confidence*). River ice cover extent decreased in TIB as well (H. Li et al., 2020; Yang et al., 2020a). Climate warming also leads to a significant reduction in the period with ice phenomena and the decrement of ice regime hazard in Russian lowland rivers (Agafonova et al., 2017), and the Inner Mongolia reach of the Yellow River in northern China (Wan et al., 2020) (*high confidence*). Lake ice and river ice in Asia are expected to decline with projected increases in surface air temperature towards the end of this century (*high confidence*) (Guo et al., 2020; Yang et al., 2020a).

Heavy snowfall and ice storm: Observed trends in heavy snowfall and ice storms are uncertain. Annual maximum snow depth decreased for the period between 1962 and 2016 on the western side of both eastern and western Japan, at rates of 12.3% and 14.6% per decade respectively (MOE et al., 2018). Observational results generally show a decrease in the frequency and an increase in the mean intensity of snowfalls in most Chinese regions (*medium confidence*) (B. Zhou et al., 2018). Because of the decrease in the snow frequency, the occurrence of large-scale snow disasters in TIB decreased (*low confidence*) (Qiu et al., 2018; S. Wang et al., 2019). Large parts of northern high-latitude continents (including Siberia and RFE) have experienced cold snaps and heavy snowfalls in the past few winters, and the reduction of Arctic sea ice would increase the chance of heavy snowfall events in those regions in the coming decades (*medium confidence*) (Song and Liu, 2017). Heavy snowfall is projected to occur more frequently in Japan's Northern Alps, the inland areas of Honshu Island and Hokkaido Island (Kawase et al., 2016, 2020; MOE et al., 2018), and the heavy wet snowfall can be enhanced over the mountainous regions in central Japan and northern part of Japan (Ohba and Sugimoto, 2020) (*medium confidence*).

Hail: The hailstorm in the Asian region shows a decreasing trend in several regions (*low confidence, limited evidence*). In China severe weather days including thunderstorms, hail and/or damaging wind have decreased by 50% from 1961 to 2010 (M. Li et al., 2016; Zhang et al., 2017), and the hail size decreased since 1980 (Ni et al., 2017). A rate of decrease of 0.214 hail days per decade has also been reported for Mongolia between 1984–2013, where the annual number of hail days averaged is 0.74 (Lkhamjav et al., 2017).

Snow avalanche: There is as yet *limited evidence* for the evolution of avalanches in Asia. Tree-ring-based snow avalanche reconstructions in the Indian Himalayas show an increase in avalanche occurrence and runout distances in recent decades (Ballesteros-Cánovas et al., 2018).

In summary, snowpack and glaciers are projected to continue decreasing and permafrost to continue thawing in Asia (*high confidence*). There is *medium confidence* of increasing heavy snowfall in some regions, but *limited evidence* on future changes in hail and snow avalanches.

12.4.2.5 Coastal and Oceanic

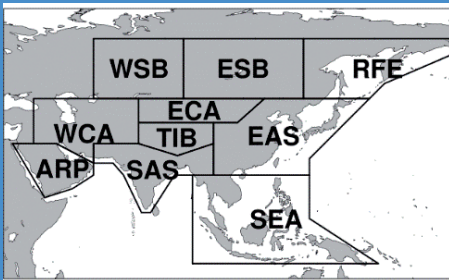

Relative sea level: Around Asia, from 1900–2018, a new tide gauge-based reconstruction finds a regional mean RSL change of 1.33 [0.80 to 1.86] mm yr⁻¹ in the Indian Ocean–Southern Pacific and 1.68 [1.27 to 2.09] mm yr⁻¹ in the North-west Pacific (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). For the period 1993–2018, the RSLR rates around Asia, based on satellite altimetry, increased to 3.65 [3.23 to 4.08] mm yr⁻¹ and 3.53 [2.64 to 4.45] mm yr⁻¹ respectively (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). The rate of RSLR along the coastline of China ranges from -2.3 ± 1.9 to $+5.7 \pm 0.4$ mm yr⁻¹ during 1980–2016; after removing the vertical land movement, the average rate of sea level rise is 2.9 ± 0.8 mm yr⁻¹ over 1980–2016 and 3.2 ± 1.1 mm yr⁻¹ since 1993 (Qu et al., 2019). However, the rates of land subsidence reported by Minderhoud et al. (2017) are substantially higher than those reported by Qu et al. (2019). RSL change in many coastal areas in Asia, especially in EAS, is affected by land subsidence due to sediment compaction under building mass and groundwater extraction (*high confidence*) (Erban et al., 2014; Nicholls, 2015; Minderhoud et al., 2019; Qu et al., 2019). During 1991–2016, the Mekong Delta in Vietnam sank on average about 18 cm as a consequence of groundwater withdrawal, and the subsidence related to groundwater extraction has gradually increased with highest sinking rates estimated to be 11 mm yr⁻¹ in 2015 (Minderhoud et al., 2017).

Relative sea level rise is *very likely* to continue in the oceans around Asia. Regional mean RSLR projections for the oceans around Asia range from 0.3–0.5 m under SSP1-2.6 to 0.7–0.8 m under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), which is within the range of projected GMSL change (Section 9.6.3.3). These RSLR projections may, however, be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

Coastal flood: The present-day 1-in-100-year ETWL is between 0.5–8 m around Asia, with values above 2.5 m or above common along the coasts of Central and north-eastern Asia (Vousdoukas et al., 2018; Kirezci et al., 2020). Sea level rise and land subsidence will jointly lead to more flooding in delta areas in Asia (*high confidence*) (Takagi et al., 2016; J. Wang et al., 2018).

Extreme total water level magnitude and occurrence frequency are expected to increase throughout the region (*high confidence*) (Figure 12.4p–r and Figure 12.SM.6). Across the region, the 5–95th percentile range of the 1-in-100-year ETWL is projected to increase (relative to 1980–2014) by 7–44 cm and by 10–52 cm by 2050 under RCP4.5 and RCP8.5 respectively. By 2100, this range is projected to be 11–91 cm and 28–187 cm under RCP4.5 and RCP8.5 respectively

Table 12.4 | Summary of confidence in direction of projected change in climatic impact-drivers in Asia, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2.

1. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.
2. Substantial parts of the coasts in these regions are projected to prograde if present-day ambient shoreline change rates continue.
3. Tropical cyclones decrease in number but increase in intensity.
4. High confidence of decrease in Indonesia (Atlas.5.4.5).
5. Medium confidence of decreasing in summer and increasing in winter.

● Already emerged in the historical period (*medium to high confidence*)

● Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

● Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

(Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, the present-day 1-in-100-year ETWL is projected to have median return periods of around 1-in-50-years by 2050 and 1-in-10-years by 2100 under RCP4.5 in most of Asia, except SEA and ARP, in which the present-day 1-in-100-year ETWL is projected occur once per year or more, both by 2050 and 2100 (Vousdoukas et al., 2018). The present-day 1-in-50-year ETWL is projected to occur around three times a year by 2100 with a SLR of 1 m across Asia (Vitousek et al., 2017). Compound impacts of precipitation change, land subsidence, sea level rise, upstream hydropower development, and local water infrastructure development may lead to larger flood extent and prolonged inundation in the Vietnamese Mekong Delta (Triet et al., 2020).

Coastal erosion: Over the past 30 years, South, South East and East Asia exhibit the most pronounced delta changes globally due to strong human-induced changes to the fluvial sediment flux (Nienhuis et al., 2020). Satellite derived shoreline change estimates over 1984–2015 indicate shoreline retreat rates between 0.5 m yr⁻¹ and 1 m yr⁻¹ along the coasts of WCA and ARP, increasing to 3 m yr⁻¹ in SAS. Over the same period, shoreline progradation has been observed along the coasts of RFE (0.2 m yr⁻¹), SEA (0.1 m yr⁻¹) and EAS (0.5 m yr⁻¹) (Luijendijk et al., 2018; Mentaschi et al., 2018). Meanwhile, there has been a gross coastal area loss of 3,590 km² in South Asia, and a loss of 2,350 km² in Pacific Asia, over a 30-year period (1984–2015) (Mentaschi et al., 2018).

Projections indicate that a majority of sandy coasts in the Asia region will experience shoreline retreat (*high confidence*) (Udo and Takeda, 2017; Ritphring et al., 2018; Vousdoukas et al., 2020b), while parts of the RFE, EAS, SEA and WCA coastline are projected to prograde over the 21st century, if present ambient shoreline change trends continue. Median shoreline change projections (CMIP5), relative to 2010, presented by Vousdoukas et al. (2020b) show that, by mid-century, sandy shorelines in Asia will retreat by between 10–50 m, except in SAS where shoreline retreat is projected to exceed 100 m, under both RCP4.5 and RCP8.5. By 2100, and under RCP4.5, shoreline retreats of around 85, 100 and 300 m are projected along the sandy coastlines of SEA and WCA, ARP and SAS respectively (50 m or less in other Asian regions), while under RCP8.5, over the same period, sandy shorelines along all regions with coastlines, except RFE and EAS, are projected to retreat by more than 100 m, with the retreat in SAS reaching 350 m (2100 RCP8.5 projections for RFE and EAS are about 60 m and about 85 m respectively; Figure 12.6).

Marine heatwave: There have been frequent marine heatwaves (MHW) in the coastal oceans of Asia, connected to the increase between 0.25°C and 1°C in mean SST of the coastal oceans since 1982–1998 (Oliver et al., 2018). There is *high confidence* that MHWs will increase around most of Asia. Mean SST is projected to increase by 1°C (2°C) around Asia by 2100, with a hotspot of around 2°C (5°C) along the coastlines of the Sea of Japan and the RFE under RCP4.5 (RCP8.5; Interactive Atlas). Under global warming conditions, MHW intensity and duration are projected to increase in the coastal zones of all sub-regions of Asia, but most notably in SEA and SAS (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Asia by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

In general, there is *high confidence* that most coastal/ocean-related climatic impact-drivers in Asia will increase over the 21st century. Relative sea level rise is *very likely* to continue around Asia, contributing to increased coastal flooding in low-lying areas (*high confidence*) and shoreline retreat along most sandy coasts (*high confidence*). Marine heatwaves are also expected to increase around the region over the 21st century (*high confidence*).

The assessed direction of change in climatic impact-drivers for Asia and associated confidence levels are illustrated in Table 12.4.

12.4.3 Australasia

For the purpose of this assessment, Australasia is divided into five sub-regions as defined in Section 1.4.5: Northern Australia (NAU), Central Australia (CAU), Eastern Australia (EAU), Southern Australia (SAU) and New Zealand (NZ).

The Fourth and Fifth IPCC Assessment Reports (AR4 and AR5) identify the most damaging historical hazards in this region to be inland flooding, drought, wildfire and episodic coastal erosion due to storms (Hennessy et al., 2007; Reisinger et al., 2014). The SR1.5 (Hoegh-Guldberg et al., 2018) projects *very likely* increases in the intensity and frequency of warm days and warm nights and decreases in the intensity and frequency of cold days and cold nights in Australasia. Furthermore, a *likely* increase in the frequency and duration of warm spells is also projected for Australia. The SROCC (IPCC, 2019b) projects a *likely* global mean sea level rise (RCP8.5) that is up to 0.1 m higher than corresponding AR5 projections. The SROCC also projects an increase of mean significant wave height across the Southern Ocean (*high confidence*) and an increase in the occurrence of historically rare (1-in-100-year) extreme sea levels to 1-in-1-year or more frequent events all around the Australasian region by 2100 under RCP8.5.

A detailed national scale climate change assessment of observed and projected climate change, based on over 40 CMIP5 models and high resolution downscaling (CSIRO and BOM, 2015), and biannual short updates thereafter are available for Australia (CSIRO and BOM, 2016, 2018, 2020). Similar national assessments for New Zealand are also available (MfE and Stats NZ, 2017, 2020; MfE, 2018). The severe extreme events such as heatwaves and river floods that have occurred in Australasia, especially over the last decade, have enabled a number of attribution studies, improving the understanding of regional climate change mechanisms that drive such extreme events (Chapter 11).

Figure 12.7 illustrates projected changes in two selected climatic impact-driver indices for Australasia.

12.4.3.1 Heat and Cold

Mean air temperature: Across Australia mean temperatures have increased by 1.44°C ± 0.24°C during the period 1910–2019, with most of the warming occurring since 1950 (Atlas.6.2; CSIRO and BOM, 2020; Trewin et al., 2020). In New Zealand, an increase of 1.1°C has been measured from 1909–2016 (Atlas.6.2; MfE and Stats NZ,

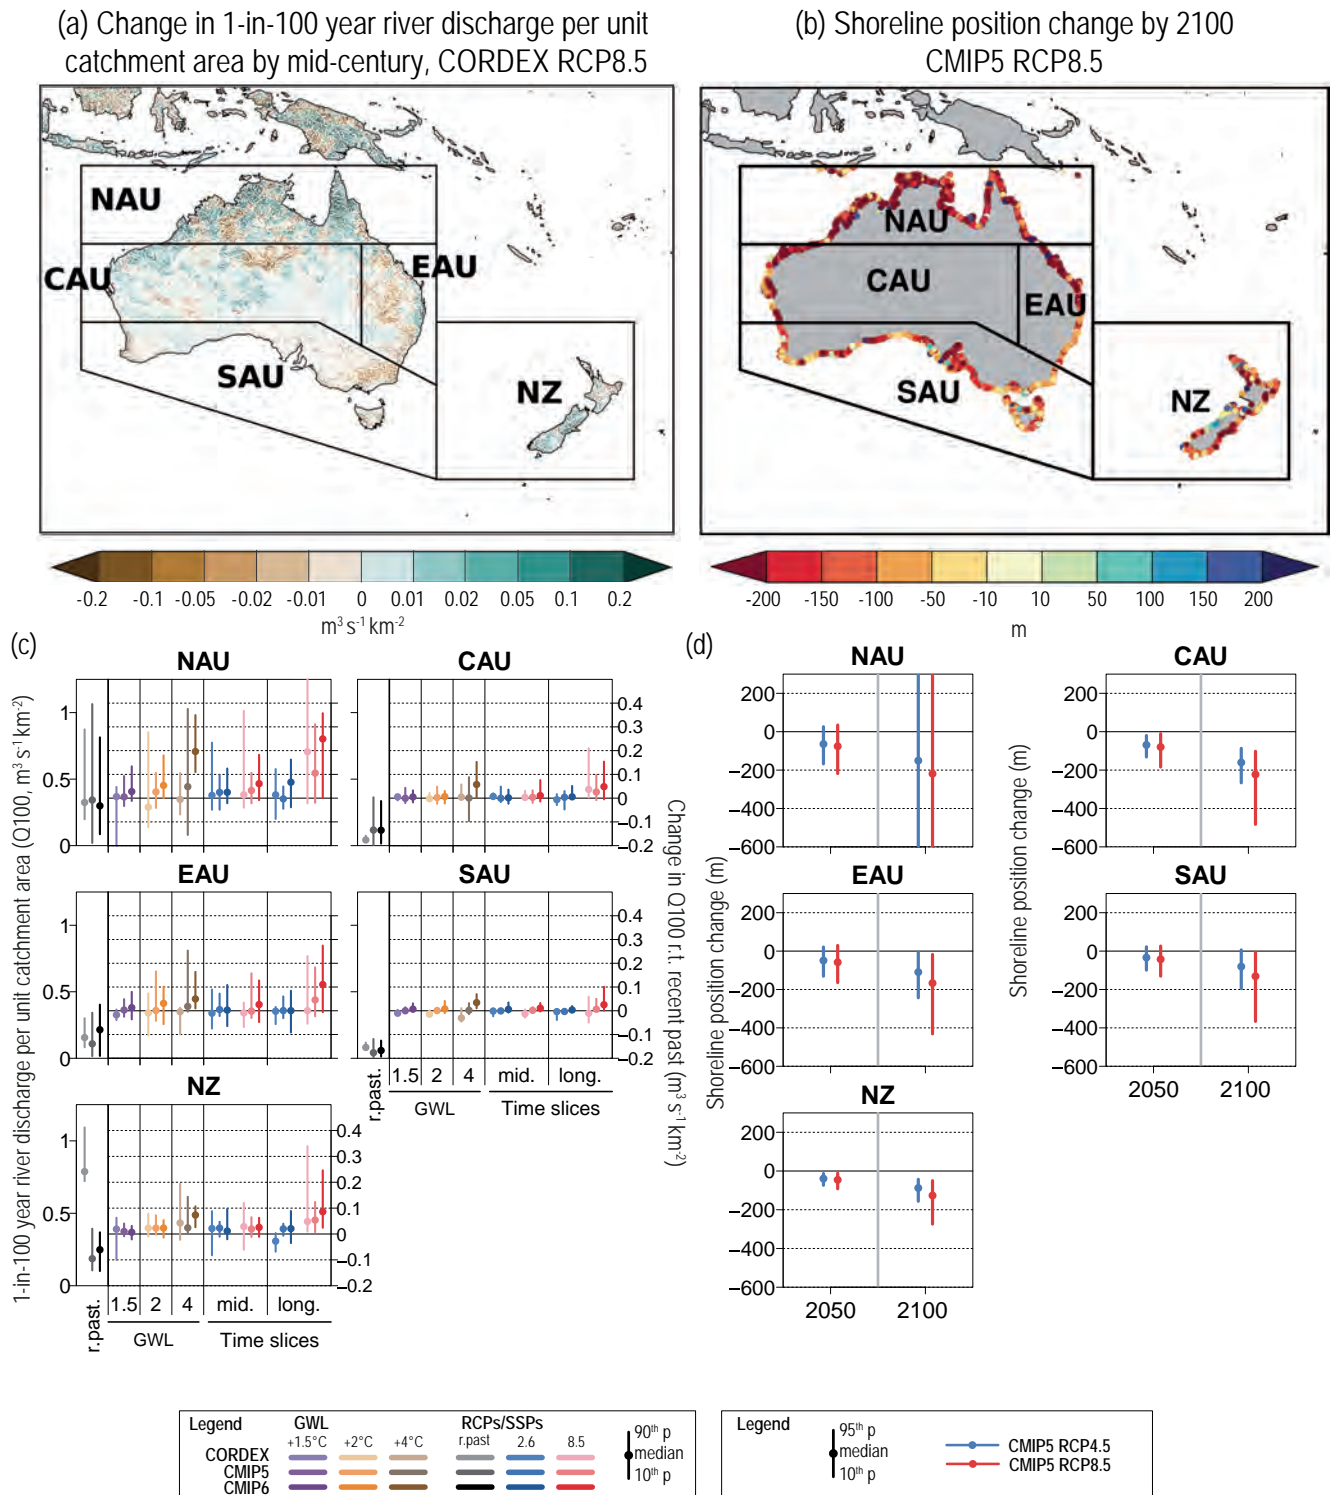

Figure 12.7 | Projected changes in selected climatic impact-driver indices for Australasia. (a) Mean change in 1-in-100-year river discharge per unit catchment area (Q_{100} , $\text{m}^3 \text{s}^{-1} \text{km}^{-2}$) from CORDEX-Australasia models for 2041–2060 relative to 1995–2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 for RCP8.5 (metres; negative values indicate shoreline retreat) from the CMIP5-based dataset presented by Vousdoukas et al. (2020b). (c) Bar plots for Q_{100} ($\text{m}^3 \text{s}^{-1} \text{km}^{-2}$) averaged over land areas for the AR6 WGI Reference Regions (defined in Chapter 1). The left-hand column within each panel (associated with the left-hand y-axis) shows the ‘recent past’ (1995–2014) Q_{100} absolute values in grey shades. The other columns (associated with the right-hand y-axis) show the Q_{100} changes relative to the recent past values for two time periods (‘mid’ 2041–2060 and ‘long’ 2081–2100) and for three global warming levels (defined relative to the pre-industrial period 1850–1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10–90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5-based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al. (2020b). Dots indicate regional mean change estimates and bars show the 5–95th percentile range of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

2020). In the period 1980–2014 a rate of increase of 0.1°C–0.3°C per decade has been observed (Atlas.11 and Atlas.20).

Mean temperature in Australasia is projected to continue to rise through the 21st century (*virtually certain*) (Atlas.6.4). Projections for Australia indicate that the average temperature will increase by +1.1°C (0.84–1.52°C 10–90th percentile range) by 2041–2060 (mid-century), and by +1.9°C (1.29–2.58°C) by 2081–2100 (end-century), relative to the baseline period of 1995–2014, under SSP2-4.5 (Interactive Atlas). For SSP5-8.5, the projected changes are up to +1.5°C (1.17–1.96°C) and +3.7°C (2.75–4.91°C) for mid- and end-century respectively. For SSP1-2.6, mean temperature is projected to rise by +0.9°C (0.55–1.26°C) and +1.0°C (0.55–1.54°C) relative to 1995–2014 by mid- and end-century respectively (Interactive Atlas). In New Zealand, an increase of mean temperature of +1.0°C (0.60–1.32°C) relative to 1995–2014 is projected by mid-century, and an increase of +1.6°C (1.03–2.26°C) by end-century under SSP2-4.5. For SSP5-8.5, the projected increase in mean temperature is +1.3°C (0.91–1.66°C 10–90th percentile range) and +3.1°C (2.20–4.05°C) relative to 1995–2014 by mid- and end-century respectively. For SSP1-2.6, the projected increase in mean temperature is +0.75°C (0.39–1.06°C) and +0.8°C (0.47–1.46°C) relative to 1995–2014 by mid- and end-century, respectively (Interactive Atlas).

Extreme heat: The region has a *very likely* trend of increasing frequency and severity of hot extremes since the 1950s (Table 11.10). Extreme minimum temperatures have increased in all seasons over most of Australia and exceeds the increase in extreme maximum temperatures (X.L. Wang et al., 2013; Jakob and Walland, 2016). Heatwave characteristics and hot extremes have increased across many Australian regions since the mid-20th century (Table 11.10; CSIRO and BOM, 2020). The number of days per year with maximum temperature greater than 35°C has increased over most parts of Australia from 1957–2015, with the largest increasing trends of 0.4–1 days/year occurring in north-western, Northern, north-eastern Australia and parts of Central Australia (CSIRO and BOM, 2016). Long-term changes of hot extremes in Australia have been attributed to anthropogenic influence (Table 11.10). In New Zealand, the number of annual heatwave days increased at 18 of 30 sites during the period 1972–2019 (MfE and Stats NZ, 2020).

More frequent hot extremes and heatwaves are expected over the 21st century in Australia (*virtually certain*) (Table 11.10). Heat thresholds potentially affecting agriculture and health, such as 35°C or 40°C, are projected to be exceeded more frequently over the 21st century in Australia under all RCPs (*high confidence*). By 2090 under RCP4.5, the average number of days per year with maximum temperatures above 35°C is highly spatially variable and is expected to increase by 50–100%, while the number of days per year with maximum temperatures above 40°C is expected to increase by 200%, relative to 1985–2005 (CSIRO and BOM, 2015). Under RCP8.5 the corresponding projected increases are even greater, with a greater than 100% increase in most of Australia, and far greater increases in Central and Northern Australia (up to a 20-fold increase in Darwin). Projections for New Zealand indicate more frequent hot extremes (*virtually certain*) (Table 11.10). Figure 12.4b, c shows CMIP6 projections of mean number of days per year with maximum temperature exceeding

35°C under SSP5-8.5, which are consistent with the above assessed literature and across the two CMIP generations, and indicate a strong difference depending on the mitigation scenario (e.g., over 100 days more per year under SSP5-8.5 in NAU, but, in general, less than 60 days more per year under SSP1-2.6 in NAU; Figure 12.SM.1).

The projected frequency of exceeding dangerous humid heat thresholds is increasing in Australia, with a strong increase in Northern Australia for RCP8.5 (*high confidence*) (Zhao et al., 2015; Mora et al., 2017; Brouillet and Jousaume, 2019), consistently across CMIP5, CMIP6 and CORDEX simulations (Figure 12.4d–f and Figure 12.SM.2). Using the HI index, by end-century, the average number of days exceeding 41°C is projected to increase in NAU by about 100 days and by about 25 days under SSP5-8.5 and SSP1-2.6, respectively. The projections for New Zealand indicate no appreciable increase in the number of days with HI > 41°C across SSPs, time periods and CMIP generations (Figure 12.4d–f and Figure 12.SM.2).

Cold spell and frost: Excepting parts of Southern Australia, the Australasian region has a significant trend of decreasing frequency in cold extremes since the 1950s (*high confidence*) (Table 11.10) and there is *high confidence* that such trends are attributable to anthropogenic influence (Table 11.10). The number of frost days per year in Australia has on average declined at a rate of 0.15 days/decade in the past century (Alexander and Arblaster, 2017), except in some regions of Southern Australia, where an increase in both number and season length has been reported (Dittus et al., 2014; Crimp et al., 2016b). The number of frost days has decreased at 12 of 30 monitoring sites around New Zealand over the period 1972–2019 (MfE and Stats NZ, 2020).

Less frequent cold extremes are *virtually certain* in Australasia (Table 11.10) while a decrease of frost days is projected with *high confidence* for the region. Projections, relative to 1986–2005, for the number of frost days per year in Australia indicate declines of 0.9 days by mid-century and 1.1 days by end-century for RCP4.5, while for RCP8.5, the projected declines are 1.0 days and 1.3 days by mid- and end-century respectively (Alexander and Arblaster, 2017; Herold et al., 2018). Projections for New Zealand indicate that the number of frost days will decrease by 30% (RCP2.6) to 50% (RCP8.5) by 2040, relative to 1986–2005. By 2090, the decrease ranges from 30% (RCP2.6) to 90% (RCP8.5) (MfE and Stats NZ, 2017).

In general, there is *high confidence* that most heat hazards in Australasia will increase and that cold hazards will decrease over the 21st century. The mean temperature in Australasia is *virtually certain* to continue to rise through the 21st century, accompanied by less frequent cold extremes (*virtually certain*) and frost days (*high confidence*), and more frequent hot extremes (*virtually certain*). Heat stress is projected to increase in Australia (*high confidence*).

12.4.3.2 Wet and Dry

Mean precipitation: Here, only increases in precipitation (under 'Wet') are addressed, with decreases (under 'Dry') addressed in 'Aridity' below.

In terms of wet climatic impact-drivers, detectable anthropogenic increases in precipitation in Australia have been reported particularly for north-central Australia for the period 1901–2010 (Knutson and Zeng, 2018). Figure Atlas.11 indicates no significant trend in precipitation over the region during the baseline period 1960–2015, except for the Global Precipitation Climatology Project (GPCP) dataset, which shows an increasing trend in north-central Australia. In New Zealand, increases in annual rainfall have been observed between 1960–2019 in the south and west of the South Island and east of the North Island. Note however, for the most part, the above reported trends in New Zealand have been classified as statistically not significant (Figure Atlas.20).

Annual mean precipitation is projected to increase in Central and north-east Australia (*low confidence*) and in the south and west of New Zealand (*medium confidence*) (Atlas.6.4). Liu et al. (2018a) show that under 1.5°C warming, Central and north-east Australia will become wetter. Projected patterns in annual precipitation exhibit increases in the west and south of New Zealand (Atlas.6.4; Liu et al., 2018a) and project that the South Island will be wetter under both 1.5°C and 2°C warming. However, there is limited model agreement for projected rainfall changes in Australasia as shown in the Atlas.

River flood: Streamflow observations in Australia have shown that negative trends dominate in annual maximum flow and that stations with significant negative trends were mostly located in the south-east and south-west (Gu et al., 2020). The observed peak flow trend in Southern Australia is attributed to the decrease of soil moisture, although an increase of flood magnitude is possible for very rare events. For the more frequent flood events, the increase of extreme precipitation is balanced by the decrease of soil moisture. (Wasko and Nathan, 2019).

While median annual runoff is projected to decrease in most of Australia (Chiew et al., 2017), consistent with projected decreases in average rainfall (CSIRO and BOM, 2015; Alexander and Arblaster, 2017), river floods are projected to increase due to more intense extreme rainfall events and associated increase in runoff (*medium confidence*). Asadieh and Krakauer (2017) found a decrease in the value of the 95% percentile of mean streamflow with RCP8.5 by the end of the century in all of Australia, except in a small part in centre of the country. In terms of relative increases, flooding is expected to increase more in Northern Australia (driven by convective rainfall systems) than in Southern Australia (where more intense extreme rainfall may be compensated by drier antecedent moisture conditions; Alexander and Arblaster, 2017; Dey et al., 2019) with flood frequency increasing in Northern Australia and along parts of the east coast and decreasing in south-western Western Australia (Hirabayashi et al., 2013). Gu et al. (2020) project larger flood magnitude and volumes under both RCP2.6 and RCP8.5 in Northern Australia, and smaller flood magnitudes and volumes in Southern Australia under the same RCPs. These findings are in general agreement with the patterns in peak flow, corresponding to the 1-in-100-year return period streamflow, shown in Figure 12.7a,c for mid-21st century under RCP8.5.

There is *medium confidence* that river flooding will increase in New Zealand. Projections for New Zealand indicate that the 1-in-50-year

and 1-in-100-year flood peaks for rivers in many parts of the country may increase by 5 to 10% by 2050 and more by 2100 (with large variation between models and emissions scenarios), with a corresponding decrease in return periods for specific flood levels (Gray et al., 2005; Carey-Smith et al., 2010; McMillan et al., 2010, 2012; Ballinger et al., 2011).

Heavy precipitation and pluvial flood: Rainfall extremes have been detected to increase in Australasia, with *low confidence* (Table 11.10). There is *high confidence* that $R \times 1$ day and $R \times 5$ day precipitation extremes will increase for 2°C or lower warming for the region as a whole, but on a sub-regional basis there is only *medium confidence* of increases in NAU and CAU and *low confidence* of increases on EAU, SAU and NZ. For warming levels exceeding 2°C, these extremes are *very likely* to increase in NAU and CAU and they are *likely* to increase elsewhere in the region (Section 11.9).

Landslide: Based on local slope characteristics, lithology and seismic activity, the South Island and the eastern half of the North Island of New Zealand are vulnerable to landslide occurrence (Broeckx et al., 2020). The potential for land and rockslides increases with, amongst other factors, total precipitation rates, precipitation intensity, mountain permafrost thaw rates, glacier retreat and air temperature (Crozier, 2010; Allen and Huggel, 2013; Gariano and Guzzetti, 2016; IPCC, 2019a). Given the increase of the magnitude of these physical variables in areas that are already highly susceptible to mass movements (MfE, 2018), there is *low confidence* that the occurrence of landslides will increase under future climate conditions.

Aridity: In terms of dry climatic impact-drivers, a substantial decrease in precipitation has been observed across Southern Australia during the cool season (April–October) (*medium confidence*). The drying trend has been particularly strong over south-west Western Australia between May and July, with rainfall since 1970 being around 20% less than the 1900–1969 average (CSIRO and BOM, 2020). Detectable decreases in mean precipitation, attributable at least in part to anthropogenic forcing, have been reported for parts of south-west Australia (Delworth and Zeng, 2014; Knutson and Zeng, 2018), south-east Australia, and Tasmania (Knutson and Zeng, 2018). In New Zealand, the north-east of the South Island and western and the northern parts of the North Island show decreasing precipitation trends during 1960–2019 (MfE and Stats NZ, 2020).

Aridity is projected to increase, especially during winter and spring, with *medium confidence* in SAU but with *high confidence* in south-west Western Australia (Table 11.11 and Atlas.6.4). In EAU and in the north and east of NZ, aridity is projected to increase with *medium confidence*, while a decrease is projected with *medium confidence* in the south and west of NZ (Atlas.6.4). Although there is only *low confidence* in the projected decrease of mean annual precipitation in south-western and eastern Australia and the north and east of New Zealand, there is *high confidence* of reduced winter and spring precipitation in Australia in future, mostly in south-western and eastern Australia (Atlas.6.4). Liu et al. (2018b) show that under 2°C warming, most of Australia is projected to become drier based on the Palmer Drought Severity Index (PDSI), with the exception of the tropical north-east. Ferguson et al. (2018) project that between 1976–2005 and 2070–2099, winters will

become drier (mainly in Southern Australia) under RCP8.5. Liu et al. (2018b) project that the North Island of New Zealand will be drier under both 1.5°C and 2°C warming.

Hydrological drought: There is *low confidence* of observed changes in hydrological droughts in Australasia, except in SAU where there is *medium confidence* of an observed increase in the south-east and south-west. Future projections indicate *medium confidence* in further hydrological drought increases for Southern Australia for warming levels of 2°C or higher (Section 11.9). Mean annual runoff in far south-east and far south-west Australia are projected to decline by median values of 20 and 50% respectively, by mid-century under RCP8.5 (Chiew et al., 2017). Prudhomme et al. (2014) assess changes in the Drought Index (DI), defined as areal runoff less than the 10th percentile over the reference period 1976–2005, and project DI increases for both Australia and New Zealand by 10–20% by 2070–2099 under RCP8.5, with the greatest effects being in the southern parts of the Australian continent. These projections are consistent with the trends shown in Figure 12.4g–i (Figure 12.SM.3). The SPI drought frequency is projected to increase in SAU and particularly in south-west Western Australia by mid-century, while by the end of the century SPI drought frequency is projected to increase all over Australia, and particularly strongly in south-west Western Australia as well as southern Victoria (see Figure 12.4g–i). For the Murray–Darling basin, Ferguson et al. (2018) project effectively no change (–1%) in mean precipitation, a 27% decrease in P–E, and 30% increase in runoff in 2070–2099 relative to 1976–2005 with RCP8.5.

Agricultural and ecological drought: There is *medium confidence* in observations of agricultural and ecological droughts increasing in SAU and decreasing in NAU, while there is *low confidence* of changes elsewhere in the region (Section 11.9). More regional studies have observed an increase in agricultural and ecological drought intensity in south-west Australia and an increase in drought intensity in parts of south-east Australia, while the length of droughts therein has increased (Section 11.9). In New Zealand, since 1972–73, soils at 7 of 30 monitored sites became drier, while the 2012–13 drought was one of the most extreme in the previous 41 years (MfE and Stats NZ, 2017). Future evaporative demand is projected to lead to *medium confidence* increases in agricultural and ecological droughts for 2°C of global warming in SAU and EAU and *low confidence* for changes in CAU, NAU and NZ, although there is *medium confidence* of increases in CAU with 4°C of global warming (Section 11.9). There is *medium confidence* for more time in agricultural and ecological drought in SAU by mid-21st century (Coppola et al., 2021b) as well as by the end of the 21st century (Herold et al., 2018). The Standardized Precipitation Evapotranspiration Index (SPEI) shows a springtime intensification in SAU with moderate and severe droughts in the south-west and moderate droughts in the south-east (Herold et al., 2018). There is consensus among the different model ensembles (CORDEX-CORE, CMIP5 and CMIP6) that the drought frequency (DF), one of several proxies for agricultural and ecological drought, will increase in all four Australian regions for both mid-century (NAU 0.2–2 DF increase, CAU 0.5–2 DF increase, SAU 1–3 DF increase and EAU 0.8–3 DF increase) and end-century (0.8–2.7 DF increase for NAU, 1.2–2 DF increase for CAU, 2.2–3.8 for SAU and 0.2–3 for EAU) for both RCP8.5 and SSP5-8.5, with CMIP6 showing the lowest increase (Figure 12.4g–i and Figure 12.SM.4; Coppola et al., 2021b).

Fire weather: Dowdy and Pepler (2018) examined atmospheric conditions conducive to pyroconvection in the period 1979–2016, and found an increased risk in south-east Australia during spring and summer, due to changes in vertical atmospheric stability and humidity, in combination with adverse near-surface fire weather conditions. CSIRO and BOM (2018) and Dowdy (2018) found that the annual 90th percentile daily Forest Fire Danger Index (FFDI) has increased from 1950–2016 in parts of Australia, especially in Southern Australia (1–2.5 per decade) and in spring and summer. These studies indicate an increase in the frequency and magnitude of FFDI extreme quantiles, as well as a shift of the fire season start towards spring, lengthening the fire season. The unprecedented large fires of austral spring and summer of 2019 in south-east Australia were a result of extreme hot and dry weather in significantly drier than average conditions that had persisted since 2017, in combination with consistently stronger than average winds, resulting in above average to highest on record FFDI values in much of the country (Abram et al., 2021). These fires have been attributed to climate change through the temperature component of fire weather indices (van Oldenborgh et al., 2021). In New Zealand, days with very high and extreme fire weather increased in 12 out of 28 monitored sites, and decreased in 8, in the period 1997–2019 (MfE and Stats NZ, 2020). Attribution studies indicate that there is *medium confidence* of an anthropogenically driven past increase in fire weather conditions, essentially due to increase in frequency of extreme heat waves. (Hope et al., 2019; Lewis et al., 2020; van Oldenborgh et al., 2021).

Fire weather indices are projected to increase in most of Australia (*high confidence*) and many parts of New Zealand (*medium confidence*), in particular with respect to extreme fire and induced pyroconvection (Dowdy et al., 2019b). Increasing mean temperature, cool season rainfall decline, and changes in tropical climate variability all contribute to a future increase in extreme fire risk in Australia (Abram et al., 2021). Projections indicate that the annual cumulative FFDI will increase by 31–33% in Southern and Eastern Australia, and by 17–25% in Northern Australia and the Rangelands by 2090 (relative to 1995) under RCP8.5 (CSIRO and BOM, 2015). Using a CMIP5 ensemble of 17 models, Abatzoglou et al. (2019) found a statistically significant positive trend for fire weather intensity and fire season length for future mid-century conditions under RCP8.5, including a detectable anthropogenic influence on fire risk magnitude and fire season length by 2040 in Western Australia and along the Queensland coastline. Using the C-Haines and FFDI indices with A2 and RCP8.5 respectively, Di Virgilio et al. (2019) and Clarke et al. (2019) have shown that extreme fire weather frequency will increase in south-eastern Australia by the end of the 21st century. Most of these projections indicate that the biggest increases in fire weather conditions will be in late spring, effectively resulting in longer (stronger) fire seasons in areas where spring is the shoulder (peak) season. In New Zealand, Watt et al. (2019) projected that the number of days with very high to extreme fire risk will increase by 71% by 2040, and by a further 12% by 2090, for the A1B scenario, with fire risk increase all along the east coast. The most marked relative changes by 2090 were projected for Wellington and Dunedin, where very high to extreme fire risk is projected to increase by, respectively, 89% to 32 days and 207% to 18 days, compared to the baseline period 1970–1999.

Annual mean precipitation is projected to increase in Central and north-east Australia (*low confidence*) and in the south and west of New Zealand (*medium confidence*), while it is projected to decrease in Southern Australia (*medium confidence*), albeit with *high confidence* in south-west Western Australia, in Eastern Australia (*medium confidence*), and in the north and east of New Zealand (*medium confidence*). Heavy precipitation and pluvial flooding are projected to increase with *medium confidence* in Northern Australia and Central Australia. There is *medium confidence* that river flooding will increase in New Zealand and Australia, with higher increases in Northern Australia. Aridity is projected to increase with *medium confidence* in Southern Australia (*high confidence* in south-west Western Australia), Eastern Australia (*medium confidence*), and in the north and east of New Zealand (*medium confidence*). Hydrological droughts are projected to increase in Southern Australia (*medium confidence*), while agricultural and ecological droughts are projected to increase with *medium confidence* in Southern Australia and Eastern Australia. Fire weather is projected to increase throughout Australia (*high confidence*) and New Zealand (*medium confidence*).

12.4.3.3 Wind

Mean wind speed: There is *low confidence* of a mean wind speed trend in the last decades (*low agreement*) (McVicar et al., 2012; Troccoli et al., 2012; Azorin-Molina et al., 2018; J. Wu et al., 2018), as long-term measurements are not homogeneous.

In future climate scenarios wind speed trends in Australia exhibit generally weak amplitudes with *low agreement* among models (Figure 12.4m–o and Figure 12.SM.5) with uncertain consequences on wind power potential (CSIRO and BOM, 2015; Karauskas et al., 2018a; Jung and Schindler, 2019). However, there is *medium confidence* that, by the end of the century, annual mean wind power will significantly increase in north-eastern Australia under RCP8.5, but there is *low confidence* of an increase by end-century under RCP4.5, and for any scenario by mid-century (Karauskas et al., 2018a). In New Zealand, mean wind patterns are projected to become more north-easterly in summer, and westerlies to become more intense in winter (*low confidence*), in agreement with the strengthening of the Southern Hemisphere storm tracks (Section 4.5.1).

Severe wind storm: There is generally *low confidence* in observed changes in extreme winds and extratropical storms in Australasia (Section 11.7.2). CMIP5 projections of severe winds indicate a general increase in north-eastern Australia, and decreases in some parts in Southern and Central Australia (*medium confidence*) by the end of the century under RCP8.5 (CSIRO and BOM, 2015; Kumar et al., 2015; Jung and Schindler, 2019). Elsewhere trends are diverse and vary across simulations with *low agreement*. Projections of changes in the 1-in-25-year return period winds (based on annual maxima) for 2074–2100 relative to 1979–2005 for RCP8.5 show an increase in tropical areas of Northern Australia (Kumar et al., 2015).

In New Zealand, the frequency and magnitude of extreme winds have decreased (from 1980–2019) at 12 of 14 monitored sites and

increased at two monitored sites (MfE and Stats NZ, 2020). Due to the intensification and the shift of the austral storm track by the end of the century (Yin, 2005), increases in extreme wind speed in New Zealand are projected over the South Island and the southern part of the North Island by mid- and end-century for all RCPs (*low confidence*) (MfE, 2018).

Tropical cyclone: In Australia, the number of TCs has generally declined since 1982, and the frequency of intense TCs that make landfall in north-eastern Australia has declined significantly since the 19th century (*medium confidence*) (Kuleshov et al., 2010; Callaghan and Power, 2011; Holland and Bruyère, 2014; Knutson et al., 2019; CSIRO and BOM, 2020). There is *high confidence* that cyclones making landfall along north-eastern and northern Australian coastlines will decrease in number and *low confidence* of an increase in their intensities for 2°C of global warming as well as for the mid-century period with scenarios RCP4.5 and above (Roberts et al., 2015, 2020; Bacmeister et al., 2018; Knutson et al., 2020), with the amplitude of changes increasing from RCP4.5 to RCP8.5 (Bacmeister et al., 2018). Decreases in frequency are projected for ‘east coast lows’ (Walsh et al., 2016b; Dowdy et al., 2019a).

Sand and dust storm: Australia is recognized to be the largest dust source in the Southern Hemisphere (Zheng et al., 2016). Land-use and land-cover change have increased dust emissions in Australia in the past 200 years (Marx et al., 2014). While projections suggest a decrease in severe winds in Central and Southern Australia, changes in vegetation due to increased aridity and hydrological drought could be expected to result in increased wind erosion and dust emission across the country (*medium confidence*) (Webb et al., 2020).

In Australasia, there is *low confidence* in projected mean wind speeds and wind power potential, with a *medium confidence* increase projected only in north-eastern Australia under high emissions scenarios and by the end of the 21st century. Tropical cyclones in north-eastern and North Australia are projected to decrease in number (*high confidence*) while their intensity is projected to increase (*low confidence*).

12.4.3.4 Snow and Ice

Snow: The snow season length in Australia has decreased by 5% during 2000–2013 relative to 1954–1999, especially in spring (Pepler et al., 2015). A shift in the date of peak snowfall has also been observed with an 11-day advance over the same period (Pepler et al., 2015). A decreasing trend in maximum snow depth has been observed for Australian alpine regions since the late 1950s, with the largest declines during spring and at lower altitudes. Maximum snow depth is highly variable and is strongly influenced by rare heavy snowfall days, which have no observed trends in frequency (CSIRO and BOM, 2020).

Projections for Southern Australia and New Zealand show a continuing reduction in snowfall during the 21st century (*high confidence*). The magnitude of decrease varies with the altitude of the region and the emissions scenario. At elevations lower than 1500 m, years without snowfall are projected from 2030 in some models. By 2090, and under

RCP8.5, such years are projected to become common (CSIRO and BOM, 2015). The number of annual snow days in New Zealand is projected to decrease under all RCPs, by up to 30 days or more by 2090 under RCP8.5, relative to 1986–2005 (MfE, 2018).

Glacier: Glacier mass and areal extent in New Zealand is projected to continue to decrease over the 21st century (*high confidence*) (Section 9.5.1.3). Glacier ice volume from 1977–2018 in New Zealand has decreased from 26.6 to 17.9 km³ (a loss of 33%; Salinger et al., 2019). Relative to 2015, glaciers in New Zealand are projected to lose 36 ± 44%, 53 ± 33% and 77 ± 27% of their mass by the end of the century under RCP2.6, RCP4.5 and RCP8.5 respectively, with the loss rates decreasing over time under RCP2.6 and increasing under RCP8.5 (Marzeion et al., 2020).

In summary, snowfall is expected to decrease throughout the region at high altitudes in both Australia (*high confidence*) and New Zealand (*medium confidence*). In New Zealand, glacier ice mass and extent are expected to decrease over the 21st century for all scenarios (*high confidence*).

12.4.3.5 Coastal and Oceanic

Relative sea level: Around Australasia, from 1900–2018, a new tide gauge-based reconstruction finds a regional mean RSL change of 1.33 [0.80 to 1.86] mm yr⁻¹ in the Indian Ocean–South Pacific region (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). For the period 1993–2018, the RSLR rates, based on satellite altimetry, increased to 3.65 [3.23 to 4.08] mm yr⁻¹ (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5).

Relative sea level is *virtually certain* to increase throughout the region over the 21st century (Section 9.6.3, Figure 9.28). Regional mean RSLR projections for the oceans around Australasia range from 0.4–0.5 m under SSP1-2.6 to 0.7–0.9 m under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), which means local RSL change falls within the range of mean projected GMSL change (Section 9.6.3.1). However these RSLR projections may be underestimated due to potential partial representation of land subsidence (Section 9.6.3.2).

Coastal flood: The most commonly used index for episodic coastal inundation in Australia is the summation of a high end SLR and the 1-in-100-year storm tide level (the combined sea level due to storm surge and tide) (CSIRO and BOM, 2016; McInnes et al., 2016). However, episodic coastal flooding is caused by extreme total water levels (ETWL), which is the combination of SLR, tides, surge and wave setup (Section 12.3.5.2). The present-day 1-in-100-year ETWL is between 0.5–2.5 m around most of Australia, except the north-western coast where 1-in-100-year ETWL can be as large as 6–7 m (Vousdoukas et al., 2018; O’Grady et al., 2019; Kirezci et al., 2020).

Extreme total water level magnitude and occurrence frequency are expected to increase throughout the region (*high confidence*) (Figure 12.4p–r and Figure 12.SM.6). Across the region, the 5–95th percentile range of the 1-in-100-year ETWL is projected increase (relative to 1980–2014) by 5–35 cm and by 10–40 cm by 2050

under RCP4.5 and RCP8.5 respectively (Figure 12.4q). By 2100 (Figure 12.4p,r), this range is projected to be 25–80 cm and 50–190 cm under RCP4.5 and RCP8.5 respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, the present-day 1-in-100-year ETWL is projected to have median return periods of around 1-in-20-years by 2050 and 1-in-1-year by 2100 in SAU and NZ and return periods of around 1-in-50-years by 2050 and 1-in-20-years by 2100 in NAU under RCP4.5 (Vousdoukas et al., 2018), while the present-day 1-in-50-year ETWL is projected to occur around three times a year by 2100 with a SLR of 1 m around Australasia (Vitousek et al., 2017).

Coastal erosion: Satellite derived shoreline retreat rates for the period between 1984–2015 show retreat rates between 0.5 and 1 m yr⁻¹ around the region, except in SAU where a shoreline progradation rate of 0.1 m yr⁻¹ has been observed (Luijendijk et al., 2018; Mentaschi et al., 2018). Mentaschi et al. (2018) report a coastal area loss of 350 km² over the same period in Western Australia from satellite observations.

Projections indicate that a majority of sandy coasts in the region will experience shoreline retreat, throughout the 21st century (*high confidence*) (Figure 12.7b,d). Median shoreline change projections (CMIP5) under both RCP4.5 and RCP8.5 presented by Vousdoukas et al. (2020b) show that, by mid-century, sandy shorelines will retreat (relative to 2010) by between 50 and 80 m all around Australasia, except in SAU and NZ where the projected retreat (relative to 2010) is between 35 and 50 m. By 2100, median shoreline retreats exceeding 100 m (relative to 2010) are projected along the sandy coasts of NAU (about 150 m), CAU (about 160 m), and EAU (about 110 m) under RCP4.5m, while projections for SAU and NZ are around 80–90 m. Under RCP8.5, shoreline retreat exceeding 100 m is projected all around the region by 2100 (relative to 2010) with retreats as high as 220 m in NAU and CAU (about 170 m in EAU and about 130 m in SAU and NZ; Figure 12.7b,d). The total length of sandy coasts in Australasia that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 12,500 and 16,000 km respectively, an increase of approximately 30%.

Distinct from long-term coastline recession, storms and storm surges also result in episodic coastal erosion. In general, the historically measured maximum episodic coastal erosion (either eroded volume or coastline retreat distance) or that due to a 1-in-100-year return period storm wave height is used as a design criterion for coastal zone management and planning in Australia (Wainwright et al., 2014; Mortlock et al., 2017).

While there is wide recognition in Australia that the combined effect of SLR, changing storm surge and wave climates will directly affect future episodic coastal erosion (McInnes et al., 2016; Ranasinghe, 2016; Harley et al., 2017) only a few projections of how this hazard may evolve are available for Australia. In one such study, Jongejan et al. (2016) provide projections of how the full exceedance probability curve of the maximum erosion per year may evolve over the 21st century (due to the combined action of SLR, storm surge and storm waves). Their results show that, for example, the 0.01 exceedance probability maximum coastline retreat in 2025 will have an exceedance probability of 0.015 by 2050 and 0.07 by 2100.

Marine heatwave: The mean SST of the ocean around Australia and east of New Zealand has warmed at a rate of about 0.22°C per decade between 1992 and 2016 (Wijffels et al., 2018), which is higher than the global average SST increase of 0.16°C per decade (Oliver et al., 2018). This mean ocean surface warming is connected to longer and more frequent marine heatwaves in the region (Oliver et al., 2018). Over the period 1982–2016, the coastal ocean of Australia experienced on average more than 1.5 marine heatwaves (MHWs) per year, with the north coast of Western Australia and the Tasman Sea experiencing on average 2.5–3 MHWs per year. The average duration was between 10 and 15 days, with somewhat longer and hotter MHWs in the Tasman Sea. In New Zealand, the south-east coast of South Island experiences the most MHWs (2.5–3 per year). The duration of MHW in New Zealand is on average 10–15 days (Oliver et al., 2018). Changes around Australasia over the 20th century, derived from MHW proxies, show an increase in frequency between 0.3 and 1.5 MHW per decade, except along the south-east coast of New Zealand (Box 9.2); an increase in duration per event; and the total number of MHW days per decade, with the change being stronger in the Tasman Sea than elsewhere (Oliver et al., 2018).

There is *high confidence* that MHWs will increase around most of Australasia. Under RCP4.5 and RCP8.5 respectively, mean SST is projected to increase by 1°C and 2°C around Australia by 2100, with a hotspot of around 2°C for RCP4.5 and of 4°C for RCP8.5 along the south-east coast between Sydney and Tasmania (Interactive Atlas). Under all RCPs, the mean SST around Australia is expected to increase in the future, with median values of around 0.4°C–1.0°C by 2030 under RCP4.5, and 2°C–4°C by 2090 under RCP8.5 (CSIRO and BOM, 2015). Warming is expected to be largest along the north-west coast of Australia, southern Western Australia, and along the east coast of Tasmania (CSIRO and BOM, 2018). More frequent, extensive, intense and longer lasting MHWs are projected around Australia and New Zealand for GWLs of 1.5°C, 2°C and 3.5°C relative to the modelled reference value for 1861–1880 (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Australasia by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

In general, there is *high confidence* that most coastal/ocean-related hazards in Australasia will increase over the 21st century. Relative sea level rise is *virtually certain* to continue in the oceans around Australasia, contributing to increased coastal flooding in low-lying areas (*high confidence*) and shoreline retreat along most sandy coasts (*high confidence*). Marine heatwaves are also expected to increase around the region over the 21st century (*high confidence*).

The assessed direction of change in climatic impact-drivers for Australasia and associated confidence levels are illustrated in Table 12.5, together with emergence time information (Section 12.5.2). No assessable literature could be found for hail and snow avalanches, although these phenomena may be relevant in parts of the region.

12.4.4 Central and South America

For the purpose of this assessment, Central and South America is divided into eight sub-regions, as defined in Chapter 1: Southern

Central America (SCA), North-Western South America (NWS), Northern South America (NSA), South American Monsoon (SAM), North-Eastern South America (NES), South-Western South America (SWS), South-Eastern South America (SES) and Southern South America (SSA). The Caribbean is placed under the Small Islands section (12.4.7) of this chapter.

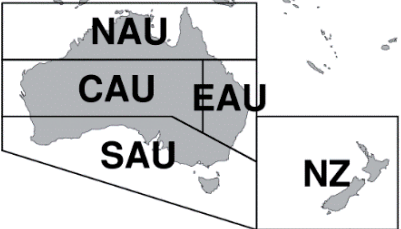

Previous assessments have documented ongoing and projected changes in several CIDs. IPCC AR5 projections (IPCC, 2014b) pointed to increases in mean temperature between 2°C and 6°C by the end of the century (*high confidence*) and increases in the occurrence of warm days and nights under various future climate scenarios (*medium confidence*). The AR5 also pointed to patterns of changes in precipitation (*medium confidence*), changes in the duration of dry spells (*medium confidence*) and decreases in water supply (*high confidence*). The SR1.5 projections indicated expected increases in river flooding and extreme runoff at 2°C warming in parts of South America, and decreases in runoff in Central America, central and Southern South America, and the Amazon basin. The SROCC reported an increased number of landslides, a decreased volume of lahars from ice and snow-clad volcanoes, and increased frequency of glacier lake outburst floods. The SROCC also indicated that regional and local-scale projections point to decreasing trends in glacier runoff.

New literature is now available for the regional climate as a result of observational research and coordinated modelling outputs of CORDEX South America (Solman, 2013; Sánchez et al., 2015) and CORDEX-CORE (Giorgi et al., 2018; Coppola et al., 2021b; Teichmann et al., 2021). Of particular interest are the new projections of both mean climate and extremes. This new regional climate information is key to main sectors sensitive to climate change in Central and South America such as water resources, infrastructure, agriculture, livestock, forestry, silviculture and fisheries (Magrin, 2015; López Feldman and Hernández Cortés, 2016), human health (changes in morbidity and mortality, and emergence of diseases in previously non-endemic areas; Núñez et al., 2016) and biodiversity (Uribe Botero, 2015), urban planning, navigation and tourism.

12.4.4.1 Heat and Cold

Mean air temperature: New literature confirms a continuous warming since the beginning of the 20th century in the majority of the eight sub-regions (Atlas.7). However, observational datasets in several areas are still short and trend estimation is hindered by year-to-year and interannual variability. Atlas projections point to a *virtually certain* warming across all sub-regions, with the largest increases taking place in the Amazon basin (NSA and SAM; Atlas.7.2.4). A consistent increase in temperature-related indices linked to several climate-sensitive sectors (e.g., growing degree days, cooling degree days) is found across CMIP5, CMIP6 and CORDEX-CORE projections, with smaller increases for cooling degree days in mid-latitude regions than in SCA and the Amazon (Coppola et al., 2021b). Daily mean temperature exceedances of a typical 21.5°C threshold for a successful incubation of disease pathogens inside many mosquito vectors (Lambrechts et al., 2011; Blanford et al., 2013; Mordecai et al., 2013, 2017) will be crossed much more frequently, potentially driving increases in the incidence of vector-borne diseases (Laporta et al., 2015; Messina et al., 2019).

Table 12.5 | Summary of confidence in direction of projected change in climatic impact-drivers in Australasia, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least medium confidence in Section 12.5.2.

 Region	Climatic Impact-driver																													
	Heat and Cold				Wet and Dry								Wind				Snow and Ice					Coastal and Oceanic				Other				
	Mean air temperature	Extreme heat	Cold spell	Frost	Mean precipitation	River flood	Heavy precipitation and pluvial flood	Landslide	Aridity	Hydrological drought	Agricultural and ecological drought	Fire weather	Mean wind speed	Severe wind storm	Tropical cyclone	Sand and dust storm	Snow, glacier and ice sheet	Permafrost	Lake, river and sea ice	Heavy snowfall and ice storm	Hail	Snow avalanche	Relative sea level	Coastal flood	Coastal erosion	Marine heatwave	Ocean acidity	Air pollution weather	Atmospheric CO ₂ at surface	Radiation at surface

1. High confidence of decrease in the south-west of the state of Western Australia.
2. Medium confidence of decrease in north and east and increase in south and west.
3. High confidence of increase in the south-west of the state of Western Australia.
4. Medium confidence of increase in the north and east and decrease in south and west.
5. Low confidence of increasing intensity, and high confidence of decreasing occurrence.
6. High confidence of decrease in glacier volume, medium confidence of decrease in snow.
7. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.

- Already emerged in the historical period (*medium to high confidence*)
- Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)
- Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

(a) Change in 1-in-100 year river discharge per unit catchment area by mid-century, CORDEX RCP8.5

(b) Shoreline position change by 2100 CMIP5 RCP8.5

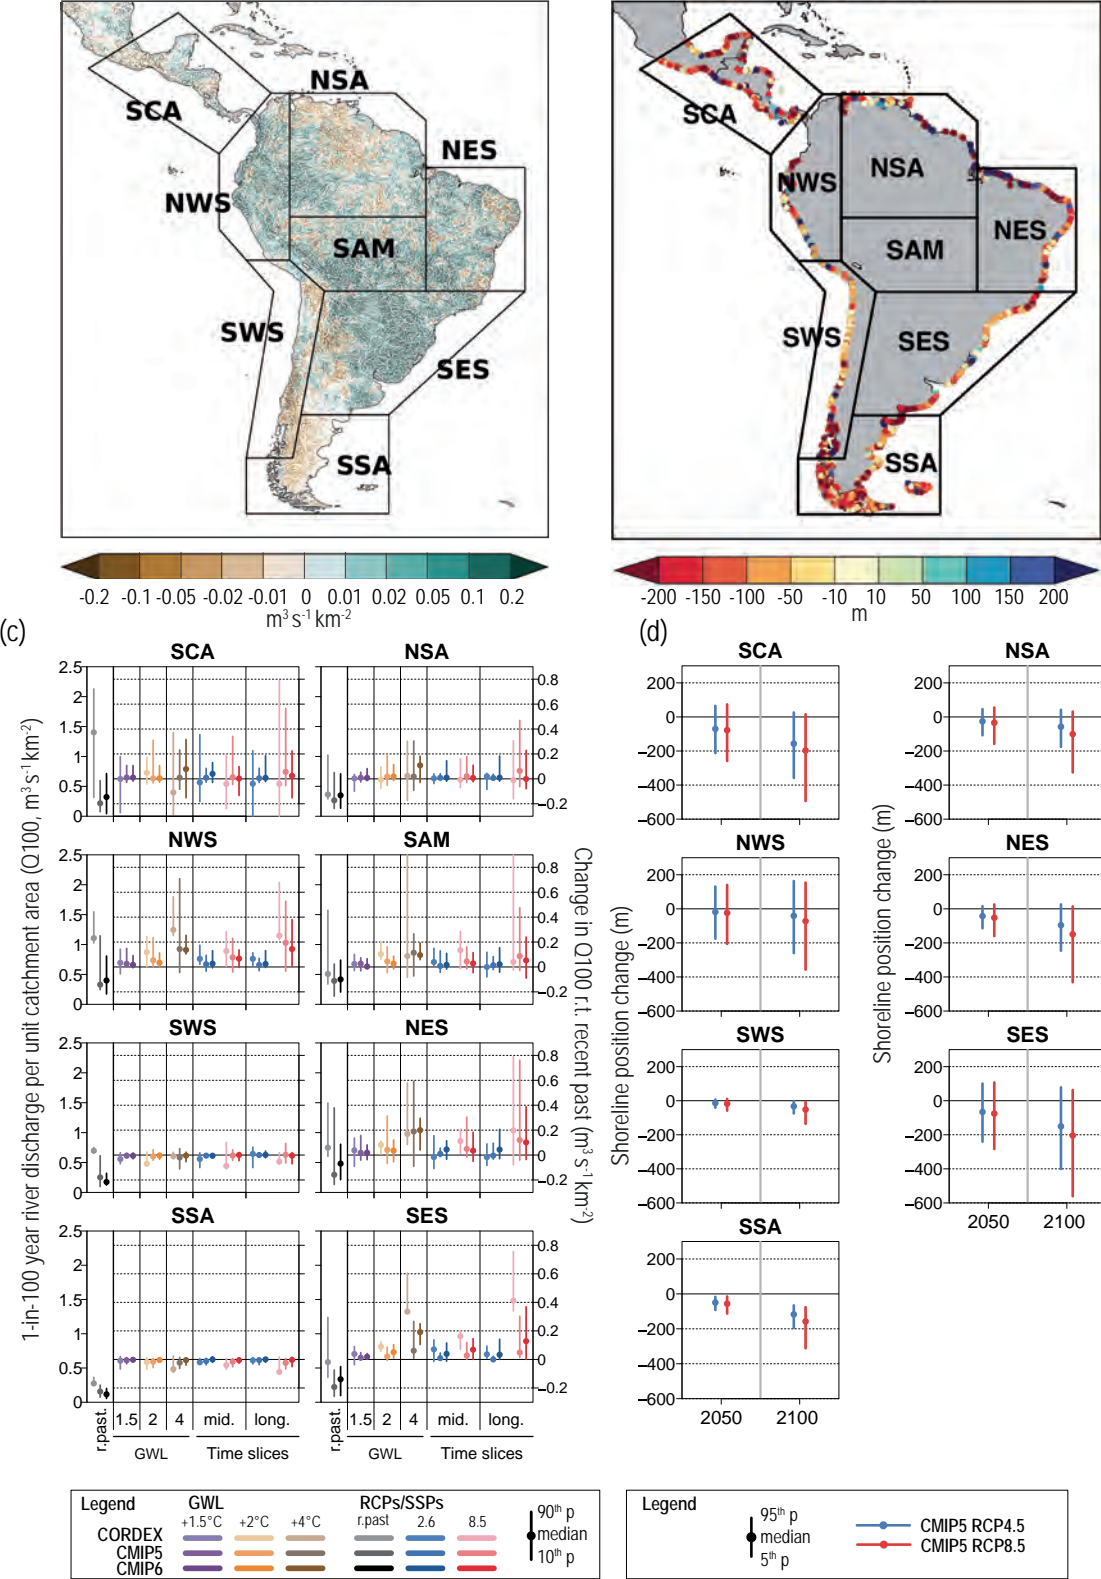

Figure 12.8 | Projected changes in selected climatic impact-driver indices for Central and South America.

Figure 12.8 (continued): (a) Mean change in 1-in-100-year river discharge per unit catchment area (Q_{100} , $m^3 s^{-1} km^{-2}$) from CORDEX-South and Central America models for 2041–2060 relative to 1995–2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 for RCP8.5 (metres; negative values indicate shoreline retreat) from the CMIP5-based dataset presented by Vousdoukas et al. (2020b). (c) Bar plots for Q_{100} ($m^3 s^{-1} km^{-2}$) averaged over land areas for the AR6 WGI Reference Regions (defined in Chapter 1). The left-hand column within each panel (associated with the left-hand y-axis) shows the ‘recent past’ (1995–2014) Q_{100} absolute values in grey shades. The other columns (associated with the right-hand y-axis) show the Q_{100} changes relative to the recent past values for two time periods (‘mid’ 2041–2060 and ‘long’ 2081–2100) and for three global warming levels (defined relative to the pre-industrial period 1850–1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10–90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5-based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al. (2020b). Dots indicate regional mean change estimates and bars show the 5–95th percentile range of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

Extreme heat: Chapter 11 found *high confidence* of increased heatwaves in all regions except SSA over the past decades. There is evidence of increasing heat stress over summer in much of SES and SWS using the wet bulb globe temperature (WBGT) index for the period 1973–2012, and this has been attributed to human influence on the climate system (Knutson and Ploshay, 2016). Climate change projections point to major increases in several heat indices across the region for all scenarios (*high confidence*). Largest increases in the frequency of hot days (maximum temperatures, $T_x > 35^\circ C$) are projected for the Amazon basin under SSP5-8.5 with more than 200 days per year at the end of the century under SSP5-8.5 relative to 1995–2014, while such increases remain moderate (50–100 days) in SSP1-2.6. For the dangerous heat threshold of $HI > 41^\circ C$, increases in frequency are similar to that in $T_x > 35^\circ C$ (Figure 12.4 and Figures 12.SM.1 and 12.SM.2; Coppola et al., 2021b; Schwingshackl et al., 2021).

Cold spell and frost: A decreasing frequency of cold days and nights has been observed in many sub-regions (Table 11.13). There is *medium confidence (limited agreement)* of a decrease in frost days in SWS, SES and SSA. Projections consistently suggest a general decrease in the frequency of cold spells and frost days in the region as indicated by several indices based on minimum temperature (Chou et al., 2014; López-Franca et al., 2016; C. Li et al., 2021). Heating degree days are consistently projected to decrease by 5 degree days per year in the Amazon region, and up to 20–30 degree days per year in NWS, SWS and SES, under RCP8.5/SSP5-8.5 by mid century (Coppola et al., 2021b).

In conclusion, it is *virtually certain* that warming will continue everywhere in Central and South America and there is *high confidence* that by the end of the century most regions will undergo extreme heat stress conditions much more often than in recent past (e.g., increase of dangerous heat with $HI > 41^\circ C$, or $T_x > 35^\circ C$) with more than 200 additional days per year under SSP5-8.5, while such conditions will be met typically 50–100 more days per year under SSP1-2.6 over the same regions. Cold spells and frost days will have a decreasing trend (*high confidence*).

12.4.4.2 Wet and Dry

Mean precipitation: The Atlas documents diverse historical precipitation trends in the region, including a small but not significant increasing trend in SCA, a decreasing trend in south-eastern and north-eastern Brazil, and an increasing trend in SSA. Projections indicate a drying signal for SCA (*medium confidence*) (Coppola et al., 2014a; Nakaegawa et al., 2014), NES and SWS

(*high confidence*) (Atlas.7.2.5) and the well-known dipole for South America, meaning increasing precipitation over subtropical regions like the Río de La Plata basin (SES) (*high confidence*) and decreasing precipitation in the Amazon (NSA) (*medium confidence*) (Chou et al., 2014; Llopart et al., 2014; Reboita et al., 2014; Sánchez et al., 2015; Teichmann et al., 2021). These features are consistent with observations (Sena et al., 2018) and are evident in regional and global model projections by mid- and end-of-century for both RCP4.5 and RCP8.5 (Jones and Carvalho, 2013).

River flood: Emerging literature in the region documents ongoing changes in river floods. Mernild et al. (2018) report decreases and increases in annual runoff west of the Andes Cordillera’s continental divide, with the greatest decreases in the number of low (<10th percentile) runoff conditions and the greatest increases in high (>90th percentile) runoff conditions. In coastal north-east Peru, extreme precipitation events recently caused devastating river floods and landslides (Son et al., 2020). In Brazil, floods are becoming more frequent and intense in wet regions but less frequent and intense in drier regions (Bartiko et al., 2019; Borges de Amorim and Chaffe, 2019), with higher propagation of hydrological changes through anthropogenically modified agricultural basins (Chagas and Chaffe, 2018). Record, catastrophic, unprecedented, and once-in-a-century flooding events have also been reported in recent decades in the tributaries of the Amazon River or along its mainstream (Sena et al., 2012; Espinoza et al., 2013; Marengo et al., 2013; Filizola et al., 2014), in Argentinean rural and urban areas (Barros et al., 2015), in the lower reaches of the Atrato, Cauca and Magdalena rivers in Colombia (Hoyos et al., 2013; Ávila et al., 2019), in basins whose mainstreams flow through important metropolitan areas such as Concepción, Chile (Rojas et al., 2017), and even in one of Earth’s driest regions, the Atacama Desert (Wilcox et al., 2016). In the Amazon basin, the significant increase in extreme flow is associated with the strengthening of the Walker circulation (Barichivich et al., 2018).

Available projections for the region show increases in river floods in SES and SAM (*medium confidence*). Projections indicate that SES and the coasts of Ecuador and Peru will experience a tendency towards wetter conditions that can be a proxy for longer periods of flooding and enhanced river discharges (Zaninelli et al., 2019). CORDEX models project the strongest changes for the peak flow with a return period of 100 years in SES by mid-century and under RCP8.5 (Figure 12.8). At the continental scale, on the contrary, Alfieri et al. (2017) suggest that 100-year river floods will decrease under RCP8.5. Regional projections of river floods have high uncertainty, however, owing to differences in

hydrological models (*low confidence*) (Reyer et al., 2017a). Fábrega et al. (2013) projected increases in surface runoff for Panama, while Zulkafli et al. (2016) identified increases in 100-year floods of 7.5 and 12.0% in projections for the Peruvian Amazon wet season under RCPs 4.5 and 8.5 respectively. Wetter conditions and $\pm 20\%$ variations in annual mean streamflow are also projected for the Río de La Plata under the warming levels of 1.5°C, 2°C and 3°C above pre-industrial conditions (Montroull et al., 2018). In central Chile, 50-year peak flows are expected to be greater by mid-century than 100-year peak flows observed over the reference period (Bozkurt et al., 2018).

Heavy precipitation and pluvial flood: Table 11.14 indicated that there is *low confidence* due to *limited evidence* of extreme precipitation trends in almost all Central and South America, except in SES where increases in the magnitude and frequency of heavy precipitation have been observed (*high confidence*). In general, data scarcity persists for a representative continental assessment. Chapter 11 projections indicate *low confidence* of increase, compared to the modern period, in the intensity and frequency of heavy precipitation in SCA and SWS for all GWLs, and *medium confidence* of increase in NSA, NES, SSA, SAM and SES for GWL of 4°C. In NWS, a wide range of changes is projected (*low confidence*).

Landslide: Several regions in Central America, as well as Colombia and south-eastern Brazil, are considered areas of high incidence of observed fatal landslides. In these areas, El Niño–Southern Oscillation (ENSO)-driven fluctuations in rainfall amounts (Sepúlveda and Petley, 2015) and climate change (Nehren et al., 2019) seem to be key factors. Rockfalls, ice- and rock-ice avalanches, lahars and landslides have been reported frequently in the southern, extratropical Andes in the last decades (Gariano and Guzzetti, 2016). A large number of ice- and moraine-dammed lakes have consequently failed, causing floods that rank amongst the largest events ever recorded (Iribarren Anaconda et al., 2015). However, published literature is largely missing for a reliable assessment of past and future trends of such hazards.

Aridity: Several regional studies suggest increasing trends in the frequency and length of droughts in the region, such as: over NWS (Domínguez-Castro et al., 2018), NSA (Marengo and Espinoza, 2016; Cunha et al., 2019) and NES (Marengo and Bernasconi, 2015), over southern Amazonia (Fu et al., 2013; Boisier et al., 2015), in the São Francisco River basin and the capital city Distrito Federal in Brazil (Borges et al., 2018; Bezerra et al., 2019), in the southern Andes (Vera and Díaz, 2015), in central southern Chile (Boisier et al., 2018), in SES (Rivera and Penalba, 2014) and, during recent years, in SSA (Rivera and Penalba, 2014). Chapter 8 indicated *medium confidence* of anthropogenic forcing on observed drying trends in central Chile. Additional discussion on droughts and aridity trends in South America is presented in Sections 8.3.1.6, 8.4.1.6 and 8.6.2.1.

Sections 8.3.2.4 and 8.4.1.6 point to two important drying hotspots in South America with long-term soil moisture decline and precipitation declines: the Amazon basin (SAM and NSA) and SWS (*medium confidence*) (Figure 12.4). End-of-century RCP8.5 projections show a longer dry season in the central part of South America and decreased precipitation over the Amazon and central Brazil (Teichmann et al., 2013; Coppola et al., 2014a; Giorgi et al., 2014;

Llopart et al., 2014; Atlas.7). Seasonal changes are also projected by end century under RCP 8.5, with decreases in June–July–August (JJA) rainfall projected for NSA, the coastal region of SES, SAM and the southern portion of SWS (Marengo et al., 2016). Decreases in December–January–February (DJF) rainfall are projected for the central part of South America in the near term (Kitoh et al., 2011; Chou et al., 2014; Cabré et al., 2016). Regional projections for Central and South America also indicate an increase in dryness in SCA and NES by mid- to end-century (*medium confidence*) (Chou et al., 2014; Marengo and Bernasconi, 2015).

Hydrological drought: Chapter 11 assessed mostly *low confidence* in observed changes in hydrological droughts given a lack of studies and clear evidence, with *medium confidence* only for a streamflow decrease in sub-regions of SWS (Table 11.15). Some trends are becoming more clear, such as the ones reported for Colombia (NWS) by Carmona and Poveda (2014), who indicated that 62% of the 25- to 50-year-long monthly average streamflow time series exhibited significant decreasing trends. However, studies of discharge changes indicate that uncertainty is still large, as argued by Pabón-Caicedo et al. (2020) for the full extent of the Andes.

A number of studies project decreases in runoff and river discharge for SCA, Colombia, Brazil and the southern part of South America by the end of this century (Nakaegawa and Vergara, 2010; Arnell and Gosling, 2013; van Vliet et al., 2013). Section 11.9 assessed *high confidence* in projections of increases in hydrological droughts in NSA, SAM, SWS, and SSA under for 4°C GWL, *medium confidence* in SCA, and *low confidence* in the rest of the sub-regions given insufficient evidence, lack of signal or mixed signals among the available studies. Signals are much more uncertain for the middle of the century (or for a 2°C GWL).

Agricultural and ecological drought: Section 11.9 assessed *low confidence* in observed changes in agricultural and ecological drought across Central and South America due to regional heterogeneity and differences depending on the drought metrics used, except in NES, which has seen a dominant increase in drought severity (*medium confidence*).

NSA and SAM are the two regions where the strongest signal of increasing number of dry days (NDD) and drought frequency (DF) is projected compared to other regions of the world (Coppola et al., 2021b). By the end of this century and under RCP8.5, the NSA area average value for NDD reaches 43, 32 and 27, within the CORDEX-CORE, CMIP5 and CMIP6 ensembles respectively. For the frequency of droughts, the NSA area average value is of about 4.6, 3.4 and 3.8. For the same period and scenario, the SAM region shows NDD and DF values of 29, 20 and 21, and of 4, 3 and 3.5 respectively (Figure 12.4j–l). In Central America, a significantly drier northern region and a wetter southern region are projected for mid-century by (Hidalgo et al., 2017), whilst Fuentes-Franco et al. (2015) pointed to more pronounced dry periods during the rainy season in SCA by the end of this century under RCP8.5. Increases in the frequency of meteorological droughts that may initiate other drought types are projected for the eastern part of the Amazon and the opposite for the west under RCP8.5 (Duffy et al., 2015). In central Chile, the

occurrence of extended droughts, such as the recently experienced 2010–2015 megadrought (which is still driving impacts), is projected to increase from one to up to five events per 100 years under RCP8.5 (Bozkurt et al., 2018). Section 11.9 highlights change in confidence in increases in drought severity in SCA, NSA, NES, SAM, SWS, and SSA from *low* to *high* under the three GWLs of 1.5°C, 2°C and 4°C. NES and SES change from *low confidence* to *medium confidence* increases in agricultural and ecological drought severity by 4°C GWL with different metrics and *high agreement* between studies. Only SAM and SSA have projections of agricultural and ecological drought increasing with *high confidence* for the middle of the century, or for a 2°C GWL, and NSA, NES and SCA are projected to increase with *medium confidence*.

Fire weather: There is evidence of increases in forest fire activity (number of fires, burned area and fire duration) in central and south-central Chile, where more conducive fire weather conditions have been proposed as the main driver (González et al., 2018; Urrutia-Jalabert et al., 2018). Projections indicate that the Amazon will be one of the regions in the world with the highest increase in fire weather indices over the 21st century and under all RCPs (*high confidence*) (Betts et al., 2015; Abatzoglou et al., 2019; Q. Sun et al., 2019). This is consistent with the large increase in the frequency of joint occurrence of extreme hot and dry days projected for a 2°C warming level or more (Vogel et al., 2020). Projections of fire weather indices also show an increased risk in SWS (*high confidence*), SSA and SCA (*medium confidence*). However, wildfires highly depend on land use and appropriate management may help mitigate future increases in fire risk (Fonseca et al., 2019).

Mean precipitation is projected to change in a dipole pattern with increases in NWS and SES and decreases in NES and SWS (*high confidence*) with further decreases in NSA and SCA (*medium confidence*). There is *medium confidence* of an increase in river floods in SAM and SES. There is *high confidence* of an increase in drought duration in NES, an increase in the number of dry days and drought frequency in NSA and SAM. Dry climatic impact-drivers are projected to increase at the regional level with higher global warming levels. The strongest signal of future increase in agricultural and ecological drought, aridity and fire weather is over the Amazon region (*high confidence*).

12.4.4.3 Wind

Mean wind speed: Due to the lack of long-term homogeneous records or limited observations in the region, past wind speed trends are difficult to establish. Global climate models project an increase in wind speeds, under all future scenarios, augmenting wind power potential in most parts of Central and South America, especially in NES, where changes lie in the range 0–20% by 2050 under RCP8.5 and 0–40% under RCP8.5 (*medium confidence*) (Karnauskas et al., 2018a; Reboita et al., 2018; Jung and Schindler, 2019). In Patagonia, wind speeds are projected to decrease. For RCP4.5 changes remain marginal and have *low confidence* (*low agreement*) (Figure 12.4m–o).

Severe wind storm: Similar observational limitations inhibit an assessment of long-term extreme wind trends. However, Pes et al. (2017) found extreme wind increases in most of Brazil over the past decades. Future projections indicate a slight decrease in the number of extratropical cyclones in mid-latitudes (*limited evidence, low confidence*) (Reboita et al., 2018), and an increase of extreme winds in tropical areas (*limited evidence, low confidence*) (Kumar et al., 2015). Climate models project a shift and an intensification of southern storm tracks, with most effects offshore over the Southern Ocean (Chapter 4), with *low confidence* (*low agreement*) of significant extreme wind changes over land and coastal areas across the 21st century (Chang, 2017; Augusto Sanabria and Carril, 2018; Reboita et al., 2021).

Tropical cyclone: CMIP5 and CMIP6 simulations, including the new High Resolution Model Intercomparison Project (HighResMIP), project a decrease in the frequency of tropical cyclones in the Atlantic and Pacific coasts of Central America for the mid-century or under a 2°C GWL, accompanied with an increased frequency of intense cyclones (*medium confidence*) (Section 11.7.1.5; Diro et al., 2014; Knutson et al., 2020; Roberts et al., 2020).

In summary, there is *limited evidence* of current trends in observed wind speed and wind storms in Central and South America. Climate projections indicate a decrease in frequency of tropical cyclones in Central America accompanied with an increased frequency of intense cyclones, and an increase in mean wind speed and wind power potential in most parts of Central and South America (*medium confidence*).

12.4.4.4 Snow and Ice

Snow: Historical studies of seasonal snow cover are limited and restricted to the Andes Cordillera. Mernild et al. (2017) indicated that much of the area north of 23°S experienced a decrease in the number of snow cover days, while the southern half of the Andes Cordillera experienced the opposite. A reduction in snow cover of about 15% was simulated for areas with altitudes in the range of 3000–5000 m, whereas in regions with altitude below 1000 m (Patagonia) snow cover extent increased. The reduced snowfall over the Chilean and Argentinean Andes mountains, which has resulted in unprecedented reductions in river flow, reservoir volumes and groundwater levels, led to the most severe and long-lasting hydrological drought (2010–2015) reported in the adjacent semi-arid foothills of the central Andes (Garreaud et al., 2017; Rivera et al., 2017; Masiokas et al., 2020). Projections (based on process understanding) in Section 9.5.3.3 point to decreases in seasonal snow cover extent and duration across South America as global climate continues to warm (*high confidence*).

Glacier: Observation and future projection of Central and South America glacier mass changes are assessed in Section 9.5.1, grouped in two main regions: Low Latitude region (98% of which is glaciers in the Andes) and the Southern Andes region. An increase in the number and areal extent of glacial lakes in the Southern Andes was reported for the period 1986–2016 (Wilson et al., 2018). Similar changes are being observed in the central Andes (Colonia et al., 2017). Since 1800 at least 15 ice-dammed lakes and 16 moraine-dammed lakes have failed in the extratropical Andes, causing high-magnitude glacial lake

outburst floods (Rojas et al., 2014; Cook et al., 2016; Wilson et al., 2018; Drenkhan et al., 2019). Partially due to glacier shrinkage and lake growth, the frequency of outburst floods has increased in the last 30–40 years (Carey et al., 2012; Iribarren Anaconda et al., 2015).

Glaciers across South America are expected to continue to lose mass and glacier area in the coming century (*high confidence*) (Section 9.5). In terms of their mass, glaciers in the Low Latitude region are projected by GlacierMIP to lose $67 \pm 42\%$, $86 \pm 24\%$ and $94 \pm 13\%$, of their 2015 baseline mass by the end of the century under RCP2.6, RCP4.5 and RCP8.5 respectively (Marzeion et al., 2020). Glaciers in the Southern Andes show decreasing mass loss rates for RCP2.6, and increasing rates for RCP8.5, which peak in the mid to late 21st century. Glaciers in the Southern Andes are projected to lose $26 \pm 27\%$, $33 \pm 26\%$ and $47 \pm 26\%$ of their 2015 mass by the end of the century under RCP2.6, RCP4.5 and RCP8.5 respectively (Section 9.5.1.3).

The central Andes will experience the highest disturbance to the thermal regime of the 21st century. As a consequence, in the Argentinean Andes up to 95% of rock glaciers in the southern desert Andes and in the central Andes will rest in areas above 0°C under the worst case scenario of warming (the freezing level might move up more than twice as much as during the entire Holocene; Drewes et al., 2018)

Permafrost: There is limited information on the ongoing changes and projections of permafrost conditions in the region. Based on model projections under the IPCC A1B scenario, permafrost areas in the Bolivian Andes will eventually be lost, but this could take years to decades or longer depending on permafrost thickness (Rangecroft et al., 2016).

In conclusion, glacier volume loss and permafrost thawing will continue in the Andes Cordillera under all climate scenarios (*high confidence*), causing important reductions in river flow and potentially high-magnitude glacial lake outburst floods.

12.4.4.5 Coastal and Oceanic

Relative sea level: Around Central and South America, over 1900–2018, a new tide gauge-based reconstruction finds a regional mean relative sea level (RSL) change of $2.07 [1.36 \text{ to } 2.77] \text{ mm yr}^{-1}$ in the South Atlantic, $2.49 [1.89 \text{ to } 3.06] \text{ mm yr}^{-1}$ in the subtropical North Atlantic and $1.20 [0.76 \text{ to } 1.62] \text{ mm yr}^{-1}$ in the East Pacific (Frederikse et al., 2020), compared to a global mean sea level (GMSL) change of around 1.7 mm yr^{-1} (Section 2.3.3.3 and Table 9.5). For the period 1993–2018, these RSLR rates, based on satellite altimetry, increased to $3.45 [3.04 \text{ to } 3.86] \text{ mm yr}^{-1}$, $4.04 [2.77 \text{ to } 5.24] \text{ mm yr}^{-1}$ and $2.35 [0.70 \text{ to } 4.06] \text{ mm yr}^{-1}$ respectively (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr^{-1} (Section 2.3.3.3 and Table 9.5).

Relative sea level rise is *extremely likely* to continue in the oceans around Central and South America. Regional mean RSLR projections for the oceans around Central and South America range from $0.3\text{--}0.5 \text{ m}$ under SSP1-2.6 to $0.5\text{--}0.9 \text{ m}$ under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), which is around the projected GMSL change (Section 9.6.3.3). These RSLR projections may, however,

be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

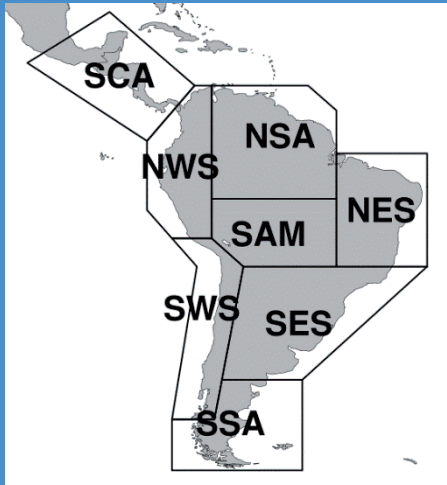

Coastal flood: The present-day 1-in-100-year ETWL ranges from 0.5 to 2.5 m around most of Central and South America, except in SSA and SWS, where 1-in-100-year ETWLs can be as large as 5 to 6 m (Vousdoukas et al., 2018). ETWL magnitude and occurrence frequency are expected to increase throughout the region (*high confidence*) (Figure 12.4p–r and Figure 12.SM.6). Across the region, the 5–95th percentile range of the 1-in-100-year ETWL is projected to increase (relative to 1980–2014) by $8\text{--}34 \text{ cm}$ and by $10\text{--}43 \text{ cm}$ by 2050 under RCP4.5 and RCP8.5 respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). By 2100, this range is projected to be $21\text{--}93 \text{ cm}$ and $34\text{--}190 \text{ cm}$ under RCP4.5 and RCP8.5 respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, under RCP4.5, the present-day 1-in-100-year ETWL is projected to have median return periods of 1-in-10-years to 1-in-50-years by 2050 and 1-in-1-year by 2100 in SES, SSA and SWS. In other regions of Central and South America, the present-day 1-in-100-year ETWL is projected to occur once per year or more by both 2050 and 2100 under RCP4.5. The present-day 1-in-50-year ETWL is projected to occur around three times a year by 2100 with a SLR of 1 m (Vitousek et al., 2017).

Coastal erosion: According to satellite data, shoreline retreat rates of around 1 m yr^{-1} have been observed along the sandy coasts of SCA, SES and SSA over the period 1984–2015, while shoreline progradation rates of around 0.25 m yr^{-1} has been observed in NWS and NSA. The sandy shorelines in NES and SWS have remained more or less stable over the same period (Luijendijk et al., 2018; Mentaschi et al., 2018). Using satellite observations, Mentaschi et al. (2018) report a coastal area loss of 250 km^2 over a 30-year period (1984–2015) along the Pacific coast of South America, and of 780 km^2 along the Atlantic coastlines.

Projections indicate that a majority of sandy coasts in the region will experience shoreline retreat throughout the 21st century (*high confidence*). Median shoreline change projections (CMIP5) for the mid-century period show that, relative to 2010, sandy shorelines will retreat by between 30 and 75 m in SCA, NES, SES and SSA under both RCP4.5 and RCP8.5, while the projected mid-century retreats are less than 30 m in NSA, NWS and SWS for both RCPs (Vousdoukas et al., 2020b). Parts of the coastline in these latter three regions are projected to prograde over the 21st century, if present ambient shoreline change trends continue (Vousdoukas et al., 2020b). By 2100, median retreats of more than 100 m are projected in SCA, NES, SES and SSA under both RCPs, while retreats between $50\text{--}100 \text{ m}$ are projected for NSA, NWS and SWS under both RCPs (Figure 12.8). Notably, the projected shoreline retreats in SCA and SES approach 150 m by 2100 under RCP4.5 and 200 m under RCP8.5. The total length of sandy coasts in Central and South America that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about $12,000$ and $15,000 \text{ km}$ respectively, an increase of approximately 30% .

Marine heatwave: The mean sea surface temperature (SST) of the Atlantic Ocean and the Caribbean around Central and South America increased from 0.25°C to 1°C over the period 1982–1998 (Oliver et al., 2018). This mean ocean surface warming is connected to longer

Table 12.6 | Summary of confidence in direction of projected change in climatic impact-drivers in Central and South America, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2 and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2.

1. Increase in extreme flow in the Amazon basin.
2. Tropical cyclones decrease in number but increase in intensity.
3. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.
4. Substantial parts of the NWS, NSA and NES coasts are projected to prograde if present-day ambient shoreline change rates continue.

- Already emerged in the historical period (*medium to high confidence*)
- Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)
- Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

and more frequent marine heatwaves (MHW) in the region (Oliver et al., 2018). Over the period 1982–2016, the coastlines experienced on average more than 1.0 MHW per year, with the Pacific coast of Northern Central America and the coast of SES (Atlantic) experiencing on average 2.5–3 MHWs per year. The average duration was between 10 and 15 days, with the notable exception of the equatorial Pacific coastline, which experiences MHWs with >30 days average duration related to ENSO conditions. In the south-western Atlantic shelf (32–38°S), more than half of the days with MHWs have occurred since 2014, and the most intense event (1.7°C above previous maximum) took place in the austral summer of 2017 (Manta et al., 2018). Changes over the 20th century, derived from MHW proxies, show an increase in frequency between 0.5 and 2 MHW per decade in the South Atlantic, the Caribbean and the Pacific coast of Northern Central America, an increase in intensity per event in the South Atlantic, and a decrease along the equatorial Pacific coastline. The total number of MHW days per year increases around Central and South America, with the exception of the equatorial Pacific coastline (Oliver et al., 2018).

There is *high confidence* that MHWs will increase around Central and South America. Mean SST is projected to increase by 1°C (2°C) by 2100, with a hotspot of about 2°C (4°C) along the coast of South-Eastern South America and North-Western South America under RCP4.5 (RCP8.5; Interactive Atlas). More frequent MHWs are projected around the region for GWLs of 1.5°C, 2°C and 3.5°C relative to the modelled reference value for 1861–1880 (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Central and South America by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

In summary, relative sea level rise is *extremely likely* to continue in the oceans around Central and South America, contributing to increased coastal flooding in low-lying areas (*high confidence*) and shoreline retreat along most sandy coasts (*high confidence*). Marine heatwaves are also expected to increase around the region over the 21st century (*high confidence*).

The assessed direction of change in climatic impact-drivers for Central and South America and associated confidence levels are illustrated in Table 12.6. No assessable literature could be found for sand and dust storm, lake and sea ice, heavy snowfall and ice storms, hail and snow avalanches, although these phenomena may be relevant in parts of the region.

12.4.5 Europe

The regional European climate and main hazards have been previously assessed in SREX, AR5 WGII, SR1.5, SROCC and SRCLL and a summary of key findings can be found in the Europe section of Atlas.8.1. For the purpose of this assessment Europe is divided into four climatic regions: Northern Europe (NEU), Western and Central Europe (WCE), Eastern Europe (EEU) and Mediterranean (MED) (Figure Atlas.24).

Since AR5 and SR1.5, a large body of literature that uses the EURO-CORDEX and MED-CORDEX ensembles of high-resolution simulations (Jacob et al., 2014; Ruti et al., 2016; Kjellström

et al., 2018; Vautard et al., 2020; Coppola et al., 2021a) to assess signals of climate change in Europe has emerged. These scenario-based simulations have been the basis of a number of impact studies (e.g., Jacob et al., 2014, 2018; Somot et al., 2018; Faggian and Decimi, 2019) highlighting the use of the climatic impact-drivers. The development of the science of attribution of weather events (Stott et al., 2016) has provided evidence of links between climate change and hazard changes such as the 2017 Mediterranean heatwave (Kew et al., 2019) and many others (Chapter 11).

The ability of global and regional models to reproduce the observed changes in mean and extreme temperature and precipitation in Europe is assessed in the literature (Atlas.8.3). In summary, both GCMs and RCMs have their limitations but, in general, the increased resolution of RCMs is shown to clearly add value in terms of resolving spatial patterns and seasonal cycles of precipitation and precipitation extremes in many European regions, especially in regions of complex topography such as the Alps and for quantities such as snowmelt-driven runoff, regional winds and Mediterranean hurricanes (Medicanes).

Examples of projected climatic impact-driver thresholds are illustrated in Figures 12.4 and 12.9 based on the most recently updated EURO-CORDEX RCM projections, CMIP5 and CMIP6 GCMs for comparison. For a more comprehensive representation of other climatic impact-driver index trends assessed in this section the reader is referred to the interactive Atlas.

12.4.5.1 Heat and Cold

Mean air temperature: Since AR5, studies have confirmed that the mean warming trend in Europe is increasing (Atlas.8.2). The observed warming trend patterns are largely consistent with those simulated by global and regional climate models and it is *very likely* that such trends are, in large part, due to human influence on climate (Section 3.3.1).

All temperature trends are *very likely* to continue for a global warming of 1.5°C or 2°C and 3°C (Atlas.8.4). Future warming leads to the exceedance of different temperature thresholds relevant for vector-borne diseases (*medium confidence*) (Caminade et al., 2012; Medlock et al., 2013), invasive allergens (*medium confidence*) (Storkey et al., 2014; Hamaoui-Laguel et al., 2015), SST thresholds in the Mediterranean (*likely* to exceed 20°C), or relevant for the *Vibrio* bacteria development (Vezzulli et al., 2015). Future warming is also projected to lead to the exceedance of cooling degree day index (>22°C) thresholds, characterizing a potential increase in energy demand for cooling in southern Europe with increases *likely* exceeding 40% in some areas (Spinoni et al., 2015) by 2050 under RCP8.5 (*high confidence*) (Section 12.3 and Atlas.8; Coppola et al., 2021a).

Extreme heat: The frequency of heatwaves observed in Europe has *very likely* increased in recent decades due to human-induced change in atmospheric composition (Section 11.3) and a detectable anthropogenic increase in a summer heat stress index over all regions of Europe has been identified based on WBGT index trends for 1973–2012 (*medium confidence, limited evidence*) (Knutson and Ploshay, 2016).

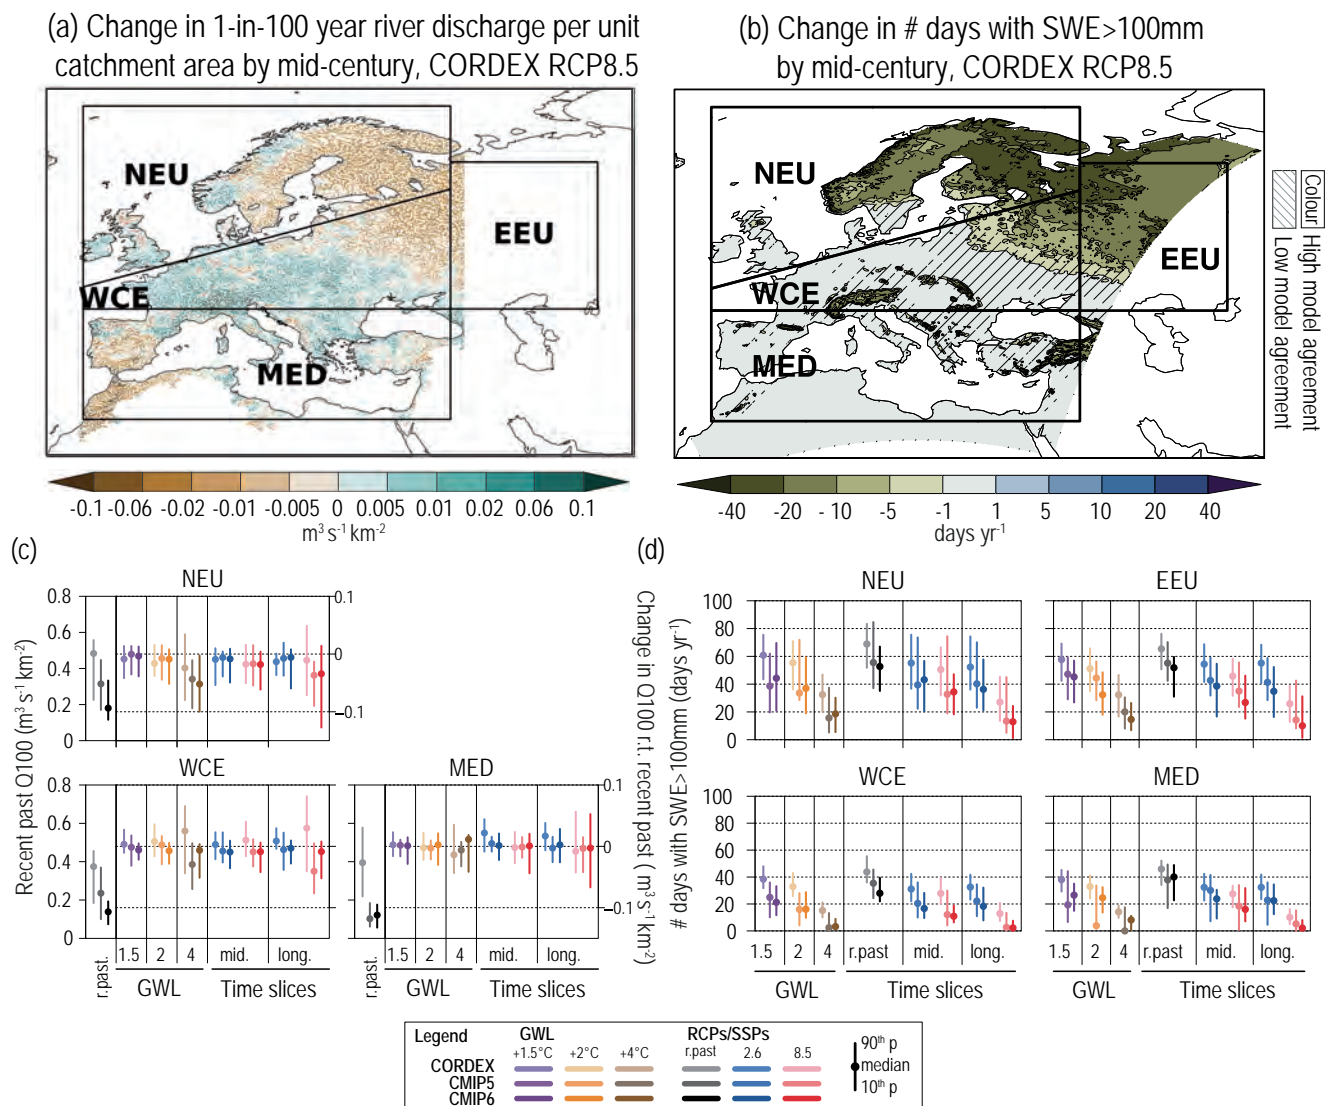

Figure 12.9 | Projected changes in selected climatic impact-driver indices for Europe. (a) Mean change in 1-in-100-year river discharge per unit catchment area (Q100 , $\text{m}^3 \text{s}^{-1} \text{km}^{-2}$), and (b) median change in the number of days with snow water equivalent (SWE) over 100 mm (from November to March), from EURO-CORDEX models for 2041–2060 relative to 1995–2014 and RCP8.5. Diagonal lines indicate where less than 80% of models agree on the sign (direction) of change. (c) Bar plots for Q100 ($\text{m}^3 \text{s}^{-1} \text{km}^{-2}$) averaged over land areas for the AR6 WGI Reference Regions (defined in Chapter 1). The left-hand column within each panel (associated with the left-hand y-axis) shows the 'recent past' (1995–2014) Q100 absolute values in grey shades. The other columns (associated with the right-hand y-axis) show the Q100 changes relative to the recent past values for two time periods ('mid' 2041–2060 and 'long' 2081–2100) and for three global warming levels (defined relative to the pre-industrial period 1850–1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10–90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) As for (c) but showing absolute values for number of days with SWE > 100mm, masked to grid cells with at least 14 such days in the recent past. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

It is *very likely* that the frequency of heatwaves will increase during the 21st century regardless of the emissions scenario in each European region, and for 1.5°C and 2°C GWLs (Section 11.3.5). Heat stress due to both high temperature and humidity, affecting morbidity, mortality and labour capacity (Section 12.3) is projected to increase under all emissions scenarios and GWLs by the middle of the century (Figure 12.4a–f). Under RCP8.5, the expected number of days with WBGT higher than 31°C is about 25, 30 and 40 days per year, as projected by EURO-CORDEX, CMIP5 and CMIP6 respectively on average over the Mediterranean region, and around 30, 40 and 60 days per year in low coastal plain areas such as the Po Valley, the Italian, Greek and Spanish coasts, and the Mediterranean islands (Coppola

et al., 2021a). An average increase of a few days per year of maximum daily temperature exceeding 35°C, a typical critical threshold for crop productivity, is expected by the mid-century in central Europe, and an increase of 10–20 days is expected for the Mediterranean areas (Figure 12.4b; Coppola et al., 2021a). By contrast, under SSP1-2.6, the increase in this number of days remains limited to less than about 10 days, and confined to the Mediterranean regions. Mitigation is expected to have a strong effect, with the dangerous heat threshold of $\text{HI} > 41^\circ\text{C}$ projected to be crossed 5–10 days more per year in the Mediterranean regions and a few days per year more in WCE and EEU under SSP5-8.5, while such increases would be virtually absent under SSP1-2.6 (Figure 12.4d–f).

Cold spell and frost: Temperature observations for winter cold spells in Europe show a long-term decreasing frequency (Brunner et al., 2018), with their probability of occurrence projected to decrease in the future (*high confidence*) and virtually disappear by the end of the century (Section 11.3). The frequency of frost days will *very likely* decrease for all scenarios and all time horizons (Lindner et al., 2014; Coppola et al., 2021a) with consequences for agriculture and forests. A simple heating degree day index, characterizing heating demand, shows a large observed decreasing trend for winter heating energy demand in Europe (Spinoni et al., 2015). This trend is *very likely* to continue through the 21st century, with decreases in the range of 20–30% for Northern Europe, about 20% for central Europe and 35% for southern Europe, by mid-century under RCP8.5 (Spinoni et al., 2018b; Coppola et al., 2021a; Interactive Atlas).

In summary, irrespective of the scenario, it is *virtually certain* that warming will continue in Europe, and there is *high confidence* that the observed increase in heat extremes is due to human activities. It is *very likely* that the frequency of heat extremes will increase over the 21st century with an increasing gradient toward the southern regions. Extreme heat will exceed critical thresholds for health, agriculture and other sectors more frequently (*high confidence*), with strong differences between mitigation scenarios. It is *very likely* that the frequency of cold spells and frost days will keep decreasing over the course of this century and it is *likely* that cold spells will virtually disappear towards the end of the century.

12.4.5.2 Wet and Dry

Mean precipitation: Precipitation has generally increased in northern Europe and decreased in southern Europe, especially in winter (Fischer and Knutti, 2016; Knutson and Zeng, 2018) but in the latter, precipitation trends are strongly dependent on the examined period (Atlas.8). These trends in precipitation increases in the north and decreases in the south are also represented by global and regional climate simulations (Jacob et al., 2014; Rajczak and Schär, 2017; Lionello and Scarascia, 2018; Coppola et al., 2021a; Atlas.8.2) and have been attributed to climate change (Sections 3.3.2, 8.3.1).

Studies since AR5, together with EURO-CORDEX and MED-CORDEX experiments and the latest CMIP6 ensemble, have increased confidence in regional projections of mean and extreme precipitation (Prein et al., 2016) despite their wet bias, and show that it is *very likely* that precipitation will increase in Northern Europe in DJF and decrease in the Mediterranean in JJA under all climate scenarios except RCP2.6/SSP1-2.6 and for both mid- and end-century periods (Coppola et al., 2021a; Atlas.8.5).

River flood: There is *high confidence* of an observed increasing trend of river floods in Western and Central Europe (WCE) and *medium confidence* of a decrease in Northern (NEU) and southern Europe (MED).

The SR1.5 shows evidence of an increase in reported floods in the UK over the period 1884–2013, and increasing trends in annual maximum daily streamflow data over 1966–2005 in parts of Europe. Although

high flow does not show uniform trends for the entire region (Hall et al., 2014; Mediero et al., 2015) or specific regions (Mudersbach et al., 2017; Vicente-Serrano et al., 2017; Trambly et al., 2019), regional patterns of significant flood trends do exist. Based on the most extended river flow database spanning the period 1960–2010, an increase in floods frequency in north-western Europe, decreasing in medium and large catchments in southern Europe and decreasing floods in Eastern Europe has been detected (Blöschl et al., 2019) in line with Mediero et al. (2014), Arheimer and Lindström (2015), Gudmundsson et al. (2017), Krysanova et al. (2017), Kundzewicz et al. (2018) and Mangini et al. (2018).

There is *high confidence* of river floods increasing in Western and Central Europe (WCE) and *medium confidence* of a decrease in Northern (NEU), Eastern (EEU) and southern Europe (MED) for mid- and end-century under RCP8.5 and *low confidence* under RCP2.6. The projected increase in WCE is roughly 10% (18% by end of century) and the projected decrease in NEU is 5% (11% by end of century) for the peak flow with a return period of 100 years for mid-century, under RCP8.5 (Di Sante et al., 2021; Figure 12.9a for mid-century (Q100) projections of flood discharges per unit catchment area (Blöschl et al., 2019) based on EURO-CORDEX models).

Using frequency analysis of extreme peak flow events above a 100-year return period as a threshold, which is the average protection level of the European river network (Rojas et al., 2013), Alfieri et al. (2017) and Alfieri et al. (2015) show that Europe is one of the regions where the largest increases in flood risk may occur, with only few countries in Eastern Europe showing a decrease (Poland, Lithuania, Belarus) (Osuch et al., 2017). They find a significant increase of events with peak discharge above 100-year return period (Q100) in most of Europe in line with Rojas et al. (2012), Hirabayashi et al. (2013), Dankers et al. (2014), Forzieri et al. (2016), Roudier et al. (2016), Thober et al. (2018), and an increase in the magnitude of floods in southern Europe, although Giuntoli et al. (2015) projects no change. A modest but significant decrease in the 100-year return period river flood is projected for southern (due to reduction of precipitation) and north-eastern European regions, the latter because of the strong reduction in snowmelt induced river floods (Thober et al., 2018; Di Sante et al., 2021).

Heavy precipitation and pluvial flood: Heavy precipitation frequency trends have been detected in Europe with *high confidence* for the NEU and Alpine regions and with *medium confidence* in WCE, and also attributed to climate change with *high confidence* in NEU (Section 11.9). Guerreiro et al. (2017), based on observations, showed that 20% of city areas in WCE and MED regions are affected by pluvial flooding and less than 10% of city areas in the northern and western coastal cities.

Projections based on multiple lines of evidence from global to convective permitting model scales show *high confidence* in extreme precipitation increase in the northern, central and eastern European regions (NEU, WCE, EEU) and in the Alpine area. Increases with *medium confidence* are projected for the Mediterranean basin (with a negative gradient towards the south) for mid- and end-century under RCP4.5, RCP8.5 and SSP5-8.5 and for 2°C GWL and higher (Section 11.9; MedECC, 2020).

Landslide: Rainfall periods connected to landslides are projected to increase in central Europe by up to one more period per year in flat areas in low altitudes and by up to 14 more periods per year at higher altitudes by mid-century, becoming even more evident by the end of the century (Schlögl and Matulla, 2018). An increase of landslides by up to 45.7% and 21.2% is projected for southern Italy (Calabria region) by mid-century under both RCP4.5 and RCP8.5 (Gariano and Guzzetti, 2016) and by up to 40% in central Italy (Umbria) during the winter season (Ciabatta et al., 2016). A decrease of landslides is projected in the Peloritani mountains in southern Italy (RCP4.5 and 8.5) by mid-century (Peres and Cancelliere, 2018). A slight increase for a 10-year return period landslide is projected in the eastern Carpathians, the Moldavian Subcarpathians and the northern part of the Moldavian Tableland and a higher increase in the 100-year return period event is projected in the western hilly and plateau areas of Romania (Jurchescu et al., 2017).

Aridity: The Mediterranean region shows evidence of large-scale decreasing precipitation trends over 1901–2010, which are at least partly attributable to anthropogenic forcing according to CMIP5 models (Knutson and Zeng, 2018). Nevertheless, there is *low agreement* among studies on observed precipitation trend in the Mediterranean region (Section 11.9.4 and Atlas.8.2).

Precipitation is projected to decrease by mid- and end-century for the RCP8.5 and SSP5-8.5 with *strong agreement* among CMIP5, CMIP6 and CORDEX regional climate ensemble models on the direction of change. With both temperature increase and precipitation decrease there is *high confidence* on increased aridity in the MED region (Sections 8.4.1.6 and 11.9.4 and Atlas.8.2; Coppola et al., 2021a). In NEU there is *high confidence* of decrease in aridity linked to mean precipitation increase (Section 8.4.1.6, Atlas 8.2) and meteorological drought decrease based on indicators like Standardized Precipitation Index and consecutive dry days (Section 11.9.4, Figure 12.4, Coppola et al., 2021a).

Hydrological drought: There is *high confidence* that hydrological droughts have increased in the Mediterranean basin with *medium confidence* in anthropogenic attribution of the signal, and *high confidence* that they will continue to increase through the 21st century for 2°C GWL and higher and all scenarios except RCP2.6/SSP1-2.6. (Sections 8.3.1.6, 8.4.1.6, and 11.9.4). There is *medium confidence* in hydrological drought increase in WCE and *low confidence* in direction of change for EEU and NEU from mid-century onwards and for 2°C GWL and higher and all scenarios except RCP2.6/SSP1-2.6 (Section 11.9 and Figure 12.4g–i).

Streamflow droughts are projected to become more severe and persistent in the Mediterranean and western Europe (current 100-year events could occur approximately every 2–5 years by 2080; Forzieri et al., 2016).

The opposite tendency is projected in Northern, Eastern and central Europe where higher precipitation that outweighs the effects of increased evapotranspiration is expected to result in a decrease in streamflow drought frequency (Forzieri et al., 2014). For a 2°C GWL droughts will become more intense in the MED and in France and longer mainly due to less rainfall and higher evapotranspiration.

A reduction of drought length and magnitude is projected for NEU and EEU (Roudier et al., 2016). In the southern Alps, both winter and summer low flows are projected to be more severe, with a 25% decrease in the 2050s (Vidal et al., 2016).

Agricultural and ecological drought: There is *medium confidence* that agricultural and ecological droughts have increased in Western and Central Europe and in the Mediterranean region, and *medium confidence* that anthropogenic drivers contributed to the Mediterranean increase (Sections 8.3.1.6 and 11.9).

Chapter 11 assesses that agricultural and ecological droughts will increase in the Mediterranean regions (*high confidence*) and Western and Central Europe (*medium confidence*) by mid-century and with *high confidence* by the end of the century for the MED for 2°C GWL and higher and all scenarios except RCP2.6/SSP1-2.6 (Section 11.9.4). *Low confidence* in direction of change is assessed for EEU and NEU under all scenarios and global warming levels (Figure 12.4k).

Recent local studies provide additional risk-relevant context to changes in European drought. Agricultural and ecological drought conditions are expected to intensify in southern Europe by end-of-century based on the 12-month rainfall Drought Severity Index (a soil moisture indicator), precipitation deficit SPI and SPEI indices. There will be regions in southern Europe where this type of drought could be up to 14 times worse than the worst drought in the historical period (Guerreiro et al., 2018). One-in-10-year drought events are projected to happen every second year (Mora et al., 2018; Ruosteenoja et al., 2018). The Mediterranean region will have 100 additional stress years (years with three consecutive months of precipitation deficits greater than 25%; Giorgi et al., 2018); an increase of both drought frequency (up to two events per decade) and severity (Spinoni et al., 2014, 2020) and an increase of consecutive dry days in the southern part of the MED region (Lionello and Scarascia, 2020). In contrast, droughts are expected to decrease in winter in Northern Europe (Section 11.9; Spinoni et al., 2018a). These findings are confirmed by the EURO-CORDEX, CMIP5 and CMIP6 ensemble that show a change of frequency of drought events in the MED between 2–3 events per decade by mid-century for scenario RCP8.5 (Figure 12.SM.3; Coppola et al., 2021a).

Fire weather: Fire weather conditions have been increasing since about 1980 over a few regions in Europe including Mediterranean areas (*low confidence*) (Venäläinen et al., 2014; Urbietta et al., 2019; Barbero et al., 2020; Giannaros et al., 2021). However, beyond a few studies, evidence is largely missing on attribution of these trends to anthropogenic climate change (Forzieri et al., 2016). An increase in fire weather is projected for most of Europe, especially western, eastern and central regions, by 2080 (current 100-year events will occur every 5–50 years), with a progressive increase in confidence and model agreement along the 21st century (*medium confidence*) (Forzieri et al., 2016; Abatzoglou et al., 2019). With increased drying and heat combined, in Mediterranean areas, an increase in fire weather indices is projected under RCP4.5 and RCP8.5, or SRES A1B, as early as by mid-century (*high confidence*) (Bedia et al., 2014; Abatzoglou et al., 2019; Dupuy et al., 2020; Fargeon et al., 2020; Ruffault et al., 2020) and an increase in burned area of 40% and 100% for a 2°C and 3°C GWL, respectively (Turco et al., 2018).

In summary, there is *high confidence* that river floods will increase in central and Western Europe and *medium confidence* that they will decrease in Northern, Eastern and southern Europe, for mid- and end of century under RCP8.5 and with *low confidence* under RCP2.6. There is *high confidence* that aridity will increase by mid- and end-century under the RCP8.5 and SSP5-8.5, and *high confidence* that agricultural, ecological and hydrological droughts will increase in the Mediterranean region by mid- and far end of century under all RCPs except RCP2.6/SSP1-2.6 and also for 2°C and higher GWLs. There is *high confidence* in fire weather increase in the Mediterranean region.

12.4.5.3 Wind

Mean wind speed: Mean surface wind speeds have decreased in Europe as in many other areas of the Northern Hemisphere over the past four decades (*medium confidence*) (AR5 WGI), with a reversal to an increasing trend in the last decade (*low confidence*) that is, however, not fully consistent across studies (Tian et al., 2019; Zeng et al., 2019; Z. Zhang et al., 2019; Deng et al., 2021; see Section 2.3.1.4.4). Re-analyses also show declining winds in Europe (Deng et al., 2021) with large interdecadal variability (Laurila et al., 2021). The declining trend has induced a corresponding decline in wind power potential indices across Europe (*low confidence*) (Tian et al., 2019). However, there is *low agreement* and *limited evidence* that climate model historical trends are consistent with observed trends (Tian et al., 2019; Deng et al., 2021). Several factors have been attributed to these trends, including forest growth, urbanization, local changes in wind measurement exposure and aerosols (Bichet et al., 2012), as well as natural variability (Zeng et al., 2019).

Due to changes in mean surface wind speed patterns (C. Li et al., 2018) and the poleward shift of the North Atlantic jet stream exit, mean surface wind speeds are projected to decrease in the Mediterranean areas under RCP4.5 and RCP8.5 by the middle of the century and beyond, or for GWLs of 2°C and higher (*high confidence*), with a subsequent decrease in wind power potential (*medium confidence*) (Hueging et al., 2013; Tobin et al., 2015, 2018; Davy et al., 2018; Karnauskas et al., 2018a; Kjellström et al., 2018; Moemken et al., 2018; Figure 12.4). However, sub-regional patterns of change are shown in regional climate models, such as an increase in wind speeds in the Aegean Sea and in the northern Adriatic Sea, where a reduction of Bora events and an increase of Scirocco events are projected for mid-century and beyond under RCP4.5 and RCP8.5 (*medium confidence*) (Tobin et al., 2016; Davy et al., 2018; Belušić Vozila et al., 2019). Projections (as cited above) also indicate a decrease in mean wind speed in Northern Europe (*medium confidence, medium agreement*) (Karnauskas et al., 2018a; Tobin et al., 2018; Jung and Schindler, 2019). Daily and interannual wind variability is projected to increase under RCP8.5 only in Northern Europe (*low confidence*) (Moemken et al., 2018), which can influence electrical grid management and wind energy production (*low confidence*). Wind speeds are projected to shift towards more frequent occurrences below thresholds inhibiting wind power production (Weber et al., 2018). Wind stagnation events may become more frequent in future climate scenarios in some areas of Europe in the second half of the 21st century (Horton et al., 2014; Vautard et al., 2018), with potential consequences on air quality (*low confidence*).

Severe wind storm: There are large uncertainties in past evolutions of windstorms and extreme winds in Europe. Extreme near-surface winds have been decreasing in the past decades (Smits et al., 2005; Tian et al., 2019; Vautard et al., 2019) according to near-surface observations. Significant negative trends of cyclone frequency in spring and positive trends in summer have been found in the Mediterranean basin for the period 1979–2008 (Lionello et al., 2016). By contrast increasing trends have been found in Arctic Ocean areas (Wickström et al., 2020). These trends are not associated with significant trends in extratropical cyclones (Sections 8.3.2.8 and 11.7.2).

There is *medium confidence* that serial clustering of storms, inducing cumulated economic losses, in future climate will increase in many areas in Europe under climate projections over Europe (Karremann et al., 2014; Economou et al., 2015). Strong winds and extratropical storms are projected to have a slightly increasing frequency and amplitude in the future in northern, western and Central Europe (Outten and Esau, 2013; Feser et al., 2015; Forzieri et al., 2016; Mölter et al., 2016; Ruosteenoja et al., 2019a; Vautard et al., 2019) under RCP8.5 and SRES A1B by the end of the century (*medium confidence*), as well as off the European coasts (Martínez-Alvarado et al., 2018) due to the increase of intensity of extratropical storms at a 2°C GWL or above (Zappa et al., 2013) in these areas. The frequency of storms, including Medicanes, is projected to decrease in Mediterranean regions, and their intensities are projected to increase, by the middle of the century and beyond for SRES A1B, A2 and RCP8.5 (*medium confidence*) (Nissen et al., 2014; Feser et al., 2015; Forzieri et al., 2016; Mölter et al., 2016; Tous et al., 2016; Romera et al., 2017; González-Alemán et al., 2019; MedECC, 2020; Chapter 11).

Projections of smaller-scale hazard phenomena such as tornadoes, wind gusts, hail storms and lightning are currently not directly available partly due to the inability of climate models to simulate such phenomena. Observational networks for such phenomena usually lack homogeneity over long periods, hindering clear trends to be detected. For instance, while no robust trends have been identified (Hermida et al., 2015; Mohr et al., 2015a; Burcea et al., 2016; Ćurić and Janc, 2016), hail storm environments (favourable atmospheric configurations) have increased in frequency (*low confidence, limited evidence*) (Sanchez et al., 2017). In future climate periods it is *more likely than not* that severe convection environments will become more frequent by the end of the century under RCP8.5 (Mohr et al., 2015b; Púčik et al., 2017), and there is *medium confidence* that such environments will become more frequent by the 2050s in RCP4.5. There is no evidence for changes in tornado frequencies in Europe in the observations (Groenemeijer and Kühne, 2014) as well as in future climate projections. Insufficient observational record length for lightning numbers does not allow an assessment of trends.

There is *high confidence* that mean wind speeds will decrease in Mediterranean areas and *medium confidence* of such decreases in Northern Europe for global warming levels of 2°C or more and beyond the middle of the century. A slightly increased frequency and amplitude of extratropical cyclones, strong winds and extratropical storms is projected for northern, central and western Europe by the middle of the century and beyond and for global warming levels of 2°C or higher (*medium*

confidence). The frequency of Medicanes is projected to decrease (*medium confidence*), but their intensity is projected to increase by mid century and beyond and for global warming levels of 2°C or more. Proxies of intense convection indicate that the large-scale conditions conducive to severe convection will tend to increase in the future climate (*low confidence*).

12.4.5.4 Snow and Ice

Snow: Widespread and accelerated declines in snow depth (Fontrodona Bach et al., 2018) and snow water equivalent (Marty et al., 2017a; see Figure 12.9b) have been observed in Europe. In the Pyrenees a slow snow cover decline has been observed starting from the industrial period with a sharp increase since 1955 (López-Moreno et al., 2020). Under the RCP2.6, RCP4.5 and RCP8.5 scenarios the reliability elevation for snowmaking will rise by 200–300 m in the Alps and 400–600 m in the Pyrenees by mid-century. End of century projections of natural snow conditions are highly dependent on the scenario, being stationary for the RCP2.6 and continuously decreasing under RCP8.5 to not have any more natural snow conditions at any of the locations in the French Alps and Pyrenees (Spandre et al., 2019). Similarly Norway and Austria will also see a rising of the natural snow elevation with consequences for the ski season (Scott et al., 2020; Steiger and Scott, 2020). In the Alps, recent simulations project a reduction in snow water equivalent (SWE) at 1500 m above sea level of 80–90% by 2100 under the A1B scenario and a snow season that would start 2–4 weeks later and end 5–10 weeks earlier than the 1992–2012 average (Schmucki et al., 2015), which is equivalent to a shift in elevation of about 700 m (Marty et al., 2017b). For elevations above 3000 m above sea level, a decline in SWE of at least 10% is expected by the end of the century even when assuming the largest projected precipitation increase. Similar trends are observed for the Pyrenees and Scandinavia (López-Moreno et al., 2009; Räisänen and Eklund, 2012). For the northern French Alps above 1500 m and the Ötztal locations in the Austrian alps SWE has a similar decreasing trend altitudinally dependent for RCP2.6, RCP4.5 and RCP8.5 until mid-century and with significant differentiation among them in the second half of the century up to snow-free conditions under RCP8.5 (Hanzer et al., 2018; Verfaillie et al., 2018).

Glacier: Observations and future projections of European glacier mass changes are assessed in Section 9.5.1 grouped in two main regions: Scandinavia and central Europe regions. It is *virtually certain* that glaciers will shrink in the future and there is *medium confidence* in the timing and mass change rates (Section 9.5.1). Central Europe is one of the regions where glaciers are projected to lose substantial mass even under low-emissions scenarios (Section 9.5.1.3; MedECC, 2020). GlacierMIP projections indicate that glaciers in the central Europe region will lose $63 \pm 31\%$, $80 \pm 22\%$ and $93 \pm 13\%$ of their 2015 mass by the end of the century under RCP2.6, RCP4.5 and RCP8.5 respectively (Marzeion et al., 2020). For the same scenarios, glaciers in Scandinavia are projected to lose $55 \pm 33\%$, $66 \pm 34\%$ and $82 \pm 24\%$ of their 2015 mass. The *virtually certain* shrink in glaciers is bolstered by RCM simulations from the EURO-CORDEX ensemble, with the Global Glacier Evolution Model (GloGEM) indicating a substantial reduction of glacier ice volumes in the European Alps by 2050 (47–52% with respect to 2017 for RCP2.6, RCP4.5 and RCP8.5). Under RCP2.6, about two-thirds ($63 \pm 11\%$) of the present-

day (2017) ice volume is projected to be lost by 2100. In contrast, under the strong warming of RCP8.5, glaciers in the European Alps are projected to largely disappear by 2100 ($94 \pm 4\%$ volume loss compared to 2017; Zekollari et al., 2019).

Permafrost: In Europe, permafrost is found in high mountains and in Scandinavia, as well as in Arctic Islands (e.g., Iceland, Novaya Zemlia or Svalbard). In recent decades permafrost has been lost (Section 9.5.2) and accelerated warming at high altitudes and latitudes has favoured an increase of permafrost temperatures of the order of $0.2 \pm 0.1^\circ\text{C}$ between 2007 and 2016 (Romanovsky et al., 2018; Noetzli et al., 2019). Over the 21st century, permafrost is *very likely* to undergo increasing thaw and degradation under all scenarios (Hock et al., 2019) and it is *virtually certain* that permafrost extent and volume will decrease with increase of global warming (Section 9.5.2).

Permafrost thawing is projected to affect the frequency and magnitude of high-mountain mass wasting processes (Stoffel and Huggel, 2012). The temporal frequency of periglacial debris flows in the Alps is *unlikely* to change significantly by the mid-21st century but is *likely* to decrease during the second part of the century under the A1B scenario, especially in summer (Stoffel et al., 2011, 2014). There is *medium confidence* that most of the Northern Europe periglacial processes will disappear by the end of the century, even in the RCP2.6 scenario (Aalto et al., 2017). The magnitude of debris flow events might increase (Lugon and Stoffel, 2010) and the debris-flow season may last longer under the A1B scenario (Stoffel and Corona, 2018). Quantitative data for the European Alps is highly site dependent (Haeblerli, 2013).

Heavy snowfall, ice storms and hail: There is *low confidence* that climate change will affect ice and snow-related episodic hazards (*limited evidence*). The change in snowpack in the Alps is expected to lead to a possible reduction in overall avalanche activity by end of the century (*low confidence*), except possibly in winter and at high altitudes (Castebrunet et al., 2014).

For ice storms, or freezing rainstorms, there is also *limited evidence* due to a limited number of studies. Heavy snowfalls have decreased in frequency in the past decades and this is expected to continue in the future climate (*low confidence*) (Beniston et al., 2018). Freezing rain is projected to increase in western, central and southern Europe by the end of the century under RCP4.5 and RCP8.5 (*low confidence*) (Kämäräinen et al., 2018). Rain-on-snow events, are decreasing in northern regions (Pall et al., 2019) and by 48% on average in southern Scandinavia (Poschloed et al., 2020) due to decreases in snowfall.

In summary, future snow cover extent and seasonal duration will reduce (*high confidence*) and it is *virtually certain* that glaciers will continue to shrink. A reduction of glacier ice volume is projected in the European Alps and Scandinavia (*high confidence*). There is *high confidence* that permafrost will undergo increasing thaw and degradation over the 21st century. Most of the Northern Europe periglacial will disappear by the end of the century even for a lower emissions scenario (*medium confidence*) and the debris-flow season may last longer in a warming climate (*medium confidence*).

12.4.5.5 Coastal and Oceanic

Relative sea level: Around Europe, over 1900–2018, a new tide gauge-based reconstruction finds a regional mean RSL change of 1.08 [0.79 to 1.38] mm yr⁻¹ in the subpolar North Atlantic (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). For the period 1993–2018, the RSLR rates around Europe, based on satellite altimetry, increased to 2.17 [1.66 to 2.66] mm yr⁻¹ (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5).

Relative sea level rise is *extremely likely* to continue in the oceans around Europe. Regional mean RSLR projections for the oceans around Europe range from 0.4–0.5 m under SSP1-2.6 to 0.7–0.8 m under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), which means that there are locally large deviations from the projected GMSL change (Section 9.6.3.3). These RSLR projections may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2). The signal is strongest for the North Sea and Atlantic coasts, followed by the Black Sea. The Baltic Sea, on the contrary, shows the lowest increase due to land uplift (Vousdoukas et al., 2017). The model agreement is higher for the Mediterranean and in line with previous findings by Gualdi et al. (2013).

Coastal flood: The present-day 1-in-100-year ETWL is between 0.5 and 1.5 m in the MED basin and 2.5 and 5.0 m in the western Atlantic European coasts, around the UK and along the North Sea coast, and lower at 1.5–2.5 m along the Baltic Sea coast (Kirezci et al., 2020). Similar values are reported by Vousdoukas et al. (2018).

There is *high confidence* that extreme total water level (ETWL) magnitude and occurrence frequency will increase throughout Europe (see Figure 12.4p–r), except in the northern Baltic Sea. Across the region, the 5–95th percentile range of the 1-in-100-year ETWL is projected to increase (relative to 1980–2014) by 4–40 cm and by 6–47 cm by 2050 under RCP4.5 and RCP8.5, respectively. By 2100, this range is projected to be 6–88 cm and 25–186 cm under RCP4.5 and RCP8.5, respectively (Figure 12.SM.6; Vousdoukas et al., 2018; Kirezci et al., 2020). Mass addition across the Gibraltar Strait may play a role, although the extent of this contribution is currently unclear (Lionello et al., 2017). Furthermore, under RCP4.5, the present day 1-in-100-year ETWL is projected to have median return periods of between 1-in-5 and 1-in-20 years by 2050 and occur at least once per year by 2100 in the Mediterranean and Black Sea, while in the rest of Europe it is mostly projected to have median return periods of between 1-in-20-years and 1-in-50-years by 2050 and between 1-in-5-years and 1-in-20-years by 2100 (Vousdoukas et al., 2018). Under RCP8.5, occurrence of the present day 1-in-100-year ETWL is projected to increase further to median return periods of 1-in-1-year to 1-in-5-years by 2050 and occur more than once per year by 2100 in the Mediterranean and Black Sea, while in the rest of Europe it is mostly projected to have median return periods between 1-in-5-years and more than once per year by 2100.

Coastal erosion: Satellite-derived shoreline change estimates over 1984–2015 indicate shoreline retreat rates of around 0.5 m yr⁻¹ along the sandy coasts of WCE and MED, around 4 m yr⁻¹ in EEU (Caspian Sea region) and more or less stable shorelines in NEU

(Luijendijk et al., 2018; Mentaschi et al., 2018). Mentaschi et al. (2018) report a coastal area loss of 270 km² over a 30-year period (1984–2015) along the Atlantic coastlines of Europe.

Projections indicate that sandy coasts throughout the continent (except those bordering the northern Baltic Sea) will experience shoreline retreat through the 21st century (*high confidence*). Median shoreline change projections (CMIP5) relative to 2010, show that, by mid-century, shorelines will retreat by between 25 m and 60 m along sandy coasts in WCE and MED under both RCP4.5 and RCP8.5 (Athanasίου et al., 2020; Vousdoukas et al., 2020b). Mid-century median projections for NEU indicate virtually no shoreline retreat under RCP4.5, but a retreat of around 40 m under RCP8.5. By 2100, median shoreline retreats of around 50 m are projected in NEU and MED under RCP4.5, increasing to around 80 m under RCP8.5. End-century median projections for WCE are far higher at 100 m (RCP4.5) and 160 m (RCP8.5). The total length of sandy coasts in Europe that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 12,000 km and 18,000 km respectively, an increase of approximately 54% (Vousdoukas et al., 2020b).

Local assessments of both long term shoreline retreat and episodic coastal erosion are given by Li et al. (2014b), Toimil et al. (2017), Bon de Sousa et al. (2018) and Le Cozannet et al. (2019). In terms of episodic coastal erosion, 31–88% of all Aegean beaches are projected to experience complete erosion, with a RCP4.5 sea level rise of 0.5 m and a surge of 0.6 m, but with substantial uncertainty (Monioudi et al., 2017).

Marine heatwave: The mean SST of the Atlantic Ocean and the Mediterranean has increased between 0.25°C and 1°C since 1982–1998. This mean ocean surface warming is correlated to longer and more frequent marine heatwaves in the region (Oliver et al., 2018). Over the period 1982–2016, the coastlines of Europe experienced on average more than 2.0 MHW yr⁻¹, with the eastern Mediterranean and Scandinavia experiencing 2.5–3 MHWs yr⁻¹. The average duration was between 10 and 15 days. Changes over the 20th century, derived from MHW proxies, show an increase in frequency of between 1.0 and 2.0 MHWs per decade in Europe, although the trend is not statistically significant; with an increase in intensity per event in the North Atlantic and the Mediterranean, and a decrease in the Atlantic off the British Isles. The total number of MHW days per decade has increased in the Mediterranean (Oliver et al., 2018).

Mean SST is projected to increase by 1°C–3°C around Europe by 2100, with a hotspot of around 4°C–5°C along the Arctic coastline of Europe under RCP4.5 and RCP8.5 scenarios (see Interactive Atlas), leading to a continued increase in MHW frequency, magnitude and duration (Oliver et al., 2018; MedECC, 2020). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Europe by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1). Darmaraki et al. (2019) project that, by the end of the 21st century and under RCP8.5, there will be one MHW occurring every year in the northern Mediterranean sea, and that these MHWs would be three months longer, four times more intense, and 42 times more severe than present day MHWs in the region. Frölicher et al. (2018) show that, in Europe, the change in the probability for the number of days of

Table 12.7 | Summary of confidence in direction of projected change in climatic impact-drivers in Europe, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRESA1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2.

Region	Climatic Impact-driver																													
	Heat and Cold				Wet and Dry								Wind				Snow and Ice					Coastal and Oceanic				Other				
	Mean air temperature	Extreme heat	Cold spell	Frost	Mean precipitation	River flood	Heavy precipitation and pluvial flood	Landslide	Aridity	Hydrological drought	Agricultural and ecological drought	Fire weather	Mean wind speed	Severe wind storm	Tropical cyclone	Sand and dust storm	Snow, glacier and ice sheet	Permafrost	Lake, river and sea ice	Heavy snowfall and ice storm	Hail	Snow avalanche	Relative sea level	Coastal flood	Coastal erosion	Marine heatwave	Ocean acidity	Air pollution weather	Atmospheric CO ₂ at surface	Radiation at surface
Mediterranean (MED)	●	●	●		●		5						6	7					●				●		2		●		●	
Western and Central Europe (WCE)	●	●	●					4									●		●				●		2		●		●

Northern Europe (NEU)	●	●	●		●	1											●		●				●	8	2,3		●		●	

1. Excluding southern UK.
2. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.
3. The Baltic Sea shoreline is projected to prograde if present-day ambient shoreline change rates continue.
4. For the Alps, conditions conducive to landslides are expected to increase.
5. Low confidence of decrease in the southernmost part of the region.
6. General decrease except in Aegean Sea.
7. Medium confidence of decrease in frequency and increase in intensities.
8. Except in the northern Baltic Sea region.

- Already emerged in the historical period (*medium to high confidence*)
- Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)
- Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

MHWs exceeding the 99th percentile of the pre-industrial level is 4%, 15% and 30% for global warming levels of 1°C, 2°C and 3.5°C, respectively. MHW increase in the Mediterranean will impact on many species that live in shallow waters and have reduced motility, with consequences for related economic activities (Galli et al., 2017).

In general, there is *high confidence* that most coastal/ocean-related climatic impact-drivers in Europe will increase over the 21st century for all scenarios and time horizons. Relative sea level rise is *extremely likely* to continue around Europe (except in the northern Baltic Sea), contributing to increased coastal flooding in low-lying areas and shoreline retreat along most sandy coasts (*high confidence*). Marine heatwaves are also expected to increase around the region over the 21st century (*high confidence*).

12.4.5.6 Other

Compound events: One typical compound event that is observed in the European area is compound flooding due to the combination of extreme sea level events and extreme precipitation events associated with high levels of runoff. In the present climate, the Mediterranean coasts are exposed to a higher probability of this type of compound flooding event (Bevacqua et al., 2019). Under RCP8.5, the probability of these events is projected to increase along northern European coasts (west coast of UK, northern France, the east and south coast of the North Sea, and the eastern half of the Black Sea), with the percentage of coastline now experiencing such events at least once every 6 years increasing by between 3% and 11% by the end of the 21st century (Bevacqua et al., 2019).

Under RCP8.5, regions in Russia, France and Germany are projected to experience an increase in the frequency and the length of wet and cold compound events, while Spain and Bulgaria are projected to stay longer in the hot and dry state by mid-century (Sedlmeier et al., 2016).

Compound events of dry and hot summers have increased in Europe. Manning et al. (2019) found that the probability of such compound events has increased across much of Europe between 1950–1979 and 1984–2013, notably in southern, eastern and western Europe. Compound hot and dry extremes are projected to increase in Europe by mid-century for the SRES A1B and RCP8.5 with a particularly strong signal projected in southern and eastern Germany and the Czech Republic (Sedlmeier et al., 2016).

The assessed direction of change in climatic impact-drivers for Europe and associated confidence levels are illustrated in Table 12.7, together with emergence time information (Section 12.5.2). No assessable literature could be found for sand and dust storms, although these phenomena may be relevant in parts of the region.

12.4.6 North America

Major changes in North American CIDs were assessed in WGII AR5 Chapter 26 (Romero-Lankao et al., 2014), with additional detail

on connections to warming levels provided by SR1.5 (IPCC, 2018), and climate information related to land degradation and land-use suitability in SRCCL (IPCC, 2019c), and ocean and coastal hazards in the SROCC (IPCC, 2019b). Recent national assessments in the USA (USGCRP, 2017, 2018) and Canada (Bush and Lemmen, 2019) enhance the local perspective and assessments across a number of CIDs and their sectoral connections. For the purpose of this assessment, North America is sub-divided into six sub-regions, as defined in Chapter 1: North Central America (NCA), Western North America (WNA), Central North America (CNA), Eastern North America (ENA), North-Eastern North America (NEN), and North-Western North America (NWN). Greenland and Arctic regions of North-Eastern and North-Western North America are further assessed in Section 12.4.9, and the Caribbean and Hawaiian Islands are assessed in Section 12.4.7.

12.4.6.1 Heat and Cold

Mean air temperature: Atlas.9.2 assessed *very likely* mean warming in observations across North America, with highest increases at higher latitudes and in the winter season. Atlas.9.4 assessed *very likely* mean warming in future decades in all North American regions, with CMIP and CORDEX models showing median increases exceeding 2°C in much of the continental interior under RCP8.5 (2041–2060 compared to 1995–2014) and higher increases towards the north. Mean temperatures at the end of century show strong scenario dependence, rising between 1°C and 2.5°C in RCP2.6 and about 4°C to 8°C in RCP8.5 (Figures Atlas.12, Atlas.26 and Atlas.27). Warming also raises stream temperatures across the continent (DOE, 2015; Trtanj et al., 2016; van Vliet et al., 2016; Chapra et al., 2017), and Hill et al. (2014) projected US stream warming by 0.6°C (±0.3°C) per 1°C increase in local air temperature. Mean warming drives shifts in the seasonal timing of temperature thresholds, including increasing growing degree days (Mu et al., 2017), longer growing seasons (Gowda et al., 2018; G. Li et al., 2018; L.A. Vincent et al., 2018), reduced chill hours (Luedeling, 2012; Lee and Sumner, 2015; Xie et al., 2015; Parker and Abatzoglou, 2019), and longer pollen and allergy seasons (Fann et al., 2016; Anenberg et al., 2017; Sapkota et al., 2019). Warmer temperatures reduce heating degree days and increase cooling degree days (*high confidence*) (Bartos et al., 2016; US EPA, 2016; Craig et al., 2018; X. Zhang et al., 2019; Coppola et al., 2021b).

Extreme heat: Section 11.9 assessed that extreme temperatures in North America have increased in recent decades (*medium evidence, medium agreement*) other than in Central and Eastern North America (*low confidence*), and extreme heat in all regions is projected to increase with climate change (*high confidence*). Observed trends in extreme heat are more positive for heat extreme indices that include temperature and humidity given historical expansion of irrigation and intensification of agriculture (Mueller et al., 2017; Grotjahn and Huynh, 2018; Thiery et al., 2020). Several studies noted statistically significant increases in intensity and particularly the frequency, duration, and seasonal length of the physiologically hazardous extreme heat conditions across North America (Grineski et al., 2015; Habeeb et al., 2015; Martínez-Austria et al., 2016; Petitti et al., 2016; L.A. Vincent et al., 2018; García-Cueto et al., 2019).

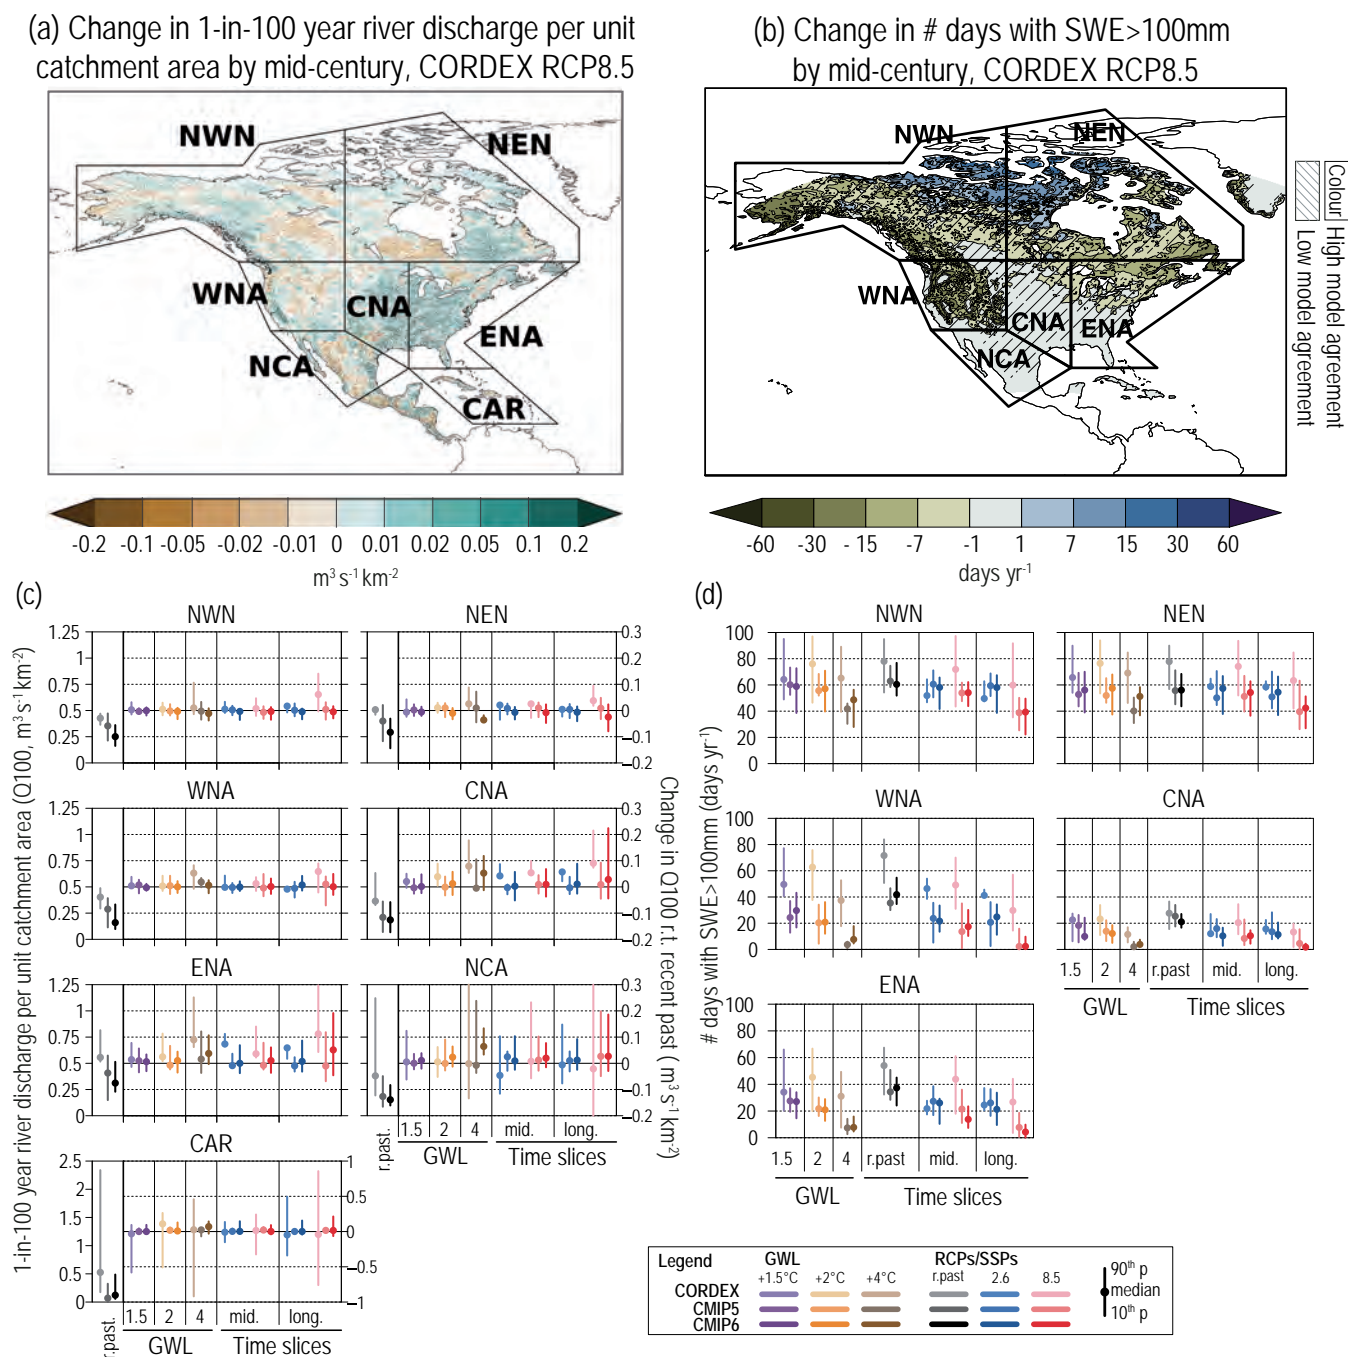

Figure 12.10 | Projected changes in selected climatic impact-driver indices for North America. (a) Mean change in 1-in-100-year river discharge per unit catchment area (Q_{100} , $\text{m}^3 \text{s}^{-1} \text{km}^{-2}$), and (b) median change in the number of days with snow water equivalent (SWE) over 100 mm (from November to March), from CORDEX-North America models for 2041–2060 relative to 1995–2014 and RCP8.5. Diagonal lines indicate where less than 80% of models agree on the sign (direction) of change. (c) Bar plots for Q_{100} ($\text{m}^3 \text{s}^{-1} \text{km}^{-2}$) averaged over land areas for the AR6 WGI Reference Regions (defined in Chapter 1). The left-hand column within each panel (associated with the left-hand y-axis) shows the 'recent past' (1995–2014) Q_{100} absolute values in grey shades. The other columns (associated with the right-hand y-axis) show the Q_{100} changes relative to the recent past values for two time periods ('mid' 2041–2060 and 'long' 2081–2100) and for three global warming levels (defined relative to the pre-industrial period 1850–1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10–90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) As for (c) but showing absolute values for number of days with SWE > 100 mm, masked to grid cells with at least 14 such days in the recent past. See Technical Annex VI for details of indices. A Caribbean (CAR) Q_{100} bar plot is included here but assessed in the Small Islands section (Section 12.4.7). Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

Figure 12.4b shows over a month of additional days at CMIP6 SSP5-8.5 mid-century where temperatures exceed 35°C across much of southern Mexico and regions near the US–Mexico border, and these extreme temperatures occur at least once per year up to southern Canada. Coppola et al. (2021b) found similar patterns in CMIP5 and CORDEX-Core. Using locally tailored heat thresholds, Maxwell et al. (2018) found that ‘very hot’ days in five US cities will occur a median of three to five times more often by 2036–2065 under RCP8.5 (2 to 3.5 times more often in RCP4.5), Oleson et al. (2018) projected that annual heatwave duration will exceed one month in Houston in RCP8.5 2061–2080, and Anderson et al. (2018) projected 7 to 12 times more exceedances of thresholds associated with high-mortality by 2061–2080 under RCP8.5 (6 to 7 times more exceedances in RCP4.5). Schwingshackl et al. (2021) found that Central and Eastern North America are among the regions with the strongest trend in heat stress indicators. Studies also project increasingly surpassed heat extreme thresholds for North American crops (Gourdji et al., 2013), airplane weight restrictions (Coffel et al., 2017), and peak load energy systems (Auffhammer et al., 2017).

The number of days crossing dangerous heat thresholds such as $HI > 41^{\circ}\text{C}$ will be very sensitive to the mitigation scenario at the end of the century (Wuebbles et al., 2014; Zhao et al., 2015; Dahl et al., 2019; Schwingshackl et al., 2021). At the end of the century under SSP5-8.5, a CMIP6 median increase of exceedances of 75–150 days per year is projected over much of North Central America, Central North America and the south-western USA while this increase is projected to remain limited below 60 days under SSP1-2.6 (Figure 12.4d,f and Figure 12.SM.2). Steinberg et al. (2018) also projected more frequent and longer ‘heat-health’ events in California extending into October.

Cold spell: Chapter 11 assessed *high confidence* in decreasing frequency and intensity of cold spells over North America (Section 11.9). The number of days with extreme wind chill hours (humidex ≤ -30) decreased at 76% of examined Canadian stations from 1953 to 2012 (Mekis et al., 2015) and cold days and coldest nights decreased in Mexico from 1980 to 2010 (García-Cueto et al., 2019).

Cold spells are projected to decrease over North America under climate change, with the largest decreases most common in the winter season (*high confidence*) (Section 11.9). Minimum winter temperatures are projected to rise faster than the mean winter temperature (Underwood et al., 2017) and alter cold-hardiness zones used to determine agricultural suitability (Parker and Abatzoglou, 2016). Wuebbles et al. (2014) projections for RCP8.5 end-of-century show that the four-day cold spell that happens on average once every five years is projected to warm by more than 10°C and CMIP5 models do not project current 1-in-20-year annual minimum temperature extremes to recur over much of the continent. Multiple studies have shown that Arctic warming can alter large-scale variability and change the frequency and duration of mid-latitude cold air outbreaks, potentially leading to increasing cold hazards in some regions (*low agreement*) (Barcikowska et al., 2019; Cohen et al., 2020; Zhou et al., 2021).

Frost: An expansion of the frost-free season is underway and projections for North America indicate a continuation of this trend

in the future (*high confidence*). Significant decreases in frost days, consecutive frost days, and ice days were identified in 1948–2016 station observations across Canada, along with a resulting lengthening of the frost-free season by more than a month in many regions (L.A. Vincent et al., 2018). Frost days also declined in nearly all Mexican cities from 1980 to 2010 (García-Cueto et al., 2019), and a 1917–2016 decline of about three weeks in frigid winter conditions challenges ecosystems in the north-east USA and south-east Canada (Contosta et al., 2020). Studies connect projections of a longer frost-free season in North America to a longer outdoor construction season, shifts in frost variance to orchard damages, and lower weight tolerances for runways (Daniel et al., 2018; DeGaetano, 2018; Jacobs et al., 2018). Frosts are projected to persist as an episodic hazard in many regions given natural variability and cold air outbreaks even as mean temperature rises (*high confidence*).

Climate change is *virtually certain* to shift the balance of temperature towards warming trends and away from cold extremes, with increases in the magnitude, frequency, duration and seasonal and spatial extent of heat extremes driving impacts across North America. The frequency of dangerous heat threshold exceedance (such as $HI > 41^{\circ}\text{C}$) is particularly sensitive to scenario pathway, with 75–150 days more under SSP5-8.5 but less than 60 days more under SSP1-2.6 by the end of the century in NCA, CNA and the south-western USA.

12.4.6.2 Wet and Dry

Mean precipitation: Atlas.9.2 found that trends in annual precipitation over 1960–2015 are generally non-significant, though there are consistent positive trends over parts of ENA and CNA, together with significant decreases in precipitation in parts of the south-western USA and north-western Mexico.

Atlas.9.4 assessed *very high confidence* in increases in mean precipitation over most of northern and Eastern North America, with *medium confidence* of decrease over Northern Central America and *low confidence* elsewhere (see Figure Atlas.26, and Cross-Chapter Box Atlas.1, Figure 1). Changes are most dramatic in the spring and winter, when wet conditions are projected to extend from the northern portions of the continent as far south as the central Great Plains, while Mexico becomes drier; in contrast, summer changes are uncertain across most of the continent other than wetter conditions in northern Canada (Easterling et al., 2017; Bukovsky and Mearns, 2020; Almazroui et al., 2021; Teichmann et al., 2021).

River flood: There is *limited evidence* and *low agreement* on observed climate change influences for river floods in North America (Section 11.5). Trends in streamflow indices are mixed and difficult to separate from river engineering influences, with large changes but little spatial coherence across the USA, making it difficult to identify trends with confidence (Peterson et al., 2013; Mallakpour and Villarini, 2015; Archfield et al., 2016; Wehner et al., 2017; Villarini and Slater, 2018; Hodgkins et al., 2019; Neri et al., 2019). There is *high confidence* in historical shifts in the timing of peak streamflow towards higher winter and earlier spring flows in snowmelt-driven basins in Canada (Burn and Whitfield, 2016; Bonsal et al., 2019) and

the USA (Dudley et al., 2017; Wehner et al., 2017; Neri et al., 2020). Some rivers show ice-jam floods occurring a week earlier, but changes are mixed, given localized positive and negative changes across the continent (Rokaya et al., 2018). There is *medium confidence* that climate change will increase river floods over the USA and Canada but *low confidence* for changes in Mexico. Wobus et al. (2017a) used a regional hydrologic model for 57,000 streams to project more than a doubling in the frequency of current 1-in-100-year flow events in many portions of the USA for RCP8.5 2050 with additional contributions from earlier snowmelt. CMIP6 projections for SSP5-8.5 2065–2099 show strongest peak USA runoff increases in the east (Villarini and Zhang, 2020); however, several studies applying global hydrological models disagree with regional streamflow projections, indicating a decrease in the magnitude or frequency of floods over a large portion of North America (e.g., Hirabayashi et al., 2013; Arnell and Gosling, 2016; see Figure 12.10a,c).

Heavy precipitation and pluvial flood: Section 11.4 assessed *high confidence* in observed increases in extreme precipitation events (including hourly totals) in Central and Eastern North America with *low confidence* in broad trends elsewhere in the continent despite observational increases in some portions of each region (L.A. Vincent et al., 2018; García-Cueto et al., 2019; X. Zhang et al., 2019).

Section 11.4 found that high precipitation is projected to increase across North America (*high confidence*) except for portions of Western North America where projections are mixed (*medium confidence* of increase). Maxwell et al. (2018) identified regional 'heavy precipitation day' thresholds for five cities across the USA and projected that a tripling (or more) of these events is possible by RCP8.5 mid-century. Projections indicate changes to intensity-duration-frequency (IDF) curves typically used for construction design and automobile hazards, as well as increases in the 10-year recurrence level of 24-hour rainfall intensities that challenge storm water drainage systems (Hambly et al., 2013; Cheng and AghaKouchak, 2015; J.E. Neumann et al., 2015; Prein et al., 2017b; Hettiarachchi et al., 2018; Ragno et al., 2018). Precise levels of regional IDF characteristics may still depend substantially on the method and resolution of downscaling applied (DeGaetano and Castellano, 2017; L.M. Cook et al., 2020).

Landslide: There is growing yet *limited evidence* for unique climate-driven changes in landslide and rockfall hazards in North America, even as theory suggests decreases in slope and rockface stability due to more intense rainfall, rain-on-snow events, mean warming, permafrost thaw, glacier retreat, and coastal erosion (Cloutier et al., 2017; Coe et al., 2018; Handwerger et al., 2019; Hock et al., 2019; Patton et al., 2019) although dry trends can decelerate mass movements (Bennett et al., 2016). Landslide frequency has increased in British Columbia (Canada; Geertsema et al., 2006) and is expected to increase in North-Western North America given the combination of these factors (*medium confidence*) (Gariano and Guzzetti, 2016). Cloutier et al. (2017) projected an increase in landslides in western Canada due to wetter overall conditions and reduced return period for extreme rainfall. Robinson et al. (2017) used scenarios based upon projection of 50-year recurrence of 7-day precipitation periods to highlight the potential for increased landslide hazards near Seattle (USA). Broad projections for the USA are more uncertain given

increases in evapotranspiration that will counteract precipitation changes over much of the country (Coe, 2016).

Aridity: Chapter 8 showed that aridity in North America generally moves opposite to mean precipitation change with an added evaporative demand from warmer temperatures (*high confidence* in aridity increase for Northern Central America; *medium confidence* for an increase in Central North America; *high confidence* for a decrease in North-Eastern North America; *medium confidence* decreases in Eastern and North-Western North America; see also Section 11.9). Projected soil moisture declines (Figure 12.4j–l) are most widespread across North America during the summer, with the largest declines in Mexico and the southern Great Plains but also extending into Canada (Section 8.4.1.6; Swain and Hayhoe, 2015; Easterling et al., 2017; Bonsal et al., 2019; J. Lu et al., 2019). Yoon et al. (2018) found net reduction in southern Great Plains groundwater storage in RCP8.5 mid-century projections despite increases in mean precipitation and both wet and dry extremes. Soil moisture drying could reach unprecedented levels by the CMIP6 RCP8.5 end-of-century, even when evaluating deeper soil columns relevant for crop rooting depth (B.I. Cook et al., 2020). Projected changes in the aridity index portray a shift the geographic range of temperate drylands northward and eastward in Central and Western North America (Schlaepfer et al., 2017; Seager et al., 2018) which also diminishes aquifer recharge rates in the southern Great Plains and in some western regions where snowpack is reduced (Meixner et al., 2016).

Hydrological drought: Section 11.9 assessed *low confidence* of significant observational trends and projected future changes in the characteristics of episodic hydrological drought in North America given *limited evidence* and *low agreement* in modeled changes. C. Zhao et al. (2020) found that increases in hydrological drought frequency (particularly the 100 yr drought) were far more prevalent than for meteorological drought across 5797 watersheds in the USA and Canada, indicating a strong influence of evaporative demand. Reductions in the overall supply of meltwater from a declining snowpack also increase the potential for intermittent hydrological droughts in the western USA (Mote et al., 2018; Livneh and Badger, 2020).

Agricultural and ecological drought: Section 11.9 assessed *medium confidence* for an increase in agricultural and ecological drought in Western North America but otherwise found *limited evidence* for broadly observed changes in North American agricultural and ecological drought, even as increasing evaporative demand intensified vegetation stress and soil moisture deficits in recent events (Sections 11.6, 11.9). Section 11.9 assessed *medium confidence* for more intense agricultural and ecological drought conditions over North Central America, Western North America and Central North America in a 2°C global warming level (about mid-century), with *medium confidence* extending to Eastern North America and *high confidence* for Northern Central America and Central North America under a 4°C global warming level associated with higher emissions scenarios past 2050. Figure 12.4g–i shows that the frequency of meteorological droughts (which often initiate hydrological, agricultural and ecological droughts) is largely projected to increase in North American areas where total precipitation decreases (and vice versa; see Section 11.9 and Coppola et al., 2021b), and higher

evaporative demand will extend the regions where more intense ecological and agricultural droughts develop when meteorological droughts occur (Wehner et al., 2017; B.I. Cook et al., 2019, 2020). Studies utilizing a variety of drought indices and soil moisture projections consistently project increased drought extending from Mexico into the southern Canadian Plains during the summer (Swain and Hayhoe, 2015; Ahmadi-pour et al., 2017; Feng et al., 2017; Bonsal et al., 2019; Tam et al., 2019; B.I. Cook et al., 2020).

Fire weather: Climatic conditions conducive to wildfire have increased in Mexico, Western and North-Western North America, primarily due to warming (*high confidence*). Abatzoglou and Williams (2016) found climate change led to higher values for eight fuel aridity indices over the western USA in recent decades, with 2000–2015 changes exposing 75% more forested area to high fuel aridity and adding nine more high fire-potential days each year, similar to 1979–2013 western USA and Mexico fire season expansion reported in Jolly et al. (2015). Increases in lightning-initiated fires have been distinguished from trends in man-made fire in western Canada and the USA (Balch et al., 2017; Hanes et al., 2019). Jain et al. (2017) identified a 1979–2015 expansion in fire weather season in eastern Canada and the south-western USA (with a smaller reduction in the northern Mountain West) along with regional shifts in the 99th percentile Canadian Fire Weather Index (FWI) and potential fire-spread days. Girardin and Wotton (2009) noted that 1951–2002 trends in the Monthly Drought Code fire index in eastern Canada could hardly be distinguished from decadal variability.

Climate change drives future increases in North American fire weather, particularly in the south-west (*high confidence*), although further studies on shifts in exposure and vulnerability are needed to understand overall fire risks (see WGII Chapter 14). A significant increase of FWI is apparent before 2050 under RCP8.5 in much of North America, including the frequency of 95th-percentile FWI days, peak seasonal FWI average, fire weather season length, and maximum fire weather index (Abatzoglou et al., 2019), and fire season across North America expands dramatically beyond 2°C global warming levels (Q. Sun et al., 2019; Jain et al., 2020). X. Wang et al. (2017b) simulated fire-spread days across Canada and found increases across most of the areas studied by 2071–2100, with median changes of –20 to +140% (RCP2.6), –20 to +250% (RCP4.5) and 40 to 360% (RCP8.5) compared to 1976–2015. Prestemon et al. (2016) found more conducive conditions for lightning-ignited fires in the south-eastern USA by mid-century, while warming conditions in Alaska increasingly push July temperatures above 13.4°C, a threshold for fire danger across Alaska's tundra and boreal forest (Partain et al., 2016; Young et al., 2017). Longer and more intense fire seasons would also raise particulate matter and black carbon concentrations in the western USA, reducing visibility at many National Parks (Yue et al., 2013; Val Martin et al., 2015).

Changes in North American wet and dry climatic impact-drivers are largely organized by the 'north-east (more wet) to south-west (more dry)' pattern of mean precipitation change, although heavy precipitation increases are widespread and increasing evaporative demand expands aridity, agricultural and ecological drought, and fire weather (particularly in summer) (*high confidence*).

12.4.6.3 Wind

Mean wind speed: Mean wind speeds have declined in North America – as in other Northern Hemisphere areas – over the past four decades (*medium confidence*) (AR5 WGI) with a reversal in the last decade (*low confidence*) not fully consistent across studies (Tian et al., 2019; Zeng et al., 2019; Z. Zhang et al., 2019). Tian et al. (2019) found a corresponding reduction in the wind power potential across the eastern parts of North America.

Mean wind speeds are expected to decline over much of North America (Figure 12.4m–o), but the only broad signal of consistent change across model types is a reduction in wind speed in Western North America (*high confidence*). These declines reduce wind power endowment by 2050 and as early as the 2020–2040 near-term period in the USA Mountain West, while there is disagreement between global- and regional-model change projections in the upper and lower Great Plains, Ohio River Valley, Mexico and eastern Canada (Karnauskas et al., 2018a; Jung and Schindler, 2019; Chen, 2020).

Severe wind storm: There is *limited evidence* and *low agreement* in observed changes in North American CID indices associated with extratropical cyclones (Section 11.7.), severe thunderstorms, severe wind bursts (*derechos*), tornadoes, or lightning strikes (Vose et al., 2014; Easterling et al., 2017; Kossin et al., 2017). Observational studies have indicated a reduction in the number of tornado days in the USA, but increases in outbreaks with 30 or more tornadoes in one day (Brooks et al., 2014), the density of tornado clusters (Elsner et al., 2015), and overall tornado power (Elsner et al., 2019).

There is *medium confidence* of a general decrease in the number of extratropical cyclones producing high wind speeds in North America, except over northernmost parts, for a global warming level of 2°C or by the end of the century under RCP4.5 and RCP8.5 (Kumar et al., 2015; Jeong and Sushama, 2018a; C. Li et al., 2018). GCMs cannot directly resolve tornadoes and severe thunderstorms, however projections of favourable environments for severe storms (based on convective available potential energy and wind shear) indicate *medium confidence* for more severe storms and a longer convective storm season in the USA, weaker increases extending north and east (Seeley and Romps, 2015; Glazer et al., 2021), and a corresponding increase in autumn and winter tornadic storms (H.E. Brooks, 2013; Diffenbaugh et al., 2013; Brooks et al., 2014; see also Section 11.7.2). Prein et al. (2017a) used a convection-permitting model to project a tripling of mesoscale convective systems over the USA for end-of-century RCP8.5.

Tropical cyclone: Section 11.7.1 identified recent reductions in tropical cyclone translation speed and higher tropical cyclone rainfall totals over the North Atlantic, as well as substantial natural variability. Projections indicate *low confidence* in change in North Atlantic tropical cyclone numbers, but *medium confidence* in Mexico and the US Gulf and Atlantic coasts for more intense storms with higher wind, precipitation, and storm surge totals when they do occur (Section 11.7.1; Diro et al., 2014; DOE, 2015; Walsh et al., 2016a; Kossin et al., 2017; Marsooli et al., 2019; Ting et al., 2019; Knutson et al., 2020). A more rapid intensification of tropical cyclone winds and destructive power also

heightens the tropical cyclone hazard (Bhatia et al., 2019). Greenhouse gas forcing is projected to shift tropical cyclones poleward (Kossin et al., 2016), while also holding the potential for higher precipitation totals (Risser and Wehner, 2017; Knutson et al., 2020) particularly given evidence that storms increasingly stall near North American coastlines (Hall and Kossin, 2019).

Sand and dust storm: Land-use change has increased dust emissions in the western USA in the past 200 years (Neff et al., 2008). However, there is *medium confidence* for observed increases in Western North American sand and dust storm activity since 1980. In their study of Valley Fever spread, Tong et al. (2017) identified a rapid intensification of dust storm activity using PM₁₀ and PM_{2.5} observations from 1980–2011 across 29 monitoring sites in the south-western USA, similar to contiguous USA observations by Brahney et al. (2013). Hand et al. (2016) attributed the earlier onset of spring dusts in the south-west in large part to the Pacific Decadal Oscillation, however. The increasing trend in dust since the 1990s in the south-western USA can be explained by precipitation deficit and surface bareness (Pu and Ginoux, 2018). Projections of future sand and dust storms over North America are based on aridity as a primary proxy for conducive conditions which lends *medium confidence* of an increase over Mexico and the south-western USA. Pu and Ginoux (2017) project about five more dusty days in spring and summer in the southern Great Plains under RCP8.5 at the end of the century, while dusty days decrease in northern regions where mean precipitation tends towards wetter conditions.

Tropical cyclones, severe wind and dust storms in North America are shifting towards more extreme characteristics, with a stronger signal towards heightened intensity than increased frequency, although specific regional patterns are more uncertain (*medium confidence*). Mean wind speed and wind power potential are projected to decrease in Western North America (*medium confidence*) with differences between global and regional models lending *low confidence* elsewhere.

12.4.6.4 Snow and Ice

Snow: The seasonal extent of snow cover has reduced over North America in recent decades (*robust evidence, high agreement*) (see also Sections 2.3.2.2 and 9.5.3, and Figure Atlas.25). The average snow-cover extent in North America decreased at a rate of about 8500 km² yr⁻¹ over the 1972–2015 period, reducing the average snow cover season by two weeks, primarily due to earlier spring melt (US EPA, 2016). Observations indicate earlier spring snowpack melting (Dudley et al., 2017) and a reduction in end-of-season snowpack metrics important to water resources over the Rocky Mountains (particularly since 1980) and Pacific Northwest (Pederson et al., 2013; Kormos et al., 2016; Kunkel et al., 2016; Fyfe et al., 2017; Mote et al., 2018). In situ measurements in Canada show more heterogeneous trends in snow amount and density (Brown et al., 2019).

Climate change is expected to reduce the total snow amount and the length of the snow cover season over most of North America, with a corresponding decrease in the proportion of total precipitation falling as snow and a reduction in end-of-season snowpack (*high confidence*)

(see Atlas.9.5). Changes include a reduction in the number of days with snowfall in across all of North America, with the exception of northern Canada (Danco et al., 2016; McCrary and Mearns, 2019), a delay of about a week in first snowfall in the western USA by 2050 under RCP8.5 (Pierce and Cayan, 2013), and more prominent reductions in Canadian snow cover in the October–December period (Mudryk et al., 2018). Reduced total snowpack and earlier snowmelt lower dry season streamflow (Kormos et al., 2016; Rhoades et al., 2018). Figure 12.10b shows a reduction in days suitable for skiing (SWE > 10 cm; Wobus et al., 2017b) across the USA and southern Canada, although some portions of northern central Canada see an increase.

Glacier: Section 9.5.1 assessed that glaciers in Alaska, western Canada and the western USA are expected to continue to lose mass and areal extent (*high confidence*). Compared to their 2015 state, glaciers in the western Canada and the USA region will lose 62 ± 30%, 75 ± 29% and 85 ± 23%, of their mass by the end of the century for RCP2.6, RCP4.5 and RCP8.5 scenarios, respectively (Marzeion et al., 2020). Meanwhile glaciers in Alaska will lose 26 ± 21%, 31 ± 24% and 44 ± 27%, of their 2015 mass under the same scenarios. The overall loss of glacial mass can act as a meltwater supply for freshwater resources, although this is expected to peak in the middle of the century and then fade as glaciers disappear (Fyfe et al., 2017; Derksen et al., 2018). Continued shrinkage of glaciers is projected to create further glacial lakes (*medium confidence*) similar to those that have led to outburst floods in Alaska and Canada (Carrivick and Tweed, 2016; Harrison et al., 2018).

Permafrost: Warmer ground temperatures are expected to extend the geographical extent and depth of permafrost thaw across northern North America (*very high confidence*) (Section 9.5.2). Observations across Canada show that permafrost temperature is increasing and the active layer is getting thicker (Section 2.3.2.5; Derksen et al., 2018; Biskaborn et al., 2019; Romanovsky et al., 2020). Slater and Lawrence (2013) note that the RCP8.5 end-of-century period in North America only has shallow permafrost as the most probable condition in the Canadian Archipelago. Melvin et al. (2017) noted the loss of shallow permafrost in five RCP8.5 CMIP5 models across a wide swathe of southern Alaska by 2050, along with increases of active layer thickness. There is *high confidence* in continued reductions in mountain near-surface permafrost area with high spatial variability given local snow and temperature changes (Section 9.5.2; Peng et al., 2018; Hock et al., 2019).

Lake, river and sea ice: Anthropogenic warming reduces the seasonal extent of lake and river ice over many North American freshwater systems, with ice-free winter conditions pushing further north with rising temperatures (*high confidence*). Observations in Central and Eastern North America show reduced average seasonal lake-ice cover duration (Benson et al., 2012; Mason et al., 2016; US EPA, 2016). Satellite observations show declines in lake ice (Du et al., 2017) and loss of more than 20% of winter river-ice length in much of Alaska (2008–2018 compared to 1984–1994; Yang et al., 2020a). Spring lake and river ice in Canada is projected to break up 10–25 days earlier while autumn freeze-up occurs 5–15 days later by mid-century, with larger declines in lake-ice season closer to the coasts (Dibike et al., 2012) and for rivers in the Rocky Mountains and north-eastern USA

(Yang et al., 2020a), although global models have difficulty with frozen freshwater system dynamics (Derksen et al., 2018). Substantial ice loss is projected over the Laurentian Great Lakes (Hewer and Gough, 2019; Matsumoto et al., 2019). The southern extent of lakes experiencing intermittent winter ice cover moves northward with rising temperature, pushing nearly out of the continental USA at low elevations under a 4.5°C GWL (Sharma et al., 2019). Higher spring flows and the potential for winter thaws are also projected to heighten the threat of ice jams (Rokaya et al., 2018; Bonsal et al., 2019) while reducing the seasonal viability of ice roads and recreational use (Pendakur, 2016; Mullan et al., 2017; Knoll et al., 2019).

Seasonal sea ice coverage along the majority of Canadian and Alaskan coastlines is declining (*robust evidence, high agreement*) and there is *high confidence* that sea ice loss continues under climate change, as further assessed in Section 12.4.9.

Heavy snowfall: There is *low agreement (limited evidence)* for observed changes in heavy snowfall in North America. Kluver and Leathers (2015) noted a 1930–2008 frequency increase for all snow intensities in the northern Great Plains but declines in heavier snow events in the Pacific Northwest and declines in the south-eastern USA. Changnon (2018) found that most extreme 30-day high-snowfall periods in the 1900–2016 record over the eastern USA occurred in the 1959–1987 period, which lies between the 1930s Dust Bowl and recent warming. There is *low agreement* and *medium evidence* for broad projected changes to heavy snowfall over North America given increased heavy precipitation and warmer winter temperatures. Several recent regional studies have projected that low-intensity events decrease more rapidly than heavy snowfall events, resulting in an increase in the snowfall proportion from heavy snowfall events even as the number of such events decreases (O’Gorman, 2014; Lute et al., 2015; Zarzycki, 2016; Janoski et al., 2018; Ashley et al., 2020).

Ice storm: There is *limited evidence* in the literature of unique changes in ice storms observed or projected over North America. Groisman et al. (2016) examined 40 years of observations and found weak decreases in freezing rain events over the south-eastern USA in the most recent decade. Ning and Bradley (2015) project that the average snow–rain transition line, which is associated with mixed precipitation, moves 2° latitude northward over Eastern North America by the end of the 21st century under RCP4.5 (4° under RCP8.5; see also Klima and Morgan, 2015).

Hail: There is *limited evidence* and *low agreement* for observed changes in the frequency or intensity of North American hail storms. J.T. Allen et al. (2015) and Allen (2018) found that temporal inconsistencies in the US and Canadian hail records made long-term climate analysis difficult, although B.H. Tang et al. (2019) identified an increasing frequency of environmental conditions conducive for large hail (diameter ≥ 5 cm) over the central and eastern USA. There is *limited evidence* and *medium agreement* in projections of increased hail damage potential over North America. Some regional and convective-permitting model projections indicate a longer hail season with fewer events and larger hail sizes that result in higher hail damage potential (Brimelow et al., 2017; Trapp et al., 2019).

Snow avalanche: There is *limited evidence* of directional changes in snow avalanches over North America. Mock and Birkeland (2000) identified a 1969–1995 decrease in snow avalanches over the western United States, although they note the heavy influence of natural variability. A similar decline was observed over western Canada (Bellaire et al., 2016; Sinickas et al., 2016), but clear trends are difficult to discern given sparse observations and shifts in avalanche management. We concur with the SROCC assessment of *medium confidence* and *high agreement* that snow avalanche hazards generally decrease at low elevations given lower snowpack, even as high elevations are increasingly susceptible to wet-snow avalanches (Hock et al., 2019; see also Lazar and Williams, 2008).

Observations and projections agree that snow and ice CIDs over North America are characterized by reduction in glaciers and the seasonality of snow and ice formation, loss of shallow permafrost, and shifts in the rain/snow transition line that alters the seasonal and geographic range of snow and ice conditions in the coming decades (*very high confidence*).

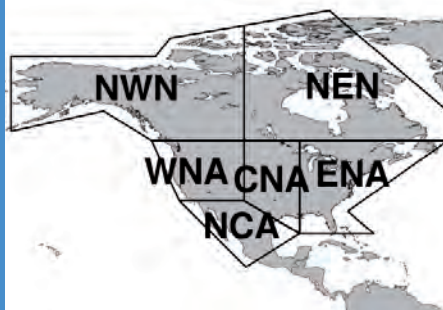

12.4.6.5 Coastal and Oceanic

Relative sea level: Chapter 9 found that observations indicate increasing sea levels along most North American coasts (*robust evidence, high agreement*), although there is substantial regional variation in relative sea level rise (*robust evidence, high agreement*). Around North America, over 1900–2018, a new tide gauge-based reconstruction finds a regional mean RSL change of 1.08 [0.79 to 1.38] mm yr⁻¹ in the subpolar North Atlantic, 2.49 [1.89 to 3.06] mm yr⁻¹ in the subtropical North Atlantic, and 1.20 [0.76 to 1.62] in the East Pacific (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). For the period 1993–2018, these RSLR rates, based on satellite altimetry, increased to 2.17 [1.66 to 2.66] mm yr⁻¹, 4.04 [2.77 to 5.24] mm yr⁻¹ and 2.35 [0.70 to 4.06] mm yr⁻¹, respectively (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3 and Table 9.5). Relative sea level (RSL) is falling in portions of southern Alaska (Sweet et al., 2018) and much of the northern part of north-eastern Canada and around Hudson Bay (where land is rising by >10 mm/year; Greenan et al., 2018).

Relative sea level rise is *virtually certain* to continue in the oceans around North America, except in the northern part of north-eastern Canada and portions of southern Alaska. Regional mean RSLR projections for the oceans around North America range from 0.4–1.0 m under SSP1-2.6 to 0.7–1.4 m under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), which means that there are locally large deviations from the projected GMSL change (Section 9.6.3.3), including decreases in RSL in northern north-eastern Canada from land uplift (see also Sweet et al., 2017; Greenan et al., 2018; Oppenheimer et al., 2019). The RSLR projections here may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

Coastal flood: Observations indicate that episodic coastal flooding is increasing along many coastlines in North America (*robust evidence, high agreement*), and this episodic coastal flooding will increase in

Table 12.8 | Summary of confidence in direction of projected change in climatic impact-drivers in North America, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2.

 Region	Climatic Impact-driver

1. Snow may increase in some high elevations and during the cold season and decrease in other seasons and at lower elevations.

2. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.

3. Increasing in northern regions and decreasing towards the south.

4. Decreasing in northern regions and increasing towards the south.

5. Higher confidence in northern regions and lower towards the south.

6. Higher confidence in southern regions and lower towards the north.

7. Higher confidence in increase for some climatic impact-driver indices during summer.

8. Increase in convective conditions but decrease in winter extratropical cyclones.

9. Relative sea level rise reduced given land uplift in southern Alaska.

● Already emerged in the historical period (*medium to high confidence*)

● Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

● Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

many North American regions under future climate change (*high confidence*) although land uplift from glacial isostatic adjustment in northern and Hudson Bay portions of North-Eastern North America leads to only *medium confidence* of coastal flood increases in that region. Sweet et al. (2018) found 2000–2015 observed increases of about 125% in high-tide flooding frequencies along the southern Atlantic USA coastline, with 75% increases along the USA Gulf Coast and USA northern Atlantic coastlines. That same study noted that a GMSL of 0.5 m in 2100 would increase high tide ('nuisance') flooding from current rates of about once a month for most coastal regions to about once every other day along the USA Atlantic and Gulf coasts and smaller increases in frequency along the Pacific coast, and Dahl et al. (2017a) found similar trends on the USA East Coast prior to mid-century. The present day 1-in-50-year ETWL is projected to occur around three times per year by 2100 with an SLR of 1 m all around North America, except in most of Eastern North America where it is expected to have return periods of 1-in-1-year to 1-in-2-years (Vitousek et al., 2017). Ghanbari et al. (2019) projected corresponding shifts towards higher frequencies of major flooding events for 20 US cities. Figure 12.4r and Figure 12.SM.6 show increases of 70 cm or more in the 100-year return period extreme total water level (ETWL) over much of the USA East Coast, British Columbia, Alaska, and the Hudson Bay under RCP8.5 by 2100 (relative to 1980–2014), with lower increases in northern Mexico, northern Canada, Labrador, and the Pacific and Gulf coasts of the USA (Vousdoukas et al., 2018). Projected increases in coastal flooding generally follow patterns of RSL change, although sea ice loss in the north also increases open water storm surge (Greenan et al., 2018).

Coastal erosion: There is *limited evidence* of changes in North American episodic storm erosion caused by waves and storm surges. Observations show increased extreme wave energy on the Pacific coast, but no clear trend on other USA coasts given substantial natural variability (Bromirski et al., 2013; Vose et al., 2014). In terms of long-term coastal erosion, shoreline retreat rates of around 1 m yr⁻¹ have been observed during 1984–2015 along the sandy coasts of NWN and NCA while portions of the US Gulf Coast have seen a retreat rate approaching 2.5 m yr⁻¹ (Luijendijk et al., 2018; Mentaschi et al., 2018). Sandy shorelines along ENA and WNA have remained more or less stable during 1984–2014, but a shoreline progradation rate of around 0.5 m yr⁻¹ has been observed in NEN. Mentaschi et al. (2018) report 1984–2015 coastal area land losses of 630 km² and 1260 km² along the Pacific and Atlantic coasts of the USA, respectively.

Projections indicate that sandy coasts in most of the region will experience shoreline retreat through the 21st century (*high confidence*). Median shoreline change projections presented by Vousdoukas et al. (2020b) show that sandy shorelines in NWN, ENA, and NCA will retreat by between 40 and 80 m by mid-century (relative to 2010) under both RCP4.5 and RCP8.5. Projections for NEN and WNA are lower at 20–30 m under the same RCPs. The highest median mid-century projection in the region is for CNA at around 125 m under both RCPs. RCP4.5 projections for 2100 show shoreline retreats of 100 m or more along the sandy coasts of NWN, CNA, and NCA, while retreats of between 40 and 80 m are projected in other regions. Under RCP8.5, retreats exceeding 100 m are projected in all regions except NEN and WNA (approximately 80 m) by 2100,

with particularly high retreats in NWN (160 m) and CNA (330 m). The total length of sandy coasts in North America that are projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 15,000 km and 25,000 km respectively, an increase of approximately 70%.

Marine heatwave: There is *high confidence* in observed increases in marine heatwave (MHW) frequency and future increases in marine heatwaves are *very likely* around North America (Box 9.2). The total number of MHW days per decade increased in the North American coastal zone, albeit somewhat more in the Pacific (Oliver et al., 2018; Smale et al., 2019). Projected increases in degree heating weeks (Heron et al., 2016) and degree heating months (Frieler et al., 2013) indicate increasing bleaching-level and mortality-level heating stress threshold events for reefs in Florida and Mexico.

Mean SST is projected to increase by 1°C (3°C) around North America by 2100, with a hotspot of around 4°C (5°C) off the North American Atlantic coastline under RCP4.5 (RCP8.5) conditions (see Interactive Atlas). Frölicher et al. (2018) projected increasing MHW frequency and spatial extent at a 2°C global warming level with the largest increases in the Gulf of Mexico and off the southern USA East Coast (>20×) as well as off the coast of the Pacific Northwest (>15×). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around North America by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

There is *high confidence* that most coastal CIDs in North America will continue to increase in the future with climate change. An observed increase in relative sea level rise is *virtually certain* to continue in North America (other than around the Hudson Bay and southern Alaska) contributing to more frequent and severe coastal flooding in low-lying areas (*high confidence*) and shoreline retreat along most sandy coasts (*high confidence*). Marine heatwaves are also expected to increase all around the region over the 21st century (*high confidence*).

The assessed direction of change in climatic impact-drivers for North America and associated confidence levels are illustrated in Table 12.8.

12.4.7 Small Islands

This section covers the climatic impact-drivers affecting small islands around the world (see definition of SIDS in the Glossary; Cross-Chapter Box Atlas.2) with a particular focus on small islands in the Caribbean (CAR) Sea and the Pacific Ocean. Caribbean and Pacific small islands have mostly tropical climates and local conditions are also influenced by diverse topography ranging from low-lying islands and atolls to volcanic and mountainous terrain. Climate variability in these islands is influenced by the trade winds, easterly waves, tropical cyclones (TC), and the migrations of the Inter-tropical Convergence Zone (ITCZ), the North Atlantic Subtropical High, and the South Pacific Convergence Zone (SPCZ), and other modes of climate variability as discussed in Cross-Chapter Box Atlas.2. Furthermore, changes in the ocean temperature and chemistry, and relative sea level have strong impacts on these small islands given their geographical location and dependence on coastal and marine ecosystem services.

The AR5 recognized the heterogeneity in these small islands in terms of physical geography, socio-economic and cultural backgrounds, as well as their vulnerability to the impacts of climate change. Similar to previous reports, these regions have been assessed together in this section, given the similarities in the challenges they face in addressing climate change impacts and risk, which were thought – until AR4 – to be dominated by sea level rise (Nurse et al., 2014; Betzold, 2015). Since then there has been a substantial increase in the number and complexity of the literature on the drivers and impacts of climate change on small islands (BOM and CSIRO, 2011, 2014; Nurse et al., 2014; Gould et al., 2018; Keener et al., 2018). There are also increasing efforts being made to produce higher resolution climate projections for small islands through downscaling methods (Elison Timm et al., 2015; McLean et al., 2015; Khalyani et al., 2016; C. Zhang et al., 2016; Stennett-Brown et al., 2017; Bhardwaj et al., 2018; Bowden et al., 2021).

The AR5 identified the key climate and ocean-related hazards affecting small islands, which occur at different time scales and have diverse impacts on multiple sectors (Christensen et al., 2013; Nurse et al., 2014). Recent findings from SR1.5 and SROCC emphasize that the multiple interrelated climate hazards currently faced by low-lying islands and coastal areas will be amplified in the future, especially at higher global warming levels (Hoegh-Guldberg et al., 2018; IPCC, 2019b).

12.4.7.1 Heat and Cold

Mean air temperature: Significant warming trends are clearly evident in the small islands, such as those in the Pacific, CAR, and western Indian Ocean, particularly over the latter half of the 20th century (see Figure Atlas.11; Atlas.10.2; Cross-Chapter Box Atlas.2, Table 1). This observed warming signal in the tropical western Pacific has been attributed to anthropogenic forcing (Wang et al., 2016). There is *high confidence* of warming over small islands even at 1.5°C GWL (Atlas.10.4 and Figure Atlas.28; Hoegh-Guldberg et al., 2018). Mean temperature is *very likely* to increase by 1°C–2°C (2°C–4°C) by 2041–2060 (2081–2100) under RCP8.5 (BOM and CSIRO, 2014) and SSP3-7.0 (Atlas.10.4, Figure 4.19 and Figure Atlas.12; Almazroui et al., 2021).

Extreme heat: Observational records indicate warming trends in the temperature extremes since the 1950s in CAR and the Pacific small islands (*high confidence*) (Sections 11.3.2 and 11.9, and Table 11.13). A detectable anthropogenic increase in summer heat stress has been identified over a number of island regions in CAR, western tropical Pacific, and tropical Indian Ocean, based on wet bulb globe temperature (WBGT) index trends for 1973–2012 (*medium confidence*) (Knutson and Ploshay, 2016). An increasing trend in the maximum daytime heat index is also noted in CAR during the 1980–2014 period, as well as more extreme heat events since 1991 (Ramirez-Beltran et al., 2017).

Compared with the recent past, it is *likely* that the intensity and frequency of hot (cold) temperature extremes will increase (decrease) in the small islands (Section 11.9 and Table 11.13; BOM and CSIRO, 2014). Warm spell conditions will occur up to half the year in CAR at 1.5°C GWL with an additional 70 days at 2°C (Hoegh-Guldberg

et al., 2018; Taylor et al., 2018), with livestock temperature–humidity tolerance thresholds increasingly surpassed (Lallo et al., 2018). In CAR, a median increase of more than a month per year where temperatures exceed 35°C is projected by end of the 21st century under SSP5-8.5 (Figure 12.4a–c and Figure 12.SM.1). Heatwaves are projected to increase in CAR by the mid- and end-century under RCP8.5 (Sections 11.3.5 and 11.9, and Table 11.13). Figure 12.4d–f and Figure 12.SM.2 also show an increase of about 30–60 days in which HI exceeds 41°C by 2041–2060 under SSP5-8.5 relative to 1995–2014 in CAR, with an additional increase of about 50–100 days by end of the 21st century for RCP8.5/SSP5-8.5, but this increase remains below 50 days for RCP2.6/SSP1-2.6. The Pacific Islands region is also among those projected to have an increase in WBGT by end-century under RCP8.5, increasing the risk of heat stress in the region (Newth and Gunasekera, 2018).

It is *very likely* that the significant recent warming trends observed in the small islands will continue in the 21st century, which will *likely* further increase heat stress in these regions.

12.4.7.2 Wet and Dry

Mean precipitation: Observational datasets have generally revealed no significant long-term trends in rainfall in the Caribbean over the 20th century when analysed at seasonal and inter-decadal timescales, except for some areas where there is evidence for decreasing trends for the period 1901–2010 but not for the period 1951–2010 (Cross-Chapter Box Atlas.2, Table 1, and Atlas.10.2; Knutson and Zeng, 2018). Although there are spatial variations, annual rainfall trends in the western Indian Ocean are mostly decreasing, with generally non-significant trends in the western tropical Pacific since the 1950s (*low confidence*). Significant drying trends are noted in the southern Pacific subtropics and south-western French Polynesia during the 1951–2015 period (McGree et al., 2019), and in some areas of Hawaii during the 1920–2012 period (*medium confidence*) (Cross-Chapter Box Atlas.2, Table 1, and Atlas.10.2).

Atlas.10.4 projects precipitation reduction over the Caribbean (*high confidence*) (Almazroui et al., 2021) and parts of the Atlantic and Indian oceans, particularly in June to August, by end of 21st century under SSP5-8.5. Precipitation is generally projected to increase under SSP5-8.5 and for higher GWLs in the small islands in parts of the western and equatorial Pacific, but there is *low confidence* in broad changes given drier conditions projected for the southern subtropical and eastern Pacific Ocean (*limited agreement* given spatial and seasonal variability) (Atlas.10.4 and Figure Atlas.28).

River flood: There is *limited evidence* on observed changes in river flooding in the small islands. Long-term records in Hawaii indicate no clear trends in peak flow, except for the significant decrease in peak streamflow in Hawaii Island over the period 1967–2016 (Bassiouni and Oki, 2013; Clilverd et al., 2019). Similarly, there is no significant trend in the frequency and height (after adjusting for average sea level rise) of river flood in Fiji over the period 1892–2013 (McAneney et al., 2017). There is *low confidence* on the direction of future change of river flooding in the small islands due to the limited literature. In Oahu, Hawaii, extreme peak flow events with high

return periods are projected to increase by end of the 21st century under RCP8.5, but there is also high uncertainty in these projections (Leta et al., 2018).

Heavy precipitation and pluvial flood: Heavy precipitation days in CAR have increased in magnitude, and have been more frequent in the northern part during the latter part of the 20th century (*low confidence*) (Section 11.4.2 and Table 11.14). The direction of change in extreme precipitation varies across the Pacific and depends on the season (*low confidence*) (Section 11.4.2 and Cross-Chapter Box Atlas.2, Table 1). Although pluvial flooding events have been observed in some islands, there is *limited evidence* for an assessment on past changes in pluvial flooding, unlike in other regions. There is *low confidence* in the projected change in magnitude of very heavy precipitation days in CAR across different GWLs (Table 11.14). On the other hand, there is *high confidence* in the increase in frequency and intensity of extreme rainfall events (i.e., 1-in-20-year rainfall events) in the western tropical Pacific in the 21st century, even for RCP2.6 scenario, based on model agreement and mechanistic understanding but *low confidence* in the magnitude of change in extreme rainfall due to model bias (BOM and CSIRO, 2014).

Landslide: Heavy rainfall, such as from tropical cyclones, can trigger landslides over steep terrain in the small islands (Bessette-Kirton et al., 2019). There is *limited evidence* to determine long-term trends in rainfall-induced landslides in the small islands (Kirschbaum et al., 2015; Sepúlveda and Petley, 2015; Froude and Petley, 2018; Bessette-Kirton et al., 2019). There is *low confidence* in future changes in landslides in the small islands. The direction of change may depend on future changes in precipitation, tropical cyclones, climate modes (e.g., El Niño–Southern Oscillation, ENSO), as well as human disturbance, but more data and understanding of the complexity of these relationships are needed, especially in these vulnerable areas (Sepúlveda and Petley, 2015; Gariano and Guzzetti, 2016; Froude and Petley, 2018).

Aridity: Current estimates identify many small islands as being under water stress and thus particularly sensitive to variations in rainfall and groundwater, population growth and demand, and land-use change, among others (Cross-Chapter Box Atlas.2; Holding et al., 2016). From 1950 to 2016, a heterogeneous but prevalent drying trend is found in CAR (*low confidence*), where drought variability is modulated by the tropical Pacific and North Atlantic oceans (Table 11.15 and Cross-Chapter Box Atlas.2, Table 1; Herrera and Ault, 2017). In the future, increased aridity and decreased freshwater availability are projected in many small islands due to higher evapotranspiration in a warmer climate that partially offsets increases or exacerbates reductions in precipitation (Karnauskas et al., 2016, 2018b; Hoegh-Guldberg et al., 2018). Increased aridity is projected for the majority of the small islands, such as in CAR, southern Pacific and western Indian Ocean, by 2041–2059 relative to 1981–1999 under RCP8.5 or at 1.5°C and 2°C GWLs, which will further intensify by 2081–2099 (*medium confidence*) (Karnauskas et al., 2016, 2018b). Groundwater recharge is projected to increase in Maui, Hawaii except on the leeward side of the island, which underscores the importance of topography and elevation on freshwater availability in different island microclimates (Brewington et al., 2019; Mair et al., 2019).

Hydrological drought: There is *low confidence* of widespread changes to hydrological drought in CAR or Pacific small islands in recent decades, although an increasing number of studies document local changes. Records in Hawaii indicate downward trends in low streamflow and base flow from 1913 to 2008 (Bassiouni and Oki, 2013). Decadal variability of Hawaiian streamflow coincides with rainfall fluctuations associated with the Pacific Decadal Variability although significant average declines in surface and baseflow runoff of about 8% and 11% per decade, respectively, have been noted during the 1987–2016 period (Clilverd et al., 2019).

There is *low confidence* in hydrological drought change projections, given low signal-to-noise ratios and the challenge in representing island scales in global analyses. Prudhomme et al. (2014) recognized CAR as one of the regions with the highest increase in regional deficit index (RDI; a measure of the fraction of area in hydrological drought conditions) by the end of the 21st century under RCP8.5. Daily streamflow and extreme low flows in two watersheds in Oahu, Hawaii are projected to decline by mid- and end of the 21st century under RCP4.5 and RCP8.5, which would result in more frequent hydrological droughts in this area (Leta et al., 2018).

Agricultural and ecological drought: Recent trends toward more frequent and severe droughts have been noted in the small islands but only with *low confidence* in broad trend patterns, given high spatial variability including heightened drought on the leeward side of islands (e.g., Frazier and Giambelluca, 2017; Herrera and Ault, 2017; McGree et al., 2019; see Table 11.15, Cross-Chapter Box Atlas.2, Table 1). Agricultural and ecological droughts are projected to increase in frequency, duration, magnitude, and extent in small islands, such as in CAR (*medium confidence*) and parts of the Pacific (*low confidence*), particularly where future declines in precipitation are compounded by higher evapotranspiration, under increasing levels of warming (Naumann et al., 2018; Taylor et al., 2018; Vichot-Llano et al., 2021). Relative to the period 1985–2014, decreases in annual surface and total column soil moisture become more robust in more areas in CAR by 2071–2100 under SSP3-7.0 and SSP5-8.5 scenarios (B.I. Cook et al., 2020), but reliably representing drought features in small island domains with global simulations is challenging (see also Section 11.9).

Fire weather: There is *limited evidence* on trends in wildfire in CAR and the Pacific. Records of wildfire in Hawaii from 2005 to 2011 indicate a peak in area burned during the hot and dry summer months, but Trauernicht et al. (2015) note the difficulty in establishing the link between past climate and wildfire trends due to human activities and vegetation changes. Availability of literature limits assessment on future fire weather in the small islands. Drying and warming trends tend to increase fire probability aside from the climate impact on fuel loading, for example, grassland fires in Hawaii (Trauernicht, 2019), and wildfires in Puerto Rico (Van Beusekom et al., 2018).

Observed and projected rainfall trends vary spatially across the small islands. Higher evapotranspiration under a warming climate are projected to partially offset future increases or amplify future reductions in rainfall, resulting in drier conditions and increased water stress in the small islands (*medium confidence*).

12.4.7.3 Wind

Mean wind speed: Scarcity of observations limits assessment of long-term changes in winds over the small islands in the Pacific and CAR. Records indicate that average daily wind speeds have slowly declined in Hawaii, but have remained constant across western and southern Pacific sites since the mid-20th century (Marra and Kruk, 2017). Recent studies of reanalyses and hindcast simulations indicate an intensification of the Pacific trade winds during the 1992–2011 period, which contributed to the ocean cooling in the tropical central and eastern Pacific (England et al., 2014; Takahashi and Watanabe, 2016). Projections estimate up to 0.4 m s^{-1} (8%) increase in annual winds in CAR under RCP8.5, which is associated with changes in the extension of the North Atlantic Subtropical High that enhances the Caribbean low-level jet during the wet season, and stronger local easterlies due to enhanced land–ocean temperature differences in the dry season (Costoya et al., 2019) (*low confidence*).

Tropical cyclone: Tropical cyclones have devastating impacts on the small islands due to intense winds, storm surge and rainfall, although the associated rainfall can also be beneficial for freshwater resources. It is *likely* that tropical cyclone intensity and intensification rates at a global scale have increased in the past 40 years but it is not clear if regional-scale changes are basin-wide or due to shifts in tropical cyclone tracks (Section 11.7.1.2). Other, less data-sensitive tropical cyclone features, such as the poleward migration of where tropical cyclones reach peak intensity in the western North Pacific since the 1940s (*medium confidence*) and the slowdown in tropical cyclone translational speed over contiguous USA since 1900 (*medium confidence*), can affect rainfall and flooding over small islands in CAR and the Pacific (Section 11.7.1.2).

Projections of global changes in tropical cyclones indicate more frequent Category 4–5 storms (*high confidence*) and increased rain rates (*high confidence*) (Knutson et al., 2020), with relative sea level rise exacerbating storm surge potential, but with large regional differences (see Section 11.7.1.5). By the late 21st century, tropical cyclones are projected to be less frequent in the basins of the western and eastern North Pacific, Bay of Bengal, Caribbean Sea and in the Southern Hemisphere, but will be more frequent in the subtropical central Pacific (Murakami et al., 2014; Yoshida et al., 2017; Bell et al., 2019; Knutson et al., 2020). Over CAR, tropical cyclone intensity is expected to increase by the end of the century under RCP8.5 due to higher sea surface temperatures but can be inhibited by increases in vertical wind shear in the region (*medium confidence*) (Kossin, 2017; Ting et al., 2019). The poleward movement of the area in which tropical cyclones reach peak intensity in the western North Pacific is *likely* to continue, which affects the tropical cyclone frequency over the small islands in the area (Section 11.7.1.5; Kossin et al., 2016). Projections also indicate an increase (decrease) in the tropical cyclone frequency during El Niño (La Niña) events in the Pacific at the end of the 21st century (Chand et al., 2017). RCP8.5 2080–2099 projections indicate a 2% increase in the number of tropical cyclones in the north-central Pacific relative to 1980–1999, with tracks shifting northward towards Hawaii (N. Li et al., 2018). Given projected reductions to the overall number of tropical cyclones but increases in storm intensity, total rainfall and storm surge potential, we assess *medium confidence* of overall changes to tropical cyclones affecting the Caribbean and Pacific small islands.

Projections indicate that small islands will generally face fewer but more intense tropical cyclones (*medium confidence*) although there is substantial variability across small island regions given projected regional shifts in storm tracks.

12.4.7.4 Coastal and Oceanic

Relative sea level: Relative sea level rise (RSLR) continues to be a major threat to small islands and atolls, since it can exacerbate the impacts of other climate hazards on low-lying coastal communities and infrastructures, ecosystems, and freshwater resources (Nurse et al., 2014; Hoegh-Guldberg et al., 2018). In the Indian Ocean–South Pacific region, a new tide gauge-based reconstruction finds a regional mean RSL change of $1.33 [0.80 \text{ to } 1.86] \text{ mm yr}^{-1}$ over 1900–2018 (Frederikse et al., 2020) compared to a GMSL change of around 1.7 mm yr^{-1} (Section 2.3.3.3 and Table 9.5). RSLR rates based on satellite altimetry for the period 1993–2018 in the region increased to $3.65 [3.23 \text{ to } 4.08] \text{ mm yr}^{-1}$ (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr^{-1} (Section 2.3.3.3 and Table 9.5).

Relative sea-level rise is *very likely* to continue surrounding the oceans in the Small Island States. Around the small islands, regional mean RSLR projections vary widely, from $0.4\text{--}0.6 \text{ m}$ under SSP1-2.6 to $0.7\text{--}1.6 \text{ m}$ under SSP5-8.5 for 2081–2100 relative to 1995–2014 (median values), but in general they are situated in areas with RSL changes ranging from the mean projected GMSL change to above-average values (Section 9.6.3.3). These RSLR projections may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

Coastal flood: Relative sea level rise, storm surges and swells contribute to coastal inundation in the small islands, where studies on historical trends in coastal flooding are currently limited. For example, a swell event due to distant extratropical cyclones in December 2008 raised extreme water levels leading to flooding affecting five Pacific island nations: Marshall Islands, Micronesia, Papua New Guinea, Kiribati and Solomon Islands (Hoeke et al., 2013; Merrifield et al., 2014). Over low-lying atoll islands in the north-west tropical Pacific, potential increases in the frequency and areal extent of coastal flooding, especially at higher SLR scenarios, are expected to have negative consequences for freshwater resources and island habitability (Storlazzi et al., 2015, 2018). Select tide gauges across the Pacific also indicate increasing trends in the frequency of minor flooding since the 1960s (Marra and Kruk, 2017).

As relative sea levels increase, the potential for coastal flooding increases in the small islands (*high confidence*). Across the Pacific and CAR small islands, the 5–95th percentile range of the 1-in-100-year ETWL is projected to increase (relative to 1980–2014) by $10\text{--}35 \text{ cm}$ and by $14\text{--}41 \text{ cm}$ by 2050 under RCP4.5 and RCP8.5, respectively (Figure 12.4q). By 2100, this range is projected to be $27\text{--}81 \text{ cm}$ and $44\text{--}188 \text{ cm}$ under RCP4.5 and RCP8.5, respectively (Figure 12.4p,r; Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, by 2050, the present-day 1-in-100-year ETWL is projected to have median return periods of between 1-in-1-year and 1-in-50-year in both the Pacific and CAR small islands, with some Pacific islands projected to experience the present-day 1-in-100-year ETWL more than once

Table 12.9 | Summary of confidence in direction of projected change in climatic impact-drivers in the small islands, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2.

Region	Climatic Impact-driver																													
	Heat and Cold			Wet and Dry						Wind			Snow and Ice					Coastal and Oceanic				Other								
	Mean air temperature	Extreme heat	Cold spell	Frost	Mean precipitation	River flood	Heavy precipitation and pluvial flood	Landslide	Aridity	Hydrological drought	Agricultural and ecological drought	Fire weather	Mean wind speed	Severe wind storm	Tropical cyclone	Sand and dust storm	Snow, glacier and ice sheet	Permafrost	Lake, river and sea ice	Heavy snowfall and ice storm	Hail	Snow avalanche	Relative sea level	Coastal flood	Coastal erosion	Marine heatwave	Ocean acidity	Air pollution weather	Atmospheric CO ₂ at surface	Radiation at surface
Caribbean (CAR)	●														5								●		6		●			
Pacific Islands	●	1			2		3	4							5								●		6		●			

1. *Very high confidence* in the direction of change, but *low to medium confidence* in the magnitude of change due to model uncertainty.
2. Decrease in eastern Pacific and southern Pacific subtropics, but increase in parts of western and equatorial Pacific; with seasonal variation in future changes.
3. *High confidence* in increase in extreme rain frequency and intensity in western tropical Pacific; *low confidence* in magnitude of change due to model bias.
4. Increase in southern Pacific.
5. Increase in intensity; decrease in frequency except over central North Pacific.
6. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.

- Already emerged in the historical period (*medium to high confidence*)
- Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)
- Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

a year (Vousdoukas et al., 2018; Oppenheimer et al., 2019). By 2100, the present-day 1-in-50-year ETWL is projected to occur around three times a year by 2100 with an SLR of 1 m at Pacific and CAR small islands (Vitousek et al., 2017). In the western tropical Pacific, the magnitude and frequency of coastal flooding due to SLR can be modulated by changes in the wave climate (Shope et al., 2016).

Coastal erosion: Recent studies have indicated variable and dynamic changes in shorelines of reef islands (*medium confidence*), including both erosion and accretion, which suggest factors other than SLR affecting shoreline changes, such as in the central and western Pacific within the past 50-to-60-year timeframe (Webb and Kench, 2010; Le Cozannet et al., 2014; Ford and Kench, 2015; Duvat and Pillet, 2017). For example, islands on atolls in the central and western Pacific have not substantially eroded or reduced in size in the past decades while sea level has been rising, but their position and morphology have changed due to anthropogenic factors (e.g., seawalls, reclamation) and climate–ocean processes (Biribo and Woodroffe, 2013; McLean and Kench, 2015). Analysis of aerial and satellite imagery revealed severe shoreline retreat in six islands and the disappearance of five vegetated reef islands in Solomon Islands in the western Pacific between 1947 and 2014, which may be due to the interaction between SLR and waves (Albert et al., 2016). In French Polynesia, changes in shoreline and island area have been observed since the 1960s, partly due to the effect of TCs on sediment changes and human activities (Duvat and Pillet, 2017; Duvat et al., 2017). Coastal erosion has also been noted over the small, low-lying, sandy islands, such as in French Polynesia and Solomon Islands, among others (Luijendijk et al., 2018; Mentaschi et al., 2018). Average shoreline retreat rates between 1 and 2 m yr⁻¹ are estimated for the islands in the equatorial Pacific and in CAR, while a retreat rate of 0.5 m yr⁻¹ is estimated for islands in the South Pacific, based on satellite observations from 1984–2016 (Luijendijk et al., 2018; Mentaschi et al., 2018). There was also a loss of 610 km² compared with a gain of 520 km² in coastal area in Oceania during the 1984–2015 period (Mentaschi et al., 2018).

Projections indicate that shoreline retreat will occur over most of the small islands in the Pacific and CAR throughout the 21st century with spatial variability (*high confidence*). Median shoreline change projections (CMIP5) relative to 2010, presented by Vousdoukas et al. (2020b), show that, by mid-century, shorelines in the islands in the equatorial Pacific and South Pacific will retreat by around 40 m, under both RCP4.5 and RCP8.5. In CAR islands, sandy shorelines are projected to retreat by about 80 m by mid-century under both RCPs. By 2100, more than 100 m of median shoreline retreat is projected for all small islands under both RCPs; notably in CAR where retreats approaching 200 m (relative to 2010) are projected under both RCPs. The total length of sandy coasts in CAR and Pacific small islands that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 1100 km and 1200 km respectively, an increase of approximately 14%.

Marine heatwave: Ocean temperatures from satellite observations noted a moderate increase of 1–4 annual marine heat wave (MHW) events between 1982–1988 and 2000–2016 over some areas in the Indian Ocean, subtropical parts of the North and South Atlantic, and central and western parts of the North and South Pacific, but

a decrease in frequency (two annual events) over the eastern Pacific Ocean (Box 9.2; Oliver et al., 2018). The intensity of MHWs has also increased between 0.2°C and 0.5°C over the equatorial portions of the North Atlantic and the South Pacific. Over the eastern tropical Pacific, the decrease in intensity and duration of MHW is between 0.5°C and 1.0°C and between 30 and 75 days, respectively (Box 9.2; Oliver et al., 2018). There is *high confidence* that MHWs will increase around all small island nations. Marine heatwaves are projected to be more intense and prolonged where the largest changes are noted in the equatorial region with maximum annual intensities up to 1.2°C (1.8°C) and annual mean duration reaching 100 days (200 days) at 1.5°C (2.0°C) warming levels (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around all small island nations by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

In summary, relative sea level rise is *very likely* in the oceans around small islands, and along with storm surges and waves will exacerbate coastal inundation in small islands. Shoreline retreat is projected along sandy coasts of most small islands (*high confidence*). There is *high confidence* that MHWs will increase around all small island nations.

The assessed direction of change in climatic impact-drivers for CAR and Pacific small islands and associated confidence levels are illustrated in Table 12.9. Cold, snow, and ice-related climatic impact-drivers, and sand and dust storms are not broadly relevant in the small islands that were assessed.

12.4.8 Open and Deep Ocean

Oceans face challenges from anthropogenic perturbations to the global Earth system, which cause increasing ocean warming, carbon dioxide-induced acidification and oxygen loss (Bindoff et al., 2019). Climate change will affect the major oceanic CIDs described in Section 12.2: mean ocean temperature, marine heatwave, ocean acidity, ocean salinity, and dissolved oxygen (O₂), as well as severe wind storm and sea ice. These changes result in a shifting profile of hazards relevant to impact and risk assessments (Section 12.3). New evidence, the SROCC (IPCC 2019b) assessments and advances in the new CMIP6 climate simulations reinforce confidence in projected changes in climatic impact-drivers in the global oceans. As the ocean has taken up about 90% of the global warming for the period 1971–2018 (Section 7.2.2.2), the emergence of the sea surface temperature increase signal has already been observed in global oceans over the last century (Hawkins et al., 2020). The signal in sea ice extent decrease has already emerged in the Arctic Ocean (Landrum and Holland, 2020), while ocean acidification and low oxygen have also already emerged in many oceanic regions and will emerge in all global oceans by 2050 under RCP8.5 (Section 12.5.2 and Table 12.10). This section assesses key climatic impact-drivers that can be linked with sectoral and regional vulnerability and exposure in open and deep oceans, drawing from previous Chapters (Chapters 2, 3, 4, 5 and 9).

Mean ocean temperature: It is *very likely* that global mean sea surface temperature (SST) has increased by 0.88 [0.68 to 1.01] °C

from 1850–1900 to 2011–2020, and 0.60 [0.44 to 0.74] °C from 1980 to 2020 (Section 2.3.1.1.6 and Table 2.4). There is *very high confidence* that the Indian Ocean, the western equatorial Pacific Ocean, and western boundary currents have warmed faster than the global average, while the Southern Ocean, the eastern equatorial Pacific, and the North Atlantic Ocean have warmed more slowly or slightly cooled (Section 9.2.1.1). It is *virtually certain* that global mean SST will continue to increase in the 21st century at a rate depending on future emissions scenario, with CMIP6 projections indicating an increase of 0.86°C (*likely* range 0.43°C – 1.47°C) under SSP1-2.6 and 2.89°C (2.01°C – 4.07°C) under SSP5-8.5, by 2081–2100, relative to 1995–2014 (Section 9.2.1.1). Global warming of 2°C above pre-industrial levels is projected to increase SST, resulting in the exceedance of numerous hazard thresholds for pathogens, seagrasses, mangroves, kelp forests, rocky shores, coral reefs and other marine ecosystems (*medium confidence*) (Poloczanska et al., 2013a, b, 2016; Liu et al., 2014; Pörtner et al., 2014; Graham et al., 2015; Schoepf et al., 2015; Gobler et al., 2017; Henson et al., 2017; Hoegh-Guldberg et al., 2017; Krueger et al., 2017; Hughes et al., 2018a, b; Perry et al., 2018). It is *virtually certain* that upper-ocean stratification has increased at a rate of $4.9 \pm 1.5\%$ during 1970–2018 and that this will continue to increase in the 21st century (Section 9.2.1.3), potentially leading to reduced nutrient supply and total productivity (*low confidence*) (Moore et al., 2018).

Marine heatwave: Marine heatwaves (MHWs) have increased in frequency over the 20th century, with an approximate doubling since the 1980s (*high confidence*), and their intensity and duration have also increased (*medium confidence*) (Box 9.2). Projections show that this increasing trend *likely* continues with 2–9 times more frequent MHWs (at global scale) projected by 2081–2100, relative to 1995–2014 under SSP1-2.6, and 4–18 times more frequent MHWs under SSP5-8.5. The largest changes in MHW frequency are *likely* to occur in the tropical ocean and the Arctic, while there is *medium confidence* of moderate increases in the mid-latitudes, and of small increases in the Southern Ocean (Box 9.2). Permanent MHWs (more than 360 days per year, relative to the historical climate conditions) are projected to occur in the 21st century in parts of the tropical ocean, in the Arctic Ocean, and around latitude 45°S , under SSP5-8.5 (Box 9.2). The occurrence of such permanent MHWs can be largely avoided under the SSP1-2.6 scenario (Box 9.2). MHWs can have devastating and long-term impacts on ecosystems (Oliver et al., 2018), making them an emerging hazard for marine ecosystems (Frölicher and Laufkötter, 2018; Smale et al., 2019). A series of MHWs that occurred in 2010–2011 had consequences for seagrass in western Australia (Wernberg et al., 2013; Arias-Ortiz et al., 2018), and for the lobster fishery in the Gulf of Maine (Pershing et al., 2018). The MHWs that occurred western Australia in 2015/2016 led to the third-highest mass coral bleaching globally (Le Nohaïc et al., 2017).

Ocean acidity: With the increasing CO_2 concentration, the global mean ocean surface pH is decreasing and is now the lowest it has been for at least a thousand years (*very high confidence*) (Section 2.3.3.5). It is *very likely* that, since the 1980s, ocean surface pH has changed at a rate of -0.016 to -0.019 per decade in the subtropical open oceans, at -0.010 to -0.026 per decade in the tropical Pacific, and at -0.003 to -0.026 per decade in open subpolar

and polar zones (Sections 2.3.3.5 and 5.3.3.2). Over the period 1870–1899 to 2080–2099, ocean surface pH is projected to decline by -0.16 ± 0.002 under SSP1-2.6, and by -0.44 ± 0.005 under SSP5-8.5 (Sections 4.3.2.5 and 5.3.4.1). Declining ocean pH will exacerbate negative impacts on marine species (*medium confidence*) (Albright et al., 2016; Kwiatkowski et al., 2016; Watson et al., 2017).

Ocean salinity: Salinity contrasts have increased since the 1950s, near the ocean surface (*virtually certain*) and in the subsurface (*very likely*), with high-salinity regions becoming more saline and low-salinity regions becoming fresher (Section 2.3.3.2). At the basin scale, it is *very likely* that the Pacific and the Southern Oceans have freshened and that the Atlantic has become more saline (Section 2.3.3.2). The SROCC (IPCC 2019b) assessment that a general pattern of fresh ocean regions getting fresher and salty ocean regions getting saltier will continue in the 21st century is confirmed in Section 9.2.2.2.

At the regional scale, by 2100 the average Arctic surface salinity is projected to decrease by 1.5 ± 1.1 psu (practical salinity units), and the liquid freshwater column in the Arctic Ocean is projected to increase by 5.4 ± 3.8 m under RCP8.5, (Shu et al., 2018). In the Indian Ocean, sea surface salinity is projected to decrease by between 0.49 and 0.75 psu by 2080, compared to 2015, under RCP2.6 and RCP2.6, respectively (Akhiljith et al., 2019). Projections for the North and South Atlantic oceans indicate increasing salinity in the upper layer (0–500 m) under both RCP4.5 and RCP8.5, due to the decreasing freshwater input from the equator and increasing net evaporation (Skirris et al., 2020). There is *medium confidence* that fresh ocean regions (Pacific, Southern and Indian oceans) will get fresher and salty ocean regions (Atlantic Ocean) will get saltier over the 21st century (Section 9.2.2.2; IPCC, 2019b). Ocean warming and high-latitude surface freshening is projected to continue to increase upper-ocean stratification in the 21st century (Section 9.2.1.3).

Dissolved oxygen: Since the middle of the 20th century, oxygen concentrations of open and coastal waters have been declining, and such deoxygenation affects biological and biogeochemical processes in the ocean (Schmidtke et al., 2017). In recent decades, low-oxygen zones in ocean ecosystems have expanded, and projections indicate an acceleration with global warming (*medium confidence*) (Diaz and Rosenberg, 2008; Gilly et al., 2013; Gobler et al., 2014). A 2% loss (4.8 ± 2.1 pmoles O_2) in total dissolved oxygen in the upper ocean layer (100–600 m) has been observed during 1970–2010 (Section 2.3.4.2), with the highest oxygen loss of up to 30 mol m^{-2} per decade in the equatorial and North Pacific, the Southern Ocean and the South Atlantic Ocean (Section 5.3.3.2). Global mean ocean oxygen concentration is projected to decrease by 6.36 ± 2.92 mmol m^{-3} under SSP1-2.6 and by 13.27 ± 5.28 mmol m^{-3} under SSP5-8.5 in the subsurface (100–600 m) by 2080–2099, compared to 1870–1899, which is respectively 71% and 40% greater than previous estimates based on CMIP5 models (Section 5.3.3.2). In the benthic ocean, projected future losses of dissolved oxygen concentration by 2080–2099, compared to 1870–1899, are -5.14 ± 2.04 mmol m^{-3} under SSP1-2.6 and -6.04 ± 2.19 mmol m^{-3} under SSP5-8.5 (Kwiatkowski et al., 2020). Section 5.3.3.2 assessed *very likely* global decreases in ocean oxygen concentrations although

there is *medium confidence* in specific regional declines that are expected to expand both anoxic and hypoxic zones, with such reductions of oxygen expected to persist for thousands of years (Yamamoto et al., 2015; Frölicher et al., 2020).

Sea ice: The Arctic sea ice area for September has decreased from 6.23 to 3.76 million km² and for March from 14.52 to 13.42 million km² between 1979–1988 and 2010–19 (Section 2.3.2.1.1). There is *high confidence* that sea ice in the Arctic will further decrease in the future under all emissions scenarios (Section 9.3.1.1). In contrast, there is no clear observed trend in the Antarctic sea ice area over the past few decades and there is *low confidence* of future changes (Section 9.3.1.1). The duration of the summer ice season in the Arctic has increased by 5 to 20 weeks between 1979 and 2013, with a significant trend ranging from 5 to 17 days per decade for earlier spring retreat and from 5 to

25 days per decade for later autumn advance, with consequences for Arctic marine mammals (AMMs) due to sea ice habitat loss (Laidre et al., 2015). The Arctic is projected to be ice-free more often during summer under 2°C global warming compared to 1.5°C global warming (Section 9.3.1.1; see also Sections 12.4.9 and 4.4.2.1), opening new shipping lanes for international commerce (Valsjö and Ulfarsson, 2011) and lengthening the season for offshore resource extraction (Schaeffer et al., 2012). Iceberg numbers are expected to increase as a result of global warming, forming an elevated hazard to shipping and offshore facilities (Bigg et al., 2018).

It is *virtually certain* that global mean SST will continue to increase throughout the 21st century, resulting in the exceedance of numerous climatic impact-driver thresholds relevant to marine ecosystems (*medium confidence*). Marine

Table 12.10 | Summary of confidence in direction of projected change in climatic impact-drivers in open and deep ocean regions, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2. Asterisks indicate regions that extend across both sides of the map.

High confidence of decrease Medium confidence of decrease Low confidence in direction of change Medium confidence of increase High confidence of increase Not broadly relevant

heatwave days are projected to increase in global oceans, with a larger increase in the tropical ocean and Arctic Ocean (*high confidence*). It is *virtually certain* that upper-ocean stratification will continue to increase in the 21st century. Future ocean warming will *very likely* assist the development of both anoxic and hypoxic zones, with such reductions of oxygen expected to persist for thousands of years. Future projections also indicate freshening of the Pacific, Southern and Indian oceans and a saltier Atlantic Ocean (*medium confidence*).

The assessed direction of change in climatic impact-drivers for open and deep ocean regions and associated confidence levels are illustrated in Table 12.10, following the AR6 WGI ocean reference regions (Figure Atlas.2b).

12.4.9 Polar Terrestrial Regions

Several recent climate assessments of polar regions describe robust patterns of recent and future climatic changes driving impacts and risk for polar environmental, societal, and economic assets. These have included the IPCC SROCC (Meredith et al., 2019), the Report on Snow, Water, Ice and Permafrost in the Arctic (AMAP, 2017), and national assessments for the USA (Markon et al., 2018) and Canada (Derksen et al., 2018). This section examines Greenland and Iceland, the Russian Arctic, Antarctica, and the Arctic portions of Northern Europe and North America (Figure 1.18c).

12.4.9.1 Heat and Cold

Mean air temperature: Atlas.11.2 shows *high confidence* in warming of the Arctic in observations and projections, measuring among the fastest-warming places at more than twice the global mean, with substantially higher temperature increases in the cold season (see also AMAP, 2017; Meredith et al., 2019). Atlas.11.1 assessed *very likely* warming in observations of West Antarctica from 1957 to 2016, but *limited evidence* of mean air temperature change across East Antarctica even as there is *high confidence* in future warming across the continent (Figure Atlas.29; Meredith et al., 2019).

Extreme heat, cold spell and frost: Ecosystem and societal temperature thresholds in polar regions often reflect lower tolerance to heat and higher tolerance to cold. Extreme heat events have increased around the Arctic and Iceland since 1979, including increases in cold season warm days and nights, melt days, and Arctic winter warm events ($T > -10^{\circ}\text{C}$) as well as decreases in cold days and nights (Mernild et al., 2014; Matthes et al., 2015; Vikhamar-Schuler et al., 2016; Graham et al., 2017; Sui et al., 2017; Dobricic et al., 2020; Peña-Angulo et al., 2020). Heatwaves causing high temperature records have been recently documented in West and East Antarctica (Wille et al., 2019; Robinson et al., 2020). There is *high confidence* that polar amplification will drive increases in Arctic heat extremes as well as continuing declines in the magnitude and frequency of cold extremes (Matthes et al., 2015; Kharin et al., 2018), although dynamical effects will still bring substantial cold air anomalies over the Arctic (Wu and Francis, 2019). There is *medium confidence* for equivalent changes in extreme heat in Antarctica based primarily

on higher mean temperatures, with J.R. Lee et al. (2017) projecting more than 50 additional degree days above freezing (2098 RCP8.5 compared with 2014) over parts of the Antarctic Peninsula but smaller changes over mainland Antarctica.

12.4.9.2 Wet and Dry

Mean precipitation: Atlas.11.2 indicated *medium confidence* in observed increases in Arctic precipitation, with the largest rises in the cold season. Antarctic precipitation showed no significant overall trend since the 1970s, with a positive trend over the 20th century (Sections 9.4.2.1 and Atlas.11.1). Increases in Arctic and Antarctic precipitation during the 21st century are *very likely*, with projected percentage increases that are much higher than most subpolar regions of the world (Figure Atlas.29).

Floods and heavy precipitation: Observations and model projections indicate *high confidence* in increasing Arctic river runoff in response to increasing total precipitation (Box et al., 2019; Durocher et al., 2019; Meredith et al., 2019) with a shift towards earlier meltwater flooding (AMAP, 2017). Higher Arctic precipitable water totals are also connected with observed increases in heavy precipitation and convective activity (*high confidence*) (Ye et al., 2015; Kharin et al., 2018; Chernokulsky et al., 2019). Higher flood magnitudes are also driven by future increases in rain-on-snow event days, amounts, and runoff, which are more significant in the Arctic than in mid-latitudes (where seasonal snow cover is often further reduced; AMAP, 2017; Jeong and Sushama, 2018b).

Landslide and snow avalanche: There is a growing number of studies on mass movements in polar regions. Although there is *low confidence* in widespread observational trends for landslides or snow avalanches, a rise in the number of future landslides is supported by strong links to increases in heavy precipitation, glacier retreat, and thawing of ice-rich permafrost that can lead to retrogressive thaw slumps in Arctic regions (Section 2.3.2.5; Kokelj et al., 2015; Derksen et al., 2018; Lewkowicz and Way, 2019; Patton et al., 2019; Ward Jones et al., 2019).

Aridity and drought: Recent decades have seen a general decrease in Arctic aridity, with projections indicating a continuing trend towards reduced aridity (*high confidence*) as increased moisture transport leads to higher precipitation, humidity and streamflow (Meredith et al., 2019) and a corresponding decrease in dry days (Khlebnikova et al., 2019a). There is *low confidence* overall of recent or projected drought changes in polar regions (Section 11.9) even as increasing evidence shows that drainage from permafrost thaw, higher potential evapotranspiration, and changing seasonal patterns of melt have caused lake reduction and soil moisture deficits in several areas that match with projections of future drought increase despite overall precipitation increases (Andresen and Loughheed, 2015; Bring et al., 2016; Spinoni et al., 2018a; Feng et al., 2019; Finger Higgins et al., 2019).

Fire weather: Fire season lengthened from 1979 to 2015 over Arctic portions of North America (Jain et al., 2017), corresponding also to a 1975–2015 increase in lightning-ignited fires in Arctic North-Western North America (Girardin et al., 2013; Veraverbeke et al., 2017).

Abatzoglou et al. (2019) climate model simulations project significant fire weather index increases in boreal forests of Arctic Europe, Arctic Russia and Arctic North-Eastern North America (*medium confidence*). Trends towards more frequent fires in tundra regions are expected to continue, driven in particular by increasing potential evapotranspiration and changes in vegetation (*high confidence*) (Hu et al., 2015; AMAP, 2017; Young et al., 2017).

12.4.9.3 Wind

Mean wind speed and severe storm: There is *medium confidence* of mean wind decrease over the Russian Arctic, Greenland and Iceland, and Arctic North-Eastern North America (Karnauskas et al., 2018a; Jung and Schindler, 2019), but *low confidence* of changes in the other Arctic regions and Antarctica. Bintanja et al. (2014) projected that a strengthening of the Southern Annular Mode would decrease easterlies along Antarctica's coasts with only small changes in katabatic winds (although this effect may diminish with stratospheric ozone recovery). In contrast, Gortler et al. (2014) regional climate model projections indicated a reduction in mean winds over the interior of Greenland by RCP4.5 2100 while coastal winds increase. Reanalysis data and climate models indicate few coherent regional trends of polar cyclone frequency or relationships with cyclone depth and size (Akperov et al., 2018, 2019; Day and Hodges, 2018; Zahn et al., 2018).

12.4.9.4 Snow and Ice

Snow: Atlas.11.1 identified *likely* increases in surface mass balance (driven by snowfall) across Antarctica in the 20th century (*medium confidence*). In the Arctic, overall snow extent and seasonal duration are projected to continue recent declines (*high confidence*), although mid-winter snowpack increases in some of the coldest and high-elevation locations given higher precipitation totals (*medium confidence*) (Section 9.5.3, Atlas.9 and Atlas.11.2; Bring et al., 2016; Danco et al., 2016; AMAP, 2017; Meredith et al., 2019). Higher temperatures result in a higher percentage of Arctic precipitation falling as rain (particularly in autumn and spring) (*high confidence*), with most land regions (outside of Greenland and Antarctica) becoming dominated by rainfall (more than 50% of total precipitation) by RCP8.5 2100 (Bintanja and Andry, 2017; Irannezhad et al., 2017).

Glacier and ice sheet: Section 9.5.1 and Section 2.3.2.3 found that glaciers have lost mass in all polar regions since 2000 (*high confidence*), and Section 9.4 assessed *high confidence* in Greenland Ice Sheet mass losses since 1980 and Antarctic Ice Sheet losses since 1992 (dominated by West Antarctica, with losses in parts of East Antarctica in the past two decades). New simulations from GlacierMIP (Marzeion et al., 2020) indicate glaciers in Iceland will lose $31 \pm 35\%$, $41 \pm 46\%$ and $53 \pm 45\%$ of their mass in 2105 by the end of the century for RCP2.6, RCP4.5 and RCP8.5 scenarios, respectively. Marzeion et al. (2020) projected mass losses (*high confidence*) for those same scenarios in the Greenland Periphery: $22 \pm 23\%$, $29 \pm 26\%$, and $42 \pm 28\%$; Svalbard: $35 \pm 34\%$, $50 \pm 36\%$, and $66 \pm 35\%$; Russian Arctic: $26 \pm 26\%$, $38 \pm 28\%$, and $52 \pm 30\%$; Northern Arctic Canada: $12 \pm 13\%$, $18 \pm 12\%$, and $27 \pm 18\%$; Southern Arctic Canada: $23 \pm 27\%$, $33 \pm 29\%$, and $48 \pm 32\%$; and

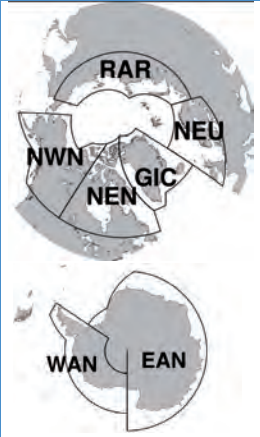

Antarctic Periphery: $7 \pm 12\%$, $13 \pm 10\%$, and $16 \pm 19\%$. Areas with receding glaciers are also potentially vulnerable to glacial lake outburst floods (Harrison et al., 2018).

Permafrost: Observations from recent decades (assessed in Section 9.5.2 and Section 2.3.2.5) show increases in permafrost temperature (*very high confidence*) and active layer thickness (*medium confidence*) across the Arctic (AMAP, 2017; Derksen et al., 2018; Markon et al., 2018; Biskaborn et al., 2019; Farquharson et al., 2019; Meredith et al., 2019; Romanovsky et al., 2020). Section 9.5.2 noted that observations of active layer thickness in Antarctica are too limited to assess long-term trends (see also Hrbáček et al., 2018; Biskaborn et al., 2019). Future projections indicate continuing increases in permafrost temperature and active layer thickness with loss of permafrost across the Arctic (Section 9.5.2). Streletskiy et al. (2019) noted that changes to Russian permafrost temperature and active layer thickness are most pronounced in areas where permafrost is continuous (underlying >90% of landmass). CMIP5 analyses by Slater and Lawrence (2013) projected that, by RCP8.5 2100, shallow (<3 m) permafrost would be most probable only in portions of the Canadian Arctic Archipelago and the Russian Arctic coastal and eastern upland regions.

Sea ice: Consistent with SROCC (Meredith et al., 2019), Section 9.3.1 and Section 2.3.2.1.1 assess *very high confidence* that Arctic sea ice thickness, extent, and average age have significantly decreased over the past four decades, with largest declines in September (when sea ice is at an annual minimum). Declines in landfast ice are most rapid in the Laptev Sea (Selyuzhenok et al., 2015), with warming also breaking perennial landfast ice blocking ocean channels ('ice plugs') in the Canadian Archipelago (Pope et al., 2017), and landfast ice declining in the cold season by 7% per decade across the Arctic (1976–2007; Yu et al., 2014). Observed trends and projections suggest that perennial sea ice is being replaced by thin, seasonal ice, although multi-year ice will persist above the Canadian Archipelago and drift into sea transportation lanes (Howell et al., 2016; Derksen et al., 2018). Trends from 1979 to 2013 show slightly earlier spring melt for Arctic sea ice, but substantially delayed autumn freeze-up and a melt season lengthened by more than 3 days per decade off northern Alaska and Canada with the exception of portions of the Bering Sea (Parkinson, 2014; Stroeve et al., 2014). Section 9.3.2 assessed *low confidence* in long-term trends in sea ice extent or thickness near Antarctica.

Future declines in Arctic sea ice are *virtually certain*, although there is *low confidence* in declines of Antarctic sea ice given dynamical processes in the Southern Ocean and the recovery of stratospheric ozone (Section 9.3; Meredith et al., 2019). Projections of an 'ice-free' Arctic vary, depending on definitions representing transportation needs, however Laliberté et al. (2016) noted that the median of 42 CMIP5 models projected <5% sea ice for the month of September by 2050, with equivalent conditions for the entirety of the August–October period by 2090. Section 9.3.1 assessed *high confidence* that practically ice-free conditions (<1 million km² in the September mean) would *likely* first appear before 2050 even under strong mitigation scenarios (Sigmond et al., 2018; Stroeve and Notz, 2018; Notz and SIMIP Community, 2020).

Table 12.11 | Summary of confidence in direction of projected change in climatic impact-drivers in the polar regions, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP2-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea level rise) to global warming levels between 2°C and 2.4°C (see Section 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural interannual variability if found with at least *medium confidence* in Section 12.5.2. Note that the Arctic portions of the NEU, NEN and NWN differ from the full AR6 regions assessed in the Europe and North America sections above (see also Figure 1.18c).

1. Snow may increase in some high elevations and during the cold season and decrease in other seasons and at lower elevations.
 2. Higher confidence in southern regions and lower toward north.
 3. Higher confidence in increase for some climatic impact-driver indices during summer.
 4. Glaciers decline even as some regional snow climatic impact-driver indices increase.
 5. Decreasing in west and increasing in east.
 6. Except for northern Baltic Sea coasts where relative sea levels fall.
 7. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.
- Already emerged in the historical period (*medium to high confidence*)
 - Emerging by 2050 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)
 - Emerging after 2050 and by 2100 at least in scenarios RCP8.5/SSP5-8.5 (*medium to high confidence*)

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase	Not broadly relevant
-----------------------------	-------------------------------	---------------------------------------	-------------------------------	-----------------------------	----------------------

Lake and river ice: There is *high confidence* in observations of significant declines in seasonal ice cover thickness and duration over most Arctic lakes, with many lakes projected to lose more than one month of ice cover by mid-century (*medium confidence*) (Meredith et al., 2019; Sharma et al., 2019). Some lakes that previously froze to the bottom ('bedfast') now maintain liquid bottom water year round, and others shift from perennial to seasonal ice cover (Surdu et al., 2016; Engram et al., 2018). Yang et al. (2020a) identified a decline in Arctic cold-season river ice extent in satellite observations (particularly in Alaska) and projected reductions in average Northern Hemisphere seasonal river ice duration of 6.10 ± 0.08 days per degree global surface air temperature.

Heavy snowfall and ice storm: There is *limited evidence* of changes in heavy snowfall due to competing influences of shortened snowfall seasonality with more intense (and larger overall) precipitation in the Arctic. Episodic heavy snowfall trends in Antarctica are difficult to separate from large interannual variability (*limited evidence*) (Gorodetskaya et al., 2014; Turner et al., 2020). *Limited evidence* also hinders clear signals in ice storms, although warming shifts the freezing line (around which ice storms occur) poleward and upslope (Bintanja and Andry, 2017). Groisman et al. (2016) used 40 years of observations to identify an increase of freezing rain events in Norway, North America, and eastern and western Russia. Increases in winter rainfall have led to more frequent development of difficult wildlife and livestock grazing conditions as basal ice conditions coat the ground below snowpack (Peeters et al., 2019).

12.4.9.5 Coastal and Oceanic

Relative sea level: Satellite altimetry and tide data show that relative sea levels (with glacial isostatic adjustment) are rising in Arctic Europe and Arctic North-Western North America, declining in portions of southern Alaska and Arctic North-Eastern North America and no clear trend in Greenland and the Russian Arctic (Sweet et al., 2018; Rose et al., 2019), which is broadly consistent with findings in Oppenheimer et al. (2019). Areas with low or negative change have substantial land uplift counteracting the global mean sea level trend (Greenan et al., 2018; Sweet et al., 2018; Madsen et al., 2019). SROCC projections indicate *high confidence* in future rises in relative sea level for all Arctic regions other than areas of substantial land uplift in north-eastern Canada, the west coast of Greenland, and narrow portions of West Antarctica (Oppenheimer et al., 2019).

Coastal flooding and erosion: Higher sea levels and reduced coastal sea ice protection will increase future extreme sea levels in the Arctic (*high confidence* for Arctic Northern Europe, the Russian Arctic, and Arctic North-Western North America (*medium confidence*) for Greenland and Iceland and Arctic North-Eastern North America given glacial isostatic adjustment). Vousdoukas et al. (2018) project that the current 1-in-100-year extreme total water level would have median return periods of 1-in-20-years to 1-in-50-years by 2050, increasing to 1-in-5-years to 1-in-20-years by 2100 under RCP4.5 along nearly the entire Arctic coastline by 2100 (excluding GIC for which projections are not available). Projections for RCP8.5 indicate that the present-day 1-in-100-year ETWL would have median return periods of 1-in-10-years to 1-in-50-years by 2050 and would occur

once every five years (or more frequently) by 2100. Arctic coastal erosion is also expected to increase with climate change (*medium confidence; high agreement but limited evidence* of projections), accelerated in some regions by subsurface permafrost thaw and increased wave energy (Gibbs and Richmond, 2015; Fritz et al., 2017; Oppenheimer et al., 2019; Casas-Prat and Wang, 2020). A longer ice-free season for the RCP8.5 2080s is projected to help drive more than 100 m of shoreline retreat in North-Western North America Arctic coastal communities (Melvin et al., 2017; Greenan et al., 2018; Magnan et al., 2019). Assessment of coastal flooding and erosion changes in Antarctica are limited by a lack of studies.

Marine heatwave: Recent years have seen marine heatwaves (MHWs) and increasing extreme coastal SSTs in Arctic systems (Lima and Wethey, 2012; Collins et al., 2019; Frölicher, 2019). Projections show increases in MHW intensity, frequency and duration will be larger over the Arctic Ocean than mid-latitude oceans due in part to low interannual variability under current sea ice (*high confidence*). Frölicher et al. (2018) used 12 CMIP5 models to project median MHW days increasing about 25-fold and 50-fold at the 2°C and 3.5°C GWLs, respectively, in response to mean ocean warming and sea ice loss, and the smallest global changes still leading to increases in the Southern Ocean around Antarctica (see also Cross-chapter Box 9.1).

Climate change has caused and will continue to induce an enhanced warming trend, increasing heat-related extremes and decreasing cold spells and frosts in the Arctic (*high confidence*), with similar changes in Antarctica but *medium confidence* for extreme heat increases and West Antarctic frost change decreases and *low confidence* for cold spell changes and East Antarctica frost. The water cycle is projected to intensify in polar regions, leading to more rainfall, higher river flood potential and more intense precipitation (*high confidence*). Projections indicate reductions in glaciers at both poles, with sea ice loss, enhanced permafrost warming, decreasing permafrost extent, and decreasing seasonal duration and extent of snow cover in the Arctic (*high confidence*) even as some of the coldest regions will see higher total snowfall given increased precipitation (*medium confidence*). Projections indicate relative sea level rises in polar regions (*high confidence*), with the exception of regions with substantial land uplift including North-Eastern North America (*high confidence*), western Greenland, the northern Baltic Sea, and portions of West Antarctica. Higher sea levels also contribute to *high confidence* for projected increases of Arctic coastal flooding and higher coastal erosion (aided by sea ice loss) (*medium confidence*) with lower confidence for those CIDs in regions with substantial land uplift.

12.4.10 Specific Zones and Hotspots

This section focuses on CIDs affecting specific zones with heightened vulnerability and coherent characteristics that cut across traditional continental regions (see also Section 12.3). It is designed to match the structure of the Cross-Chapter Papers in the WGII Report, although

polar regions were addressed in more extensive detail in Sections 12.4.8 and 12.4.9 of this Report and the Mediterranean Region will not be handled separately given that its climatic impact-drivers are discussed in Sections 12.4.1 and 12.4.5 as well as in Cross-Chapter Box 10.3.

12.4.10.1 Hotspots of Biodiversity (Land, Coasts and Oceans)

Hotspots of biodiversity are defined by the AR6 WGII as 'geographic areas with exceptionally high richness of species, including rare (endemic) species' (WGII Cross-Chapter Paper 1). The AR6 assessment is based on 238 distinctive regions often called the 'Global 200 ecoregions' (Olson and Dinerstein, 2002).

Mean temperature increase is a major climatic impact-driver for biodiversity hotspots, and it is *very likely* that it will affect all hotspot areas identified in the literature, at various rates in all climate scenarios, except those located in the North Atlantic where warming is uncertain (see Chapter 4). Terrestrial ecosystems will experience an enhanced warming compared to ocean ecosystems, because land temperatures are warming faster than ocean temperatures (Chapter 4). Marine ecoregions will experience ocean acidification and temperatures that increase faster in high latitudes (*high confidence*), but critical temperature and oxygen thresholds are projected to be crossed earlier (by mid-century RCP8.5) in tropical areas (Hughes et al., 2017a; Bruno et al., 2018). A warming trend is also expected for freshwater ecosystems, with different local magnitudes due to combined effects of groundwater system inertia as well as hydrology changes (Knouft and Ficklin, 2017). In tropical land areas, because interannual temperature variability is weak compared to mean changes, the temperature distribution range is *likely* to be shifted to a very different range in all projection scenarios, with unprecedented values relative to pre-industrial conditions. High climate velocities are particularly noteworthy for biodiversity hotspots given complex ecosystem dynamics and niche climates not easily replicated under shifted geographies (Burrows et al., 2014; Halpern et al., 2015; Dobrowski and Parks, 2016). In some regions (e.g., Central Africa, Amazon, South East Asia) the mean temperature change is already beyond the normal range of variations as it has reached levels higher than three (and up to six) times larger than the standard deviation of the interannual variations (Hawkins et al., 2020). Together with global warming, land and marine heatwaves are *very likely* to increase in the future climate in biodiversity hotspots (Sections 12.4.1–12.4.7).

There is *low confidence* in broad patterns of future drying or wet trends across the land and freshwater biodiversity hotspots in the humid tropics, although drying trends have been detected and predicted in parts of the Amazon (Fu et al., 2013; Boisier et al., 2015). There is *medium confidence (limited evidence, high agreement)* that in several regions the length of the dry season has already increased and is projected to further increase in some parts of the Mediterranean, Amazonia and sub-Saharan Africa (Debortoli et al., 2015; Dunning et al., 2018; Hochman et al., 2018; Saeed et al., 2018). Longer dry seasons also extend the seasonal length and geographical extent of fire weather in all future scenarios (*medium confidence*) (Jolly et al., 2015; Abatzoglou et al., 2019).

In conclusion, biodiversity hotspots around the world will each face unique challenges as climatic impact-drivers change. However, heat, drought and length of dry season, fire weather, sea surface temperature and deoxygenation are relevant drivers to terrestrial, freshwater and marine ecosystems, and have marked increasing trends.

12.4.10.2 Cities and Settlements by the Sea

Cities and settlements by the sea are exposed to specific climate and climate change patterns and to compound coastal hazard risks (AR6 WGII Cross-Chapter Paper 2). The AR5 WGII found that, in general, 'urban climate change-related risks are increasing (including rising sea levels and storm surges, heat stress, extreme precipitation, inland and coastal flooding, landslides, drought, increased aridity, water scarcity, and air pollution)' (Revi et al., 2014). Since AR5 a number of studies have been carried out to understand urban climate and its change. Box 10.3 identified a continuing strong role of the urban heat island in amplifying heat extremes in cities, although changes in the urban heat island are an order of magnitude smaller than projected localized warming trends (*very high confidence*).

Coastal cities' proximity to the sea somewhat mitigates the effect of urban heat islands (*high confidence*) (Salvati et al., 2017; Santamouris et al., 2017; Y. Wang et al., 2018; Martinelli et al., 2020). Cities and settlements by the sea typically experience higher humidity levels than inland regions, combining with heat to enhance heat stress and induce exceedance of critical heat stress thresholds for outdoor activities, with potential enhanced exposure to heat for informal settlements (J. Wang et al., 2019). Such threshold exceedances are projected to increase for many coastal areas (*high confidence*), including the Persian Gulf where heat stress is projected to be extreme (Pal and Eltahir, 2016; Ahmadelipour and Moradkhani, 2018), and some low-lying areas in Europe such as the Po Valley and coastal Mediterranean areas (Coppola et al., 2021a; Schwingshackl et al., 2021; see also the heat stress index shown in Figure 12.4d–f).

Climate change-related variations in oceanic drivers (e.g., relative sea level, storm surge, ocean waves), combined with tropical cyclones, extreme precipitation and river flooding, are expected to lead to more frequent and more intense coastal flooding and erosion (*very high confidence*) impacting cities and settlements located especially in low-elevation coastal zones and mega-deltas (Chan et al., 2012, 2018; Karymbalis et al., 2012; Hemer et al., 2013; Aerts et al., 2014; B. Neumann et al., 2015; Hauer et al., 2016; Ranasinghe, 2016; Hinkel et al., 2018; Mavromatidi et al., 2018; Marcos et al., 2019; see also Sections 12.3, 12.4.1–12.4.7 and 12.4.9). Coastal erosion and flooding also pose challenges to critical infrastructure such as roads, subway tunnels, electricity and phone networks, wastewater management plants and buildings (Grahn and Nyberg, 2017; Pregnolato et al., 2017). Compound flooding due to simultaneous storm surges and high river flows have been found to be increasingly frequent in several cities and/or low-lying areas in Europe and the USA (*high confidence*) (Wahl et al., 2015; Bevacqua et al., 2019; Ganguli and Merz, 2019). Chapter 11 found that the frequency of such compound flood events is projected to increase (*high confidence*). In addition to changes induced by sea level change, many cities and settlements by the sea are in regions where tropical

cyclones are projected to become more intense and severe tropical cyclones more frequent (*high confidence*) (Section 11.7).

The SROCC highlighted coastal settlements in the Arctic as being particularly exposed to several CID changes (Magnan et al., 2019). Enhanced waves, due to extended season of sea ice retreat, are projected to foster coastal flooding and erosion (Section 12.4.9; Gudmestad, 2018; Casas-Prat and Wang, 2020). Climate change is also affecting sea ice quality and season length along coasts of the Arctic Ocean where populations depend on sea ice for hunting or transportation (Section 12.4.9; Pearce et al., 2015).

In summary, coastal cities and settlements are particularly affected by a number of climatic impact-drivers that have already changed and will continue to change whatever the emissions scenario. These include increases in extreme heat, pluvial floods, coastal erosion and coastal flood (*high confidence*). Increasing relative sea level, compounding with increasing tropical cyclone storm surge and rainfall intensity, will increase the probability of coastal city flooding (*high confidence*). Arctic coastal settlements are particularly exposed to climate change due to sea ice retreat (*high confidence*).

12.4.10.3 Deserts and Semi-arid Areas

Drylands, which include hyper-arid, arid, semi-arid and dry sub-humid areas (IPCC, 2019c), lie on all continents and cover 46% of the global land area and host more than one-third of the current population (Olsson et al., 2019). Huang et al. (2016b) found that aridity changes have helped expand dryland area by about 4% from 1948 to 2004, with the largest expansion of drylands occurring in semi-arid regions since the early 1960s. Section 4.5.1 assessed *high confidence* of a future poleward expansion of the Hadley cell, leading to a poleward shift of dryland areas in all scenarios considered. There is no evidence of a future global trend in aridification of drylands (IPCC, 2019a), but *high confidence* of aridification in some areas (e.g., Mediterranean, Central America, Southern Africa; IPCC, 2019a; see also Figure 12.4j–l). However, drivers of desertification largely include land-cover changes and land-use management, along with climate change (IPCC, 2019a).

Warming temperatures and extreme heat are major climatic impact-drivers with multiple potential impacts on societies, health, and habitability in semi-arid and arid regions that are already near physiological limits for outdoor activities. Semi-arid regions will *very likely* undergo a warming in all future scenarios (Chapter 4 and Atlas) and *likely* undergo an increase in duration, magnitude and frequency of heatwaves (Chapter 11) (Figure 12.4a–c). It is *likely* that heat stress will be much more intense by the end of the century in many areas under all scenarios, such as deserts and semi-arid zones in Asia (Murari et al., 2015; Mishra et al., 2017), Australia and Africa (Zhao et al., 2015; Xia et al., 2016; Guo et al., 2017; Dosio et al., 2018; Schwingshackl et al., 2021), with consequences for labour productivity with respect to high heat-humidity conditions (Figure 12.4d–f).

Drought is another major climatic impact-driver for semi-arid areas, imposing major challenges on agriculture given existing water availability constraints (Kusunose and Lybbert, 2014;

Barlow et al., 2016; Otto et al., 2018). Over the period 1961–2013, the annual area of drylands in drought has increased, on average by slightly more than 1% per year, with large interannual variability (Olsson et al., 2019). In general, droughts have increased in several arid and semi-arid areas over the last decades (*medium confidence*), and are *likely* to increase in the future as indicated by a number of indices calculated from climate (Liu et al., 2018b; Zkhiri et al., 2019; Coppola et al., 2021b; Driouech et al., 2021; see also Figure 12.4j–l).

Deserts and semi-arid areas are prone to dust storms, which can drive impacts on health and several other sectors (X. Zhang et al., 2016; Tong et al., 2017). The SRCL indicated that the evolution of dust under climate change is uncertain (Mirzabaev et al., 2019), and there is a lack of evidence and agreement of a change in their frequency or intensity so far in most regions (Sections 12.4.1–12.4.9). Model projections of future changes in dust are hindered by the uncertainties in future regional wind and precipitation as the climate warms (Evan et al., 2016); in the effect of CO₂ fertilization on source extent (Huang et al., 2017); and in the impact of human activities upon the land surface (Ginoux et al., 2012; see Chapter 10). Projected trends in dust storms and dust loads in deserts and semi-arid areas vary from region to region. Dust loadings are expected to decrease over most of the Sahara and Sahel (*low confidence*) (Section 12.4.1), increase over Mexico and the south-west USA (*medium confidence*) (Section 12.4.6), and there is *low confidence* of a future trend due to climate change in other continents (Sections 12.4.2–12.4.5).

In conclusion, desert and semi-arid areas are strongly affected by climatic impact-drivers such as extreme heat, drought and dust storms. Heat hazards are *very likely* increasing in all future climate scenarios, but uncertainty remains regarding any broadly consistent future changes in other climatic impact-drivers for deserts and semi-arid regions.

12.4.10.4 Mountains

Mountains cover about 30% of the land areas on Earth (not counting Antarctica) and deliver a number of vital services to humanity (WGII Cross-Chapter Paper 5; IPCC, 2019b). Climate change in high mountains was addressed in SROCC, which emphasized changes in several climatic impact-drivers. These included an observed general decline in low-elevation snow cover, glaciers and permafrost (*high confidence*), which induced changes in natural hazards such as decrease in slope stability (*high confidence*), changes to the frequency of glacial lake outbursts (*limited evidence*), and climate effects on other climatic impact-drivers (avalanche, rain-on-snow floods) with various degrees of confidence (Hock et al., 2019).

There is a growing body of literature indicating elevation-dependent warming (EDW; different rates of warming by altitude although not necessarily increasing with altitude) in several mountain regions but not globally (Hock et al., 2019; Pepin et al., 2019; Ahmed et al., 2020; B. Li et al., 2020; Williamson et al., 2020; You et al., 2020; Micu et al., 2021). Statistically significant elevational enhancement to long-term trends in maximum near-surface air temperatures and diurnal temperature range were observed in southern central Himalaya and in the Swiss Alps (Rottler et al., 2019; Thakuri et al., 2019).

Aguilar-Lome et al. (2019) reported that winter daytime land surface temperatures in the Andean region between 7°S and 20°S show the strongest trends at higher elevations: +1.7°C per decade above 5000 m above sea level. Palazzi et al. (2019) identified changes in albedo and downward thermal radiation as key drivers of EDW according to the simulation outputs of a high-spatial-resolution model in three important mountainous areas: the Colorado Rocky Mountains, the Greater Alpine Region and the Himalayas–Tibetan Plateau, but mechanisms for EDW remain complex (Hock et al., 2019). Warming is also affecting mountain lake surface temperatures, increasing probabilities of ice-free winters and the frequency and duration of ‘lake heatwaves’ (*high confidence*) (O’Reilly et al., 2015; Woolway et al., 2020, 2021) with a high variability from lake to lake.

Elevation-dependent warming could speed up the observed, rapid upward shifts of the freezing level height (FLH) in several mountainous regions of the world and lead to faster changes in the snowline, the glacier equilibrium-line altitude and the snow/rain transition height (*high confidence*). In the Indus, Ganges and Brahmaputra basins in Asia, the FLH is projected to rise at a rate of 4.4 to 10.0 m yr⁻¹ under RCP8.5 (Viste and Sorteberg, 2015). In the Argentinian Andes, FLH is projected under RCP8.5 to move up more than twice as much by 2070 as during the entire Holocene under the worst case scenario (Drewes et al., 2018). On the western slope of the subtropical Andes (30°S–38°S) in central Chile, the mean value of the free tropospheric height of the 0°C isotherm under wet conditions is projected to be close to or higher than the upper quartile of the distribution in the current climate, towards the end of the century and under RCP8.5 (Mardones and Garreaud, 2020). In the Alps and the Pyrenees, Spandre et al. (2019) projected a rise in the natural snow elevation of between 200–300 m and 400–600 m by mid-century under RCP2.6 and RCP8.5, respectively. In the same region, the environmental equilibrium-line altitude is projected to exceed the maximum elevation of 69%, 81% and 92% of the glaciers by the end of the century under RCPs 2.6, 4.5 and 8.5, respectively (Žebre et al., 2021).

Orographic effects enhance convection and stratiform heavy precipitation (due to uplift) and make mountains prone to extreme precipitation events. These events are projected to increase in major mountainous regions (Alps, parts of the Andes, British Columbia, North-Western North America, Calabria, Carpathian, Hindu-Kush-Himalaya, Rocky Mountains, Umbria; *medium to high confidence* depending on location), with potential cascading consequences of floods, landslides and lake outbursts in mountainous areas in all scenarios (*medium confidence*) (Chapter 11 and Sections 12.4.1–12.4.9; Geertsema et al., 2006; Gaire et al., 2015; Kim et al., 2015; Ciabatta et al., 2016; Gariano and Guzzetti, 2016; Kharuk et al., 2016; Syed and Al Amin, 2016; Cloutier et al., 2017; Gądek et al., 2017; Jurchescu et al., 2017; Rajczak and Schär, 2017; Alvioli et al., 2018; Coe et al., 2018; Schlögl and Matulla, 2018; C.-W. Chen et al., 2019; Handwerger et al., 2019; Hock et al., 2019; Patton et al., 2019; Vaidya et al., 2019; Kirschbaum et al., 2020; Coppola et al., 2021b).

Declines in low-elevation snow depth and seasonal extent are projected for all SSP-RCPs (see Sections 12.4.1–12.4.6), along with reductions in mountain glacier surface area, increases in permafrost temperature, decreases in permafrost thickness, changes in lake and

river ice, changes in the amount and seasonality of streamflows and hydrologic droughts in snow-dominated and glacier-fed river basins (e.g., in Central Asia; Sorg et al., 2014; Reyer et al., 2017b) (*medium confidence*), and decreases in the stability of mountain slopes and snowfields. Glacier recession could lead to the creation of new glacial lakes in places like the Himalaya-Karakoram region (Linsbauer et al., 2016) and in Alaska and Canada (Carrivick and Tweed, 2016; Harrison et al., 2018) (*medium confidence*). With increasing temperature and precipitation these can increase the occurrence of glacier lake outburst floods and landslides over moraine-dammed lakes (*high confidence*) (Carey et al., 2012; Rojas et al., 2014; Iribarren Anaconda et al., 2015; Cook et al., 2016; Haeblerli et al., 2017; Kapitsa et al., 2017; Narama et al., 2018; Wilson et al., 2018; Drenkhan et al., 2019; S. Wang et al., 2020).

In conclusion, mountains face complex challenges from specific climatic impact-drivers drastically influenced by climate change: regional elevation-dependent warming (*high confidence*), low-to-mid-altitude snow cover and snow-season decrease even as some high elevations see more snow (*high confidence*), glacier mass reduction and permafrost thawing (*high confidence*), and increases in extreme precipitation and floods in most parts of major mountain ranges (*medium confidence*).

12.4.10.5 Tropical Forests

Tropical forests, which are among the world’s most biologically diverse ecosystems, are essentially located in Central and South America, Africa and South East Asia (AR6 WGII Cross-Chapter Paper 7). The AR5 and SR1.5 indicated several specific climatic impact-driver changes that are particularly important to tropical forests: mean temperature increase, long-term drying trends (including shifts in the length of the dry season), prolonged drought, wildfires and surface CO₂ increase for inland forests (IPCC, 2013, 2018). The SRCCL assessed an enhanced risk and severity of wildfires in tropical rainforests (*high confidence*), but fires are not only a natural process but are also affected by deforestation and other human influences (IPCC, 2019a).

Temperature is rising in all tropical regions covered with forests and will *very likely* continue to rise, reaching levels unprecedented in recent decades as the temperature trends rapidly emerge from weak historical interannual variability (Sections 12.4.1–12.4.4 and 12.5.2; see also Chapter 4 and Atlas).

Regional patterns of increasing drought or unusual wet and dry periods are predicted with agreement over many climate models such as over the Amazon basin (Boisier et al., 2015; Duffy et al., 2015; Zulkafli et al., 2016; Coppola et al., 2021b). There is *medium confidence (limited evidence, high agreement)* that in several tropical-forest regions (e.g., Amazonia, West Africa) the dry season length has increased (Fu et al., 2013; Debortoli et al., 2015; Saeed et al., 2017; Dunning et al., 2018; Wadsworth et al., 2019), and there is *low confidence (limited evidence)* that deforestation influences the shift in the onset of the wet season in south Amazonia (Leite-Filho et al., 2019). In contrast, the wet season is increasing in northern Australia tropical forests (Catto et al., 2012).

Tropical forests typically reach peak fire weather conditions in the dry season (Taufik et al., 2017), in particular during long-lived droughts (Brando et al., 2014; Marengo et al., 2018), with consequences for tree mortality, forest and carbon sink loss (Brando et al., 2019), and on the hydrological cycle in South America (Martinez and Dominguez, 2014; Espinoza et al., 2020). Observations and reanalyses over the past three to four decades, combined into fire risk indices, show that the fire weather season length has been increasing by about 20% globally (Jolly et al., 2015), and this index exhibits particularly high trend values over tropical forest areas of South and Central America and Africa. There is generally *low confidence* in future projections of general fire weather risk evolution in tropical forests and evolutions depend on the region (Abatzoglou et al., 2019). Over the Amazon basin the fire risk increase is projected to emerge well before 2050 while for other equatorial forests no significant evolution is found. In Savanna areas the risk increase is found to be more general.

In conclusion, most tropical forests are challenged by a mix of emerging warming trends that are particularly large in comparison to historical variability (*medium confidence*). Water cycle changes bring prolonged drought, longer dry seasons, and increased fire weather to many tropical forests, with plants also responding to CO₂ increases (*medium confidence*).

12.5 Global Perspective on Climatic Impact-drivers

12.5.1 A Global Synthesis

Section 12.4 assessed changes in climatic impact-drivers by region, primarily based on a large number of local- and regional-scale studies (even though global studies are also used). This section presents an assessment of changes in CIDs at the global scale. It is based on both a bottom-up synthesis of the results in Section 12.4, and a top-down assessment from global-scale studies undertaken here. Cross-Chapter Box 12.1 summarizes global-scale CIDs with levels of warming.

Global-scale studies use similar indices of climatic impact-drivers across space, although these indices may not always be those used at the local or regional scale. Most published global-scale studies concentrate on single sectors or climatic impact-drivers, but some take a multi-sectoral perspective (e.g., Warszawski et al., 2014; Arnell et al., 2016, 2019; Schleussner et al., 2016; Mitchell et al., 2017; Betts et al., 2018; Byers et al., 2018; Mora et al., 2018; O'Neill et al., 2018; Zscheischler et al., 2018). Only a few published global-scale studies (e.g., Coppola et al., 2021; Schwingshackl et al., 2021) have used CMIP6 scenarios to date.

All regions will experience, before 2050, increased warming, an increase of extreme heat and a decrease in cold spells, regardless of the emissions trajectory (*high confidence*). Tropical regions, but also mid-latitude regions to a lesser extent, will experience an increasing number of days with heat indices crossing dangerous thresholds used to characterize heat stress, such as HI > 41°C (Figure 12.4). The increase, by the end of century, exceeds 100 days per year in most tropical areas under SSP5-8.5 but remains much more limited

(almost half) under SSP1-2.6. Several global-scale studies have shown that high temperature extremes will increase everywhere (*high confidence*) (Gourdji et al., 2013; Perkins-Kirkpatrick and Gibson, 2017; Harrington et al., 2018; Jones et al., 2018; Lehner et al., 2018; Shi et al., 2018; Tebaldi and Wehner, 2018; Arnell et al., 2019; Russo et al., 2019; Schwingshackl et al., 2021), although the change depends on the indicator (see also Chapter 11). For example, by 2080, at least 80% of the land surface is expected to experience average summer temperatures greater than the historical (1920–2014) maximum with high (RCP8.5) emissions (Lehner et al., 2018). The areas of rice and maize cropland with damaging extreme temperatures during the reproductive season will increase by a factor of three under RCP8.5 (Gourdji et al., 2013). Under a high emissions scenario, heatwaves that are currently considered rare are projected to become the norm almost everywhere by the end of the century (Russo et al., 2014). Heat stress as a combined function of temperature and humidity also increases at the global scale, especially with high emissions (e.g., Matthews et al., 2017). Growing degree-days and cooling degree-days also increase everywhere (Arnell et al., 2019) with the absolute and proportional changes depending on temperature threshold. Increases in temperatures will result in reductions in heating degree days (Arnell et al., 2019; Coppola et al., 2021b) and a widespread reduced frequency of cold extremes (*high confidence*).

Integrating the results of the regional assessments in Section 12.4 shows that changes in CIDs linked with the water cycle or atmospheric dynamics (e.g., storms) vary more among regions, largely due to the spatial pattern of changes in atmospheric circulation and changes in precipitation and evaporation (Chapters 8 and 11). There is *high confidence* that heavy precipitation and pluvial floods will be increasing in a majority of land regions, primarily due to the well-understood Clausius–Clapeyron relationship describing the increase in moisture content with air temperature (Chapters 8 and 11), but there is a large spatial variability in fluvial flood hazards. Top-down global-scale studies show that although fluvial flood hazards are projected to decrease in regions where there are large reductions in seasonal rainfall totals or where warmer temperatures mean less accumulated snow, at the global scale, fluvial flood hazard (characterized as the area affected, size of peak or likelihood of an event) is projected to increase substantially through the century (Giuntoli et al., 2015; Arnell and Gosling, 2016; Winsemius et al., 2016; Alfieri et al., 2017; Dottori et al., 2018; Arnell et al., 2019). Projected changes in agricultural and hydrological drought characteristics are dependent on the indicator used to define drought (Sections 11.6 and Section 12.3.2), but there is at least *medium confidence* of an increase in the drought hazard in many parts of the world. This is also reflected in global-scale studies, with Naumann et al. (2018), for example, showing that the global mean average drought duration (based on the SPEI index which is calculated from the difference between precipitation and potential evaporation) increased from 7 months with the current climate to 18.5 months for a global warming level of 3°C. The apparent global increase in drought occurrence is greater when evaporation is captured in the drought indicator (e.g., SPEI) than when the indicator is based on precipitation alone (as in SPI; Carrão et al., 2018). There is evidence that the likelihood of simultaneous events in several locations will increase: Trnka et al. (2019) found that the proportion of wheat-growing areas

experiencing simultaneous severe water stress events (based on SPEI) in a year increased from 15% under current conditions to up to 60% at the end of the 21st century under high emissions.

The regional assessment in Section 12.4 shows that fire weather is projected to increase with *medium* or *high confidence* in every continent of the world, including Arctic polar regions. Globally, fire weather is projected to increase in future, primarily due to higher temperatures and exacerbated where precipitation reduces. By 2050, 60% of the global land area would see a significant increase in fire weather under RCP8.5 (Abatzoglou et al., 2019). There is less confidence in the projected distribution of change in fire weather across regions in global-scale studies. For example, Moritz et al., (2012) projected an increase in fire weather in mid- and high latitudes but a reduction in the tropics, whilst Yu et al. (2019) and Bedia et al. (2015) projected an increase in the tropics. These differences reflect differences in methodologies and fire weather indices adopted in different studies.

Integration of the results of Section 12.4 shows that the total number of tropical cyclones is projected to decrease through the 21st century, particularly with high emissions, but the number of very intense tropical cyclones is projected to increase in most areas (at least *medium confidence*) (e.g., Bacmeister et al., 2018; see Section 11.7.1). Furthermore, regions with glaciers will lose glacier mass and regions concerned with snow cover will see a reduction in snow depth, the duration, or extent of cover (*medium confidence* in polar regions, *high confidence* elsewhere).

Relative sea level rise (RSLR) is projected in all regions (except for a few Arctic polar regions) with likelihoods varying from *very likely* to *virtually certain* depending on the region. This will increase the frequency of extreme sea levels and, depending on the level of coastal flood protection, coastal flooding (Vousdoukas et al., 2018; Kirezci et al., 2020). In terms of globally averaged extreme total water level (ETWL) frequency changes, the present-day 1-in-100-year event is projected to become 1-in-30-year and 1-in-20-year events by 2050

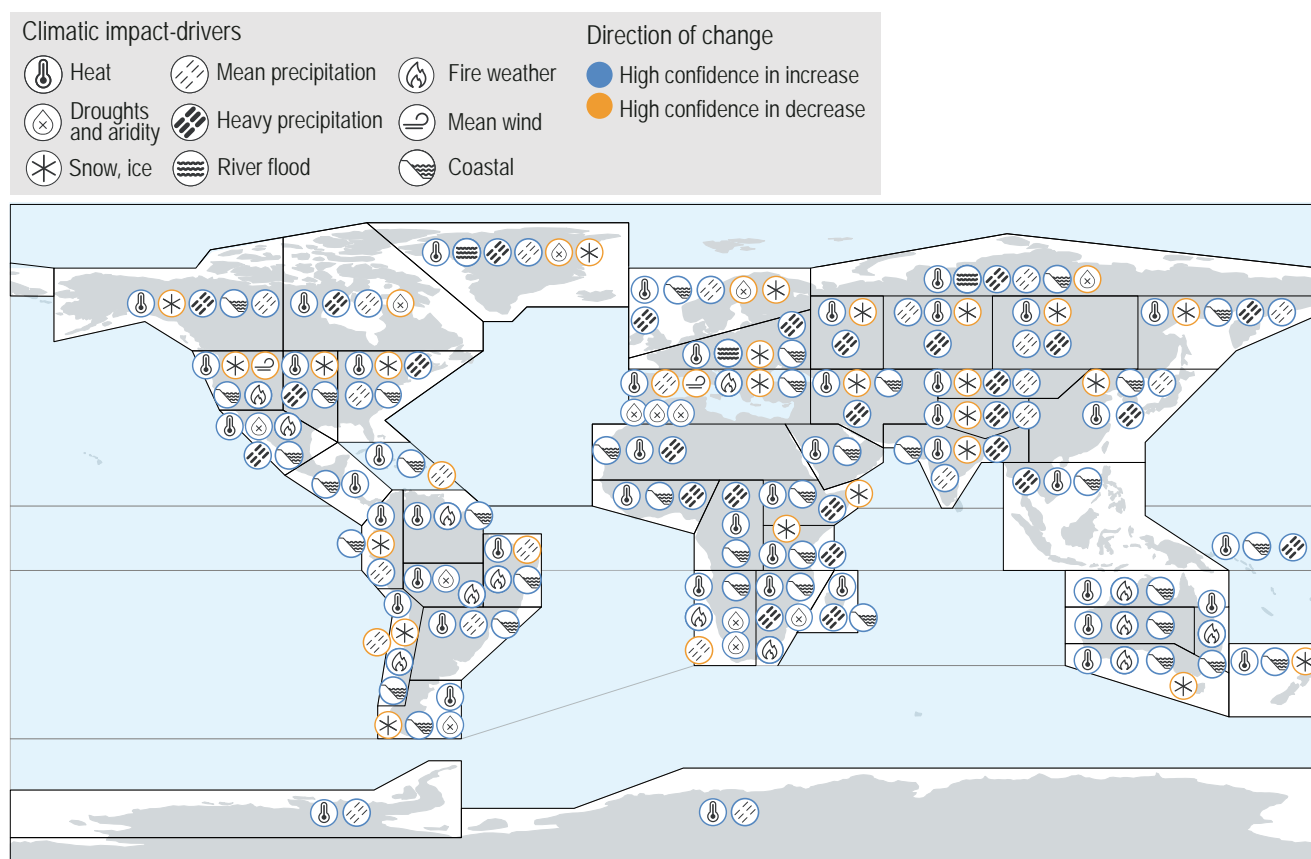

Figure 12.11 | Synthesis of the climatic impact-driver (CID) changes projected by 2050 (2041–2060) with high confidence, relative to reference period (1995–2014), together with the sign (direction) of change. Information is taken from the CID tables in Section 12.4. Some CIDs are grouped in order to streamline the information in order to fit in all information in the figure. Mean temperature, extreme heat, cold spells and frost are grouped under a single ‘heat’ icon, as they are projected to change simultaneously, albeit heat and cold are changing in opposite directions. Coastal CIDs (relative sea level, coastal flooding and coastal erosion at sandy beaches) are also grouped. In the figure, the ‘coastal’ icon indicates regions where at least two of the three individual coastal CIDs are projected to change with high confidence. Cases where only two of the three CIDs increase with high confidence are in Arctic Northern Europe, Russian Arctic and Arctic North-Western North America. A single icon is used for aridity, hydrological drought, and agricultural and ecological drought, and only the number of drought types that change is indicated. For the ‘Snow, ice’ icon, information is taken from the evolution of the ‘Snow, glacier and ice sheet’ CID; most regions also have similar changes for ‘permafrost’ and ‘lake, river and sea ice’. Exceptions are for North-Eastern North America, Russian Arctic and Arctic North-Western North America where snow is decreasing with *medium confidence* (thus not appearing in the figure), while permafrost and lake, river and sea ice is decreasing with *high confidence*. The location of the icons within the regions is arbitrary. Icon sources: <https://www.flaticon.com/authors/freepik>.

under RCP4.5 and RCP8.5, respectively. The present day 1-in-100-year ETWL is projected to become a 1-in-5-year event by 2100 under RCP4.5, while under RCP8.5, such events are projected to occur more than once a year (Vousdoukas et al., 2018).

There is *high confidence* that most of the world's sandy coasts will experience shoreline retreat, in the absence of terrestrial or offshore sediment sources. Median projections presented by (Vousdoukas et al., 2020b) indicate that 13.6% (36,097 km) and 15.2% (40,511 km) of the world's sandy beaches could retreat by more than 100 m by 2050 (relative to 2010) under RCP4.5 and RCP8.5 respectively, implying a 12% increase in severely threatened shoreline length under RCP8.5, relative to RCP4.5. These median projections increase to 35.7%–49.5% (RCP4.5 and RCP8.5, respectively; or 95,061 km–131,745 km) by the end of the century, implying a 38% increase in severely threatened shoreline length under RCP8.5, relative to RCP4.5.

Figure 12.11 highlights that each region will, with *high confidence*, experience changes in multiple CIDs, challenging the vulnerability of the region and its adaptation and mitigation capacity. All non-polar regions with a coastline will see an increase in relative sea level, extreme sea level and coastal erosion, and will also see an increase in hot extremes, a decrease in cold extremes, and many will experience an increase in heavy precipitation. One cluster of regions – East Southern and West Southern Africa regions, the Mediterranean, Northern Central America, Western North America, several regions in South America and Australia – will experience, in addition to the aforementioned globally changing CIDs, increases in either drought/aridity or fire weather (*high confidence*). This will impact upon agricultural resources, infrastructure and health and ecosystems. A second cluster of regions including mountainous areas or regions with seasonal snow cover will experience (in addition to increases in heat extremes, more intense short-duration rainfall, and increases in coastal hazards where coasts exist) reductions in snow and ice cover and/or increases in river flooding in many cases (Western, North-Western, Central and Eastern North America, Arctic regions, Andes regions, Europe, Siberia, Central and East Asia, Southern Australia and New Zealand) (*high confidence*). These are places where energy production, ski tourism, river transportation, and infrastructure could in particular face increased risks.

In a few other regions, only a small number of CIDs are projected to change with *high confidence* (e.g., Sahara, Central Africa, Western Africa, Madagascar, Arabian Peninsula, South-Eastern South America, New Zealand, Small Islands). The lower confidence levels associated with changes in CIDs in these regions can be due either to weaker change signals compared to natural variability, or due to *limited evidence* and model uncertainties leading to *low agreement*, and does not mean that climate change will affect these regions any less than in other regions.

In summary, there is *high confidence* that all regions of the world will experience changes in several climatic impact-drivers by mid-century, albeit at region-specific rates of change and confidence levels for each CID. Consequently, changing CIDs have the potential to affect climate-related risks in all regions of the world.

12.5.2 Emergence of Climatic Impact-drivers Across Time and Scenarios

The emergence of a climate change signal occurs when that signal exceeds some critical threshold (usually taken to be a measure of natural variability; see for example, Hawkins and Sutton, 2012) or when the probability distribution of an indicator becomes significantly different to that over a reference period (e.g., Chadwick et al., 2019; see also Chapter 10 and Section 1.4.2), in which case external anthropogenic forcings can be detected as causal factors. The 'time of emergence' (ToE) or 'temperature of emergence' is the time or global warming level thresholds associated with this exceedance. Emergence is particularly relevant to impacts, risk assessment and adaptation because human and natural systems are largely adapted to natural variability but may be vulnerable if exposed to changes that go beyond this variability range; this is not to say that changes within natural variability have no impact, as occurrence of damaging extremes proves. Emergence also informs the timing of adaptation measures. The emergence of a change is always relative to a reference period (e.g., the pre-industrial period or a recent past), depending on the framing question. In the former case, the goal is to estimate the amplitude of an anthropogenically driven change while in the latter, it is to estimate the amplitude of change relative to a baseline that is familiar to stakeholders. Both questions are important for risk assessment, but the former may be more directly interpretable in a mitigation context. The variability also refers to a time scale, generally interannual to inter-decadal. See Section 1.4.2 and Chapter 10 for more details about how emergence is defined and used in the literature.

Changes in climatic impact-drivers may remain within the range of natural variability or have a time of emergence that varies by region and scenario. This section assesses the evidence for the effects of anthropogenic climate change on the emergence of changes in CID index, past, present and future, as evidenced by the literature assessed in other chapters, as well as additional literature assessed here, at both global and regional scales. In many cases, however, sufficient literature for a robust region-by-region assessment of ToE is lacking. The assessment herein is made by CID. Regional emergence assessment is reported in Tables 12.3–12.11 but is undertaken in this section.

Estimations of ToE must be done with caution given the many sources of inherent uncertainties, such as observations representing only a single realization of climate history, internal variability (whose frequency – e.g., annual or decadal – needs to be precisely defined), model biases, and potential low-frequency changes in variability (Chapter 10; Lehner et al., 2017). In addition, a homogeneous interpretation of multiple studies is hampered by heterogeneous methodologies used to calculate emergence. In this section, we assess emergence and its confidence level based on such multiple methods as provided by the literature, and unless specified otherwise, emergence here refers to a signal to noise ratio $S/N > 1$ relative to a pre-industrial baseline and interannual variability (the 'noise'). Furthermore, observed trends and attribution are taken into account in combination with climate simulations (historical or projections) for assessing whether a trend has already emerged in the historical period.

Mean air temperature: Warming of mean annual temperatures has already emerged in all land regions, as obtained from past observations and confirmed by historical simulations (*high confidence*) (Figure 1.13; King et al., 2015; Hawkins et al., 2020), with S/N ratios larger than two. In the current climate, the highest S/N ratios exceed five over Central Africa, Amazonia, East and South East Asia. Seasonal warming emergence depends on the season. Because the temperature variability in the mid-latitudes is higher in winter than in summer, the emergence of seasonal warming occurs for summer but not for winter in most of this part of the world. In Europe, summer warming has emerged in all regions (*medium confidence, medium agreement*), and in North America, it has emerged only over Eastern and Western regions while in winter there is *low confidence* of an emergence in warming in all regions for both Europe and North America (Lehner et al., 2017; Hawkins et al., 2020). When considering the climate of the end of the 20th century (i.e., recent past) as a baseline, the emergence of mean temperature is projected at very different times depending on the scenario. For instance, emergence is reached by 2050 under RCP8.5 in most areas of Europe, Australia or East Asia, but it does not occur within the 21st century under RCP2.6 (*medium confidence*) (Sui et al., 2014; Im et al., 2021). This means that under RCP2.6, mean temperatures stay within the recent climate variability range observed in the mid-latitudes. However, even under RCP2.6, mean temperatures in tropical regions that have not already emerged are projected to emerge before 2050 (*medium confidence*).

Extreme heat and cold: An increase in heat extremes has emerged or will emerge in the coming three decades in most land regions (*high confidence*) (Chapter 11; King et al., 2015; Seneviratne and Hauser, 2020), relative to the pre-industrial period, as found by testing significance of differences in distributions of yearly temperature maxima in simulated 20-year periods. In tropical regions, wherever observed changes can be established with statistical significance, and in most mid-latitude regions, there is *high confidence* that hot and cold extremes have emerged in the historical period, but only *medium confidence* elsewhere. In other regions emergence is projected at the latest in the first half of the 21st century under RCP8.5 (*high confidence*) (King et al., 2015; Seneviratne and Hauser, 2020). Relative to the end of 20th-century conditions, changes in humid heat stress as characterized by wet bulb temperature, indicates a ToE as early as in the first two decades of the 21st century in RCP8.5 at least in many tropical regions (most of Africa in the band 20°S–20°N, South Asia and South East Asia) (*medium confidence*) (Im et al., 2021). By 2050 and under RCP8.5, wet bulb temperature is projected to emerge in many other areas such as Southern Africa, North Africa, Europe, and most of Central, Southern and Eastern Asia and Northern and Eastern Australia, while under RCP2.6, emergence is either reached later in the century (Europe, Central Asia, Northern Australia), or never reached in the century (Im et al., 2021). Decrease of cold spells has already emerged above the interannual variability in Australasia, Africa and most of Northern South America, and they are projected to emerge before 2050 in the northern mid-latitudes and in Southern South America (King et al., 2015) under RCP8.5 (*medium confidence, limited evidence and high agreement*).

Mean precipitation: Mean precipitation changes only emerged over a few regions in the historical period (increase in Northern and

Eastern Europe and decrease in West Africa and Amazonia) from observations with an S/N ratio larger than one (*low confidence*) (Hawkins et al., 2020). The emergence of increasing precipitation before the middle of the 21st century is found across scenarios in Siberian regions, Russian Far East, Northern Europe, Arctic regions and the northernmost parts of North America (*high confidence*) and later in other northern mid-latitude areas, depending on the scenario, albeit with different methods and emergence definitions used in climate projections (Chapter 8; Giorgi and Bi, 2009; Maraun, 2013; King et al., 2015; Akhter et al., 2018; Kumar and Ganguly, 2018; Nguyen et al., 2018; Barrow and Sauchyn, 2019; Rojas et al., 2019; Kusunoki et al., 2020; Pohl et al., 2020; W. Li et al., 2021). Decreases in mean precipitation are projected to emerge in parts of Africa by the middle of the century, and later in the Mediterranean and Southern Australia, but the emergence depends on the scenario, and specific seasons for crop growth (Nguyen et al., 2018; Rojas et al., 2019). Mean precipitation does not emerge in any of these regions at any time in the 21st century under RCP2.6, but emerges in all under RCP8.5. ToE under RCP4.5 is projected to be around 25 years later relative to RCP8.5 in many of the early emergence regions, highlighting the importance of mitigation to gain more time for adaptation.

Heavy precipitation and floods: There is *low confidence* in the emergence of heavy precipitation and pluvial and river flood frequency in observations, despite trends that have been found in a few regions (Chapters 8 and Chapter 11, and across Section 12.4). In climate projections, the emergence of increase in heavy precipitation strongly depends on the scale of aggregation (Kirchmeier-Young et al., 2019), with, in general, no emergence before a 1.5°C or 2°C warming level, and before the middle of the century (*medium confidence*), but results depend on the method used for the calculation of the ToE (Maraun, 2013; King et al., 2015; Kusunoki et al., 2020). Emergent increases in heavy precipitation are found in several regions when aggregated at a regional scale in Northern Europe, Northern Asia and East Asia, at latest by the end of the century in SRES A1B or RCP8.5 scenarios or when considering the decadal variability as a reference (*medium confidence*) (Maraun, 2013; W. Li et al., 2018, 2021; Kusunoki et al., 2020). There have been few emergence studies for streamflow and flooding, although one study showed emergence of different hydrological regimes at different times during the 21st century across the USA (Leng et al., 2016). Variability in extreme streamflows from year to year can be high relative to a trend (Zhuan et al., 2018). Given the heterogeneity of methods and results, there is only *low confidence* in the emergence of heavy precipitation and flood signals in any region when considering the S/N ratio.

Droughts, aridity and fire weather: There is *low confidence* in the emergence of drought frequency in observations, for any type of drought, in all regions. Even though significant drought trends are observed in several regions with at least *medium confidence* (Sections 11.6 and 12.4), agricultural and ecological drought indices have interannual variability that dominates trends, as can be seen from their time series (*medium confidence*) (H. Guo et al., 2018; Spinoni et al., 2019; Haile et al., 2020; M. Wu et al., 2020). Studies of the emergence of drought with systematic comparisons between trends and variability of indices are lacking, precluding

a comprehensive assessment of future drought emergence. Historical climate simulations indicate that fire weather indices have already emerged in several regions (the Amazon basin, Mediterranean, Central America, West and Southern Africa) (*low confidence, limited evidence*) (Abatzoglou et al., 2019), and emergence is projected with *low confidence* by the middle of the century in several other regions (Southern Australia, Siberia, most of North America and Europe) when considering several indices together.

Wind: Observed mean surface wind speed trends are present in many areas (Section 12.4), but the emergence of these trends from the interannual natural variability and their attribution to human-induced climate change remains of *low confidence* due to various factors such as changes in the type and exposure of recording instruments, and their relation to climate change is not established. For future conditions, there is *limited evidence* of the emergence of trends in mean wind speeds due to the lack of studies quantifying wind speed changes and their interannual variability. The same limitation also holds for wind extremes (severe storms, tropical cyclones, sand and dust storms).

Snow and ice: The decrease in the Northern Hemisphere snow cover extent in spring has already emerged from natural variability (Section 3.4.2). The snow cover duration period is projected to emerge over large parts of Eastern and Western North America and Europe by the mid-century both in spring and autumn, and emergence is expected in the second half of the 21st century in the Arctic regions in the high RCP8.5 scenario (*medium confidence*) (Chapter 9, SROCC). For snow depth or snow water equivalent, there is *low confidence (limited evidence)* of the emergence of a decrease before 2050 because climate change also increases the variability of the snow depth signal, for example in Europe (Section 3.4.2; Willibald et al., 2020). Terrestrial permafrost is warming worldwide due to climate change (Sections 2.3.2.5 and 9.5.2). Due to weak interannual variability of permafrost temperatures, terrestrial permafrost warming has emerged above natural variability in almost all observed time series of the Northern Hemisphere (*medium confidence, limited evidence, high agreement*) (Biskaborn et al., 2019), but the active layer thickness exhibits considerable interannual variability inhibiting evidence for emergence (Chapter 9).

Sea ice: Sea ice area decrease in the Arctic in all seasons has already emerged from the interannual variability (*high confidence*) (Chapter 9). By contrast, the Antarctic sea ice area shows no significant trend, and therefore no emergence.

For other snow and ice CIDs (heavy snowfall and ice storm, hail, snow avalanche), there is *limited evidence* of emerging signals.

Relative sea level, coastal flood and coastal erosion: Near-coast RSLR will emerge before 2050 for RCP4.5 along the coasts of all AR6 regions (with coasts) except East Asia, the Russian Far East, Madagascar, the southern part of Eastern North America and the Antarctic regions (*medium confidence*) (Section 9.6.1.4; Bilbao et al., 2015). Under RCP8.5, emergence of near-coast RSLR is projected by mid-century along the coasts of all AR6 regions (with coasts), except WAN where emergence is projected to occur before 2100

(Section 9.6.1.4; Lyu et al., 2014) (*medium confidence*). Emergence studies for ETWL and coastal erosion are lacking and hence it is not currently possible to robustly assess emergence in these CIDs.

Mean ocean temperature and marine heatwave: The emergence of the sea surface temperature increase signal has been observed in global oceans over the last century, and the largest S/N values are found in the tropical Atlantic and tropical Indian oceans (Hawkins et al., 2020). There is *high confidence* in the widespread occurrence of marine heatwaves in all basins and marginal seas over the last decades (Chapter 9), but the emergence of this signal above the natural variability has not yet been addressed in detail.

Ocean acidity, ocean salinity and dissolved oxygen: The global ocean pH decline has *very likely* emerged from natural variability for more than 95% of the global open ocean (SROCC, Chapter 2). The regional signals are more variable, but in all ocean basins, the signal of ocean acidification in the surface ocean is projected to emerge in the early 21st century (Chapter 5). The mean ToE for acidity in the coastal subtropical to temperate north-east Pacific and north-west Atlantic is above two decades (*high agreement, medium evidence*) (Section 5.3.5.2). Salinity change signals have already emerged with 20–45% of the zonally averaged basin in the Atlantic, 20–55% in the Pacific and 25–50% in the Indian oceans and will be reaching 35–55% in the Atlantic in 2050 to 55–65% in 2080; 45–65% to 60–75% in the Pacific; and 45–65% to 60–80% in the Indian oceans (Chapter 9; Silvy et al., 2020). Deoxygenization has already emerged in many open oceans. The signal is most evident in the Pacific and Southern oceans but not evident in the North Atlantic Ocean (Andrews et al., 2013; Levin, 2018). However, there is *medium confidence* in the emergence of the anthropogenic signal in many other oceanic regions by 2050 (Henson et al., 2017; Levin, 2018).

There is *high confidence* that several CID changes have already emerged above historical period natural variability in many regions (e.g., mean temperature in most regions, heat extremes in tropical areas, sea ice, salinity). Heat and cold CIDs (excluding frost) that have not already emerged will emerge by 2050 whatever the scenario in almost all land regions (*medium confidence*). The emergence of increasing precipitation before the middle of the century is also projected in Siberian regions, Russian Far East, Northern Europe and the northernmost parts of North America and Arctic regions across scenarios with the various methods and emergence definitions used (*high confidence*). Studies are missing to properly assess S/N emergence for droughts and for wind CIDs. Arctic sea ice extent declines have mostly emerged above noise level (*medium to high confidence*), and the emergence of declining snow cover is expected by the end of the century under RCP8.5. There is *medium confidence* that, under RCP8.5, the anthropogenic forced signal in near-coast relative sea level change will emerge by mid-century in all regions with coasts, except in the West Antarctic region where emergence is projected to occur before 2100. In all ocean basins, the signal of ocean acidification in the surface ocean is projected to emerge before 2050 (*high confidence*).

Table 12.12 | Emergence of CIDs in different time periods, as assessed in this section. The colour corresponds to the confidence of the region with the highest confidence: white cells indicate where evidence is lacking or the signal is not present, leading to overall *low confidence* of an emerging signal.

Climatic Impact-driver Type	Climatic Impact-driver Category	Already Emerged in Historical Period	Emerging by 2050 at Least for RCP8.5/SSP5-8.5		Emerging Between 2050 and 2100 for at Least RC8.5/SSP5-8.5	
Heat and Cold	Mean air temperature	1				
	Extreme heat	2	3			
	Cold spell	4	5			
	Frost					
Wet and Dry	Mean precipitation		6	7		
	River flood					
	Heavy precipitation and pluvial flood				8	
	Landslide					
	Aridity

	Dissolved oxygen	14				
Other	Air pollution weather					
	Atmospheric CO ₂ at surface					
	Radiation at surface					

1. *High confidence* except over a few regions (CNA and NWS) where there is *low agreement* across observation datasets.
2. *High confidence* in tropical regions where observations allow trend estimation and in most regions in the mid-latitudes, *medium confidence* elsewhere.
3. *High confidence* in all land regions.
4. Emergence in Australia, Africa and most of Northern South America where observations allow trend estimation.
5. Emergence in other regions.
6. Increase in most northern mid-latitudes, Siberia, Arctic regions by mid-century, others later in the century.
7. Decrease in the Mediterranean area, Southern Africa, South-west Australia.
8. Northern Europe, Northern Asia and East Asia under RCP8.5 and not in low-end scenarios.
9. Europe, Eastern and Western North America (snow).
10. Arctic (snow).
11. Arctic sea ice only.
12. Everywhere except WAN under RCP8.5.
13. With varying area fraction depending on basin.
14. Pacific and Southern oceans then many other regions by 2050.

High confidence of decrease	Medium confidence of decrease	Low confidence in direction of change	Medium confidence of increase	High confidence of increase

Cross-Chapter Box 12.1 | Projections by Warming Levels of Hazards Relevant to the Assessment of Representative Key Risks and Reasons for Concern

Contributors: Claudia Tebaldi (United States of America), Guofinna Aolageirsdottir (Iceland), Sybren Drijfhout (United Kingdom), John Dunne (United States of America), Tamsin Edwards (United Kingdom), Erich Fischer (Switzerland), John Fyfe (Canada), Richard Jones (United Kingdom), Robert Kopp (United States of America), Charles Koven (United States of America), Gerhard Krinner (France), Friederike Otto (United Kingdom/Germany), Alex C. Ruane (United States of America), Sonia I. Seneviratne (Switzerland), Jana Sillmann (Norway/Germany), Sophie Szopa (France), Prodromos Zanis (Greece)

A consistent risk framework (Reisinger et al., 2020) has been adopted across the three Working Groups (WGs) in IPCC AR6 while recognizing the diversity of risk concepts across disciplines. WGI is assessing changes in climatic impact-drivers (CIDs), which are physical climate system conditions (e.g., means, events and extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions (Sections 12.1–12.3). In the assessment of Representative Key Risk (RKR) categories and Reasons for Concern (RFCs) in WGII Chapter 16, the focus lies on the adverse consequences of climate change, for which many types of CIDs (i.e., ‘hazards’ in the context of identified risks) play a key role. This box synthesizes the assessment of such hazards according to global warming levels (GWs) from various chapters of WGI to inform understanding of their potential changes and associated risks with temperature levels in general, and in particular to facilitate WGII integrated assessments of RKRs and RFCs. Cross-Chapter Box 11.1, connects the organization of regional information according to GWs to the other common dimension along which future projections are organized: that is, scenarios. Section 1.6 describes all dimensions of integration adopted in this Report, adding cumulative carbon emissions to GWs and scenarios.

Eight RKRs are identified within WGII Chapter 16:

- RKR-A: risk to the low-lying coastal socio-ecological systems;
- RKR-B: risk to terrestrial and ocean ecosystems;
- RKR-C: risks associated with critical physical infrastructure, networks and services;
- RKR-D: risk to living standards;
- RKR-E: risk to human health;
- RKR-F: risk to food security;
- RKR-G: risk to water security; and
- RKR-H: risks to peace and to human mobility.

RFCs further synthesize the landscape of risks from climatic changes into five categories (from the IPCC Third Assessment Report onward; Smith et al., 2001):

- RFC1: risks to unique and threatened systems;
- RFC2: risks associated with extreme weather events;
- RFC3: risks associated with the distribution of impacts;
- RFC4: risks associated with global aggregate impacts; and
- RFC5: risks associated with large-scale singular events.

Importantly, the assessment of risk in WGII considers hazards as only one component of an integrated assessment that involves their complex interaction with exposure and vulnerability of the systems at risk (Reisinger et al., 2020).

Hazards relevant to RKRs and RFCs are identified among aspects of the climate system that have an episodic, short-term nature, like extreme events (particularly relevant to RFC2 but contributing to many other risk categories). Increasing GWs translate into changing characteristics of frequency, duration, intensity, seasonality and spatial extent for many of these hazards that are also apparent in scenario-based results (Chapters 11 and 12, and Sections 12.4 and 12.5.1). Other relevant hazards coincide with long-term trends embodying a gradual change that may result in unfavourable environmental conditions. Also, increasing GWs increase the likelihood of compound temporal or spatial occurrence of similar or different hazards (Section 11.8). Furthermore, RFC5’s focus on singular events includes concern surrounding potential tipping points and irreversible behaviour in the physical climate system.

Cross-Chapter Box 12.1, Table 1 organizes information by hazard and presents current state and future change assessments with increasing GWs (defined by increasing global surface air temperature, GSAT; see Cross-Chapter Box 2.3). We draw on individual chapters across the WGI report for the assessment of how these hazards vary with GWL. Hazards for which a relation to GWs has not been assessed are not reported in the table.

Cross-Chapter Box 12.1 (continued)

Cross-Chapter Box 12.1, Table 1 | Summary of CIDs/hazards that are identified as driving RKR and RFCs. The behaviour of each (in most cases considered at the global scale, but for some types in terms of spatially resolved patterns) as a function of GWLs is described and when possible quantified, together with the level of confidence of the assessment, to be found in more detail in the chapter/sections indicated in the corresponding column. For the relation with GSAT levels, two columns detail current state, which can be associated to about 1°C of global warming, and future behaviour. Tipping Points and Irreversibility are comprehensively assessed with CMIP6 models up to GWL = 3°C, with fewer studies and lower confidence at higher GWLs up to 5°C.

Hazard Category Sub-category	RKR/RFC Relevance	Behaviour at About 1°C (Present)	Behaviour as a Function of GWL (Future)	WGI Chapter References
Extreme Events				
Hot and Cold Extremes	All RKRs; RFC2, RFC3	Frequency and intensity of hot extremes increased and cold extremes decreased at the global scale and in most regions since 1950 (GSAT change about 0.6°C) (<i>virtually certain</i>). Number of warm days and nights increased; intensity and duration of heatwaves increased; number of cold days and nights decreased (<i>virtually certain</i>). Regional-to-continental scale trends generally consistent with global-scale trends (<i>high confidence</i>). Limited data in a few regions (especially Africa) hampers trend assessment.	Strong linear relation between magnitude and intensity of heat and cold extremes and GSAT, detectable from warming as low as 1.5°C; changes in the extreme metrics twice as large (in mid-latitude regions) or more (in high-latitude regions) than GSAT warming (<i>very likely</i>); metrics related to frequency of exceedance may show stronger than linear relationships (exponential) (<i>very likely</i>). Compared to today, changes in extremes at +2°C at least two times larger than at +1.5°C, and four times larger at +3°C.	Sections 11.3, 11.9, 12.4; Figures 11.3, 11.4, 11.6, 11.11, 11.12; Table 11.2.
Extreme Precipitation Events	All RKRs; RFC2, RFC3	Frequency and intensity of heavy precipitation events increased at the global scale over a majority of land regions with good observational coverage (<i>high confidence</i>) and at the continental scale in North America, Europe and Asia. Larger percentage increases in heavy precipitation observed in the northern high latitudes in all seasons, and in the mid-latitudes in the cold season (<i>high confidence</i>). Regional increases in the frequency and/or intensity of heavy rainfall also observed in most parts of Asia, north-west Australia, northern Europe, South-Eastern South America, and most of the USA (<i>high confidence</i>), and West and Southern Africa, Central Europe, the eastern Mediterranean region, Mexico, and North-Western South America (<i>medium confidence</i>). GHGs <i>likely</i> the main cause.	Precipitation events – including those associated with tropical cyclones (TCs) – increase with GSAT. For GWLs >2°C very rare (e.g., 1-in-10 or more years) heavy precipitation events more frequent and more intense over all continents (<i>virtually certain</i>) and nearly all AR6 regions (<i>likely</i>). Likelihood lower at lower GWLs and for less-rare events. At the global scale, intensification of heavy precipitation generally follows Clausius–Clapeyron (about 6–7% per °C of GSAT warming; <i>high confidence</i>). Increase in frequency of heavy precipitation events accelerates with warming, higher for rarer events (<i>high confidence</i>), with approximately a doubling and tripling frequency of 10-year and 50-year events, respectively, at 4°C of global warming.	Sections 11.4, 11.7, 12.4; Figures 11.4, 11.7, 11.15, 11.16; Table 11.2.
Drought	All RKRs; RFC2, RFC3	Increased atmospheric evaporative demand in dry seasons over a majority of land areas due to human-induced climate change (<i>medium confidence</i>). Especially observed in dry summer climates in Europe, North America and Africa (<i>high confidence</i>).	Upward trend with GSAT (<i>high confidence</i>).	Sections 11.6, 12.4; Figure 11.18; Table 11.2.
Inland Floods	All RKRs; RFC2, RFC3		Upward trend with GSAT for flooded area extent, starting from 2°C compared with 1.5°C and higher levels. Increase in the frequency and magnitude of pluvial floods (<i>high confidence</i>). Increasing flood potential in urban areas where heavy precipitation projected to increase, especially at high GWLs (<i>high confidence</i>).	Sections 11.5, 12.4; Table 11.2.
Tropical Cyclones (TCs)	All RKRs; RFC2, RFC3	Human contribution to extreme rainfall amount from specific TC events (<i>high confidence</i>). Global proportion of major TC intensities <i>likely</i> increased over the past four decades.	Increase in precipitation from TC with GSAT; average peak TC wind speeds, proportion of intense TCs, and peak wind speeds of most intense TCs increase globally with GSAT (<i>high confidence</i>). Decrease or lack of change in global frequency of TCs (all categories) with GSAT (<i>medium confidence</i>).	Sections 11.7.1, 12.4; Table 11.2.
Marine Heatwaves (MHWs)	RKR A,B,F; RFC1,2,3	<i>High confidence</i> that MHWs have increased in frequency over the 20th century, with an approximate doubling from 1982 to 2016, and <i>medium confidence</i> that they have become more intense and longer since the 1980s.	MHWs <i>very likely</i> become 2–9 times more frequent in 2081–2100 compared to 1985–2014 under SSP1-2.6 corresponding to a GWL of 2.0 [1.3 to 2.8] °C (95% CI), or 3–15 times more frequent under SSP5-8.5 corresponding to a GWL of 4.8 [3.6 to 6.5] °C. Spatial heterogeneity with larger changes in the tropical oceans and Arctic Ocean (<i>medium confidence</i>).	Section 12.4; Box 9.2.

Cross-Chapter Box 12.1 (continued)

Hazard Category Sub-category	RKR/RFC Relevance	Behaviour at About 1°C (Present)	Behaviour as a Function of GWL (Future)	WGI Chapter References
Concurrent Events in Time and Space	All RKR; RFC2, RFC3	Higher frequency already detected: more frequent concurrent heatwaves and droughts. Increased compound flooding risk (storm surge, extreme rainfall and/or river flow) in some locations; the probability of concurrent events <i>likely</i> increased.	Higher frequency with increasing GSAT. Increasing trend in more frequent concurrent heatwaves and droughts with GSAT (<i>high confidence</i>). More frequent concurrent (in time) extreme events at different locations with increasing GSAT, for GWLs > 2°C (<i>high confidence</i>). Compound flooding risk (storm surge, extreme rainfall and/or river flow) increasing with GSAT (<i>high confidence</i>).	Section 11.8; Table 11.2; Boxes 11.2, 11.4.
Trends				
Fire Weather Trends	RKR-B, C; RFC1,2,3	Weather conditions that promote wildfire (compound hot, dry and windy events) more probable in some regions over the last century (<i>medium confidence</i>).	Weather conditions promoting wildfire (compound hot, dry and windy events) <i>likely</i> more frequent with GSAT.	Section 12.4; Table 11.2.
Air Pollution Weather	RKR-E; RFC3	Not discernible.	Behaviour to first order controlled by emissions and policies, not by meteorology. Ozone decreases with GSAT in low-polluted regions (–0.2 to –2 ppbv per °C). Ozone increases with GSAT in regions close to sources of precursors (0.2 to 2 ppbv per °C).	Sections 6.5, 12.4.
Patterns of Mean Warming	RKR-B, D, F, RFC1,3,4	Spatial patterns of temperature changes associated with the 0.5°C difference in GMST warming between 1991–2010 and 1960–1970 consistent with projected changes under 1.5°C and 2°C of global warming.	Temperatures scale approximately linearly with GSAT, largely independently of scenario (<i>high confidence</i>). High latitudes of Northern Hemisphere warm faster (<i>virtually certain</i>). Antarctic polar amplification smaller than Arctic (<i>high confidence</i>). Arctic annual mean temperatures warm between 2 and 2.4 times faster for GWLs between 1.5°C and 4°C. In the Southern Hemisphere relatively high rates of warming in subtropical continental areas of South America, Southern Africa and Australia (<i>high confidence</i>).	Sections 4.6.1.1, 12.4; Atlas; Figures 4.31, Atlas.13 and all Atlas Sections' figures for mean temperature changes.
Arctic Warming Trends	RKR-A,C,G,H; RFC1, RFC3	Emerged already from internal variability.	<i>Very likely</i> more pronounced (2–2.4 times faster) than the global average over the 21st century (<i>high confidence</i>).	Sections 4.6.1, 7.4.4.1, 12.4.9 Atlas.11; Figures 4.19, 4.31, Atlas.29; Table 4.2.
Patterns of Precipitation Change	RKR-B, D, F, RFC1, RFC3	Regional patterns of recent trends, over at least the past three decades, consistent with documented increase in precipitation over tropical wet regions and decrease over dry areas.	Changes in large-scale atmospheric circulation and precipitation with each 0.5°C of warming (<i>high confidence</i>). Stable pattern of change over time and scenarios. Some departures from linearity possible at regional scale (<i>medium confidence</i>). Precipitation increase on land higher at 3°C and 4°C compared to 1.5°C and 2°C. Precipitation increases in large parts of the monsoon regions, tropics and high latitudes, decreases in the Mediterranean and large parts of the subtropics (<i>high confidence</i>).	Sections 2.3.1.3.4, 4.5.1, 4.6.1, 12.4; Figures 2.15, 4.32, Atlas.13.
Sea Surface Temperature (SST) Warming	RKR-A, B, D; RFC1, RFC4	Increased 0.81 (0.65–0.94) per °C of GSAT (1850–1900 average compared with 2009–2018 average).	Models and observations show globally averaged SSTs warming at a lower rate of about 80% that of GSAT. It is <i>virtually certain</i> that SST will continue to increase at a rate depending on future emissions scenario ranging from 0.4°C–1.5°C in 2081–2100 relative to 1995–2014 under SSP1-2.6, corresponding to a GWL of 2.0 [1.3 to 2.8] °C, to 2°C–4°C under SSP5-8.5, corresponding to a GWL of 4.8 [3.6 to 6.5] °C.	Sections 2.3.1.1.3, 9.2.1, 12.4.
Ocean Acidification/pH	RKR-A,B; RFC1, RFC4	<i>Virtually certain</i> decline of surface pH globally over the last 40 years at a rate of 0.017–0.027 pH units per decade; decline also in the subsurface over the past 2–3 decades (<i>medium confidence</i>). Surface pH now the lowest of at least the last 26,000 years (<i>very high confidence</i>).	Increase of net ocean carbon flux throughout the century irrespective of the emissions scenario considered (<i>high confidence</i>). Decrease of ocean surface pH through the 21st century, except for SSP1-1.9 and SSP1-2.6 where values increase slightly starting from 2070–2100 (<i>high confidence</i>).	Sections 2.3.3.5, 4.3.2.4, 5.3.4, 5.4.2, 12.4; Figure 4.8.
SPEI Index Global	RKR-B,F,G,H; RFC3	9.4% chance of at least three months of drought in a year at current levels (about 1°C).	Increase at the global scale in the chance of at least three months of drought in a year to about 20 [15 to 30] % at 1.5°C, 35 [20 to 45] % at 2°C to 60 [45 to 75] % at 4°C.	Sections 12.4, 12.5.1.

Cross-Chapter Box 12.1 (continued)

Hazard Category Sub-category	RKR/RFC Relevance	Behaviour at About 1°C (Present)	Behaviour as a Function of GWL (Future)	WGI Chapter References
El Niño–Southern Oscillation (ENSO) Variability	RKR-B,D,F,G; RFC2,3,5	<i>Medium confidence</i> that both ENSO amplitude and frequency of high-magnitude events since 1950 higher than over the pre-industrial period (before 1850) but <i>low confidence</i> of this being outside the range of internal variability. No clear evidence shifts in ENSO or associated features or its teleconnections.	No change in the amplitude of ENSO variability (<i>medium confidence</i>); enhanced ENSO-related variability of precipitation under SSP2-4.5 and higher (<i>high confidence</i>). <i>Likely</i> shift eastward of the pattern of teleconnection over North Pacific and North America.	Sections 2.4.2, 4.3.3.2, 4.5.3.2; Figure 4.10.
Sea Ice Loss	RKR-A, B, H; RFC1,3,5	Arctic sea ice area decreased for all months since 1970s; strongest decrease in summer (<i>very high confidence</i>). Arctic sea ice younger, thinner and faster moving (<i>very high confidence</i>). Current pan-Arctic sea ice levels unprecedented since 1850 (<i>high confidence</i>). <i>Low confidence</i> in all aspects of Antarctic sea ice prior to the satellite era. Antarctic sea ice area experienced little net change since 1979 (<i>high confidence</i>).	The Arctic Ocean will <i>likely</i> become sea ice-free in September before 2050 in all considered SSP scenarios; such disappearance consistently occurring in most years at 2°C–3°C (<i>medium confidence</i>) and including several months in most years at 3°C–5°C (<i>high confidence</i>).	Sections 2.3.2, 4.3.2.1, 9.3.1, 9.3.2, 12.4.9; Figures 4.2c, 4.5.
Permafrost Thaw	RKR-A,C; RFC3,5	Increases in permafrost temperatures in the upper 30 m over the past three to four decades throughout the permafrost regions (<i>high confidence</i>).	Global permafrost volume in the top 3 m decreasing by about $25 \pm 5\%$ per °C for GWLs <4°C. Relative to 1995–2014: at 1.5°C and 2°C decreasing by less than 40% (<i>medium confidence</i>), at 2°C and 3°C by less than 75% (<i>medium confidence</i>), at 3°C and 5°C by more than 60% loss (<i>medium confidence</i>).	Sections 2.3.2.5, 9.5.2, 12.4.9.
Sea Level Change	RKR-A,C,D,E,F, G,H; RFC1,3,4	Global mean sea level (GMSL) is rising at an accelerated rate since the 19th century (<i>high confidence</i>), almost doubled during past two decades (about 0.1 mm yr ⁻²). GMSL increase over the 20th century faster than over any preceding century in at least the last three millennia (<i>high confidence</i>).	Up to 2050, limited scenario/GWL dependency (<i>likely</i> sea level rise about 0.15–0.30 m). By 2100, <i>likely</i> GMSL rise with respect to 1995–2014 of 0.51 (0.40–0.69) m, 0.62 (0.50–0.81) m and 0.70 (0.58–0.91) m for, respectively, GWLs of 2.0°C, 3.0°C, and 4.0°C (<i>medium confidence</i>). Deep uncertainty in projections for GWLs >3°C because of ice-sheet behaviour. For example, incorporation of <i>low confidence</i> ice-sheet processes under SSP5-8.5 (approximately 5°C) leads to a rise of 0.6–1.6 m rather than 0.7–1.1 m.	Sections 9.6.1.2, 9.6.3.3, 9.6.3.4, 12.4.
Sea-Level Change Commitment (2,000 years after peak GWL)	RFC5		GMSL commitment (over the 2000-year-long period following peak warming) of 2–6 m for 2°C peak warming, 4–10 m for 3°C peak warming, 12–16 m for 4°C peak warming, and 19–22 m for 5°C peak warming (<i>medium agreement, limited evidence</i>).	Section 9.6.3.5.
Northern Hemisphere (NH) Spring Snow Cover	RKR-G, RFC1,3	Substantial reductions in spring snow cover extent in the NH since 1978 (<i>very high confidence</i>). Since 1981, general decline in NH spring snow water equivalent (<i>high confidence</i>).	Linear change of NH snow cover in spring of about 8% (area) per °C of global warming (for GWLs <4°C). Relative to 1995–2014: at 1.5°C–2°C NH spring snow cover extent <i>likely</i> decreases by less than 20% (<i>medium confidence</i>); at 2°C–3°C <i>likely</i> decreases by less than 30%; at 3°C–5°C, <i>likely</i> decreases by more than 25%.	Sections 2.3.2.2, 9.5.3, 12.4.
Mass Loss of Glaciers	RKR-B,G; RFC1, RFC3	<i>Very high confidence</i> global glaciers continuing retreat since about 1850. Current global glacier mass loss highly unusual over at least the last 2000 years (<i>medium confidence</i>). Increased rate of glacier mass loss over the last 3 to 4 decades (<i>high confidence</i>). Glaciers not in balance with respect to current climate conditions and will continue to lose mass for at least several decades.	For 1.5°C–2°C about 50–60% (<i>low confidence</i>) of glacier mass outside the two ice sheets and excluding peripheral glaciers in Antarctica remaining, predominantly in the polar regions. At 2°C–3°C about 40–50% (<i>low confidence</i>) of current glacier mass outside Antarctica remaining. At sustained 3°C–5°C 25–40% (<i>low confidence</i>) of current glacier mass outside Antarctica remaining. <i>Likely</i> nearly all glacier mass lost in low latitudes, Central Europe, Caucasus, western Canada and USA, North Asia, Scandinavia and New Zealand.	Sections 2.3.2.3, 9.5.1, 12.4.
Tipping Points/Irreversibility				
Amazon Forest Dieback	RFC1, RFC5	Highly dependent on human disturbance.	Amazon drying and deforestation expected to cause a rapid change in the regional water cycle, possibly linked to the crossing of a climate threshold. <i>Low confidence</i> change will occur by 2100.	Sections 5.4.9, 8.6.2.1, 12.4.10; Table 4.10.

Cross-Chapter Box 12.1 (continued)

Hazard Category Sub-category	RKR/RFC Relevance	Behaviour at About 1°C (Present)	Behaviour as a Function of GWL (Future)	WGI Chapter References
Boreal Forest Dieback	RFC1, RFC5	Highly dependent on human disturbance.	Possible if climate threshold is exceeded, but counteracted by poleward expansion.	Section 5.4.9.
Ice Sheets	RFC5	Greenland Ice Sheet mass-loss rate increased substantially since the turn of the 21st century (<i>high confidence</i>). The Antarctic Ice Sheet has lost mass between 1992 and 2017 (<i>very high confidence</i>), with an increasing mass-loss rate over this period (<i>medium confidence</i>).	At sustained warming levels between 1.5°C and 2°C, the ice sheets will continue to lose mass (<i>high confidence</i>); on time scales of multiple centuries, the Greenland and West Antarctic ice sheets will partially be lost (<i>medium confidence</i>); there is <i>limited evidence</i> that the Greenland and West Antarctic ice sheets will be lost almost completely and irreversibly over multiple millennia; at sustained warming levels between 2°C and 3°C, there is <i>limited evidence</i> that the Greenland and West Antarctic ice sheets will be lost almost completely and irreversibly over multiple millennia, and <i>high confidence</i> in increasing risk of complete loss and increasing rate of mass loss for higher warming; At sustained warming levels between 3°C and 5°C, near-complete loss of the Greenland Ice Sheet and complete loss of the West Antarctic Ice Sheet will occur irreversibly over multiple millennia (<i>medium confidence</i>); substantial parts or all of Wilkes Subglacial Basin in East Antarctica will be lost over multiple millennia (<i>low confidence</i>).	Sections 2.3.2.4, 9.4.1, 9.4.2; Table 4.10.
Glaciers	RFC5	See Trends section of this table.	Continuing substantial global mass loss.	Sections 9.5.1, 12.4.9.
Global Ocean Temperature	RFC5	See Trends section of this table.	Centennial-scale irreversibility of ocean warming.	Sections 4.7.2, 9.6.3; Table 4.10.
Sea Level Rise (SLR)	RFC5	See Trends section of this table.	Centennial-scale irreversibility of sea level rise. Tipping point linked to ice-sheet behaviour. Deep uncertainty on SLR above 3°C warming.	Sections 4.7.2, 9.6.3; Table 4.10.
Atlantic Meridional Overturning Circulation (AMOC)	RFC5	<i>Low agreement</i> on 20th century trend between models and most reconstructions. Observed decline since the mid-2000s cannot be distinguished from internal variability (<i>high confidence</i>).	There is <i>medium confidence</i> an abrupt collapse will not occur before 2100; for 1.5–2°C, 2–3°C, 3–5°C warming in 2100, AMOC decline is 29, 32 and 39%, respectively, of its pre-industrial strength.	Sections 2.3.3.4.1, 9.2.3.1; Table 4.10.
Permafrost Carbon	RFC5	See Trends section of this table.	Will contribute as a feedback with warming, of approximately 18 ± 12 PgC per °C. Possibly non-linear but <i>low confidence</i> in the value of any threshold for such behaviour. Likely irreversible at centennial time scales.	Section 5.4.9; Table 4.10; Box 5.1.
Arctic Sea Ice	RFC5	Abrupt change already observed.	Reversible within years to decades; no tipping point or threshold beyond which loss of ice becomes irreversible (<i>high confidence</i>).	Sections 4.3.2, 9.3.1; Table 4.10.
Snow Cover of Northern Hemisphere	RFC5	See Trends section of the table	Not anticipated to present tipping point/irreversible behaviour.	Section 9.5.3.
Global Monsoon	RFC5	Has <i>likely</i> increased over the last 40 years (<i>medium confidence</i>) and can be explained by a phase change in Atlantic Multi-decadal Variability.	Not anticipated to present tipping point/irreversible behaviour, unless AMOC collapse occurs.	Sections 4.4.1.4, 4.5.1.5, 8.6.1; Table 4.10.
ENSO	RFC5	See Trends section of the table.	Not anticipated to present tipping point/irreversible behaviour.	Section 4.5.3.2.
Methane Clathrates	RFC5	Methane release from shelf clathrates is $<10 \text{ TgCH}_4 \text{ yr}^{-1}$.	Not anticipated to present tipping point/irreversible behaviour.	Section 5.4.9; Table 4.10.

12.6 Climate Change Information in Climate Services

Climate services are a significantly evolving source of climate change information to support adaptation, mitigation and risk management decisions. As an evolving field, there are multiple definitions of climate services (Brasseur and Gallardo, 2016). The Global Framework for Climate Services defines a climate service as the provision of climate information to assist decision-making. The service includes appropriate engagement from users and providers, is based on scientifically credible information and expertise, has an effective access mechanism, and responds to user needs (Hewitt et al., 2012).

The AR5 WGII introduced climate services as bridging the generation and application of climate knowledge, also describing their history and concepts (Jones et al., 2014). Since then, this transdisciplinary field has been growing rapidly (Brasseur and Gallardo, 2016; Hewitt et al., 2020a), with the social sciences in particular pointing out knowledge requirements for co-design and co-development of climate services (Larosa and Mysiak, 2019; Daniels et al., 2020; Steynor et al., 2020). Climate services differ from more research-driven vulnerability, impacts, and adaptation research in their orientation towards decision support (Stone and Meinke, 2005; Ruane et al., 2016; Golding et al., 2019), but overlaps exist (Bruno Soares and Buontempo, 2019). Climate services are often targeted at building resilience to climate-related hazards from near real-time to seasonal and multi-decadal time horizons, to inform adaptation to climate variability and change (Hewitt et al., 2012), widely recognized as an important challenge for sustainable development and risk management (Moss et al., 2010; Jones et al., 2014; Vaughan et al., 2018). This section focuses largely on climate change time scales (past, present and future), which are the focus of AR6 WGI.

This section introduces the current climate services landscape, assesses climate service practices and products related to climate change information and associated challenges. Cross-Chapter Box 12.2 provides concrete examples of climate services. The section builds on the introduction to climate services in Section 1.2.3.3 and the assessment of regional climate information construction – including storylines – discussed in Sections 10.3.4.2, 10.5.3 and Cross-Chapter Box 10.3. The Atlas supports the provision of climate information across WGs by providing interactive maps and further details to the material made publicly accessible for use in climate services. WGII (Chapter 17) further elaborates on climate services as enablers for climate risk management.

12.6.1 Context of Climate Services

The idea of climate services is not new and has its roots in meteorology and climatology (Larosa and Mysiak, 2019). It can be traced back to the late 1970s and the US National Climate Program Act of 1978 (Henderson, 2016). The development of the Global Framework for Climate Services (GFCS) after the World Climate Conference-3 in Geneva brought international attention and renewed impetus to the climate services field (Hewitt et al., 2012). As a result, large investments have been made globally and regionally in the development of

user-driven climate services. WMO has created Regional Climate Centres (RCCs) to facilitate climate service development by regional and national providers (Hewitt et al., 2020a). The European Union declared its ambition to stimulate ‘the creation of a community of climate services application developers and users that matches supply and demand for climate information and prediction’, giving primacy to climate services that are user-driven and science-informed (Lourenço et al., 2016), thus embracing concepts of co-design, co-development and co-evaluation of climate services (Street, 2016). Diverse and action-driven international initiatives allowed climate services to progressively shift from mitigation towards adaptation (Larosa and Mysiak, 2019). Opportunities for the development of climate services have emerged through the 2015 Agendas (Paris Agreement, Sustainable Development Goals and Sendai Framework), Nationally Determined Contributions, National Adaptation Plans, Multilateral Development Banks and Task Force on Climate-related Financial Disclosure (see Section 1.2.2).

Scientific advancements in climate services related to meteorology and climatology are still closely linked to essential climate variables (Larosa and Mysiak, 2019) and benefit from consistently growing computational power, infrastructure and storage capacity to meet the demands of higher spatially and temporally resolved climate information (Buontempo et al., 2020). Climate services also focus on impact chains, providing decision makers with information on climate change with cross-sectoral impact assessments for adaptation (Jacob and Solman, 2017). Today there is a diversity of climate services that involve interpretation, analysis, and communication of different sources of climate data, ideally combining different types of knowledge (scientific/technical, experiential, indigenous, etc.), to a targeted group of decision makers (Parris et al., 2016; Olazabal et al., 2018; Peziz et al., 2019). Jacobs and Street (2020) argue that climate services should be expanded to also address societal challenges, such as system transformation, that include climate in the context of other risks and development challenges.

Climate services are undertaken in public and private sectors at global, regional, national, and local scales (Hewitt et al., 2012, 2020b; Cortekar et al., 2020). Intermediaries such as private sector consulting companies, national climate service providers, research organizations, government agencies or academic institutions provide climate services that translate aspects of climate research to the specific context of decision makers (see also Section 10.5). The EU Roadmap for Climate Services (EC, 2015; Street, 2016) focuses on developing a market for climate services comprising of both public and private domains. The GFCS, under the leadership of several United Nations Agencies, emphasizes the public domain by supporting national and regional capacity building and development of climate services mainly through National Meteorological and Hydrological Services (Hewitt et al., 2012; Domingos et al., 2016; Sivakumar and Lucio, 2018; WMO, 2018). There are ongoing debates about the commercialization of climate services (M.S. Brooks, 2013; WMO, 2015; Webber and Donner, 2017; Hoa, 2018; Troccoli et al., 2018; Bruno Soares and Buontempo, 2019; Hewitt et al., 2020a). Some argue that the commercialization of climate services is needed to meet the diverse needs of specific clients and to drive innovation in the field (M.S. Brooks, 2013; Troccoli, 2018a). Others argue that if

climate services shift incentives for climate science away from the public interest towards profit-seeking, this will result in less publicly accessible and transparent climate information and more private knowledge (Keele, 2019; Tart et al., 2020).

Some climate adaptation planning already uses climate information as provided by the IPCC. However, depending on the decision context, this information may be too coarse, too broad or too disciplinary to directly inform decision-making at the scale where adaptation measures are taken (Howarth and Painter, 2016; Nissan et al., 2019). Thus, while the IPCC's role is clearly perceived as that of a reference – an authoritative starting point – there is a need for complementary information to translate the assessments at the national, local or sectoral level (Howarth and Painter, 2016; Kjellström et al., 2016; van den Hurk et al., 2018; Vaughan et al., 2018). The AR6 Interactive Atlas (see Atlas.2) does provide a collection of observational data and global and regional climate projections. It is designed as a climate service towards the needs of WGI and beyond, to assess the state of the climate by offering data, maps and a level of expert analysis by aggregation of results to regions, scenarios and warming levels.

12.6.2 Assessment of Climate Services Practice and Products Related to Climate Change Information

The climate services landscape is fast growing and very broad, as reflected in the vast diversity of practices and products that can be found in the peer-reviewed literature (*very high confidence*). However, a large part of climate services practices and products is published in 'grey' literature (i.e., non-peer reviewed or non-academic) by private consultancy and non-scientific civil organizations, many of which are not in the public domain. In addition, the respective climate service context of a specific stakeholder in a sector dictates what climate information is required and on what scales and in what format it is most usefully provided. The extent and type of engagement between scientists and users is another critical aspect of climate services (see Cross-Chapter Box 12.2, Figure 1, and Section 10.5). The assessment here can thus only provide a partial and rather general representation of available practices and products in the evolving climate services field.

User needs and decision-making contexts are very diverse and there is no 'one size fits all' solution to climate services (*very high confidence*) (Hewitt et al., 2017b; K. Vincent et al., 2018b). In many cases this requires recognizing that stakeholders make decisions through a combination of scientific information and additional values (Vanderlinden et al., 2017; Parker and Lusk, 2019; see also Sections 1.2.3 and 10.5.4). The emerging climate service literature may clarify some features of climate information requested by users, for instance climatic impact-driver identification and prioritization through stakeholder engagement; the specification of thresholds for various regions/sectors; the types of metrics (magnitude/intensity, frequency, duration, timing, spatial extent) that are of primary interest; and decision support systems where informatics allow stakeholders to custom-make impact-relevant thresholds and then query databases to understand current and future characteristics (Bachmair et al., 2016; Buontempo et al., 2020). However, users also ask for capacity building

activities related to basic knowledge in climate change sciences and climate-related risks (De Bruin et al., 2020; Sultan et al., 2020).

Since AR5 and SROCC (Chapter 2) there has been considerable progress in understanding climate information user needs (Baztan et al., 2017; Golding et al., 2017a, b, 2019; Bruno Soares et al., 2018a; Hewitt and Golding, 2018; Singh et al., 2018; Sivakumar and Lucio, 2018; Bessembinder et al., 2019; Hewitt et al., 2020b; Sultan et al., 2020; Y. Wang et al., 2020), better facilitation of user engagement (Buontempo et al., 2014, 2018; Buontempo and Hewitt, 2018) and an appreciation from climate scientists of the need to involve communication specialists and social scientists to support the co-design and co-development process that is fundamental to a successful climate service (Buontempo et al., 2014; Gregow et al., 2016; Damm et al., 2020).

Climate services require user engagement and can take various forms in which climate information and data are delivered or communicated to the users (*very high confidence*). Different levels of user engagement exist, which can range from passive engagement to interactive group activities, to focused relationships between climate service provider and users. These result in different types of climate service products including websites, capacity building, and co-design of tailored climate indices (Cross-Chapter Box 12.2, Figure 1; Hewitt et al., 2017a). The fundamental basis for climate service development is the co-production process between climate service provider and user (Valiela, 2006; Briley et al., 2015; Golding et al., 2017a; K. Vincent et al., 2018a; Bruno Soares and Buontempo, 2019; Schipper et al., 2019), which can be very resource intensive (Buontempo et al., 2018; Falloon et al., 2018; Kolstad et al., 2019) and varies strongly from case to case (Reinecke, 2015; Bremer et al., 2019; Goodess et al., 2019; Jung and Schindler, 2019). Climate services scholars and practitioners can better facilitate and embrace the knowledge co-production process if it is recognized as a multi-faceted phenomenon with several dimensions (e.g., constitutive, interactional, institutional, pedagogical, empowerment) (Kruk et al., 2017; Knaggård et al., 2019; Weichselgartner and Arheimer, 2019).

Information moves from 'useful' to 'usable' only when users effectively incorporate this information into a decision process (Lemos et al., 2012; Bruno Soares and Dessai, 2016; Prokopy et al., 2017; see also WGII, Chapter 17). Climate services include a range of knowledge brokerage activities such as: identifying knowledge needs; dissemination of knowledge; coordinating and networking; compiling and translating; building capacity through informed decision-making; analysing, evaluating and developing policy; and personal consultation (e.g., De Bruin et al., 2020). When analysing four European climate services, Reinecke (2015) found that different climate services emphasized different knowledge brokerage activities.

There are various types of climate service providers and products related to key sectors and regions, such as those described in Sections 12.3 and 12.4 (Hewitt et al., 2017b). For instance, studies have described sectoral climate services in support of agriculture (Falloon et al., 2018; Hansen et al., 2019), health (Janclous et al., 2014; Lowe et al., 2017), tourism (Morin et al., 2018; Damm et al., 2020; Matthews et al., 2021), energy (Troccoli, 2018b; Goodess et al., 2019; Soret et al., 2019), disaster risk reduction (Golding et al., 2019; Street et al., 2019), water

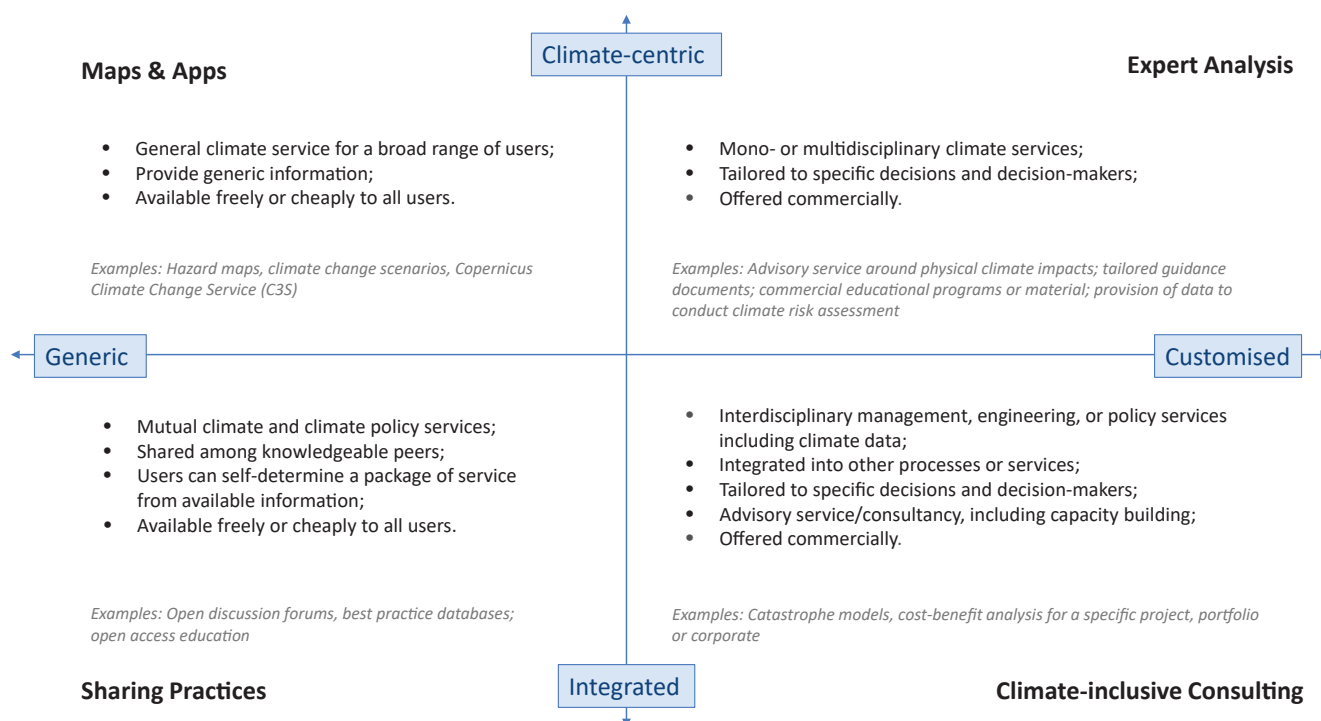

Figure 12.12 | Illustration of different types of climate services. Products, for instance, can focus only on climate-related information or can be designed to integrate climate information with other decision-relevant context (vertical axis) and they can be very generic in terms of relevance to a wide range of sectors or stakeholders or customized to fit the needs of a specific sector or stakeholder (horizontal axis). Figure adapted from Visscher et al. (2020).

(van den Hurk et al., 2016; Vano et al., 2018), ocean and coastal ecosystems (Weisse et al., 2015; Le Cozannet et al., 2017), cities (Rosenzweig and Solecki, 2014; Rosenzweig et al., 2015; Gidhagen et al., 2020), and cultural heritage (ICOMOS, 2019). Many countries (including almost every country in Europe – see Atlas.8.2) have established a climate service centre, which follow different practices of user engagement and provide different products (e.g., Kjellström et al., 2016; Skelton et al., 2017; Kolstad et al., 2019). Climate services in other countries may be distributed across agencies and programmes, although these are often not centrally coordinated (Parris et al., 2016). One of the key pillars of the GFCIS is the Climate Services Information System (CSIS), which is the principal mechanism through which information about past, present and future climate is archived, analysed, modelled, exchanged and processed for users (Hewitt et al., 2020a). Some national governments also have organized national climate projections to be used for official planning (e.g., EEA, 2018). A list of available national products (e.g., observational datasets) and projections can be found in the Atlas (e.g., Atlas.1.4).

Figure 12.12 maps a general categorization of practices and products that have emerged from reviewing climate service literature and user interviews (Visscher et al., 2020). The categories range from very generic products or expert analysis focused particularly on climate information (climate-centric approaches) to more integrated products that include shared open-source products and capacity building as well as tailored products that treat climate information as part of a larger decision-making context (climate-inclusive approaches). Three specific examples that elaborate in more detail on specific practices and products related to those general categories are provided in Cross-Chapter Box 12.2.

12.6.3 Challenges

Climate services set new scientific challenges to physical climate research (*high confidence*). Over at least the last decade, for instance, many questions have appeared in terms of optimal estimation of changes and uncertainties from projections of model ensembles, ensemble optimization, or adjustment of model biases while preserving essential information on trends and cross-variable, time and space consistencies, downscaling information at the local scale (Benestad et al., 2017; Hewitt et al., 2017b; Marotzke et al., 2017; Hewitt and Lowe, 2018; Knutti, 2019; see also Section 10.5). Other challenges related to climate services are the inter-operability of data (Giuliani et al., 2017), access to data (open/FAIR Guiding principles; Wilkinson et al., 2016; Georgeson et al., 2017), format of data (including moving away from percentile-based probabilistic forecasts (e.g., Haines, 2019)) and funding mechanisms (Bruno Soares and Buontempo, 2019).

Understanding and modelling of weather and climate extremes is of great relevance for climate services and is continuing to set challenges for research, such as modelling changes in impact-relevant threshold exceedance and return periods for a variety of extremes (Maraun et al., 2015; Sillmann et al., 2017; Hewitt et al., 2021; Schwingshackl et al., 2021; see also Chapter 11). Extreme event attribution has also been used in context of climate services (Philip et al., 2020) as it is of interest to some stakeholder groups (Sippel et al., 2015; Marjanac and Patton, 2018; Jézéquel et al., 2019, 2020). The usefulness or applicability of available extreme event attribution methods (Section 11.2.4 and Cross-Working Group Box on Attribution in Chapter 1) for assessing climate-related risks remains subject to debate (Shepherd, 2016; Mann et al., 2017; Lloyd and Oreskes, 2018).

The design of climate services involves addressing certain key challenges, such as a domain challenge where users, tasks and data may be unknown; or an informational challenge related to the use and adoption of novel and complex scientific data (Christel et al., 2018). This includes challenges in the uptake of climate information in terms of coordinated delivery of data, information, expertise and training by public research institutes, the inclusion of climate change adaptation in public and private regulation, and uncertainties and confidence in climate projections (Cavelier et al., 2017). Quality control and quality assurance are still weak elements in the development of climate service products (Jacob, 2020). Quality criteria or standards (that go beyond good practice) will have to be developed and agreed (Baldiessa Pacchetti et al., 2021). These challenges reflect the dilemma that exists at the interface between the climate modelling community and climate services regarding: (i) the purposes of the models for climate research versus service development; (ii) the gap between the spatial and temporal scales of the models versus the scales needed in applications; and (iii) tailoring climate model results to real-world applications (Benestad et al., 2017; Hackenbruch et al., 2017; van den Hurk et al., 2018).

Climate services require a sustained engagement between scientists, service providers and users that is often hindered by limited resources for the co-design and co-production process (*high confidence*). There are recurring challenges related to successful climate service applications: (i) climate services are not visible and are poorly understood by ‘end users’ (Weichselgartner and Arheimer, 2019); (ii) data can be of unknown or poor quality, data formats can be hard to access or process, and it can be difficult to utilize data disseminated from large databases (e.g., Section 1.5.4) without appropriate user guidance; (iii) users are unsure how to choose from available climate services to meet their needs (Rössler et al., 2019); (iv) building trust between climate service users and providers (Baztan et al., 2020); (v) the lack of understanding of users and their contexts by the climate science and service community (Porter and Dessai, 2017); (vi) the difficulty in scaling up services (Tall et al., 2014;

van Huysen et al., 2018); (vii) the lack of trained scientists skilled at conducting societally relevant research (Rozance et al., 2020).

Challenges also arise in determining the effectiveness and added value of climate services, particularly in terms of providing quantitative estimates of economic benefits and making a business case for climate services (Bruno Soares, 2017). The market for climate services is still in its infancy (Cavelier et al., 2017; Bruno Soares et al., 2018b; Tall et al., 2018; Damm et al., 2020). One form of value may be determined by a particular user community’s willingness to pay (Acquah and Onumah, 2011; Ouédraogo et al., 2018; Antwi-Agyei et al., 2021), which however cannot reflect the value of climate services as a public good and for society as a whole (Hewitt et al., 2012). Literature is only recently emerging on the socio-economic benefits of weather and climate services (Vaughan et al., 2019). Early studies and guidelines from the WMO focus on cost–benefit ratios (Perrels et al., 2013; WMO, 2015). Issues related to demand-driven versus supply-driven climate services (Lourenço et al., 2016; Street, 2016; Daniels et al., 2020), public versus private climate services (Hewitt et al., 2020a) and business models for climate services (Hoa, 2018) have been raised. A large share of climate services documented in peer-reviewed literature is currently provided in non-market frameworks (e.g., public service obligations and research and development grants) (Hoa, 2018; Kolstad et al., 2019; Cortekar et al., 2020).

Other challenges related to governance and dealing with complex systems are sometimes acknowledged but less well described in the climate services domain (Hewitt et al., 2020a). Importantly, decision contexts are strongly rooted in past practice (which often does not even make optimal use of past climate information), stakeholder experience, and history. Even important emerging concepts of co-production, entry points, and champions do not always fall naturally into these realities without significant effort. The social sciences have an important role in helping understand and tackle these challenges (Bruno Soares and Buontempo, 2019).

Cross-Chapter Box 12.2 | Climate Services and Climate Change Information

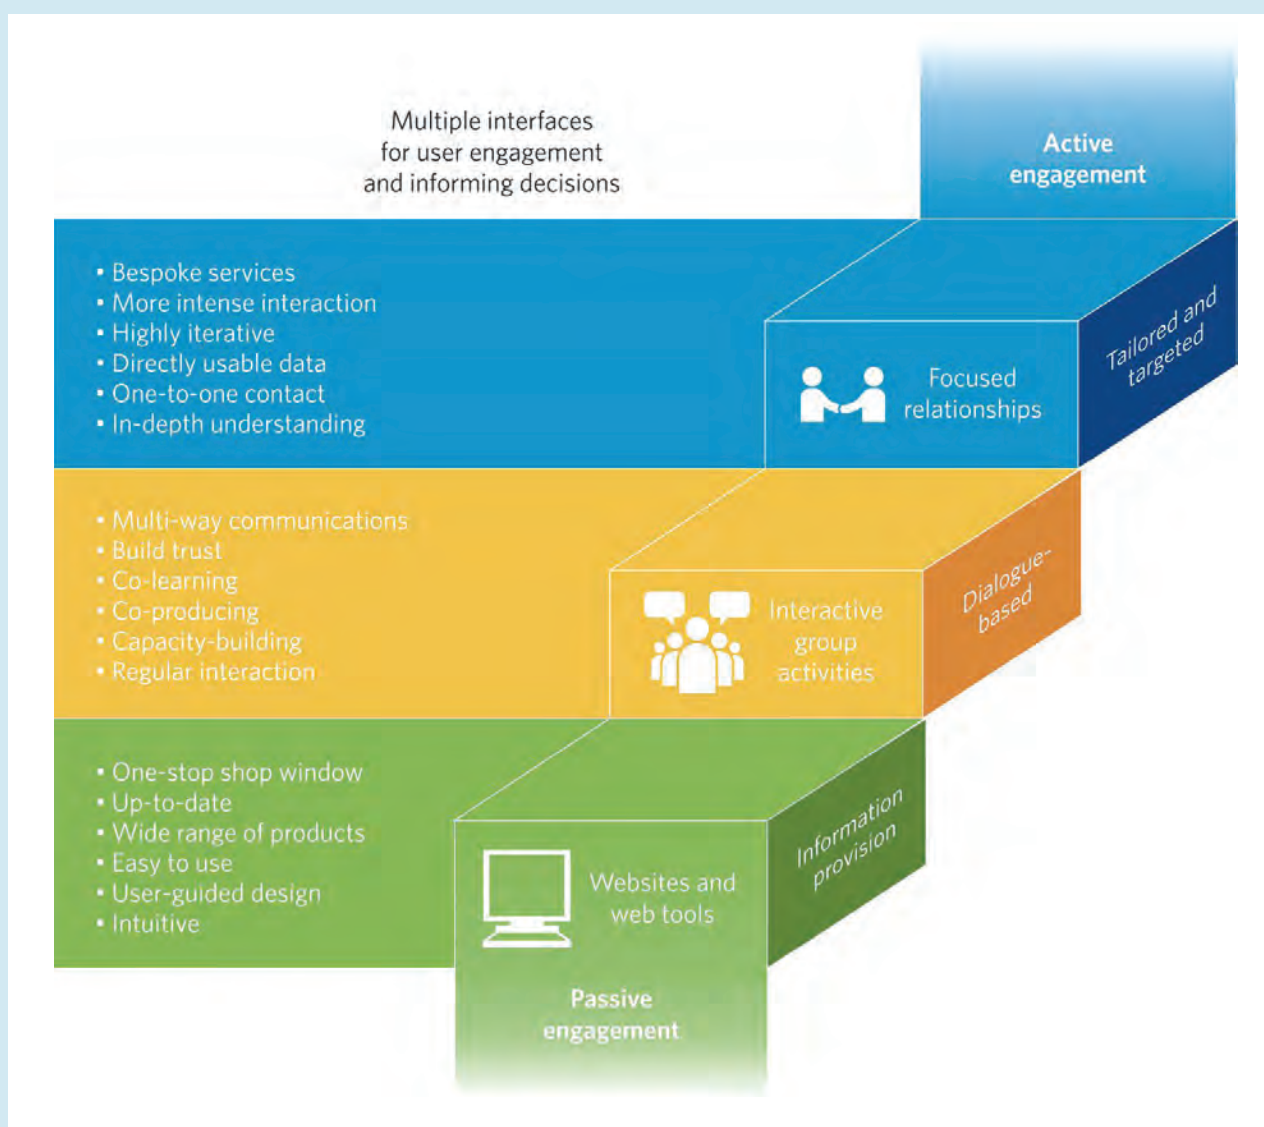

Contributing Authors: Suraje Dessai (United Kingdom/Portugal), Jana Sillmann (Norway/Germany), Carlo Buontempo (United Kingdom/Italy), Cecilia Conde (Mexico), Aida Diongue-Niang (Senegal), Francisco J. Doblas-Reyes (Spain), Christopher Jack (South Africa), Richard Jones (United Kingdom), Benjamin Lamprey (Niger/Ghana), Xianfu Lu (United Kingdom/China), Douglas Maraun (Austria/Germany), Ben Orlove (United States of America), Roshanka Ranasinghe (Netherlands/Sri Lanka/Australia), Alex C. Ruane (United States of America), Anna Steynor (South Africa), Bart van den Hurk (Netherlands), Robert Vautard (France)

Climate services involve the provision of climate information in such a way as to assist decision-making. The service needs to have appropriate engagement from users and providers; be based on scientifically credible information and expertise; have an effective access mechanism; and meet the users’ needs (Hewitt et al., 2012). Predominantly, climate services are targeted at informing and enabling risk management in adaptation to climate variability and change (Jones et al., 2014; Vaughan et al., 2018). Chapter 1 introduces climate services in a broader context of interaction between science and society, including how climate information can be tailored and co-produced for greatest utility in specific contexts. Chapter 10 assesses the key foundations for the generation of climate information about regional climate change. Chapters 11, 12 and Atlas comprehensively assess regional climate change information. The Interactive Atlas gives access to various repositories of quantitative climate information. In WGII, Chapter 17 assesses climate services in the context of climate risk management.

Cross-Chapter Box 12.2 (continued)

Climate service contexts are diverse and complex. They can be characterized using different factors such as sectors, regions, purposes, time horizons, data sources, level of processing of climate data, background knowledge, type of climate service providers, as well as the nature of the interactions between providers, users and other stakeholders (Bessembinder et al., 2019). To illustrate the wide diversity of climate change information in climate services, a useful categorization is by user–provider engagement of climate services (Cross-Chapter Box 12.2, Figure 1). One broad category includes ‘websites and web tools’ which generally focuses on data and information provision (Hewitson et al., 2017). Websites are generally able to reach many users, but engagement is passive through one-way transfer of information. The second broad category involves ‘interactive group activities’, such as workshops, meetings and interactive forums, which create a stronger dialogue between climate service providers and decision makers. Multi-way communication and regular interaction enable building of trust, co-learning and co-production of products and services. The third broad category involves ‘focused relationships’ which are tailored, targeted and address very specific needs of the user. Effective engagement arises from an iterative process between the provider and user to ensure the user’s needs are being addressed appropriately (Hewitt et al., 2017a).

The diversity of climate services practices and products is illustrated here using three case studies each representing one of the broad categories of user–provider engagement (Cross-Chapter Box 12.2, Figure 1).

Cross-Chapter Box 12.2, Figure 1 | Schematic of three broad categories of engagement between users and providers of climate services. Figure adapted from Hewitt et al. (2017a).

*Cross-Chapter Box 12.2 (continued)***Case study 1: Websites and web tools**

The Copernicus Climate Change Service (C3S) provides free and open access to climate data, tools and information through a website. It also includes demonstration projects that show how C3S data can be used in practice through case studies, training sessions and workshops (Thepaut et al., 2018). A large audience of the service is composed of intermediate users, loosely defined as the community of operators in one of the intermediate steps between the primary producers of climate data and the ultimate beneficiaries.

To address this audience, the strategy of C3S is to provide free and open access climate data and tools such as historical observations (both satellite and ground-based), climate data records relevant for a number of Essential Climate Variables (Bojinski et al., 2014), global and regional reanalyses, climate monitoring bulletins, seasonal predictions, as well as both global (a selection of simulations from the Coupled Model Intercomparison Project, CMIP; Taylor et al., 2012; Eyring et al., 2016) and regional climate projections from the Coordinated Regional Downscaling Experiment (Euro- and Med-CORDEX; Jacob et al., 2014; Ruti et al., 2016). A number of indices for various sectors can be calculated through cloud-based tools. For instance, in order to address the specific needs of key sectoral users, climate impact indicators for common variables such as 'heating degree days' can be calculated by the users and made available to others (Buontempo et al., 2020). All this material is quality controlled following a standardized, transparent and traceable framework.

C3S also facilitates the tailoring process, by providing a series of working open-source, cloud-based demonstrators which show how climate data can be transformed into actionable information to meet specific user requirements. This tailoring process covers the chain between the definition of key indicators all the way to the user interface. The definition and production of C3S products involve scientists that produced and assessed the data. A variety of potential users are involved in the definition of indicators and other products.

Through its quality assurance process and demonstrators, C3S provides a basic evaluation of all climate data; it provides access, and it encourages the users to develop their own case-specific analysis within the C3S infrastructure. Trustworthiness and relevance of such an analysis are substantially strengthened through a distillation process, co-designed by the user and data provider, and drawing upon multiple lines of evidence and process-based evaluation of model fitness (Section 10.5).

Case study 2: Interactive group activities

Science-application engagement is extremely challenging, especially in critically important but complex contexts such as rapidly growing cities in developing nations (Culwick and Patel, 2017). The publicly funded Future Resilience for African CITIES And Lands (FRACTAL) project was conceived and designed in response to extensive and strong evidence and experience that useful and useable climate services require strong mutual relationships across the science-application interface that can be built using supportive processes and structures (A. Taylor et al., 2017).

Informed by this understanding, FRACTAL was grounded in a very reflexive and context-guided approach with city decision-making at its core (A. Taylor et al., 2017). Representatives from selected southern African cities were included in the proposal design and, throughout the project, a core principle was to allow the city partners to lead and guide the process.

Two important elements were deployed in FRACTAL: 'embedded researchers' and 'learning labs'. Embedded researchers were seconded into the municipality and served as the essential connection for the learning process within each city (Steynor et al., 2020). Learning labs (Arrighi et al., 2016) were interactive structures in which participants from academia, local city government and councils, state-owned enterprises, communities and community development institutions, and others could interact. Embedded researchers and learning labs were the backbone of ongoing learning processes within each city and resulted in more focused small-group dialogues, capacity development and training processes, and within-city research and engagement activities. Each learning lab focused initially on identifying 'burning issues' without a requirement that they involve strong climate linkages. However, with the overarching focus on resilience, discussions evolved in that direction and the burning issues identified often centred around water in peri-urban areas, for example in Windhoek, Namibia (Scott et al., 2018).

The learning labs also introduced and developed the concept of Climate Risk Narratives (CRNs) as a process and product to generate and integrate climate and socio-economic information relevant to adaptation and resilience (see Cross-Chapter Box 12.2, Figure 2, and Box 10.2 on storylines) (Jack et al., 2020). The first CRNs were informed primarily by climate evidence, but also included some tentative socio-economic impact elements gleaned from literature and other studies. Their content was intentionally provocative and designed to promote debate and discussion, and subsequent iteration. Many participants noted that this was the first time that various important conversations across governance structures and disciplinary areas had occurred around what climate change may actually mean. This demonstrates the engagement value of CRNs as a key element in an iterative co-production process to ensure important details are included correctly, such as the local context, terms and names as well as providing reality checks on the impacts and societal responses (Jack et al., 2020).

Cross-Chapter Box 12.2 (continued)

This case study emphasizes the positive contributions of the fit, tailoring and contextualization of climate information with respect to the specific decision-making needs of particular users (Section 10.5; AR6 WGII Section 17.4.4.2.2), the importance of participatory planning for risk management in urban areas (AR6 WGII Sections 6.3.3.3 and 6.4.2) and the importance of networks and organizations which link researchers, policymakers and end-users to promote adaptation in African cities (AR6 WGII Box 9.4). Upscaling this type of interactive activity to cater for the large number of user demands remains a challenge.

Windhoek's future climate impacts & adaptations examples

Projections of the future climate from climate models show a range of outcomes for Namibia. Three plausible scenarios for the 2040s and their impacts on the city-region of Windhoek are described here:

1: Much hotter with a drier rainy season

- More than 2 deg C warmer
- Twice as many very hot days
- 1/3 less rainfall

2: Hotter with rainfall later in the season

- 1.5 – 2 deg C warmer
- 50% more very hot days
- More rain later in the rainy season

3: Warmer with a similar rainy season

- 1 – 1.5 deg C warmer
- Annual average rainfall totals similar
- More intense rainfall

Water security & efficiency

- In all climate futures evaporation from reservoirs increases as temperatures rise.
- Continued migration to Windhoek increases pressure on water resources which become more limited.
- Adaptations could include additional water treatment or desalination plants.

Energy efficiency & renewable energy

- In climate futures 1 and 2, rainy days are fewer with more sunshine hours available for solar power.
- Increased temperatures sees greater demand for air conditioning.
- Local promotion of the National Energy Efficiency Programme and City of Windhoek's Renewable Energy Policy could help adoption of energy-efficient technologies and practices such as waste-to-energy power plants.

Healthy communities

- All climate futures are warmer, with many more very hot days in futures 1 and 2. Vulnerable people suffer from heat related illness.
- Flooding likely in climate futures 2 and 3 affecting sanitation. Cholera, Hepatitis B and similar diseases rise.
- Measures to improve sanitation services and general health of residents could help resilience to illness.

Biodiversity & Ecosystem goods & services

- Rises in temperature and changes to rainfall patterns likely in all climate futures with resulting biodiversity loss, shift in habitats and invasive species.
- Degradation to landscape or wildlife impacts on tourism.
- Game farming more resilient in a hotter future climate.
- Impacts mitigated through sustainable land management and conservation measures.

Cross-Chapter Box 12.2, Figure 2 | Climate Risk Narrative infographic developed through the FRACTAL Windhoek Learning Lab process. Figure adapted from Jack et al. (2020).

Case study 3: Focused relationships

This broad category involves one-to-one engagement between a provider and a user with very specific needs. One such user is the Asian Development Bank (ADB), which has committed to making all its investments climate resilient by implementing a climate risk management framework (ADB, 2014, 2018; Lu, 2019). The climate risk management framework mandates all climate-sensitive investment projects undertake a climate risk and adaptation assessment, to identify material risks of a changing climate to the proposed project and potential adaptive measures to be incorporated into project design, implementation, maintenance and/or monitoring. Typically, loan project processing teams procure consulting services for a bespoke climate risk and adaptation assessment (CRA)

Cross-Chapter Box 12.2 (continued)

for a specific project. The user–provider engagement is highly targeted and goal-oriented. An example of such a focused user–provider engagement is the CRA carried out as part of an investment project in Vietnam, the Water Efficiency Improvement in Drought-Affected Provinces (WEIDAP) project.

In the wake of the El Niño-induced 2015–2016 severe drought, which caused major damage to agricultural land in the Central Highlands of Vietnam, the WEIDAP project was initiated to improve water productivity of irrigated agriculture. Proposed project interventions include a package of both ‘soft’ (e.g., policy, institutional and capacity building, on-farm water efficiency practices) and ‘hard’ (modernized irrigation schemes) activities. To ensure that the project delivers expected benefits under a changing climate, consultants were recruited to carry out a detailed CRA, working as part of the overall project processing team. Through extensive consultations with the rest of the project team and review of literature including relevant climate projections, the CRA consultants chose to construct three broad climate scenarios for the 2050s (a time frame appropriate for the lifetime of the irrigation schemes being proposed under the project): a warm-and-wet, a hot-and-wet, and a hotter future. Outputs from a selection of CMIP5 models were analysed under these three scenarios, to derive changes in temperature, rainfall and potential evapotranspiration, which in turn were used as inputs to hydrological, crop and agro-economics models to assess the impacts of climate change on the overall project performance. Table 1 presents the summary of the key parameters under the three scenarios. Recommendations from the CRA included (largely minor) refinements and additional activities for drought planning, detailed engineering design of the relevant project components (such as access roads, river crossings and foundations), and support for poorer farmers who may not be able to afford access to water and climate-resilient technologies.

This case study illustrates that climate information distillation including a sustained iterative engagement between climate information users, producers and translators can improve the quality of the information and the decision-making (Section 10.5; WGII Section 17.4.4.2.2).

Cross-Chapter Box 12.2, Table 1 | Summary of annual province-level changes in temperature, precipitation and evapotranspiration under the three broad scenarios in southern Vietnam. Scenario 1: warm-and-wet; Scenario 2: hot-and-wet; Scenario 3: hotter. Source: Table 3 in ADB (2020).

Item	Province and Scenario Number														
	Bình Thuận			Đắk Lắk			Đắk Nông			Khánh Hòa			Ninh Thuận		
	1	2	3	1	2	3	1	2	3	1	2	3	1	2	3
ΔT (°C)	1.1	1.8	2.6	1.1	1.5	2.0	1.2	2.1	2.7	1.1	1.8	2.6	1.1	1.5	2.6
ΔP (%)	28	–12	4	8	17	–8	8	–8	7	3	–10	7	27	1	5
ΔPET (%)	3	6	8	4	5	7	4	7	9	3	6	8	3	5	8

ΔT = change in temperature; ΔP = change in precipitation; ΔPET = change in potential evapotranspiration.

Note: Colour scale indicates significance of changes for the water balance.

High negative impact	Medium negative impact	Medium positive impact	High positive impact	No significant change
----------------------	------------------------	------------------------	----------------------	-----------------------

12.7 Final Remarks

The assessment in this chapter is based on a rapidly growing body of new evidence from the peer-reviewed literature, direct calculations of climate projections from several new model ensembles, and results from other AR6 WGI chapters. Although a large amount of new information on CID changes and their uptake in climate services has become available since AR5, some challenges still remain. This section summarizes some of these main challenges, with a view to facilitating improved assessments in future. The section is organized following the order of chapter sections and consolidated according to key assessment components.

- The adoption of the climatic impact-driver (CID) framework could benefit from stronger connections across disciplines, including between physical climate and impact scientists, and between the

science community and practitioners/stakeholders on the ground. Co-development of CID index definitions with impact scientists or stakeholders helps ensure their salience and utility (Sections 12.1, 12.2, 12.3 and 12.6).

- The ability to project all aspects of shifting CID profiles and their effects at fine, local scales is often reliant on dynamical downscaling and additional impact modelling steps, making a robust and full quantification of the uncertainties involved more challenging. Availability of multiple models and ease of connecting physical climate models at different scales can facilitate assessment (Sections 12.2, 12.3, 12.4 and 12.5).
- Regional and sub-regional differences in coverage and access of homogeneous historical records, in the deployment of regional model ensembles and the exploration of scenarios, and ultimately in peer-reviewed studies addressing the full range of past and current behaviour, detection and attribution, and future

projections challenge a uniformly robust assessment across all CIDs and regions of the world (Sections 12.4 and 12.5).

- Efforts to assess a consistent global, large-scale view of CID changes across regions and sectors would benefit from additional coordinated studies adopting common CID indices, model protocols, time horizons and scenarios or global warming levels (Sections 12.3 and 12.5).
- Even though the body of peer-reviewed literature regarding climate services practices and products is growing, a large part is still documented only in grey literature arising from commercial consultancy, and thus is not publicly and freely accessible (Section 12.6).

Frequently Asked Questions

FAQ 12.1 | What Is a Climatic Impact-driver (CID)?

A climatic impact-driver is a physical climate condition that directly affects society or ecosystems. Climatic impact-drivers may represent a long-term average condition (such as the average winter temperatures that affect indoor heating requirements), a common event (such as a frost that kills off warm-season plants), or an extreme event (such as a coastal flood that destroys homes). A single climatic impact-driver may lead to detrimental effects for one part of society while benefiting another, while others are not affected at all. A climatic impact-driver (or its change caused by climate change) is therefore not universally hazardous or beneficial, but we refer to it as a ‘hazard’ when experts determine it is detrimental to a specific system.

Climate change can alter many aspects of the climate system, but efforts to identify impacts and risks usually focus on a smaller set of changes known to affect, or potentially affect, things that society cares about. These *climatic impact-drivers* (CIDs) are formally defined in this Report as ‘physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions’. Because people, infrastructure and ecosystems interact directly with their immediate environment, climate experts assess CIDs locally and regionally. CIDs may relate to temperature, the water cycle, wind and storms, snow and ice, oceanic and coastal processes or the chemistry and energy balance of the climate system. Future impacts and risk may also be directly affected by factors unrelated to the climate (such as socio-economic development, population growth, or a viral outbreak) that may also alter the vulnerability or exposure of systems.

CIDs capture important characteristics of the average climate and both common and extreme events that shape society and nature (see FAQ 12.2). Some CIDs focus on aspects of the average climate (such as the seasonal progression of temperature and precipitation, average winds or the chemistry of the ocean) that determine, for example, species distribution, farming systems, the location of tourist resorts, the availability of water resources and the expected heating and cooling needs for buildings in an average year. CIDs also include common episodic events that are particularly important to systems, such as thaw events that can trigger the development of plants in spring, cold spells that are important for fruit crop chill requirements, or frost events that eliminate summer vegetation as winter sets in. Finally, CIDs include many extreme events connected to impacts such as hailstorms that damage vehicles, coastal floods that destroy shoreline property, tornadoes that damage infrastructure, droughts that increase competition for water resources, and heatwaves that can strain the health of outdoor labourers.

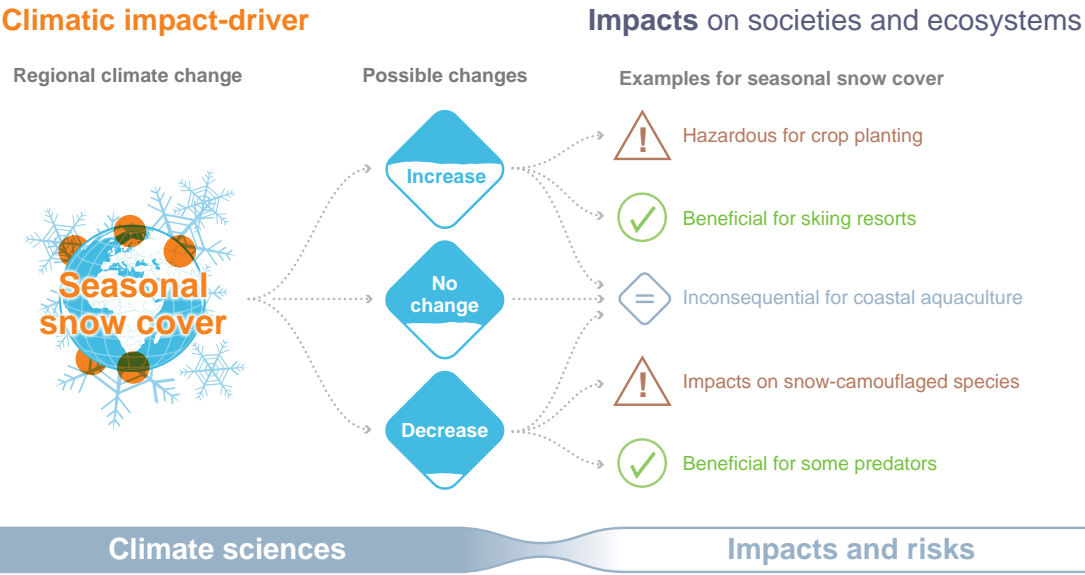

Many aspects of our daily lives, businesses and natural systems depend on weather and climate, and there is great interest in anticipating the impacts of climate change on the things we care about. To meet these needs, scientists engage with companies and authorities to provide climate services – meaningful and possibly actionable climate information designed to assist decision-making. Climate science and services can focus on CIDs that substantially disrupt systems to support broader risk management approaches. A single CID change can have dramatically different implications for different sectors or even elements of the same sector, so engagement between climate scientists and stakeholders is important to contextualize the climate changes that will come. Climate services responding to planning and optimization of an activity can focus on more gradual changes in operating climate conditions.

FAQ 12.1, Figure 1 tracks example outcomes of seasonal snow cover changes that connect climate science to the need for mitigation, adaptation and regional risk management. The length of the season with snow on the ground is just one of many regional climate conditions that may change in the future, and it becomes a CID because there are many elements of society and ecosystems that rely on an expected seasonality of snow cover. Climate scientists and climate service providers examining human-driven climate change may identify different regions where the length of the season with snow cover could increase, decrease, or stay relatively unaffected. In each region, change in seasonal snow cover may affect different systems in beneficial or detrimental ways (in the latter case, changing seasonal snow cover would be a ‘hazard’), although systems such as coastal aquaculture remain relatively unaffected. The changing profile of benefits and hazards connected to these changes in the seasonal snow cover CID affects the profile of impacts, risks and benefits that stakeholders in the region will grapple with in response to climate change.

FAQ 12.1 (continued)

FAQ 12.1: What is a climatic impact-driver (CID)?

A **climatic impact-driver (CID)** is a climate condition that directly affects elements of society or ecosystems. Climatic impact-drivers and their changes can lead to **positive**, **negative**, or **inconsequential** outcomes (or a mixture).

FAQ 12.1, Figure 1 | A single climatic impact-driver can affect ecosystems and society in different ways. A variety of impacts from the same climatic impact-driver change, illustrated with the example of regional seasonal snow cover.

Frequently Asked Questions

FAQ 12.2 | What Are Climatic Thresholds and Why Are They Important?

Climatic thresholds tell us about the tolerance of society and ecosystems so that we can better scrutinize the types of climate changes that are expected to impact things we care about. Many systems have natural or structural thresholds. If conditions exceed those thresholds, the result can be sudden changes or even collapses in health, productivity, utility or behaviour. Adaptation and risk management efforts can change these thresholds, altering the profile of climate conditions that would be problematic and increasing overall system resilience.

Decision makers have long observed that certain weather and climate conditions can be problematic, or hazardous, for things they care about (i.e., things with socio-economic, cultural or intrinsic value). Many elements of society and ecosystems operate in a suitable climate zone selected naturally or by stakeholders considering the expected climate conditions. However, as climate change moves conditions beyond expected ranges, they may cross a climatic ‘threshold’ – a level beyond which there are either gradual changes in system behaviour or abrupt, non-linear and potentially irreversible impacts.

Climatic thresholds can be associated with either natural or structural tolerance levels. Natural thresholds, for instance, include heat and humidity conditions above which humans cannot regulate their internal temperatures through sweat, drought durations that heighten competition between species, and winter temperatures that are lethal for pests or disease-carrying vector species. Structural thresholds include engineered limits of drainage systems, extreme wind speeds that limit wind turbine operation, the height of coastal protection infrastructure, and the locations of irrigation infrastructure or tropical cyclone sheltering facilities.

Thresholds may be defined according to raw values (such as maximum temperature exceeding 35°C) or percentiles (such as the local 99th percentile daily rainfall total). They also often have strong seasonal dependence (see FAQ 12.3). For example, the amount of snowfall that a deciduous tree can withstand depends on whether the snowfall occurs before or after the tree sheds its leaves. Most systems respond to changes in complex ways, and those responses are not determined solely or precisely by specific thresholds of a single climate variable. Nonetheless, thresholds can be useful indicators of system behaviours, and an understanding of these thresholds can help inform risk management decisions.

FAQ 12.2 Figure 1 illustrates how threshold conditions can help us understand climate conditions that are suitable for normal system operation and the thresholds beyond which impacts occur. Crops tend to grow most optimally within a suitable range of daily temperatures that is influenced by the varieties being cultivated and the way the farm is managed. As daily temperatures rise above a ‘critical’ temperature threshold, plants begin to experience heat stress that reduces growth and may lower resulting yields. If temperatures reach a higher ‘limiting’ temperature threshold, crops may suffer leaf loss, pollen sterility, or tissue damage that can lead to crop failure. Farmers typically select a cropping system with some consideration to the probability of extreme temperature events that may occur within a typical season, and so identifying hot temperature thresholds helps farmers select their seed and field management strategies as part of their overall risk management. Climate experts may therefore aim to assist farm planning by providing information about the climate change-induced shifts to the expected frequency of daily heat extremes that exceed crop tolerance thresholds.

Adaptation and other changes in societies and environment can shift climatic thresholds by modifying vulnerability and exposure. For example, adaptation efforts may include breeding new crops with higher heat tolerance levels so that corresponding dangerous thresholds occur less frequently. Likewise, increasing the height of a flood embankment protecting a given community can increase the level of river flow that may be tolerated without flooding, reducing the frequency of damaging floods. Stakeholders therefore benefit from climate services that are based on a co-development process, with scientists identifying system-relevant thresholds and developing tailored climatic impact-driver indices that represent these thresholds (FAQ 12.1). These thresholds help focus the provision of action-relevant climate information for adaptation and risk management.

FAQ 12.2 (continued)

FAQ 12.2: What are climatic thresholds and why are they important?

Many systems have thresholds that can lead to sudden changes, if climate conditions exceed them. Adaptation and risk management efforts can increase overall system resilience by identifying and changing tolerance thresholds.

FAQ 12.2, Figure 1 | Crop response to maximum temperature thresholds. Crop growth rate responds to daily maximum temperature increases, leading to reduced growth and crop failure as temperatures exceed critical and limiting temperature thresholds, respectively. Note that changes in other environmental factors (such as carbon dioxide and water) may increase the tolerance of plants to increasing temperatures.

Frequently Asked Questions

FAQ 12.3 | How Will Climate Change Affect the Regional Characteristics of a Climate Hazard?

Human-driven climate change can alter the regional characteristics of a climate hazard by changing the magnitude or intensity of the climate hazard, the frequency with which it occurs, the duration that hazardous conditions persist, the timing when the hazard occurs, or the spatial extent threatened by the hazard. By examining each of these aspects of a hazard's profile change, climate services may provide climate risk information that allows decision makers to better tailor adaptation, mitigation and risk management strategies.

A *climate hazard* is a climate condition with the potential to harm natural systems or society. Examples include heatwaves, droughts, heavy snowfall events and sea level rise. Climate scientists look for patterns in climatic impact-drivers to detect the signature of changing hazards that may influence stakeholder planning (FAQ 12.1). Climate service providers work with stakeholders and impacts experts to identify key system responses and tolerance thresholds (FAQ 12.2) and then examine historical observations and future climate projections to identify associated changes to the characteristics of a regional hazard's profile. Climate change can alter at least five different characteristics of the hazard profile of a region (FAQ 12.3, Figure 1):

Magnitude or intensity is the raw value of a climate hazard, such as an increase in the maximum yearly temperature or in the height of flooding that results from a coastal storm with a 1% change of occurring each year.

Frequency is the number of times that a climate hazard reaches or surpasses a threshold over a given period. For example, increases to the number of heavy snowfall events, tornadoes, or floods experienced in a year or in a decade.

Duration is the length of time over which hazardous conditions persist beyond a threshold, such as an increase in the number of consecutive days where maximum air temperature exceeds 35°C, the number of consecutive months of drought conditions, or the number of days that a tropical cyclone affects a location.

Timing captures the occurrence of a hazardous event in relation to the course of a day, season, year, or other period in which sectoral elements are evolving or co-dependent (such as the time of year when migrating animals expect to find a seasonal food supply). Examples include a shift towards an earlier day of the year when the last spring frost occurs or a delay in the typical arrival date for the first seasonal rains, the length of the winter period when the ground is typically covered by snow, or a reduction in the typical time needed for soil moisture to move from normal to drought conditions.

Spatial extent is the region in which a hazardous condition is expected, such as the area currently threatened by tropical cyclones, geographical areas where the coldest day of the year restricts a particular pest or pathogen, terrain where permafrost is present, the area that would flood following a common storm, zones where climate conditions are conducive to outdoor labour, or the size of a marine heatwave.

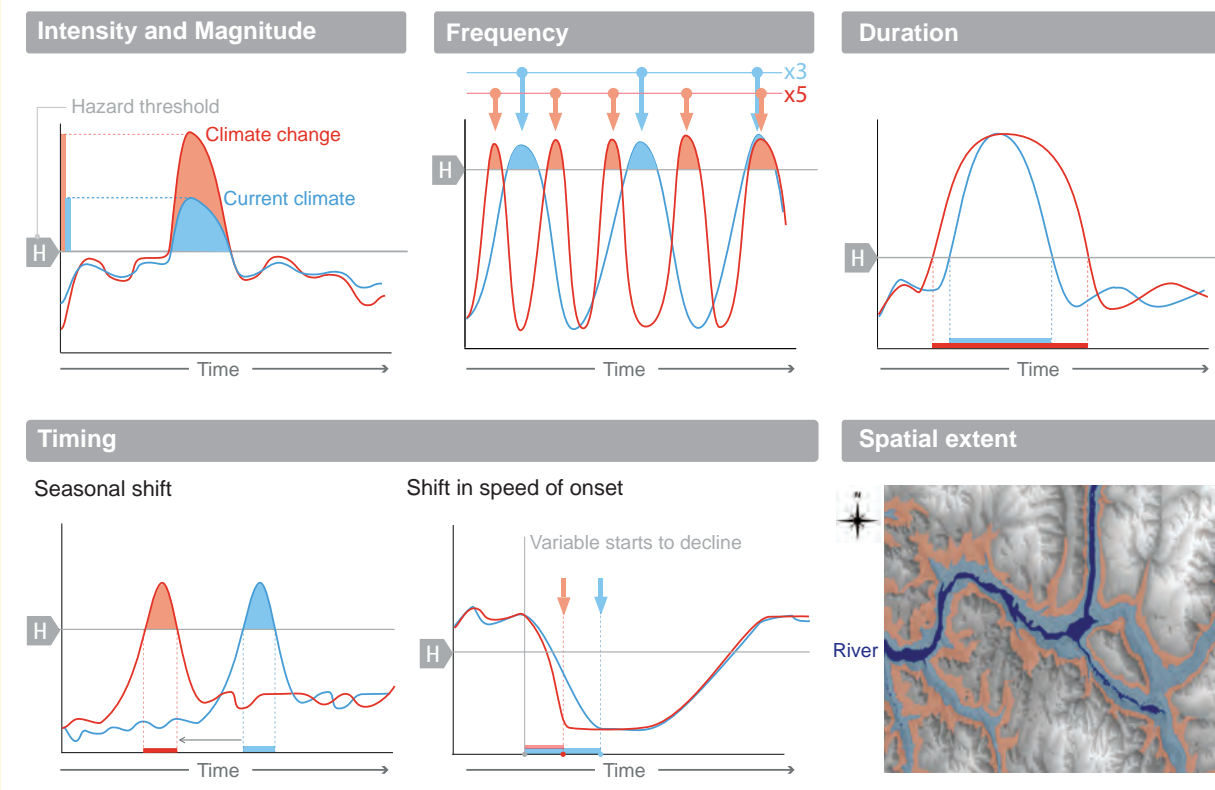

Hazard profile changes are often intertwined or stem from related physical changes to the climate system. For example, changes in the frequency and magnitude of extreme events are often directly related to each other as a result of atmospheric dynamics and chemical processes. In many cases, one aspect of hazard change is more apparent than others, which may provide a first emergent signal indicating a larger set of changes to come (FAQ 1.2).

Information about how a hazard has changed or will change helps stakeholders prioritize more robust adaptation, mitigation and risk management strategies. For example, allocation of limited disaster relief resources may be designed to recognize that tropical cyclones are projected to become more intense even as the frequency of those storms may not change. Planning may also factor in the fact that even heatwaves that are not record-breaking in their intensity can still be problematic for vulnerable populations when they persist over a long period. Likewise, firefighters recognize new logistical challenges in the lengthening of the fire weather season and an expansion of fire conditions into parts of the world where fires were not previously a great concern. Strong engagement between climate scientists and stakeholders therefore helps climate services tailor and communicate clear information about the types of changing climate hazards to be addressed in resilience efforts.

FAQ 12.3 (continued)

FAQ 12.3: How will climate change affect climate hazards?

Climate change can alter the intensity and magnitude, frequency, duration, timing and spatial extent of a region's climate hazards.

FAQ 12.3, Figure 1 | Types of changes to a region's hazard profile. The first five panels illustrate how climate changes can alter a hazard's intensity (or magnitude), frequency, duration, and timing (by seasonality and speed of onset) in relation to a hazard threshold (horizontal grey line, marked 'H'). The difference between the historical climate (blue) and future climate (red) shows the changing aspects of climate change that stakeholders will have to manage. The bottom right-hand panel shows how a given climate hazard (such as a current once-in-100-year river flood, geographic extent in blue) may reach new geographical areas under a future climate change (extended area in red).

Dedication

Gemma Teresa Narisma
(12 April 1972 – 5 March 2021)

The Atlas of the Working Group I Contribution to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC), is dedicated to the memory of Gemma Teresa Narisma, one of the Atlas Coordinating Lead Authors.

Gemma was an internationally renowned scientist, Executive Director of the Manila Observatory (MO) and Professor of physics at the Ateneo de Manila University in the Philippines. She undertook and coordinated research into land–atmosphere interactions, the implications of land-use/biosphere changes on local and regional climate and aerosols and monsoons. She also worked in Australia and the United States and was a key figure in regional climate research in South East Asia. In the Philippines, she undertook multidisciplinary research involving local stakeholders and government on climate impacts and risks to support climate change policy, risk assessment and development planning.

Gemma was also an inspirational teacher, mentor and colleague. She supported and encouraged the young scientists she taught and worked with and focused on ensuring her research would help and empower those most at risk. And with her kindness and generosity, her soft, strong and positive energy, her sweet smile and personality she was an exceptional Coordinating Lead Author, building consensus, motivating and supporting the team whilst also linking to other chapters and Working Group II. Her loss is felt deeply, and she will always be remembered with great affection.

Executive Summary

This Atlas chapter assesses changes in mean climate at regional scales, in particular observed trends and their attribution and projected future changes. The main focus is on changes in temperature and precipitation (including snow and derived variables in polar regions) over land regions, though other variables, including for oceanic regions, are also discussed. Projected changes are presented both as relative to levels of global warming and for future time periods under a range of emissions scenarios. In order to facilitate summarizing assessment findings, a new set of WGI reference regions is used within the chapter which were derived following broad consultation and peer review. These are used in other chapters for summarizing regional information. This includes the assessment of climatic impact-driver (CID) changes in Chapter 12, which incorporates the changes in mean climate assessed in the Atlas. Another important new development since AR5 is the AR6 WGI Interactive Atlas, which is described in this chapter and is used to generate results both for the Atlas and other regional chapters. It is also a resource allowing exploration of datasets underpinning assessment findings in other chapters of the report.

Observed Trends and Projections in Regional Climate

Most land areas have warmed faster than the global average (*high confidence*) and *very likely* by at least 0.1°C per decade since 1960. A surface temperature change signal has *likely* emerged over all land areas. Many areas *very likely* warmed faster since the 1980s, including areas of northern, eastern and south-western Africa, Australia, Central America, Amazonia and West Antarctica (0.2°C–0.3°C per decade), the Arabian Peninsula, Central and East Asia and Europe (0.3°C–0.5°C per decade), and Arctic and near-Arctic land regions (up to 1°C per decade, or more in a few areas). {Figure Atlas.11, Interactive Atlas, Atlas.3.1, Atlas.4.2, Atlas.5.1.2, Atlas.5.2.2, Atlas.5.3.2, Atlas.5.4.2, Atlas.5.5.2, Atlas.6.1.2, Atlas.6.2.2, Atlas.7.2, Atlas.8.2, Atlas.9.2, Atlas.10.2, Atlas.11.1.2, Atlas.11.2.2}

Significant positive trends in precipitation have been observed in most of North Asia, parts of West Central Asia, South-Eastern South America, Northern Europe, Eastern North America, Western Antarctica and the Arctic (*medium confidence*). Significant negative trends have been observed in the Horn of Africa and south-west of the state of Western Australia (*high confidence*), parts of the Russian Far East, some parts of the Mediterranean and of the Caribbean, south-east and north-east Brazil, and southern Africa (*medium confidence*), with the trend in southern Africa attributed to anthropogenic (human-caused) warming of the Indian Ocean. In many other land areas there are no significant trends in annual precipitation over the period 1960–2015 though increases in average precipitation intensity have been observed in the Sahel and South East Asia (*medium confidence*). {Figure Atlas.11, Interactive Atlas, Atlas.3.1, Atlas.4.2, Atlas.5.1.2, Atlas.5.2.2, Atlas.5.3.2, Atlas.5.4.2, Atlas.5.5.2, Atlas.6.1.2, Atlas.6.2.2, Atlas.7.2, Atlas.8.2, Atlas.9.2, Atlas.10.2, Atlas.11.1.2, Atlas.11.2.2}

The observed warming trends are projected to continue over the 21st century (*high confidence*) and over most land regions at a rate higher than the global average. At a global warming level of 4°C (i.e., relative to an 1850–1900 baseline) it is *likely* that most land areas will experience a further warming (from a 1995–2014 baseline) of at least 3°C and in some areas significantly more, including increases of 4°C–6°C in the Sahara/Sahel; South West, Central and North Asia; Northern South America and Amazonia; Western and Central, and Eastern Europe; and Western, Central and Eastern North America; and up to 8°C or more in some Arctic regions. Across each of the continents, higher warming is *likely* to occur in northern Africa, the central interior of southern and Western Africa; in North Asia; in Central Australia; in Amazonia; in Northern Europe and northern North America (*high confidence*). Ranges of regional warming for global warming levels of 1.5°C, 2°C, 3°C and 4°C, and for other time periods and emissions scenarios are available in the Interactive Atlas from Coupled Model Intercomparison Project Phases 5 and 6 (CMIP5, CMIP6) and Coordinated Regional Climate Downscaling Experiment (CORDEX) projections. {Figure Atlas.12, Interactive Atlas, Atlas.4.4, Atlas.5.1.4, Atlas.5.2.4, Atlas.5.3.4, Atlas.5.4.4, Atlas.5.5.4, Atlas.6.4, Atlas.7.4, Atlas.8.4, Atlas.9.4, Atlas.10.4, Atlas.11.4}

For given global warming levels, model projections from CMIP6 show future regional warming and precipitation changes that are similar to those projected by CMIP5. However, the larger climate sensitivity in some CMIP6 models and differences in the model forcings lead to a wider range of and higher projected regional warming in CMIP6 compared to CMIP5 projections for given time periods and emissions scenarios. {Figure Atlas.13, Atlas.4.4, Atlas.5.1.4, Atlas.5.2.4, Atlas.5.3.4, Atlas.5.4.4, Atlas.5.5.4, Atlas.6.1.4, Atlas.6.2.4, Atlas.7.4, Atlas.8.4, Atlas.9.4, Atlas.10.4, Atlas.11.1.4, Atlas.11.2.4}

Precipitation will change in most regions, either through changes in mean values or the characteristics of rainy seasons or daily precipitation statistics (*high confidence*). Regions where annual precipitation is *likely* to increase include the Ethiopian Highlands; East, South and North Asia; South-Eastern South America; Northern Europe; northern and Eastern North America and the polar regions. Regions where annual precipitation is *likely* to decrease include northern and south-western southern Africa, Indonesia, the northern Arabian Peninsula, south-western Australia, Central America, South-Western South America and southern Europe. Changes in monsoons are *likely* to result in increased precipitation in eastern and northern China and in South Asia in summer (*high confidence*). Precipitation intensity will increase in many areas, including in some where annual mean reductions are *likely* (e.g., southern Africa) (*high confidence*). Ranges of regional mean precipitation change for global warming levels of 1.5°C, 2°C, 3°C and 4°C, and for other time periods and emissions scenarios are available in the Interactive Atlas from CMIP5, CORDEX and CMIP6 projections. {Figure Atlas.13, Interactive Atlas, Atlas.4.4, Atlas.5.1.4, Atlas.5.2.4, Atlas.5.3.4, Atlas.5.4.4, Atlas.5.5.4, Atlas.6.1.4, Atlas.6.2.4, Atlas.7.4, Atlas.8.4, Atlas.9.4, Atlas.10.4, Atlas.11.1.4, Atlas.11.2.4}

Cryosphere, Polar Regions and Small Islands

Many aspects of the cryosphere either have seen significant changes in the recent past or will see them during the 21st century (*high confidence*). Snow cover duration has *very likely* reduced over Siberia and Eastern and Northern Europe. Also, it is *virtually certain* that snow cover will experience a decline in these regions and over most of North America during the 21st century, in terms of water equivalent, extent and annual duration. Over the Hindu Kush Himalaya, glacier mass is *likely* to decrease considerably (nearly 50%) under the RCP4.5 and RCP8.5 scenarios. Snow cover has declined over Australia as has annual maximum snow mass over North America (*medium confidence*). Some high-latitude regions have experienced increases in winter snow (parts of North Asia, *medium confidence*) or will do so in the future (*very likely* in parts of northern North America) due to the effect of increased snowfall prevailing over warming-induced increased snowmelt. {2.3.2.2, 3.4.2, Atlas.5.2.2, Atlas.5.3.4, Atlas.6.2, Atlas.8.2, Atlas.8.4, Atlas.9.2, Atlas.9.4}

It is *very likely* that the Arctic has warmed at more than twice the global rate over the past 50 years and that the Antarctic Peninsula experienced a strong warming trend starting in 1950s. It is *likely* that Arctic annual precipitation has increased, with the highest increases during the cold season. Antarctic precipitation and surface mass balance showed a significant positive trend over the 20th century, while strong interannual variability masks any existing trend over recent decades¹ (*medium confidence*). Significant warming trends are observed in other West Antarctic regions and at selected stations in East Antarctica since the 1950s (*medium confidence*). Under all assessed emissions scenarios, both polar regions are *very likely* to have higher annual mean surface air temperatures and more precipitation, with temperature increases higher than the global mean, most prominently in the Arctic. {Atlas.11.1.2, Atlas.11.1.4, Atlas.11.2.2, Atlas.11.2.4}

It is *very likely* that most Small Islands have warmed over the period of instrumental records. Precipitation has *likely* decreased since the mid-20th century in some parts of the Pacific poleward of 20° latitude in both hemispheres and in the Caribbean in June–July–August. It is *very likely* that sea levels will continue to rise in Small Island regions and that this will result in increased coastal flooding. Observed temperature trends are generally in the range of 0.15°C–0.2°C per decade. Rainfall trends in most other Pacific Ocean and Indian Ocean Small Islands are mixed and largely non-significant. There is *limited evidence* and *low agreement* on the cause of the Caribbean drying trend, though it is *likely* that both this and the Pacific drying trends will continue in coming decades with drying also projected in the part of the Western Indian and Atlantic oceans. Small Island regions in the western and Equatorial Pacific Ocean, and in the northern Indian Ocean are *likely* to be wetter in the future. {Cross-Chapter Box Atlas.2, Atlas.10.2, Atlas.10.4}

Model Evaluation, Technical Infrastructure and the Interactive Atlas

The regional performance of CMIP6 global climate models (GCMs) has improved overall compared to CMIP5 in simulating mean temperature and precipitation, though large errors still exist in some regions (*high confidence*). In particular, improvements have been seen over Africa which has belatedly become a focus for GCM model development. Other specific improvements include over East Asia for temperature and the winter monsoon, over parts of South Asia for the summer monsoon, over Australia (including influences of modes of variability), in simulation of Antarctic temperatures and Arctic sea ice. Notable errors include large cold biases in mountain ranges in South Asia, a significant wet bias over Central Asia, in the East Asia summer monsoon and in Antarctic precipitation. An in-depth evaluation of CMIP6 models is lacking for several regions (North and South East Asia, parts of West Central Asia, Central and South America), though CMIP5 models have been evaluated for many of these. {3.3.1, 3.3.2, Atlas.4.3, Atlas.5.1.3, Atlas.5.2.3, Atlas.5.3.3, Atlas.5.4.3, Atlas.5.5.3, Atlas.6.1.3, Atlas.6.2.3, Atlas.7.3, Atlas.8.3, Atlas.9.3, Atlas.10.3, Atlas.11.1.3, Atlas.11.2.3}

Since AR5, the improvement in regional climate modelling and the growing availability of regional simulations through coordinated dynamical downscaling initiatives such as CORDEX, have advanced the understanding of regional climate variability, adding value to CMIP global models, particularly in complex topography zones, coastal areas and small islands, and in the representation of extremes (*high confidence*). In particular, regional climate models (RCMs) with polar-optimized physics are important for estimating the regional and local surface mass balance and are improved compared to reanalyses and GCMs when evaluated with observations (*high confidence*). There is still a lack of high-quality and high-resolution observational data to assess observational uncertainty in climate studies, and this compromises the ability to evaluate models (*high confidence*). {Atlas.4.3, Atlas.5.1.3, Atlas.5.2.3, Atlas.5.3.3, Atlas.5.4.3, Atlas.5.5.3, Atlas.6.1.3, Atlas.6.2.3, Atlas.7.3, Atlas.8.3, Atlas.9.3, Atlas.10.3, Atlas.11.1.3, Atlas.11.2.3}

Significant improvements in technical infrastructure, open tools and methodologies for accessing and analysing observed and simulated climate data, and the progressive adoption of FAIR (findability, accessibility, interoperability and reusability) data principles have *very likely* broadened the ability to interact with these data for a wide range of activities, including fundamental climate research, providing inputs into assessments of impacts, building resilience and developing adaptations. Tools to analyse and assess climate information have improved to allow development of information that goes beyond averages (e.g., on future climate thresholds and extremes) and that is relevant for regional climate risk assessments. {Atlas.2.2, Atlas.2.3}

¹ The term 'recent decades' refers to a period of approximately 30 to 40 years which ends within the period 2010–2020. This is used as many studies in the literature will analyse datasets over a range of climatologically significant periods (i.e., 30 years or more) with precise start and end dates and periods depending on data availability and the year of the study. An equivalent approximate description using specific years would be 'since the 1980s'.

The Interactive Atlas is a new WGI product developed to take advantage of the interactivity offered by web applications by allowing flexible and expanded exploration of some key products underpinning the assessment (including extreme indices and climatic impact-drivers). This provides a transparent interface for access to authoritative IPCC results, facilitating their use in applications and climate services. The Interactive Atlas implements FAIR principles and builds on open tools and, therefore, is an important step towards making IPCC results more reproducible and reusable. {Atlas.2, Interactive Atlas}

Atlas.1 Introduction

Atlas.1.1 Purpose

The Atlas is the final chapter of this Working Group I (WGI) Sixth Assessment Report (AR6) and comprises the Atlas Chapter and an online interactive tool, the Interactive Atlas. The Atlas assesses fundamental aspects of observed, attributed and projected changes in regional climate in coordination with other WGI chapters (Chapters 2, 3, 4, 6, 8, 9, 10, 11 and 12). In particular, it provides analyses and assessments of regional changes in mean climate (specifically surface temperature, precipitation and some cryospheric variables, such as snow cover and surface mass balance) and expands on and integrates results from other chapters across different spatial and temporal scales. The Atlas considers multiple lines of evidence including assessment of different global and regional observational datasets, attribution of observed trends and multiple model simulations from the Coupled Model Intercomparison Projects CMIP5 (K.E. Taylor et al., 2012) and CMIP6 (Eyring et al., 2016; O'Neill et al., 2016), and the Coordinated Regional Downscaling Experiment (CORDEX; Gutowski Jr. et al., 2016). The Atlas chapter also assesses model performance and summarizes cross-referenced findings from other chapters relevant for the different regions.

The Interactive Atlas is a novel product of this Report that allows for a flexible spatial and temporal analysis of the results presented in the Atlas and other chapters, the Technical Summary (TS) and the Summary for Policymakers (SPM), supporting and expanding on their assessments. The Interactive Atlas includes two components. The first

component (Regional Information) includes information from global observational (and paleoclimate simulation) datasets assessed in Chapter 2 and projections of relevant extreme indices (used in Chapter 11) and climatic impact-drivers (CIDs, used in Chapter 12) allowing for a regional analysis of the results (Section Atlas.2.2). It provides information on CIDs relevant to sectoral and regional chapters of the Working Group II (WGII) report, being informed by and complementing the work of Chapter 12 in creating a bridge to WGII. The second component (Regional Synthesis) provides synthesis information about changes in CIDs in several categories such as heat and cold, wet and dry, or coastal and oceanic, supporting exploration of the regional assessment findings summarized in the TS and the SPM. An overview of the main components of the Atlas chapter is provided in Figure Atlas.1. The Interactive Atlas is described in Atlas.2 and is available online at interactive-atlas.ipcc.ch.

Atlas.1.2 Context and Framing

Information on global and regional climate change in the form of maps, tables, graphs and infographics has always been a key output of IPCC reports. With the consensus that climate has changed and will continue to do so, policymakers are focusing more on understanding its implications, which often requires an increase in regional and temporal details of observed and future climate. The WGI contribution to AR5 included globally comprehensive coverage of land regions and some oceanic regions in the Atlas of Global and Regional Climate Projections (IPCC, 2013a), focusing on projected changes in temperature and precipitation. In the WGII contribution, Chapter 21,

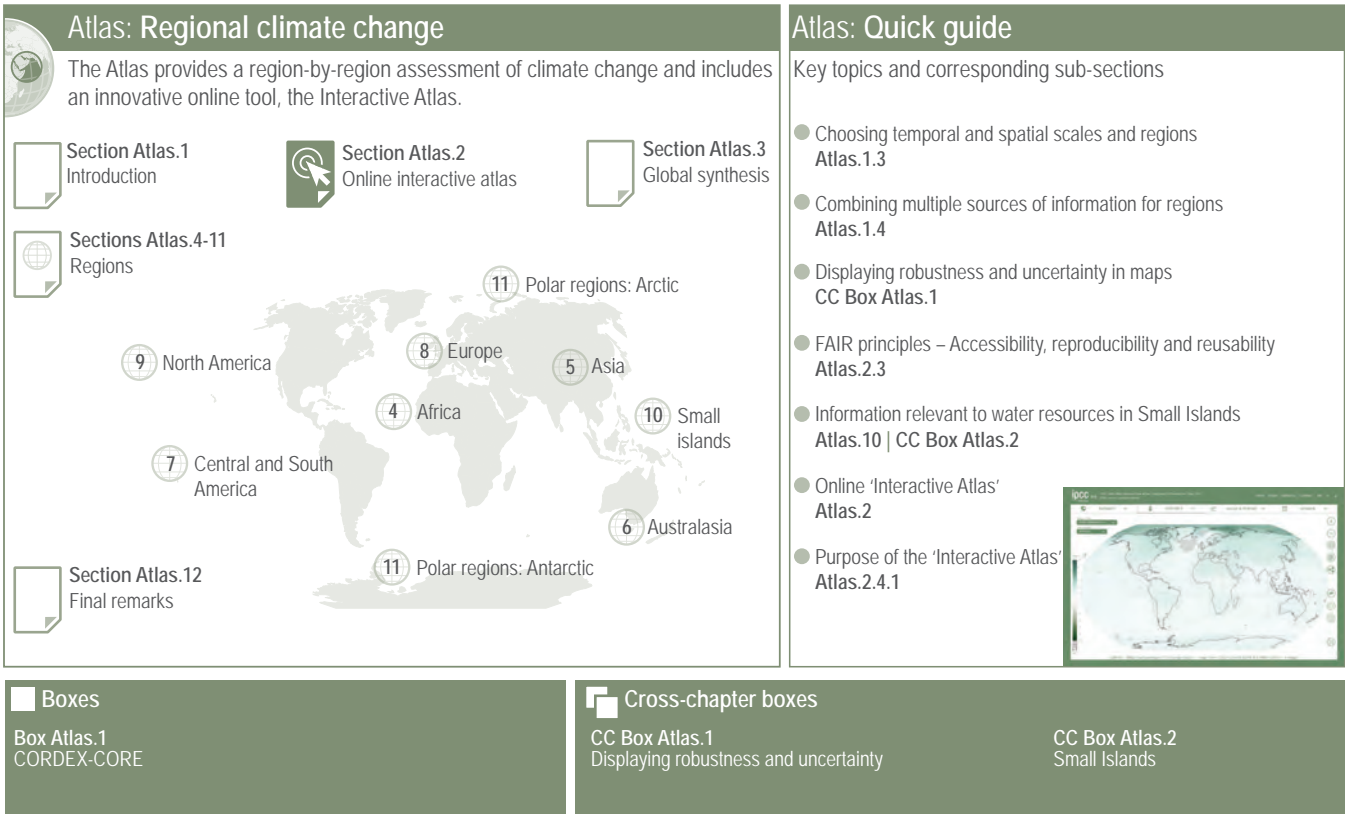

Figure Atlas.1 | Visual guide to the Atlas chapter with (lower right) a screenshot from the online Interactive Atlas.

Regional Context (Hewitson et al., 2014) included continental-scale maps of observed and future temperature and precipitation changes, sub-continental changes in high percentiles of daily temperature and precipitation, and a table of changes in extremes over sub-continental regions (updating an assessment in the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation; SREX). However, there was only limited coordination between these two contributions despite the largely common data sources and their relevance across the two working groups and to wider communities of climate change-related policy and practice. This resulted in inefficiencies and the potential for confusing or inconsistent information. The Atlas, with its links with other WGI/II/III chapters, has been designed to help address this.

Given the aims of the Atlas, there are several important factors to consider. There is a clear requirement for climate change information over a wide range of 'regions', and classes thereof, and temporal scales. There is also often the need for integrated information relevant for policy, practice and awareness raising. However, most other chapters in WGI are disciplinary, focusing on specific processes in the climate system or on its past or future behaviour, and have limited space to be spatially and temporally comprehensive. The Atlas provides an opportunity to facilitate this integration and exploration of information.

Developing this information often requires a broad range of data sources (various observations, global and regionally downscaled baselines and projections) to be analysed and combined and, where appropriate, reconciled. This is a topic which is assessed from a methodological perspective in Chapter 10 using a limited set of examples (see also Cross-Chapter Box 10.3). The Atlas then builds on this work with a more comprehensive treatment of the available results, largely (but not exclusively) based on CMIP5, CMIP6 and CORDEX, to provide wider coverage and to further demonstrate techniques and issues. These multiple lines of evidence are integrated in the Interactive Atlas, a new AR6 WGI product described in Atlas.2 allowing for flexible spatial and temporal analysis of this information with a predefined granularity (e.g., flexible seasons, regions and baselines, and future periods of analysis including time slices and warming levels).

Generating information relevant to policy or practice requires understanding the context of the systems that they focus on. In addition to the hazards these systems face, their vulnerability and exposure, and the related socio-economic and other physical drivers, also need to be understood. To ensure this relevance, the Atlas is informed by the assessments in Chapter 12 and the regional and thematic chapters and cross-chapter papers of WGII. Therefore, it focuses on generating information on climatic impact-drivers and hazards applicable to assessing impacts on and risks to human and ecological systems whilst noting the potential relevance of these to related contexts such as the United Nations (UN) Sustainable Development Goals and the UN Sendai Framework for Disaster Risk Reduction.

Transparency and reproducibility are promoted in the Atlas chapter implementing FAIR principles for Findability, Accessibility, Interoperability, and Reusability of data (Wilkinson et al., 2016). More specifically, the Interactive Atlas provides full metadata of

the displayed products (describing both the underlying datasets and the applied post-processing) and most of the figures included in the Atlas chapter can be reproduced using the scripts and data provided in the WGI-Atlas repository (see Iturbide et al., 2021 and <https://github.com/IPCC-WG1/Atlas>).

Atlas.1.3 Defining Temporal and Spatial Scales and Regions

Over the past decades scientists have engaged in a wide array of investigations aimed at quantifying and understanding the state of the components of the land surface-ocean-atmosphere system, the complex nature of their interactions and impacts over different temporal and spatial scales. As a result, a great deal has been learned about the importance of an appropriate choice of these scales when estimating changes due to internal climate variability, trends, characterization of the spatio-temporal variability, and quantifying the range of and establishing confidence in climate projections. It is therefore important to be able to explore a whole range of spatial and temporal scales and this section presents the basic definitions of those, and the domains of analysis, used by the Atlas accounting for potential synergies between WGI and WGII.

Atlas.1.3.1 Baselines and Temporal Scales of Analysis for Projections Across Scenarios

Chapter 1 has extensively explored this topic in Section 1.4.1 and Cross-Chapter Box 1.2. A summary of the main points relevant to the Atlas chapter and the Interactive Atlas are provided here.

There is no standard baseline in the literature although the World Meteorological Organization (WMO) recommends a 30-year baseline approach such as the climate-normal period 1981–2010. However, it retains the 1961–1990 period as the historical baseline for the sake of supporting long-term climate change assessments (WMO, 2017). Using the WMO standards also provides sample sizes relevant to calculating changes in statistics other than the mean. The AR6 WGI has established the 1995–2014 period as the recent-past baseline period – for similar reasons to the 1986–2005 period used in AR5 WGI (IPCC, 2013b) – since 2014 (2005) is the final year of the historical simulations of the models (more details in Cross-Chapter Box 1.2).

The choice of a baseline can significantly influence the analysis results for future changes in mean climate (Cross-Chapter Box 1.2; Hawkins and Sutton, 2016) as well as its variability and extremes. Thus, assessing the sensitivity of results to the baseline period is important. The Interactive Atlas (Atlas.2) allows users to explore and investigate a wide range of different baseline periods when analysing changes for future time slices or global warming levels:

- 1995–2014 (AR6 20-year baseline);
- 1986–2005 (AR5 20-year baseline);
- 1981–2010 (WMO 30-year climate normal);
- 1961–1990 (WMO 30-year long-term climate normal);
- 1850–1900 (baseline used in the calculation of global warming levels).

This promotes cross-Working Group consistency and facilitates comparability with previous reports and across datasets. For instance, the AR5 and long-term WMO baselines facilitate the intercomparison of CMIP5, CORDEX and CMIP6 projections since all have historical simulations in these periods. Using more recent baselines introduces discontinuity for the CMIP5 and CORDEX models, since historical simulations end in 2005. A pragmatic approximation to deal with this issue is to use scenario data to fill the missing segment, for example for 2006–2014 use the first years of RCP8.5-driven transient projections in which the emissions are close to those observed. This approach is used in the Atlas chapter and Chapter 12.

When assessing changes over the recent past, many studies analyse datasets using a range of climatologically significant periods (i.e., 30 years or more) with precise start and end dates depending on data availability and the year of the study. To account for this, when generating assessments from this literature the term ‘recent decades’ is used to refer to a period of approximately 30 to 40 years which ends within the period 2010–2020. An equivalent approximate description using specific years would be ‘since the 1980s’.

Regarding the future reference periods, the Interactive Atlas presents projected global and regional climate changes at near-, mid- and long-term periods, respectively 2021–2040, 2041–2060 and 2081–2100, for a range of emissions scenarios (Atlas.1.4.3 and Cross-Chapter Box 1.4).

Atlas.1.3.2 Global Warming Levels

Noting the approach taken in the recent IPCC Special Report on Global Warming of 1.5°C (SR1.5) above 1850–1900 levels (IPCC, 2018b), the Atlas also presents global and regional climate change information at different global warming levels (GWLs, see Cross-Chapter Box 11.1). In particular, to provide policy-relevant climate information and represent the range of outcomes from the emissions scenario and time periods considered, GWLs of 1.5°C, 2°C, 3°C and 4°C are considered. The information is computed from all available scenarios (e.g., only 1.5°C and 2°C GWL information can be computed from projections under the SSP1-2.6 scenario). The Interactive Atlas allows comparison of timings for global warming across the different scenarios and of spatial patterns of change, for example information at 2°C GWL is calculated from SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 projections (Section 4.2.4).

To calculate GWL information for the datasets used in the Atlas (CMIP6 and CMIP5; see Atlas.1.4), this chapter adopted the procedure used in Cross-Chapter Box 11.1. A model future climate simulation reaches the defined GWL of 1.5°C, 2°C, 3°C or 4°C when its global near-surface air temperature change averaged over successive 20-year periods first attains that level of warming relative to its simulation of the 1851–1900 climate (1851–1900 defines the pre-industrial baseline period for calculating the required global surface temperature baseline, Cross-Chapter Box 1.2). Note that this process is different from the one used in the SR1.5 report which used 30-year future periods. If a projection stabilizes before reaching the required threshold it is unable to simulate climate at that GWL and is thus discarded. For CORDEX simulations, the periods of the driving

GCM are used, as in Nikulin et al. (2018). Detailed reproducible information on the GWLs used in the Atlas is provided in the Atlas repository (Iturbide et al., 2021).

Climate information at many temporal scales and over a wide range of temporal averaging periods is required for the assessment of climate change and its implications. These range from annual to multi-decadal averages required to characterize low-frequency variability and trends in climate to hourly or instantaneous maximum or minimum values of impactful climate variables. In between, information on, for example, seasonal rainfall is important and implies the need to include averaging periods whose relevance are geographically dependent. As a result, the Atlas chapter presents results over a wide range of time scales, from daily to decadal, and averaging periods with the Interactive Atlas allowing a choice of user-defined seasons and a range of predefined daily to multi-day climate indices.

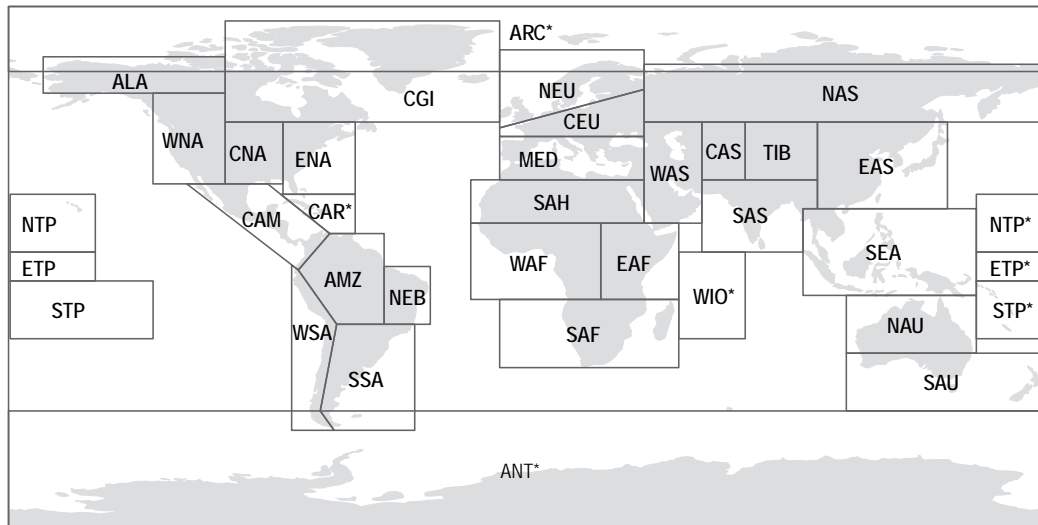

Atlas.1.3.3 Spatial Scales and Reference Regions

Many factors influence the spatial scales and regions over which climate information is required and can be reliably generated. Despite all efforts in researching, analysing and understanding climate and climate change, a key factor in determining spatial scales at which analysis can be undertaken is the availability and reliability of data, both observational and from model simulations. In addition, information is required over a wide range of spatial domains defined either from a climatological or geographical perspective (e.g., a region affected by monsoon rainfall or a river basin) or from a socio-economic or political perspective (e.g., least-developed countries or nation states). Chapter 1 provides an overview of these topics (Section 1.5.2). This subsection discusses some relevant issues, summarizes recent advances in defining domains and spatial scales used by AR6 analyses and how these can be explored with the Interactive Atlas.

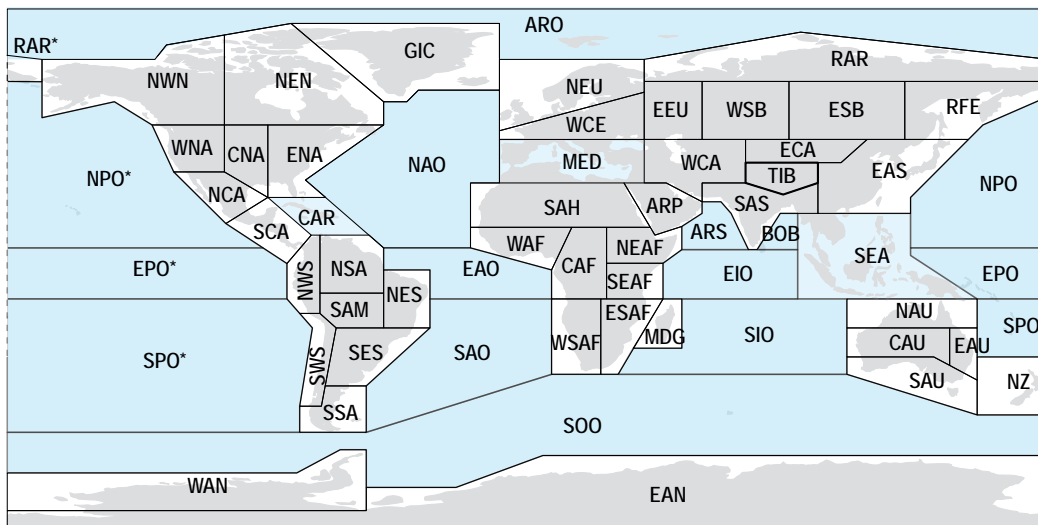

Recent IPCC reports – AR5 Chapter 14 (Christensen et al., 2013) and SR1.5 Chapter 3 (Hoegh-Guldberg et al., 2018) – have summarized information on projected future climate changes over sub-continental regions defined in the SREX report (Seneviratne et al., 2012) and later extended in AR5 from the 26 regions in SREX to include the polar, Caribbean, two Indian Ocean, and three Pacific Ocean regions (hereafter known as AR5 WGI reference regions; Figure Atlas.2a). In recent literature, new sub-regions have been used, for example for North and South America, Africa and Central America, together with the new definition of reference oceanic regions. Iturbide et al. (2020) describes an updated version of the reference regions which is used in this report (hereafter known as AR6 WGI reference regions) and is shown in Figure Atlas.2b. The goal of these subsequent revisions was to ensure that they represented sub-continental areas of greater climatic coherency.

The rationale followed for the definition of the reference regions was guided by two basic principles: 1) climatic consistency and better representation of regional climate features, and 2) representativeness of model results (i.e., sufficient number of model grid boxes). The finer resolution of CMIP6 models (as compared, on average, to CMIP5) yields better model representation of the reference regions allowing them to be revised for better climatic consistency

Figure Atlas.2 | WGI reference regions used in the (a) AR5 and (b) AR6 reports (Ilturbide et al., 2020). Asterisks indicate regions that extend across both sides of the map.

Figure Atlas.2 (continued): The latter includes both land and ocean regions and it is used as the standard for the regional analysis of atmospheric variables in the Atlas chapter and the Interactive Atlas. The codes used in the Interactive Atlas are included in the figure. The full description of the regions (grouped by continents) is as follows. North America: NWN (North-Western North America), NEN (North-Eastern North America), WNA (Western North America), CNA (Central North America), ENA (Eastern North America); Central America: NCA (Northern Central America), SCA (Southern Central America), CAR (Caribbean); South America: NWS (North-Western South America), NSA (Northern South America), NES (North-Eastern South America), SAM (South American Monsoon), SWS (South-Western South America), SES (South-Eastern South America), SSA (Southern South America); Europe: GIC (Greenland/Iceland), NEU (Northern Europe), WCE (Western and Central Europe), EEU (Eastern Europe), MED (Mediterranean); Africa: MED (Mediterranean), SAH (Sahara), WAF (Western Africa), CAF (Central Africa), NEAF (North Eastern Africa), SEAF (South Eastern Africa), WSAF (West Southern Africa), ESAF (East Southern Africa), MDG (Madagascar); Asia: RAR (Russian Arctic), WSB (West Siberia), ESB (East Siberia), RFE (Russian Far East), WCA (West Central Asia), ECA (East Central Asia), TIB (Tibetan Plateau), EAS (East Asia), ARP (Arabian Peninsula), SAS (South Asia), SEA (South East Asia); Australasia: NAU (Northern Australia), CAU (Central Australia), EAU (Eastern Australia), SAU (Southern Australia), NZ (New Zealand); Antarctica: WAN (Western Antarctica), EAS (Eastern Antarctica). The definition of the regions and companion notebooks and scripts are available at the Atlas repository (Iturbide et al., 2021). Figure from Iturbide et al. (2020).

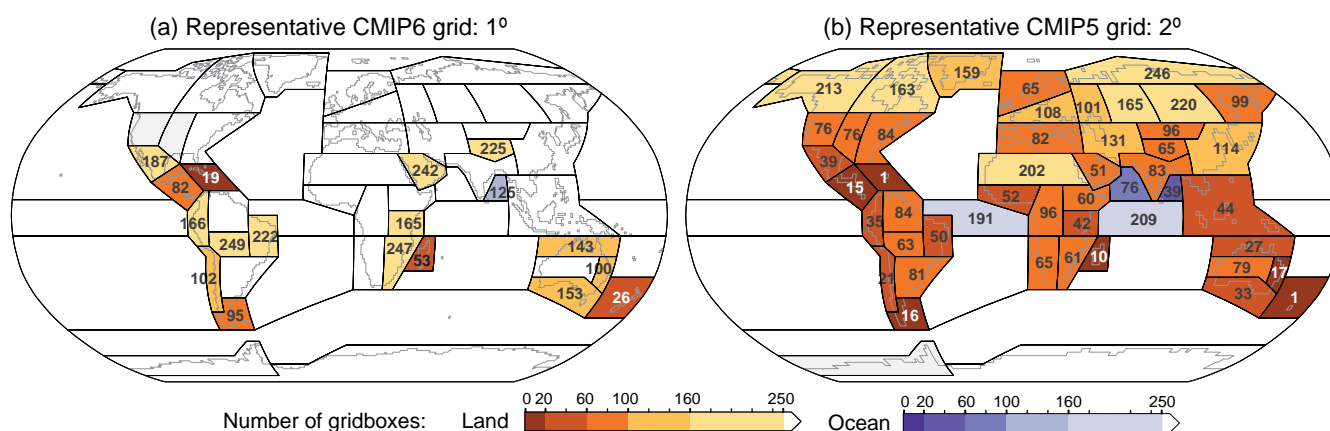

Figure Atlas.3 | Number of land grid boxes for each AR6 WGI reference region for the reference grids representative of (a) CMIP6 and (b) CMIP5, at 1° and 2° resolution respectively. Colour shading indicates regions with fewer than 250 grid boxes (the darkest shading is for regions with fewer than 20 grid boxes). The polygons show the AR6 WGI reference regions of Figure Atlas.2. Detailed information on the grids used is provided at the Atlas repository (Iturbide et al., 2021).

(e.g., dividing heterogeneous regions) while preserving the model representation. Figure Atlas.3 illustrates this issue, displaying the number of grid boxes (over land for land regions) in the AR6 reference regions for two Interactive Atlas reference grids of horizontal resolutions of 1° and 2°, representative of the typical resolution of CMIP6 and CMIP5 models respectively. This figure shows that the new reference regions are well suited for the assessment of model results, with poorest model coverage for the New Zealand (NZ), Caribbean (CAR) and Madagascar (MAD) regions.

The AR6 WGI (land and open ocean) reference regions are used in the Interactive Atlas as the default regionalization for atmospheric variables. However, these regions are not optimum for the analysis of oceanic variables since, for instance, the five upwelling regions (Canary, California, Peru, Benguela and Somali) are mostly included in 'land' regions. Therefore, the alternative set of oceanic regions defined by their biological activity (Figure Atlas.4) is used in the Interactive Atlas for the regional analysis of oceanic variables (see Fay and McKinley, 2014; Gregor et al., 2019). Due to the many potential definitions of the regions relevant for WGI and WGII, some additional typological and socio-economic regions have also been included in the Interactive Atlas.

Atlas.1.3.4 Typological and Socio-economic Regions

In addition to contiguous spatial domains discussed in the previous section, some domains are defined by specific climatological, geographical, ecological or socio-economic properties where climate

is an important determinant or influencer. In these cases the domains are subject to particular physical processes that are important for its climatology or that involve systems affected by the climate in a way that observations and climate model simulations can be used to understand. Many of these are the basis of the chapters and cross-chapter papers of the AR6 WGII report, namely river basins, biodiversity hotspots, tropical forests, cities, coastal settlements, deserts and semi-arid areas, the Mediterranean, mountains and polar regions. It is therefore important to generate climate information relevant to these typological domains and some examples of these used in the Interactive Atlas are shown in Figure Atlas.4.

Atlas.1.4 Combining Multiple Sources of Information for Regions

This section introduces the observational data sources and reanalyses that are used in the assessment of regional climate change and for evaluating and bias adjusting the results of models (more information on observational reference datasets is available in Annex I). It also introduces the different global and regional climate model outputs that are used for regional climate assessment considering both historical and future climate projections (Annex II). Many of these models are run as part of coordinated Model Intercomparison Projects (MIPs), including CMIP5, CMIP6 and CORDEX, described below. Combining information from these multiple data sources is a significant challenge (see Section 10.5 for an in-depth treatment of the problem) though if they can be used

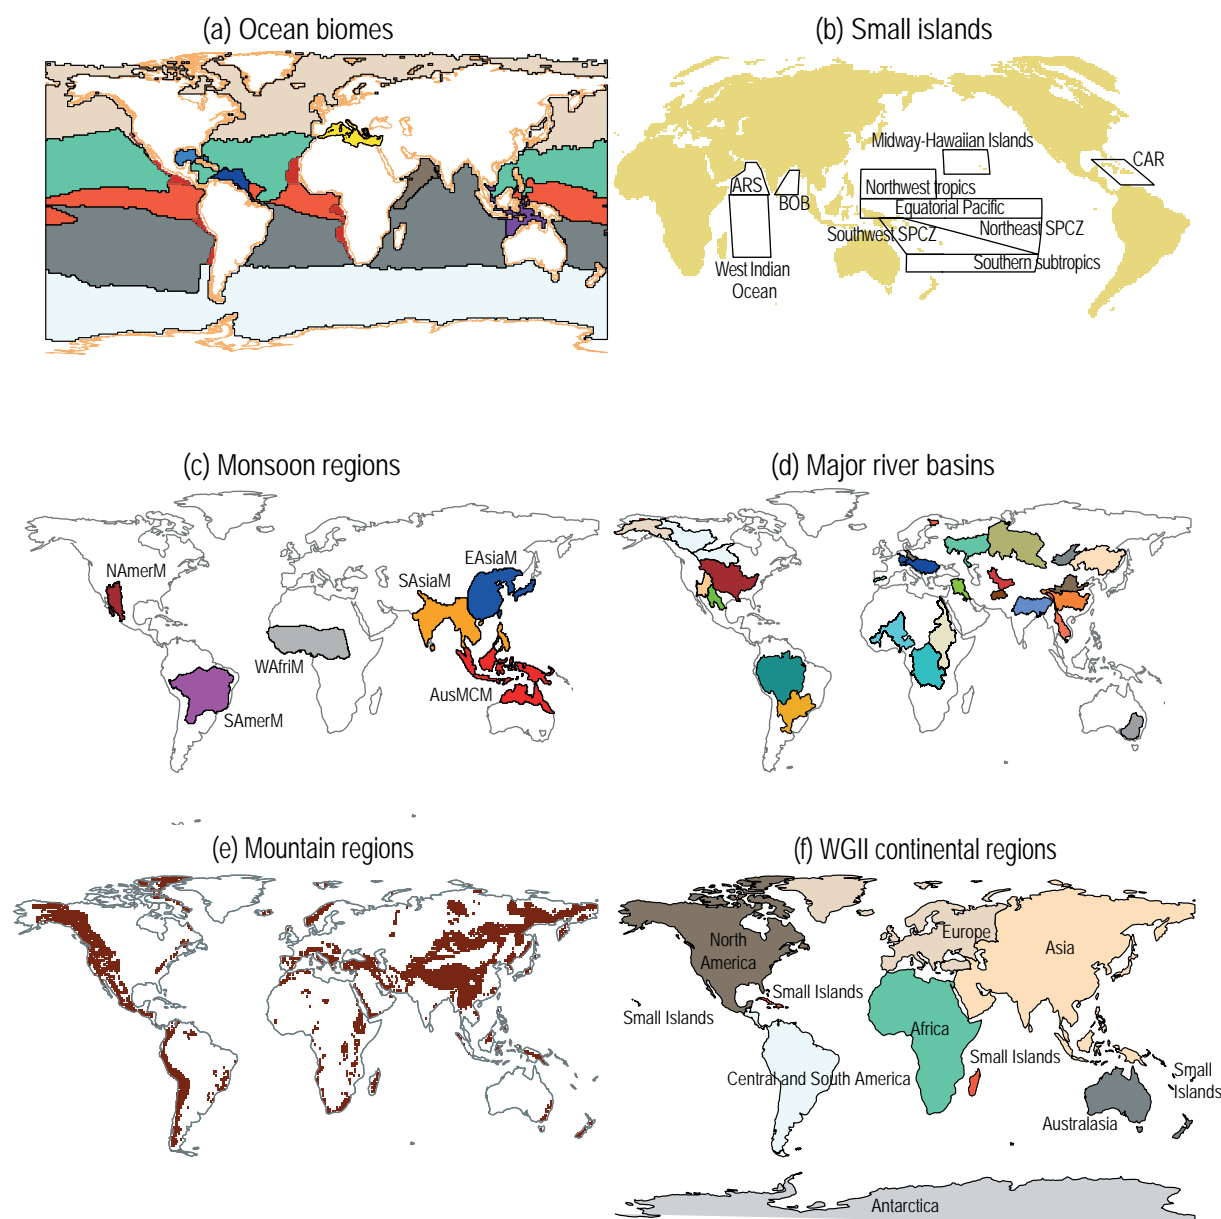

Figure Atlas.4 | Typological and socio-economic regions used in the Interactive Atlas. (a) Eleven ocean regions defined by their biological activity and used for the regional analysis of oceanic variables; (b) ocean regions for Small Islands, including the Caribbean (CAR) and the north Indian Ocean (ARS and BOB); (c) land monsoon regions of North America, South America, Africa, Asia and Australasia; (d) major river basins; (e) mountain regions; (f) WGII continental regions. These regions can be used alternatively to the reference regions for the regional analysis of climatic variables in the Interactive Atlas. The definition of the regions and companion notebooks and scripts are available at the Atlas repository (Iturbide et al., 2021).

to generate robust information on regional climate change it can guide policy and support decisions responding to these changes. An important and necessary part of this process is to check for consistency amongst the data sources.

Atlas.1.4.1 Observations

There are various sources of observational information available for global and regional analysis. Observational uncertainty is a key factor when assessing and attributing historical trends, so assessment should build on integrated analyses from different datasets (disparity, inadequacy and contradictions in existing datasets are assessed in Section 10.2). The Atlas chapter can supplement and complement

Chapter 10 by providing the opportunity to visualize and expand on its assessment. This includes displaying maps of density of stations' observations (including those that are used in the different datasets) and assessing observational uncertainty by using multiple datasets.

Two of the most commonly used variables in climate studies are gridded surface air temperature and precipitation. There are many datasets available (Annex I) and Chapter 2 provides an assessment of key global datasets, including blended land-air and sea surface temperature datasets to assess global mean surface temperature (GMST). The Atlas separately analyses atmospheric and oceanic variables, and for the former a number of common global datasets supporting the assessment done in other chapters is used, including

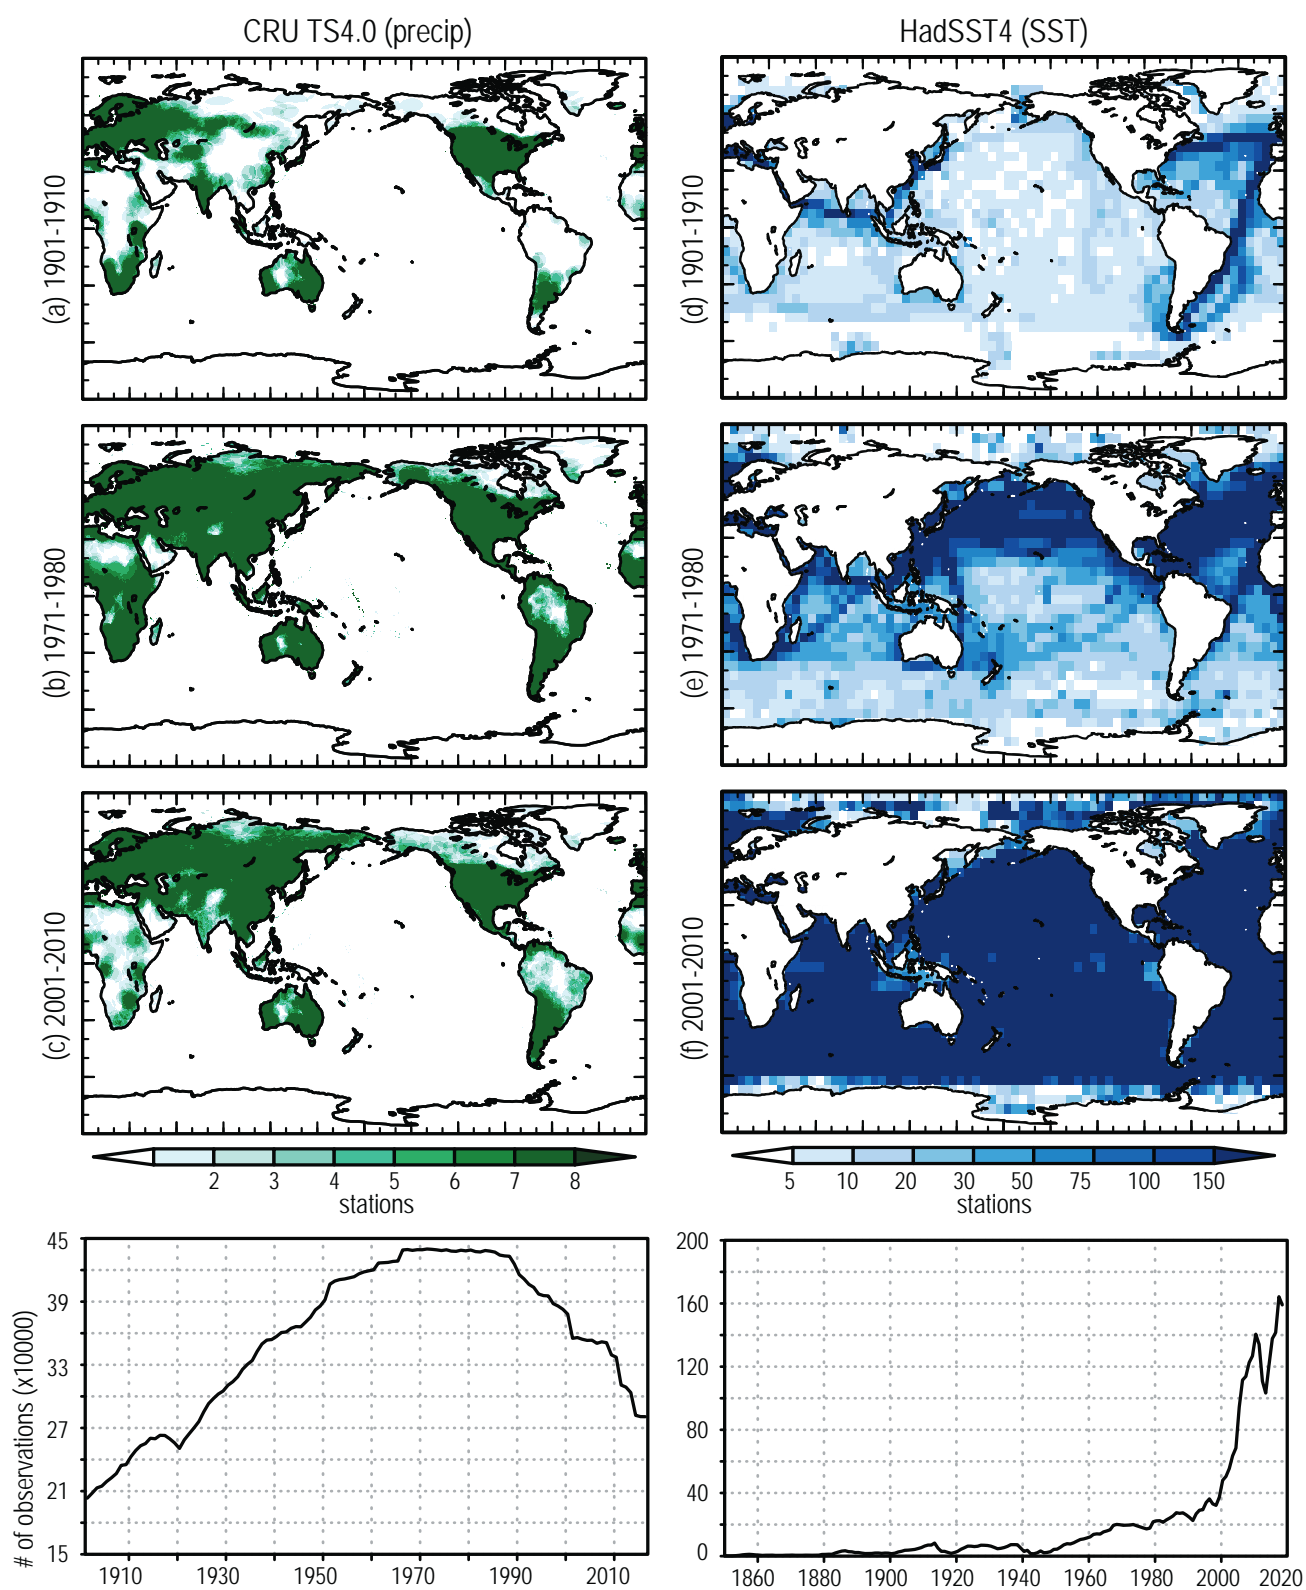

Figure Atlas.5 | Number of stations per $0.5^\circ \times 0.5^\circ$ grid cell reported over the periods of 1901–1910, 1971–1980, and 2001–2010 (rows 1–3), and the global total number of stations reported over the entire globe (bottom row) for precipitation in the CRU TS4 dataset (left) and the HadSST4 dataset (right). Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

those selected in Chapter 2, but considering land-only information for the blended products. In particular, for air temperature the Atlas uses CRUTEM5 – the land component of the HadCRUT5 dataset – (Osborn et al., 2021), Berkeley Earth (Rohde and Hausfather, 2020) and the Climatic Research Unit CRU TS4 (version 4.04 used here; Harris et al., 2020). For precipitation the Atlas includes CRU TS4, the Global Precipitation Climatology Centre (GPCC, v2018 used here; Schneider et al., 2011), and Global Precipitation Climatology Project (GPCP; monthly version 2.3 used here; Adler et al., 2018). Although the ultimate source of these datasets is surface-station reported values (GPCP also includes satellite information), each has access to different numbers of stations and lengths of records and employs different ways of creating the gridded product and ensuring quality control. For oceanic variables, the most widely used sea surface temperature (SST) datasets are HadSST4 (Kennedy et al., 2019), which is the oceanic component of the HadCRUT5 dataset, ERSST (B. Huang et al., 2017), and KaplanSST (Kaplan et al., 1998).

Figure Atlas.5 shows the spatial coverage of the total number of observation stations for different periods (1901–1910, 1971–1980, and 2001–2010) for two illustrative datasets: the CRU TS4 dataset for precipitation and the SST data in HadSST4. The former illustrates spatially the declining trend of station observation data used in the precipitation datasets for certain regions (South America and Africa) after the 1990s. This demonstrates the regional inhomogeneity and temporal change in station density, which is in part a consequence of many stations not reporting to the WMO networks and their data being held domestically or regionally. During early years (before 1950) a limited number of observations are available. This information is used in the Interactive Atlas to blank out regions not constrained with observations in those datasets providing station density information.

In addition to surface observations, satellites have been widely used to produce rainfall estimates. The advantage of satellite-based rainfall products is their global coverage including remote areas but there is significant uncertainty in these products over complex terrain (Rahmawati and Lubczynski, 2018; Satgé et al., 2019). Another recent development has been on gridded datasets for climate extremes based on surface stations, such as HadEX3 (Dunn et al., 2020), as described in Section 11.2.2.

There are some studies assessing observational datasets globally (Beck et al., 2017; Q. Sun et al., 2018) and regionally (Manzanas et al., 2014; Salio et al., 2015; Prakash, 2019), reporting large differences among them and stressing the importance of considering observational uncertainty in regional climate assessment studies. Uncertainty in observations is also a key limitation for the evaluation of climate models, particularly over regions with low station density (Kalognomou et al., 2013; Kotlarski et al., 2019). More detailed information on these issues is provided in Section 10.2.

For regional studies, observational datasets with global coverage are complemented by a range of regional observational analyses and gridded products, such as E-OBS (Cornes et al., 2018) over Europe, Daymet (Thornton et al., 2016) over North America, or APHRODITE (Yatagai et al., 2012) over Asia. These are highlighted in various other chapters and the Atlas expands on their treatment, complementing

discussions on discrepancies/conflicts in observations presented in Chapter 10 and expanding on and replicating their results for other regions. In particular, the Interactive Atlas includes the global and regional observational products described here to assess observational uncertainty over the different regions analysed.

Atlas.1.4.2 Reanalysis

There are currently many atmospheric reanalysis datasets with different spatial resolution and assimilation algorithms (see Annex I and Section 1.5.2). There are also substantial differences among these datasets due to the types of observations assimilated into the reanalyses, the assimilation techniques that are used, and the resolution of the outputs, amongst other reasons. For example, 20CR (Slivinski et al., 2019) only assimilates surface pressure and sea surface temperature (SST) to achieve the longest record but at relatively low resolution, while ERA-20C (Poli et al., 2016) only assimilates surface pressure and surface marine winds. At the other extreme, very sophisticated assimilation systems using multiple surface, upper air and Earth observation data sources are employed, for example ERA5 (Hersbach et al., 2020) and JRA-55 (Harada et al., 2016), which also have much higher resolutions. Most reanalysis datasets cover the entire globe, but there are also high-resolution regional reanalysis datasets which provide further regional detail (Kaiser-Weiss et al., 2019).

The Atlas and Interactive Atlas use information from ERA5 and from the bias-adjusted version WFDE5 (Cucchi et al., 2020) which is combined with ERA5 information over the ocean and used as the Inter-Sectoral Impact Model Intercomparison Project (ISI-MIP) observational reference dataset W5E5 (Lange, 2019b). This reference is also used in the Atlas for model evaluation (Atlas.1.4.4) and for bias-adjusting model outputs (Atlas.1.4.5).

Atlas.1.4.3 Global Model Data (CMIP5 and CMIP6)

The Atlas chapter (and the Interactive Atlas) uses global model simulations from both CMIP5 and CMIP6, mainly historical and future projections performed under ScenarioMIP (O'Neill et al., 2016). This facilitates backwards comparability and thus the detection of new salient features and findings from recent science and the latest CMIP6 ensemble. The selection of the models is based on availability of scenario data for the variables assessed in the Atlas chapter and for those included in the Interactive Atlas (Atlas.2.2). In particular, in order to harmonize the results obtained from the different scenarios as much as possible, only models providing data for the historical scenario and at least two emissions scenarios, RCP2.6, RCP4.5 and/or RCP8.5 (for CMIP5), and SSP1-2.6, SSP2-4.5, SSP3-7.0 and/or SSP5-8.5 (for CMIP6), were chosen, resulting in 29 and 35 models, respectively (see Cross-Chapter Box 1.4 for a description of the scenarios). In the Atlas chapter (similarly to the regional Chapters 11 and 12) a single simulation is taken from each model (see Atlas.12 for limitations of this choice). Since the RCP and SSP emissions scenarios are not directly comparable due to different regional forcing (Section 4.2.2), the Atlas includes GWLs as an alternative dimension of analysis (Cross-Chapter Box 11.1), which allows intercomparison of results from different scenarios as an alternative to the standard

analysis based on time slices for particular scenarios (Atlas.1.3.1). This dimension allows for enhanced comparability of CMIP5 and CMIP6, since it constrains the regional patterns to the same global warming level for both datasets.

Building on this information, the Interactive Atlas displays a number of (mean and extreme) indices and climatic impact-drivers (CIDs), considering both atmospheric and oceanic variables (Atlas.2.2). Some of these indices have been selected in coordination with Chapters 11 and 12, in order to support and extend the assessment performed in these chapters (see Annex VI for details on the indices). In order to harmonize this information, the indices have been computed for each individual model on the original model grids and the results have been interpolated to a common 2° (for CMIP5) and 1° (CMIP6) horizontal resolution grids. In addition, for the sake of comparability with CMIP6 results (in particular when using baselines going beyond 2005), the historical period of the CMIP5 and CORDEX datasets has been extended to 2006–2014 using the first years of RCP8.5-driven transient projections (Atlas.1.3.1). Tables listing the CMIP5 and CMIP6 models used in the Atlas and in the Interactive Atlas for different scenarios and variables are included as Supplementary Material (Tables Atlas.SM.1 and Atlas.SM.2, respectively); moreover, full inventories including details on the specific Earth System Grid Federation (ESGF) versions are given in the Atlas GitHub repository (Iturbide et al., 2021).

Chapter 3 and Flato et al. (2013) describe the evaluation of CMIP6 and CMIP5 models, respectively, assessing surface variables and large-scale indicators. Section 10.3.3 assesses the general capability of GCMs to produce climate output for regions.

Information from the existing CMIP5 and CMIP6 datasets is supplemented with downscaled regional climate simulations from CORDEX. This facilitates an assessment of the effects from higher resolution, including whether this modifies the projected climate

change signals compared to global models and adds any value, especially in terms of high-resolution features and extremes.

Atlas.1.4.4 Regional Model Data (CORDEX)

Global model data, as generated by the CMIP ensembles, although available globally, have spatial resolutions that are limited for reproducing certain processes and phenomena relevant for regional analysis (around 2° and 1° for CMIP5 and CMIP6, respectively). The Coordinated Regional Climate Downscaling Experiment (CORDEX; Gutowski Jr. et al., 2016) facilitates worldwide application of Regional Climate Models (RCMs, see Section 10.3.1.2), focusing on a number of regions (Figure Atlas.6) with a typical resolution of 0.44° (but also at 0.22° and 0.11° over some domains, such as Europe). However, only a few simulations are available for some domains (Annex II, Table AII.1), thus limiting the level of analysis and assessment that can be performed using CORDEX data in some regions. Moreover, there are regions where several domains overlap, thus providing additional lines of evidence. The use of multi-domain grand ensembles to work globally with CORDEX data have recently been proposed (Legasa et al., 2020; Spinoni et al., 2020). Ongoing efforts, such as the multi-domain CORDEX-CORE simulations are promoting more homogeneous coverage and thus more systematic treatment of CORDEX domains (Box Atlas.1).

A lot of progress has been made by the regional climate modelling community since AR5 (Table AII.1) to produce and make available evaluation (reanalysis-driven) simulations over the different CORDEX domains along with downscaled CMIP5 historical and future climate projection information under a range of emissions scenarios, mainly RCP2.6, RCP4.5 and RCP8.5 (Tables AII.3 and AII.4). However, these ensembles cover only a fraction of the uncertainty range spanned by the full CMIP5 ensemble in the different domains (e.g., Figures Atlas.16, Atlas.17, Atlas.21, Atlas.22, Atlas.24, Atlas.26,

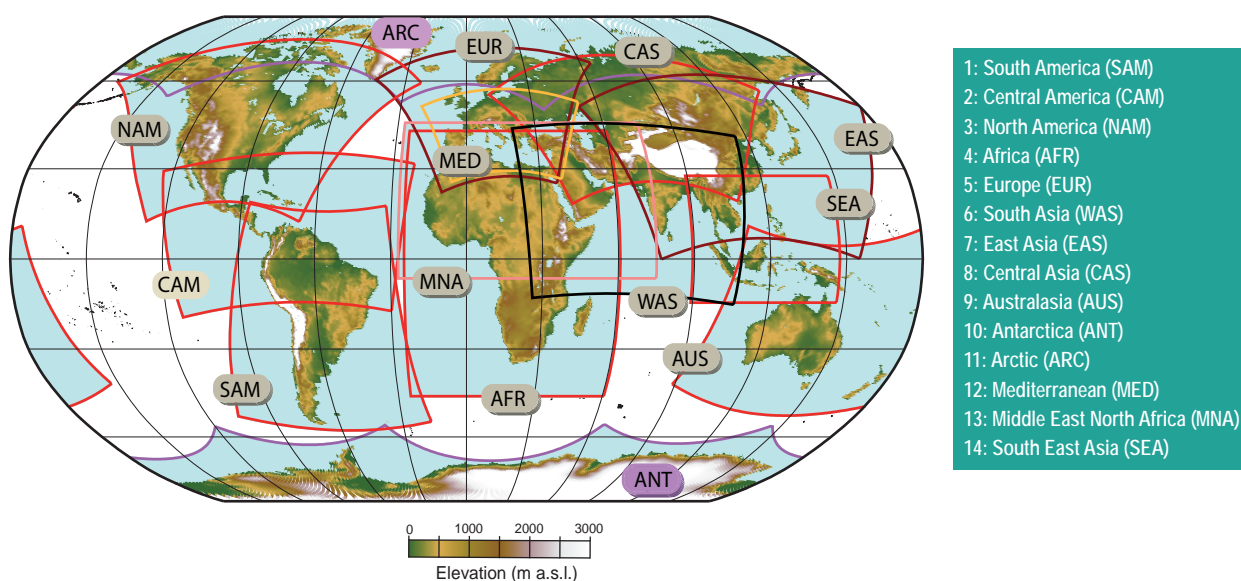

Figure Atlas.6 | CORDEX domains showing the curvilinear domain boundaries resulting from the original rotated domains. The topography corresponding to the standard CORDEX 0.44° resolution is shown to illustrate the orographic gradients over the different regions.

Atlas.28 and Atlas.29; Ito et al., 2020b). Therefore, comparison of CMIP5 and CORDEX results should be performed carefully, providing results not only for the full CMIP5 ensemble but also for the sub-ensemble formed by the driving models since results can diverge (Fernández et al., 2019; Iles et al., 2020).

The Atlas chapter and the Interactive Atlas use CORDEX information for the following 11 individual CORDEX domains (out of the 14 domains shown in Figure Atlas.6): North, Central and South America; Europe; Africa; South, East and South East Asia; Australasia; Arctic and Antarctica; in addition, oceanic information has been used from the Mediterranean domain, which provides simulations from coupled atmosphere–ocean regional climate models (RCMs). In order to harmonize the information across domains and to maximize the size of the resulting ensembles, all the available simulations for each individual CORDEX domain (including the standard 0.44° CORDEX and the 0.22° CORDEX-CORE) have been interpolated to a common regular 0.5°-resolution grid to provide a grand ensemble covering the historical and future emissions scenarios RCP2.6, RCP4.5 and RCP8.5,

and also the reanalysis-driven simulations for evaluation purposes. In the case of the European domain, the dataset considered is the 0.11° simulations (CORDEX EUR-11, the same dataset as used in Chapter 12), which has been interpolated to a regular 0.25° resolution grid (the same used for the regional observations). In the case of the Mediterranean domain, oceanic information (sea surface temperature, SST) is interpolated to a regular 0.11° grid. In all cases, the indices are computed on the original grids and the interpolation process is applied to the resulting indices. Moreover, for the sake of comparability with CMIP6 results (in particular when using baseline periods beyond 2005), the historical period of the CORDEX datasets has been extended to 2006–2014 using the first years of RCP8.5-driven transient projections in which the emissions are close to those observed (see Atlas.1.3.1); note that this procedure is also applied to CMIP5 simulations.

For the different CORDEX domains, the full ensembles of models (GCM-RCM matrix) used in the Atlas for the different scenarios and variables are described in the Supplementary Material (Tables Atlas.SM.3–Atlas.SM.14) and in the Atlas repository (Iturbide et al., 2021),

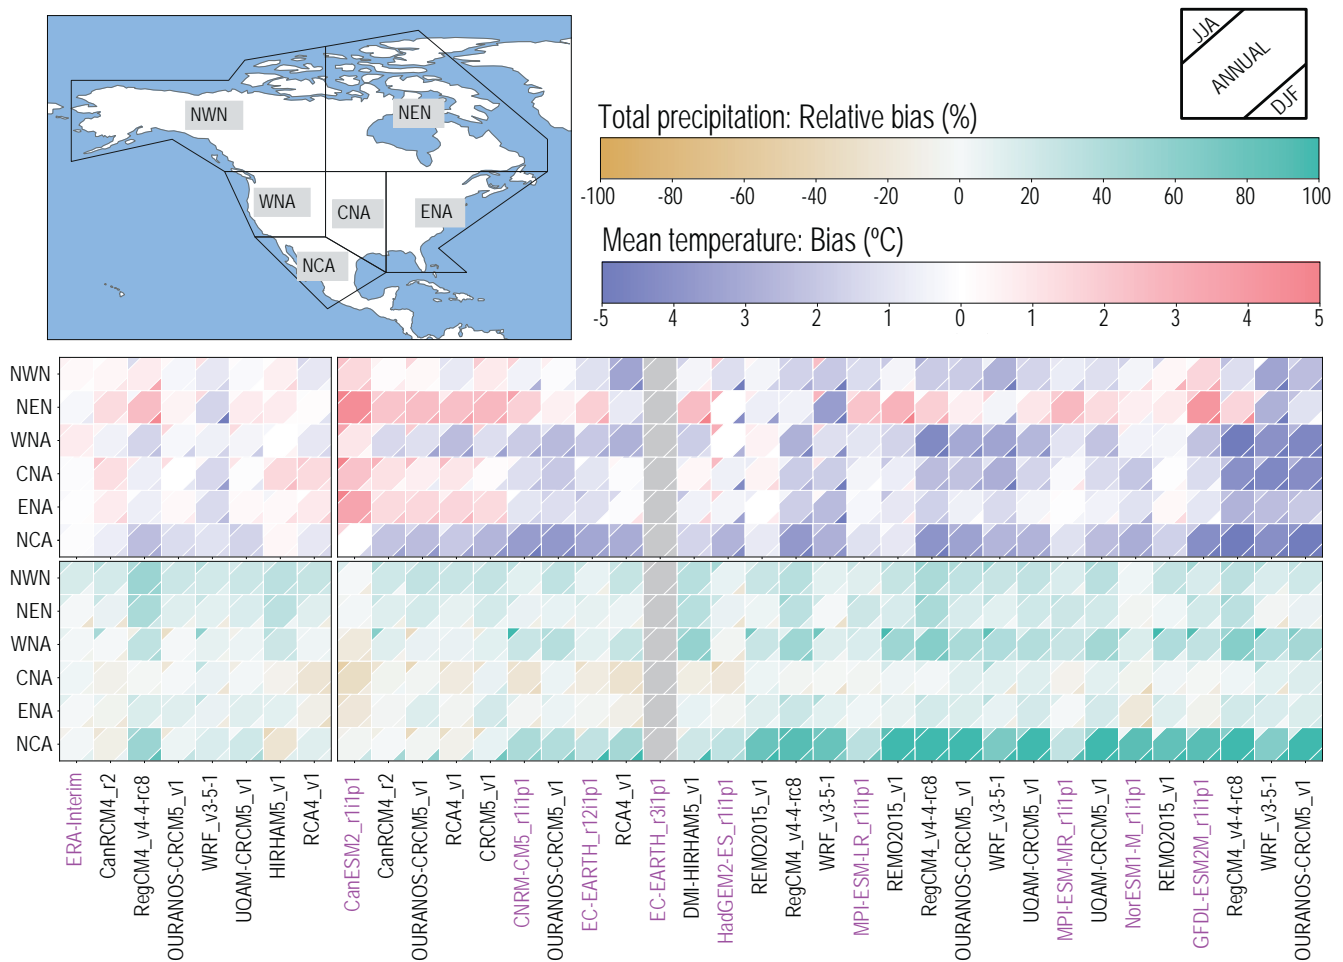

Figure Atlas.7 | Evaluation of annual and seasonal air temperature and precipitation for the six North America sub-regions, NWN, NEN, WNA, CNA, ENA and NCA (land only) for CORDEX-NAM RCM simulations driven by reanalysis or historical GCMs. Seasons are June–July–August (JJA) and December–January–February (DJF). Rows represent sub-regions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in the first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Atlas.1.4.2). Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

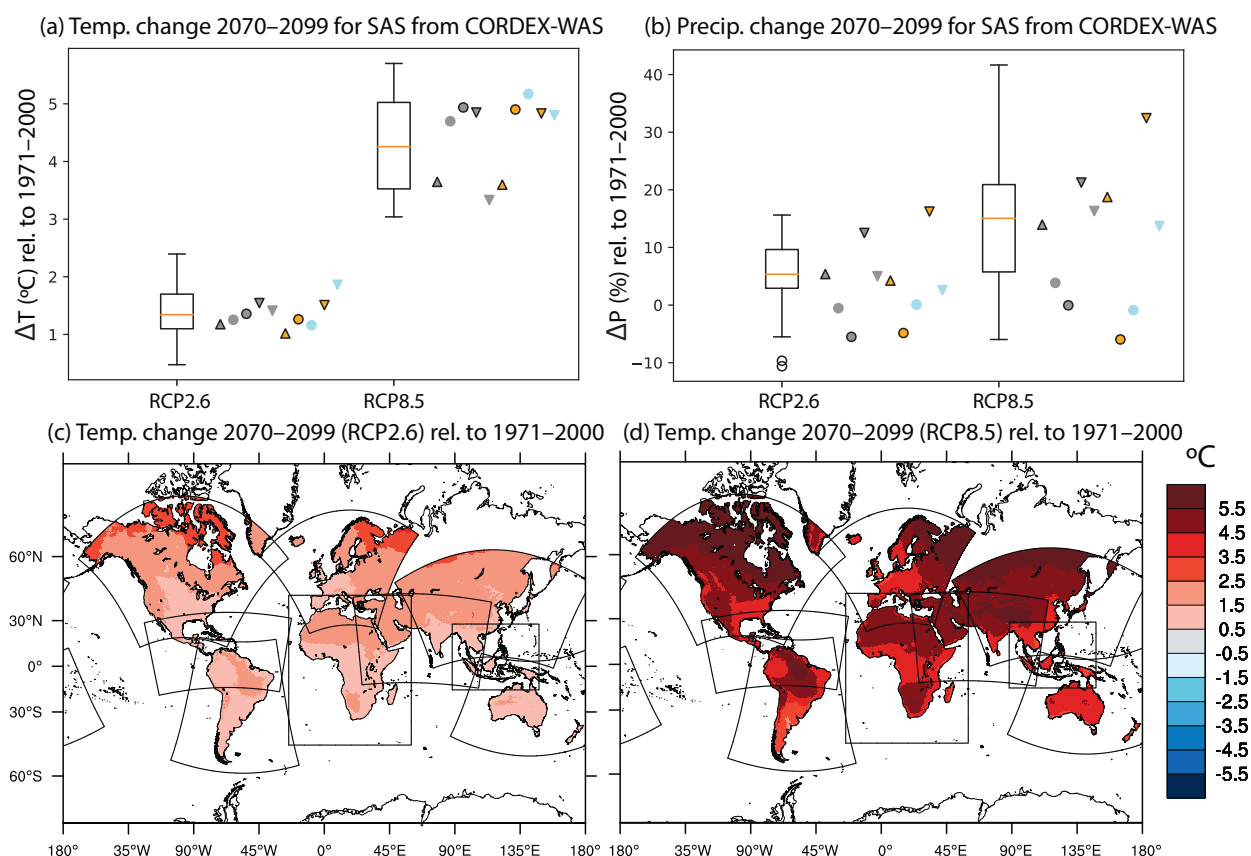

including full metadata relative to ESGF versions used and the periods with data available for the different simulations. In particular, the historical scenario information is only available from 1970 onwards for some models and therefore the common period 1970–2005 is used for historical CORDEX data in the Atlas. As a result, the WMO baseline period 1961–1990 is not available in the Interactive Atlas for CORDEX data.

Sections Atlas.4 to Atlas.11 assess research on CORDEX simulations over different regions, analysing past and present climate as well as future climate projections. They also focus on regional model evaluation in order to extend and complement the validation of global models in Chapter 3, considering the specific regional climate and relevant large-scale and regional phenomena, drivers and feedbacks (Section 10.3.3). Besides the literature assessment, some simple evaluation diagnostics have been computed for the simulations used in the Atlas chapter to provide some basic information on model performance across regions. In particular,

biases for mean temperature and precipitation have been calculated for the 11 CORDEX domains analysed.

Figure Atlas.7 shows mean temperature and precipitation biases over the North American domain in RCM simulations driven by reanalysis and historical GCM simulations (Section 10.3.2.5). Annual and seasonal (December–January–February (DJF) and June–July–August (JJA)) biases are computed for both the RCMs and driving GCMs. Biases in the reanalysis-driven RCMs result from intrinsic model errors, with the results displayed being spatially aggregated for each reference region. This same analysis is performed for the GCM-driven RCM simulations over the historical period 1986–2005. This allows comparison of the intrinsic bias of the RCMs with the biases resulting when driven by the different GCMs and patterns of behaviour in the RCMs, for example intrinsic warm and dry biases in ENA and WNA respectively or reduced RCM warm biases compared to the CCCma GCM in NEN and ENA. Similar results for the other CORDEX domains are included as Supplementary Material (Figures Atlas.SM.1–Atlas.SM.10).

Box Atlas.1 | CORDEX-CORE

Box Atlas.1, Figure 1 | Temperature and precipitation climate change signals at the end of the century (2070–2099). The top panels show climate change signals for (a) temperature and (b) precipitation for the entire CMIP5 ensemble (box-whisker plots) and the CORDEX-CORE driving GCMs (grey symbols) of the respective CORDEX-CORE results (non-grey symbols) in the South Asia (SAS) reference region. The shape of the grey symbols represents the climate sensitivity of the driving GCMs: triangles pointing upwards (low equilibrium), circles (medium equilibrium), triangles pointing downwards (high equilibrium). The corresponding RCM results are drawn using the same symbols, but in orange for REMO and in blue for RegCM. The bottom panels show the warming signal by 2070–2099 over the CORDEX regions for RCP2.6 (c) and RCP8.5 (d) (Figure from Teichmann et al., 2021).

Box Atlas.1 (continued)

The main objective of CORDEX-CORE is to provide a global homogeneous foundation of high-resolution regional climate model (RCM) projections to improve understanding of local phenomena and facilitate impact and adaptation research worldwide (Gutowski Jr. et al., 2016). The experimental framework is designed to produce homogeneous regional projections for most inhabited land regions using nine CORDEX domains at 0.22° resolution (Figure Atlas.6): North, Central and South America (NAM, CAM, SAM); Europe (EUR); Africa (AFR); East, South and Southeast Asia (EAS, WAS, SEA); and Australasia (AUS). Due to computational requirements, three GCMs were selected to drive the simulations, HADGEM2-ES, MPI-ESM and NorESM, covering, respectively, the spread of high-, medium- and low-equilibrium climate sensitivities from the CMIP5 ensemble at a global scale (with MIROC5, EC-Earth and GFDL-ES2M as secondary GCMs), focusing on two scenarios RCP2.6 and RCP8.5 (see Box Atlas.1, Figure 1). Two RCMs have contributed so far to this initiative (REMO and RegCM4) constituting an initial homogeneous downscaled ensemble to analyse mean climate change signals and hazards (Coppola et al., 2021b; Teichmann et al., 2021), and there are ongoing efforts to extend the CORDEX-CORE ensemble with additional regional simulations (e.g., the COSMO-CLM community) to increase the ensemble size. CORDEX-CORE simulations are distributed as part of the information available for the different CORDEX domains at the Earth System Grid Federation (ESGF).

CORDEX-CORE spans the spread of the CMIP5 climate change signals for interquartile ranges of annual mean temperature and precipitation for most of the reference regions covered (Box Atlas.1, Figure 1; Teichmann et al., 2021). However, it is still a small ensemble and for other variables like extremes or climatic impact-drivers it has only been partially investigated in Coppola et al. (2021b) and needs further analysis.

Atlas.1.4.5 Bias Adjustment

Bias adjustment is often applied to data from climate model simulations to improve their applicability for assessing climate impacts and risk (e.g., in the Inter-Sectoral Impact Model Intercomparison Project, ISIMIP; Rosenzweig et al., 2017). Bias-adjustment approaches (Section 10.3.1.3) are particularly beneficial when threshold-based indices are used, but they can introduce other biases, in particular when applied directly to coarse-resolution GCMs (Cross-Chapter Box 10.2). Bias-adjustment techniques should be chosen carefully for a specific application. In the Atlas, bias adjustment is not applied systematically (in particular, it is not applied for the variables assessed in the Atlas chapter), and only some threshold-dependent

extreme indices and climatic impact-drivers (CIDs) included in the Interactive Atlas are bias adjusted (in particular TX35 and TX40 in coordination with Chapter 12). To facilitate integration with WGII, the Atlas uses the same bias-adjustment method as in ISIMIP3 (Lange, 2019a) and the same observational reference (W5E5, see Atlas.1.4.2), upscaled to the same resolution as the model to avoid downscaling artefacts (Cross-Chapter Box 10.2). The ISIMIP3 bias-adjustment method is a trend-preserving approach that is recommended for general applications, as it reduces biases while preserving the original climate change signal (Casanueva et al., 2020). Following the recommendations given in Chapter 10, results in the Interactive Atlas are displayed for both the adjusted and the raw model output.

Cross-Chapter Box Atlas.1 | Displaying Robustness and Uncertainty in Maps

Coordinators: José Manuel Gutiérrez (Spain), Erich Fischer (Switzerland)

Contributors: Alessandro Dosio (Italy), Melissa I. Gomis (France/Switzerland), Richard G. Jones (UK), Maialen Iturbide (Spain), Megan Kirchmeier-Young (Canada/USA), June-Yi Lee (Republic of Korea), Stéphane Sénési (France), Sonia I. Seneviratne (Switzerland), Peter W. Thorne (Ireland/UK), Xuebin Zhang (Canada)

Spatial information on observed and projected future climate changes has always been a key output of IPCC reports. This information is typically represented in the form of maps of historical trends (from observational datasets) and of projected changes for future reference periods and scenarios relative to baseline periods (from multi-model ensembles). These maps usually include information on the robustness or uncertainty of the results such as the significance of trends or the consistency of the change across models. Visualization of this information combines two aspects that are intertwined: the core methodology (measures and thresholds) and its visual implementation. For observed trends, robustness can be simply ascertained by using an appropriate statistical significance test. However, for multi-model mean changes, the consistency across models for the sign of change (model agreement) and the magnitude of change relative to unforced climate variability (signal-to-noise ratio) provide two complementary measures allowing for simple or more comprehensive approaches to represent robustness and uncertainty. While they can be visually represented in various ways

Cross-Chapter Box Atlas.1 (continued)

with more or less complexity (Retchless and Brewer, 2016), the most common implementation for maps in the climate science community remains the overlay of symbols and/or masking of the primary variable. This Cross-Chapter Box reviews the approaches followed in previous IPCC reports and describes the methods used across this WGI report, presenting the rationale and discussing its relative merits and limitations.

The objectives in AR6 for representing robustness and uncertainty in maps are: 1) adopting a method that can be as coherent as possible across the different global/regional chapters while accommodating different needs, 2) being visually consistent across WGs, and 3) making the different layers of information on the maps as accessible as possible for the reader. As a result, a single approach is selected for observations and two alternative approaches (simple and advanced) are adopted for projected future changes. It is important to highlight that, as in previous reports, these approaches are implemented in maps at a grid-box level and, therefore, are not informative for larger spatial scales (e.g., over AR6 reference regions) where the aggregated signals are less affected by small-scale variability leading to an increase in robustness. This is particularly relevant for the AR6 regional assessments and approaches (e.g., for trend detection and attribution; Cross-Chapter Box 1.4, Section 11.2.4) which are performed for climatological regions and not at grid-box scale (Chapters 11 and 12, and Atlas). Both small and large scales are relevant (e.g., adaptation occurs at smaller scales but also at the level of countries, which are typically larger than a few grid boxes). They are both addressed in the Interactive Atlas, which implements the above approaches for representing robustness in maps at the grid-box level, but also enables the analysis of region-wide signals (e.g., AR6 WGI reference regions, monsoon regions, etc.), helping to isolate background changes happening at larger scales (Atlas.2.2).

Approaches used in previous reports

Recent IPCC reports adopted different approaches for mapping uncertainty/robustness, including their calculation method and/or their visual implementation. In AR5 WGI '+' symbols were used to represent significant trends in observations at grid-box level. For future projections, different methods for mapping robustness were assessed (AR5 Box 12.1, Collins et al., 2013), while proposing as a reference an approach based on relating the multi-model mean climate change signal to internal variability, calculated as the standard deviation of non-overlapping 20-year means in the pre-industrial control runs. Regions where the multi-model mean change exceeded two standard deviations of the internal variability and where at least 90% of the models agreed on the sign of change were stippled (as an indication of a robust signal). Regions where the multi-model change was less than one standard deviation were hatched (small multi-model mean signal). However, this category did not distinguish areas with consistent small changes from areas of significant but opposing/divergent signals. In addition, the unstippled/unhatched areas were left undefined, since the categories were not mutually exclusive.

The AR5 WGII (Hewitson et al., 2014) used hatching to represent non-significant trends in observations. For future projections, an elaborated approach with four mutually exclusive and exhaustive categories was proposed (to avoid some of the limitations of the AR5 WGI approach): very strong agreement (same as in WGI); strong agreement; divergent change; and little or no change. These depended on the percentage of models showing change greater than the baseline variability and/or agreeing on sign of change (using a 66% agreement threshold). Leaving the robust regions uncovered minimized any interference with the perception of underlying colours that encoded the primary information of the figure.

The two special reports IPCC SR1.5 (Hoegh-Guldberg et al., 2018) and SROCC (IPCC, 2019a, c) adopted a simplified approach, using only model agreement ($\geq 66\%$ of models agree on sign of change) to characterize robustness. However, cross-hatching was used in SR1.5 to highlight robust areas where models agree, whereas the SROCC used hatching/shading to represent regions where models disagree. Similarly, stippling was used in SR1.5 to indicate regions with significant trends, whereas it was used in SROCC to represent regions where the trends were not significant.

Recent methodologies

Since AR5 there has been a growing interest for disentangling small consistent climate change signals from significant divergent opposite changes resulting in conflicting information (Tebaldi et al., 2011), and different statistical tests have been applied to assess the significance of signals working with the individual models forming the ensemble (Dosio and Fischer, 2018; Yang et al., 2018; Morim et al., 2019). Moreover, new approaches have been proposed to identify large changes of opposite sign that compensate in the mean (Zappa et al., 2021). Recent literature has also highlighted the respective risks of Type I vs Type II errors, which can be associated with the determination of robustness in analysed signals (Lloyd and Oreskes, 2018; Knutson et al., 2019). Type I errors are identifying signals when there are none, while Type II errors are concluding there is no signal when there is one. In the case of grid-box level analysis, the focus on small-scale features with inherently large signal-to-noise ratio may emphasize noise even though signals are

Cross-Chapter Box Atlas.1 (continued)

present when aggregated at larger scale (Sections 11.2.4 and 11.2.5). Consequently, changes averaged over regions or a number of grid boxes emerge from internal variability at a lower level of warming than at the grid-box level (e.g., Cross-Chapter Box Atlas.1, Figure 2). Hence, focus on grid-box significance enhances the risk of Type II errors for overlooking signals significant at the level of AR6 regions. The significance of signals is also affected by the interdependence of single simulations considered in a given ensemble, for example when several come from the same modelling group and share parametrizations or model components (Knutti et al., 2013; Maher et al., 2021). The risk of Type II errors increases when a model ensemble includes several related simulations showing no signal.

The AR6 WGI approach

The AR6 WGI adapts the approaches applied in previous IPCC reports into a comprehensive framework based on the two general principles followed by AR5 WGII: 1) not obscuring (with stippling or hatching) the areas where relevant/robust information needs to be highlighted (since stippling and hatching obstruct the visualization of the colours, which can affect the perception/interpretation of the underlying data); 2) using mutually exclusive and exhaustive categories to avoid leaving areas undefined. The three adopted approaches (one for observations and two for model projections) are described in Cross-Chapter Box Atlas.1, Table 1. This framework integrates as much as possible the specificities of each WGI Chapter, proposing in some cases alternative thresholds.

Approach A is intended for observations and consists of two categories, one for areas with significant trends (colour, no overlay) and one for non-significant ones (coloured areas overlaid with 'x'), typically using a two-sided test for a significance level of 0.1; Chapter 2 and Atlas trends have been calculated using ordinary least squares regression accounting for serial correlation (Santer et al., 2008).

Approach B is the simple alternative for model projections. It consists of two categories, one for model agreement (at least 80% of the models agree on the sign of change; colour, no overlay) and the other one for non-agreement (hatching). It is noted that model agreement is computed using 'model democracy' (i.e., without discarding/weighting models), since quantifying and accounting for model interdependence (shared building blocks) still remains challenging (Section 4.2.6). Different thresholds have been used in previous reports and in the literature. In CORDEX studies, 80% has been widely used (Dosio and Fischer, 2018; Kjellström et al., 2018; Nikulin et al., 2018; Yang et al., 2018; Akperov et al., 2019; Rana et al., 2020), partially due to the small ensemble sizes available in some cases; this also helps to reduce the impact of model interdependence in the final results. Although 90% (used in AR5 WGI) provides high confidence on the forced change, it is deemed too stringent for precipitation-like variables and regional assessments and was therefore not included (see Cross-Chapter Box Atlas.1, Figure 1). The 66% threshold, which has been used in previous reports (e.g., SR1.5 and SROCC) and in the literature, is not used to avoid communicating weak confidence. Cross-Chapter Box Atlas.1, Figure 1 illustrates the application of this approach.

Approach C is a more advanced alternative for model projections, extending the AR5 WGI and simplifying the AR5 WGII approaches (fewer categories). It consists of three categories: 'robust change', 'conflicting change', and 'no change or no robust change' (see the details in Cross-Chapter Box Atlas.1, Table 1). The first two categories can be interpreted as areas where the climate change signal likely emerges from internal variability (i.e., it exceeds the variability threshold in $\geq 66\%$ of the models). The variability threshold is defined as $\gamma = \sqrt{2} \cdot 1.645 \cdot \sigma_{20yr}$, where σ_{20yr} is the standard deviation of 20-year means, computed from non-overlapping periods in the pre-industrial control (after detrending with a quadratic fit as in AR5 WG1); in cases where this information is not available (e.g., for CORDEX or HighResMIP), the following approximation is used instead: $\gamma = \sqrt{2/20} \cdot 1.645 \cdot \sigma_{1yr}$, where σ_{1yr} is the interannual standard deviation measured in a linearly detrended modern period (note that for white noise $\sigma_{20yr} = \sigma_{1yr}/\sqrt{20}$). The factor $\sqrt{2}$ is used as in the AR5 WGI approach to account for the fact that the variability of a difference in means (the climate change signal) is of interest. This approach is an evolution of the AR5 WGI method with three notable differences: (a) AR6 uses a lower threshold for internal variability (1.645 corresponding to a 90% confidence level, instead of 2 as used in AR5 WG1); (b) the threshold on agreement in sign is lowered from $\geq 90\%$ to $\geq 80\%$, leading to more grid boxes classified as robust as opposed to conflicting signal; (c) the AR6 method compares signal to variability in each individual model and consequently introduces a 66% cut-off on significant changes, implying that the climate change signal *likely* emerges from internal variability in the baseline period.

Cross-Chapter Box Atlas.1, Figure 1 illustrates the application of this method considering the effect of the baseline period (1850–1900 versus 1995–2014) and shows that it provides similar results to related approaches proposed in the literature (Zappa et al., 2021).

The two alternative approaches discussed above allow visualization of different levels of detail of information on the projected change and are intended for different communication purposes. Approach B just informs on the consistency of the sign of change independent

Cross-Chapter Box Atlas.1 (continued)

of its significance relative to internal variability, whereas approach C puts the projected changes into the context of internal variability and allows the highlighting of areas of conflicting signals. It is important to note that different approaches can be applied to the same variable between different chapters for different communication purposes. For example, in maps showing multi-model mean changes of precipitation, Chapter 4 adopts approach C but Chapter 8 applies approach B.

In terms of visual implementation, the approach follows recommendations resulting from conversations with IPCC national delegations: 1) having a consistent approach across WGs would aid consistency and reduce the risk of confusion; 2) defining 'hatching' as 'diagonal lines' in the caption would aid accessibility for non-expert audiences; 3) a clear and concise legend that explains what these patterns represent should be included directly in the figure; 4) information about model uncertainty should be overlaid such that it does not detract from the data underneath.

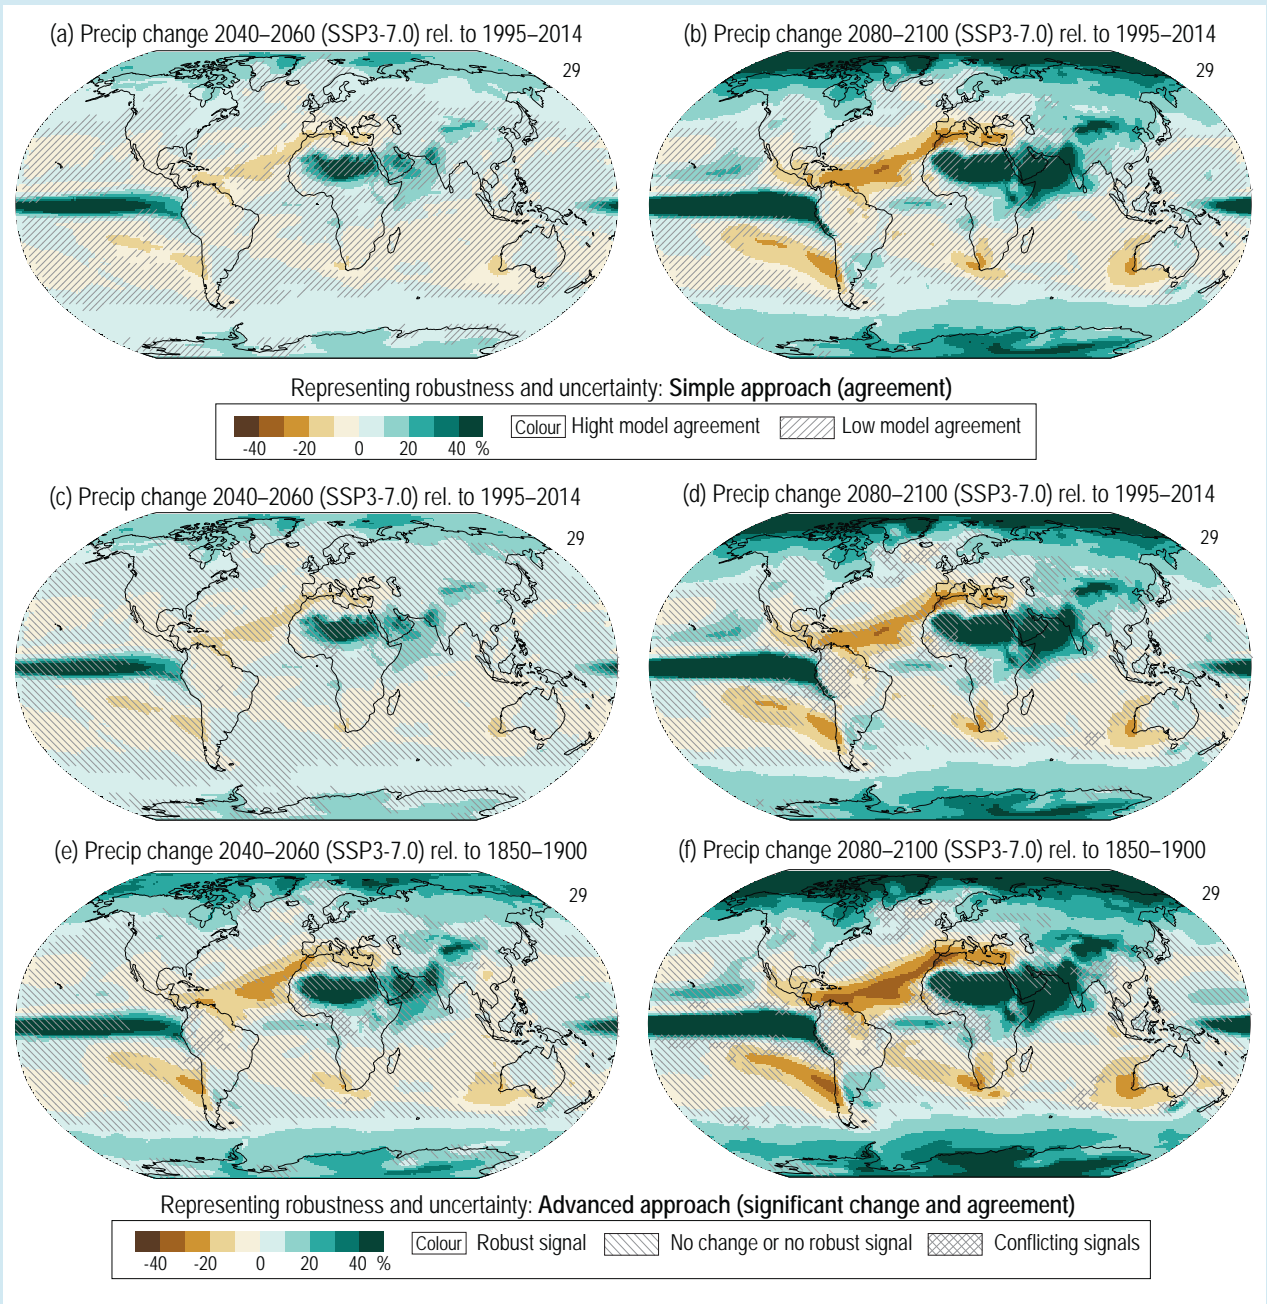

Since stippling is commonly used to represent statistical significance, diagonal lines were chosen to 'obscure' the problematic categories in the above approaches; it also facilitates the visualization of uncertainty in the Interactive Atlas when zooming in. To avoid confusion, methods or thresholds that were unrelated to the three approaches hereby presented were visualized with a different pattern (i.e., model improvement between low- and high-resolution simulations in Chapter 3; agreement between observation-based products in Chapter 5; correlation between two variables in Chapter 6).

Cross-Chapter Box Atlas.1, Table 1 | Approaches for representing robustness (uncertainty) in maps of observed (approach A) and projected (approaches B and C) climate changes.

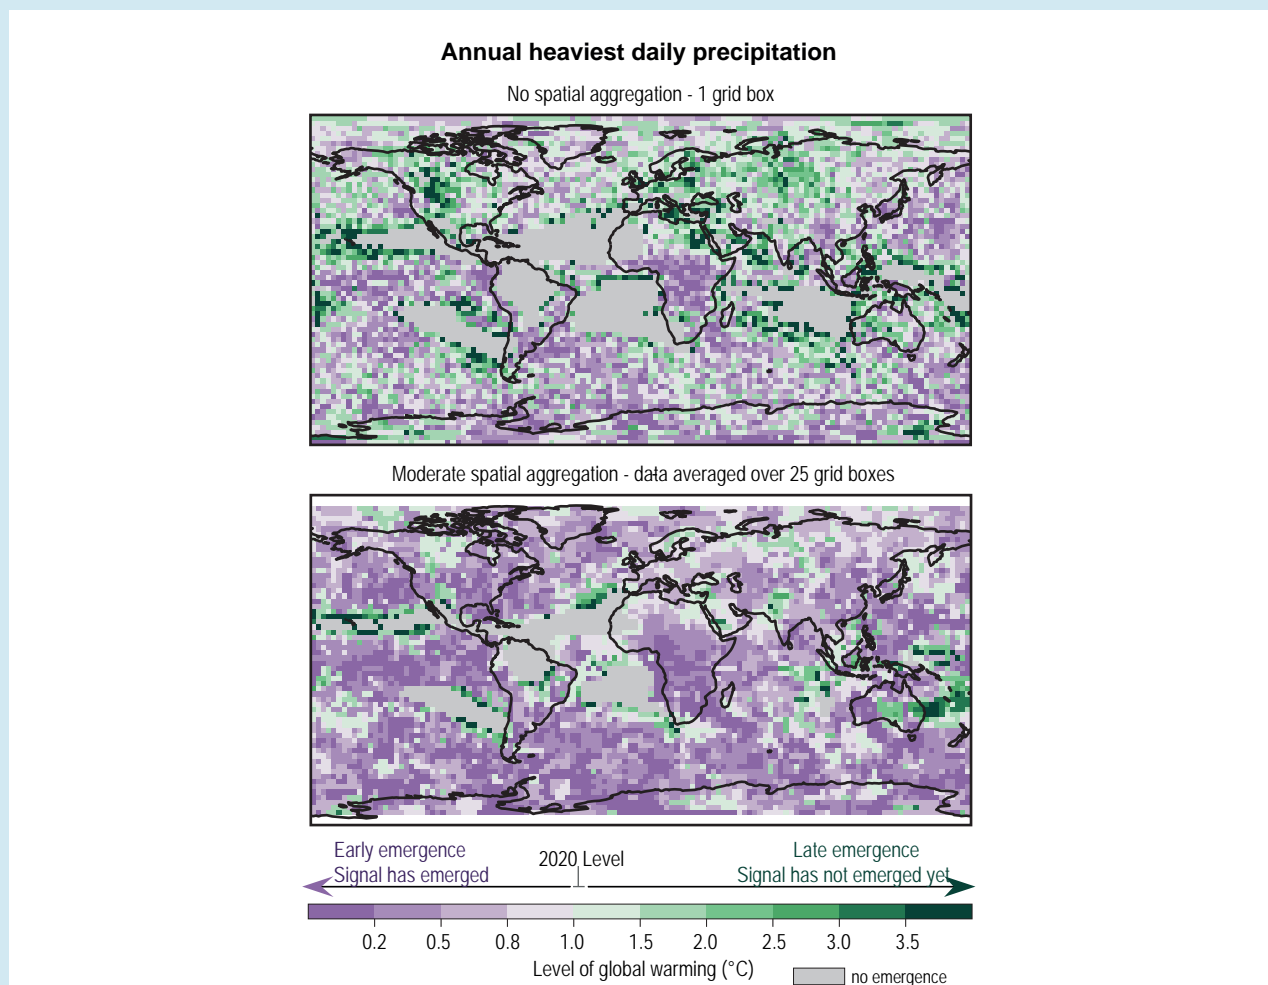

Approach	Category	Definition	Visual Code
A. Observations (significance)	A.1. Significant	Significant (0.1 level) trend	Colour (no overlay) 
	A.2. Non-significant	Non-significant trend	Cross 
B. Model projections, Simple approach (agreement)	B.1. High model agreement	≥80% of models agree on sign of change For Chapter 6 (<5 model ensembles): more than $(n-1)/n$ models agree on the sign of change	Colour (no overlay) 
	B.2. Low model agreement	<80% agree on sign of change For Chapter 6: fewer than $(n-1)/n$ models agree on the sign of change	Diagonal 
C. Model projections, Advanced approach (significant change and agreement)	C.1. Robust signal (significant change and high agreement)	≥66% of models show change greater than variability threshold γ and ≥80% of all models agree on sign of change	Colour (no overlay) 
	C.2. No change or no robust signal	<66% of models show change greater than variability threshold	Reverse diagonal 
	C.3. Conflicting signals (significant change but low agreement)	≥66% of models show change greater than variability threshold γ and <80% of all models agree on sign of change	Crossed lines 

Uncertainty at the grid-box and regional scales: interpreting areas with diagonal lines

There is no one-size-fits-all method for representing robustness or uncertainty in future climate projections from a multi-model ensemble. One of the main challenges is the dependence of the significance on the spatial scale of interest: while a significant trend may not be detected at every location, a fraction of locations showing significant trends can be sufficient to indicate a significant change over a region, particularly for extremes (e.g., it is *likely* that annual maximum one-day precipitation has intensified over the land regions globally even though there are only about 10% of weather stations showing significant trends; Figure 11.13). The approach adopted in WGI works at a grid-box level and, therefore, is not informative for assessing climate change signals over larger spatial scales. For instance, an assessment of the amount of warming required for a robust climate change signal to emerge can strongly depend on the considered spatial scale. A robust change in the precipitation extremes averaged over a region or a number of grid boxes emerge at a lower level of warming than at the grid-box level because of larger variability at the smaller scale (Cross-Chapter Box Atlas.1, Figure 2).

Cross-Chapter Box Atlas.1, Figure 1 | Illustration of the simple, (a) and (b), and advanced, (c–f), approaches (B and C in Cross-Chapter Box Atlas.1, Table 1) for uncertainty representation in maps of future projections. Annual multi-model mean projected precipitation change (%) from CMIP6 for the period 2040–2060 (left) and 2080–2100 (right) relative to the baseline periods 1995–2014 (a–d) and 1850–1900 (e and f) under a high-emissions (SSP3-7.0) future. Diagonal and crossed lines follow the indications in Cross-Chapter Box Atlas.1, Table 1. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Cross-Chapter Box Atlas.1, Figure 2 | Climate change signals are more separable from noise at larger spatial scales. The figure shows the global warming level associated with the emergence of a significant increase in the probability, due to anthropogenic forcing, in the 1-in-20-year daily precipitation event. It uses a 500-year sample from the CanESM2 large ensemble simulations. The left panel uses data analysed over a single grid box, with no spatial aggregation, while the right box uses data averaged over 25 grid boxes to represent the regional scale, with moderate spatial aggregation. Aggregation over 25 grid boxes reduces natural variability, resulting in a smaller warming required for a clear separation between the signal and noise (after Kirchmeier-Young et al., 2019).

Atlas.2 The Online 'Interactive Atlas'

The WGI Interactive Atlas is a new AR6 product developed as part of the Atlas in consultation with other chapters to facilitate flexible synthesis information for regions, and to support the Technical Summary (TS) and the Summary for Policymakers (SPM), as well as the handshake with WGII. It includes multiple lines of evidence to support the assessment of observed and projected climate change by offering information for regions using both time slices across scenarios and GWLs. Coordination has been established with other chapters (particularly the regional chapters), adopting their methodological recommendations (Chapter 10) and using common datasets and agreed extreme indices and climatic impact-drivers (CIDs) to support and expand their assessment (Chapters 11 and 12).

The Interactive Atlas includes two components. The first component (Regional Information) allows for flexible spatial and temporal analysis (Atlas.1.3) with a predefined granularity (predefined climatological and typological regions, and user-defined seasons) through a wide range of maps, graphs and tables generated in an interactive manner building on a collection of global and regional observational datasets and climate projections (including CMIP5, CMIP6 and CORDEX; Atlas.1.4). In particular, the Interactive Atlas provides trends and changes for observations and projections in the form of interactive maps for predefined historical and future periods of analysis, the former including the recent past and paleoclimate (Cross-Chapter Box 2.1) and the latter including future time slices (near, medium and long term) across scenarios (RCPs and SSPs; see Cross-Chapter Box 1.4) and GWLs (1.5°C, 2°C, 3°C and 4°C; see Cross-Chapter Box 11.1).

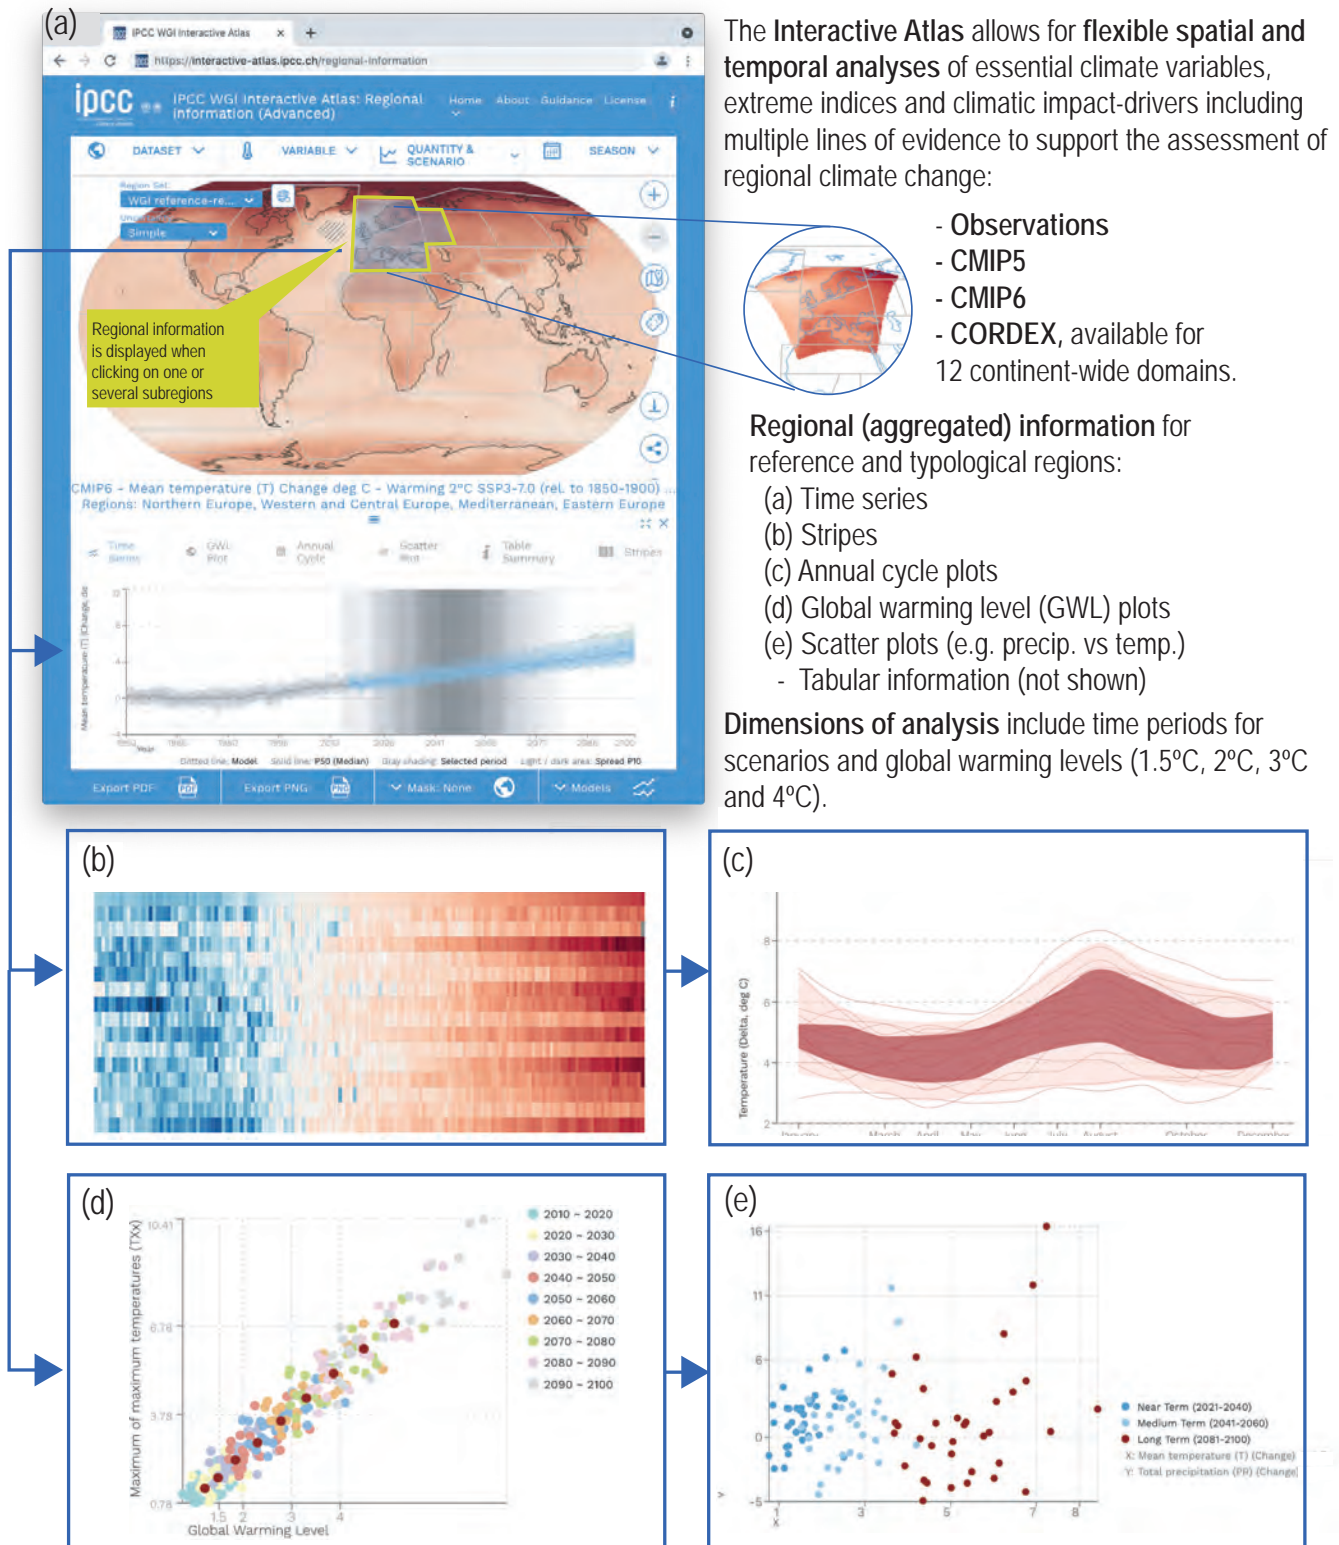

Figure Atlas.8 | Screenshots from the Interactive Atlas (regional information). (a) The main interface includes a global map and controls to define a particular choice of dataset, variable, period (reference and baseline), and season (in this example, annual temperature change from CMIP6 for a global warming level of 2°C under SSP3-7.0 relative to 1850–1900). (b–e) Various visuals for the regionally averaged information for the selected reference regions.

It also provides regional information (aggregated spatial values) for a number of predefined (reference and typological) regions in the form of time series, annual cycle plots, scatter plots (e.g., temperature versus precipitation), table summaries, and ensemble and seasonal stripe plots. This allows for a comprehensive analysis (and intercomparison, particularly using GWLs as a dimension of integration) of the different datasets at a global and regional scale.

The second component of the Interactive Atlas (Regional Synthesis) provides synthesis information about changes in CIDs in several categories such as heat and cold, wet and dry, or coastal and oceanic, supporting exploration of the regional assessment findings summarised in the TS and the SPM.

The Interactive Atlas can be consulted online at <http://interactive-atlas.ipcc.ch>. Figure Atlas.8 illustrates the main functionalities available: the controls at the top of the window allow the interactive selection of the dataset, variable, period (reference and baseline) and season which define a particular product of interest (e.g., annual temperature change from CMIP6 for a global warming level of 2°C under SSP3-7.0 relative to 1850–1900 in this illustrative case). Regionally aggregated information can be obtained interactively by clicking on one or several sub-regions on the map and by selecting one of the several options available for visuals (time series, annual cycle plots, scatter and stripe plots) and tables.

A major goal during the development of the Interactive Atlas has been ensuring transparency and reproducibility of results, and promoting open science and Findability, Accessibility, Interoperability, and Reuse (FAIR) principles (Wilkinson et al., 2016) described in Atlas.2.3. As a result, full metadata are provided in the Interactive Atlas for each of the products, and the scripts used to generate the intermediated products (e.g., extreme indices and CIDs) and figures are available online in a public repository (Iturbide et al., 2021), which also includes simple notebooks illustrating key parts of the code suitable for reusability. These scripts are based on the climate4R open-source framework (Iturbide et al., 2019) and full metadata have been generated for all final products using the METACLIP framework (Bedia et al., 2019), which builds on standards and describes provenance of the datasets as well as the post-processing workflow.

Atlas.2.1 Why an Online Interactive Atlas in AR6?

The idea of an online interactive Atlas was first discussed in the IPCC Expert Meeting on Assessing Climate Information for the Regions (IPCC, 2018a). The meeting stressed the need for the AR6 regional Atlas to go beyond the AR5 experience in supporting and expanding the assessment of key variables/indices and datasets conducted in all chapters, ensuring traceability, and facilitating the ‘handshake’ between WGI and WGII. One of the main limitations of previous products, including the AR5 WGI Atlas (IPCC, 2013a), is their static nature with inherent limited options and flexibility to provide comprehensive regional climate information for different regions and applications. For instance, the use of standard seasons limits the assessment in many cases, such as regions affected by monsoons or seasonal rainband migrations or other phenomena-driven seasons.

The limited number of variables which can be treated on a printed Atlas also prevents the inclusion of relevant extreme indices and CIDs. The development of an online Interactive Atlas for AR6 was proposed as a solution to overcome these obstacles, facilitating the flexible exploration of key variables/indices and datasets assessed in all chapters through a wide range of maps, graphs and tables generated in an interactive manner, and thus also providing support to the TS and SPM. One of the main concerns raised by this new online interactive product was the potential danger of having an unmanageable number of final products impossible to assess following the IPCC review process. This was addressed by designing the Interactive Atlas with limited and predefined functionality and granularity, thus facilitating the review process and including use of open-source tools and code for traceability and reproducibility of results.

Atlas.2.2 Description of the Interactive Atlas: Functionalities and Datasets

The Interactive Atlas builds on the work done in the context of the Spanish National Adaptation Plan (PNACC – AdapteCCA; <http://escenarios.adaptecca.es>) to develop an interactive online application centralizing and providing key regional climate change information to assist the Spanish climate change impact and adaptation community. The functionalities included in the AR6 WGI Interactive Atlas are an evolution of those implemented in AdapteCCA and have been adapted and extended to cope with the particular requirements of the datasets and functionalities it includes. In particular, the Interactive Atlas allows analysis of global and regional information on past trends and future climate changes through a wide range of maps, graphs and tables generated in an interactive manner, and building on six basic products (Figure Atlas.8):

1. Global maps of ensemble mean values averaged over time slices across scenarios and GWLs, with robustness represented using the approaches described in Cross-Chapter Box Atlas.1.
2. Temporal series, displaying all individual ensemble members and the multi-model median, with robustness represented as ranges across the ensemble (25th–75th and 10th–90th percentile ranges). The selected reference period of analysis is also displayed as context information, either a time slice (near, mid- or long term) or a GWL (defined for a given model as the first 20-year period where its average surface temperature change first reaches the GWL relative to its 1850–1900 temperature).
3. Annual cycle plots representing individual models, the multi-model median and ranges across the ensemble.
4. Stripe and seasonal stripe plots, providing visual information on changes across the ensemble (different models in rows with the multi-model median on the top) and across seasons (months in rows, using the signal from the multi-model mean), respectively.
5. Two-variable scatter plots (e.g., temperature versus precipitation) and GWL plots representing regional/global changes of a particular variable versus global mean warming.
6. Tables with summary information.

The first of these products provides spatial information about the ensemble mean, while the latter five convey (spatially) aggregated

information of the multi-model ensemble for particular region(s) selected by the user from a number of predefined alternatives (see Atlas.1.3.3 and Atlas.1.3.4 for reference and typological regions, respectively).

The Interactive Atlas includes both atmospheric (daily mean, minimum and maximum temperatures, precipitation, snowfall and wind) and oceanic (sea surface temperature, pH, sea ice, and sea level rise) essential variables assessed in the Atlas chapter and Chapters 4, 8 and 9, as well as some derived extreme indices used in Chapter 11 and a selection of CIDs used in Chapter 12 (see Annex VI):

- Maximum of maximum temperatures (TXx) – see Chapter 11.
- Minimum of minimum temperatures (TNn) – see Chapter 11.
- Maximum 1-day precipitation (Rx1day) – see Chapter 11.
- Maximum 5-day precipitation (Rx5day) – see Chapter 11.
- Consecutive dry days (CDD) – see Chapter 11.
- Standardized Precipitation Index (SPI-6) – see Chapters 11 and 12.
- Frost days (FD), both raw and bias adjusted – see Chapters 11 and 12.
- Heating degree days (HD) – see Chapter 12.
- Cooling degree days (CD) – see Chapter 12.
- Days with maximum temperature above 35°C (TX35), both raw and bias adjusted – see Chapter 12.
- Days with maximum temperature above 40°C (TX40), both raw and bias adjusted – see Chapter 12.

The essential variables are computed for observations and reanalysis datasets as described in Atlas.1.4.1 and Atlas.1.4.2 (note that the Atlas does not include observational datasets for extremes). Trend analyses are available for two alternative baseline periods (1961–2015 and 1980–2015, selected according to data availability). This expands the information available in Chapter 2 for global observational datasets, including new periods of analysis and new regional observational datasets which provide further insight into observational uncertainty. The Interactive Atlas also includes paleoclimate information from the Paleoclimate Model Intercomparison Projects PMIP3/4 for temperature and precipitation for the Last Glacial Maximum, Last Interglacial, mid-Holocene and mid-Pliocene periods (see Cross-Chapter Box 2.1).

Both essential variables and indices/CIDs are computed for CMIP5, CMIP6 and CORDEX model projections (Atlas.1.4.3 and Atlas.1.4.4). The calculations are performed on the original model grids and results are interpolated to the reference regular grids at horizontal resolutions of 2° (CMIP5), 1° (CMIP6) and 0.5° (CORDEX) (Iturbide et al., 2021). Information is available for the historical, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 scenarios for CMIP6, and historical, RCP2.6, RCP4.5 and RCP8.5 for CMIP5 and CORDEX, as documented in the supplementary material Tables Atlas.SM.1–2 (for CMIP5/CMIP6) and Tables Atlas.SM.3–14 (for the different CORDEX domains). All products (maps, graphs and tables) are available for different reference periods of analysis, either time slices (2021–2040, 2041–2060 and 2081–

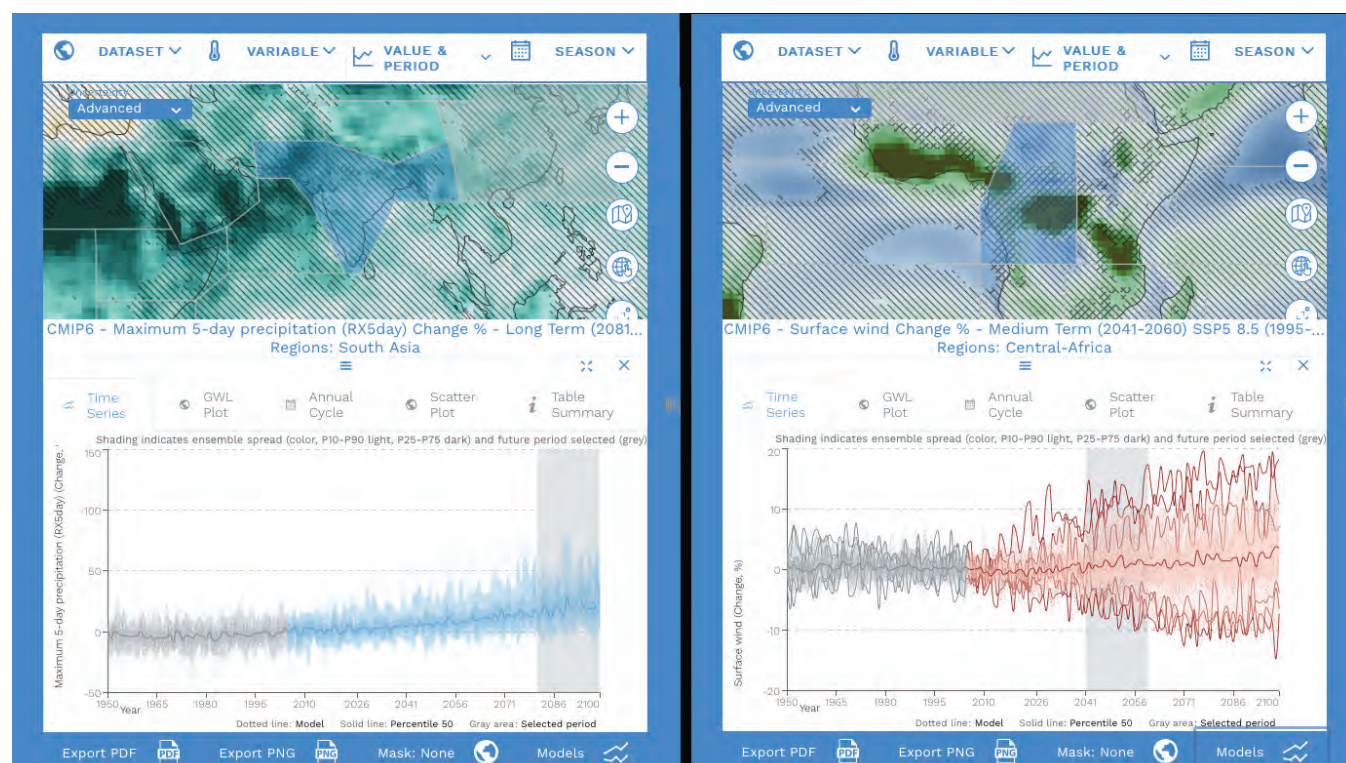

Figure Atlas.9 | Analysing robustness and uncertainty in climate change signals across spatial scales using the Interactive Atlas. The left panel shows projected annual relative changes for maximum five-day precipitation from CMIP6 for 2081–2100 relative to a 1995–2014 baseline under the SSP3-7.0 scenario, through a map of the ensemble-mean changes (panel top) and information on the regional aggregated signal over the South Asia reference region as a time series (panel bottom). This shows non-robust changes (diagonal lines) at the grid-box level (due to the large local variability), but a robust aggregated signal over the region. The right panel shows projected surface wind-speed changes from CMIP6 models for 2041–2060 relative to a 1995–2014 baseline under the SSP5-8.5 scenario, again with the ensemble-mean changes in the map (panel top) and a regionally aggregated time series over Central Africa for each model (panel bottom). This shows conflicting changes (crossed lines) at the grid-box level due to signals of opposite sign in the individual models displayed in the time series.

2100 for near-, mid- and long-term future periods, respectively; see Atlas.1.3.1), or GWLs (1.5°C, 2°C, 3°C or 4°C; see Atlas.1.3.2), with changes relative to a number of alternative baselines (including 1850–1900 pre-industrial, and 1995–2014 recent past; see Atlas.1.3.1). Note that instead of blending the information from the different scenarios, the Interactive Atlas allows comparison of the GWL spatial patterns and timings across the different scenarios (Cross-Chapter Box 11.1).

Some of the above indices (in particular, TX35 and TX40) are highly sensitive to model biases and the application of bias-adjustment techniques is recommended to alleviate this problem (see Cross-Chapter Box 10.2). Bias adjustment is performed as explained in Atlas.1.4.5.

The Interactive Atlas implements the approaches for representing robustness in maps at the grid-box level described in Cross-Chapter Box Atlas.1. These approaches are not necessarily informative for assessing trends and climate change signals over larger spatial scales where signals are less affected by small-scale variability leading to an increase in robustness. For regional analysis, the Interactive Atlas allows the analysis of aggregated region-wide signals and assessing their robustness at a regional scale, thus complementing the previous approach for grid-box robustness representation. For example, Figure Atlas.9 shows large hatched areas for maximum five-day precipitation in the South Asia region. When aggregated spatially, the region exhibits a robust wetting signal, with most ensemble members agreeing on the sign. This highlights that signals may not have emerged at the station or grid-box scale but have clearly at aggregated scales, particularly for variables with high variability (e.g., extreme precipitation or cold extremes; see Cross-Chapter Box Atlas.1).

The advanced approach for representing robustness includes a new category for identifying conflicting signals, where models are projecting significant changes but of opposite signs. This is demonstrated in Figure Atlas.9 which shows a region of central Africa where models have significant changes in surface winds with some projecting increases and others decreases. This is clearly demonstrated in the time series below the map which shows these wind-speed changes aggregated over the CAF reference region for each of the CMIP6 models and the opposing signals in many of these.

Atlas.2.3 Accessibility, Reproducibility and Reusability (FAIR Principles)

The accessibility and reproducibility of scientific results have become a major concern in all scientific disciplines (Baker, 2016). During the design and development of the Interactive Atlas, special attention was paid to these issues in order to ensure the transparency of the products feeding into the Interactive Atlas (which are all publicly available). Accessibility is implemented in collaboration with the IPCC Data Distribution Centre (DDC), since all products underpinning the Interactive Atlas, including the intermediate products required for the indices and CIDs (monthly aggregated data), are curated and distributed by the IPCC-DDC and include full provenance information as part of their metadata. Atlas products are generated using the open-source climate4R framework (Iturbide et al., 2019) for data processing

(e.g., regridding, aggregation, index calculation, bias adjustment), evaluation and quality control (when applicable). Full metadata are generated for all final products using the METACLIP framework (Bedia et al., 2019), based on the Resource Description Framework (RDF) standard to describe the datasets and data-processing workflow.

In summary, a number of actions have been conducted in order to implement open access, reproducibility and reusability of results, including:

- Use of standards and open-source tools.
- Open access to raw data and derived Atlas products via the IPCC-DDC.
- Provision of full provenance metadata describing the product generation workflow.
- Access to code through an online repository (Iturbide et al., 2021), including the scripts needed for calculating the intermediate datasets and for reproducing some of the figures of the Atlas chapter.
- Provision of annotated (Jupyter) notebooks describing key elements of the code to provide guidance and facilitate reusability.

All final products visualized in the Interactive Atlas can be exported in a variety of formats, including PNG and PDF for bitmap and vector information, respectively. Moreover, in the case of the global maps, the final data underlying these products can be downloaded in NetCDF and GIS format (GeoTIFF), thus facilitating reusability of the information. Note that the images are final IPCC products (covered by the IPCC terms of use), whereas the underlying data are distributed by the IPCC-DDC under a more flexible license which facilitates reusability. Moreover, a comprehensive provenance metadata description has been generated, including all details needed for reproducibility, from the data sources to the different post-processes applied to obtain the final product. In these cases, there is also the possibility to download a PNG file augmented with attached metadata information (in JSON format). This metadata information (including the source code generating the product) can be accessed and interpreted automatically using specific JSON software/libraries. However, for the sake of simplicity, a human-readable version of the metadata is accessible directly from the Interactive Atlas, describing the key information along the workflow.

Provenance is defined as a ‘record that describes the people, institutions, entities, and activities involved in producing, influencing, or delivering a piece of data or a thing’. This information can be used to form assessments about their quality, reliability or trustworthiness. In the context of the outcomes of the Interactive Atlas, having an effective way of dealing with data provenance is a necessary condition to ensure not only the reproducibility of results, but also to build trust on the information provided. However, the relative complexity of the data and the post-processing workflows involved may prevent a proper communication of data provenance with full details for reproducibility. Therefore, a special effort was made in order to build a comprehensive provenance metadata model for the Interactive Atlas products.

Provenance frameworks are typically based on RDF (Resource Description Framework), a family of World Wide Web Consortium (W3C) specifications originally designed as a metadata model

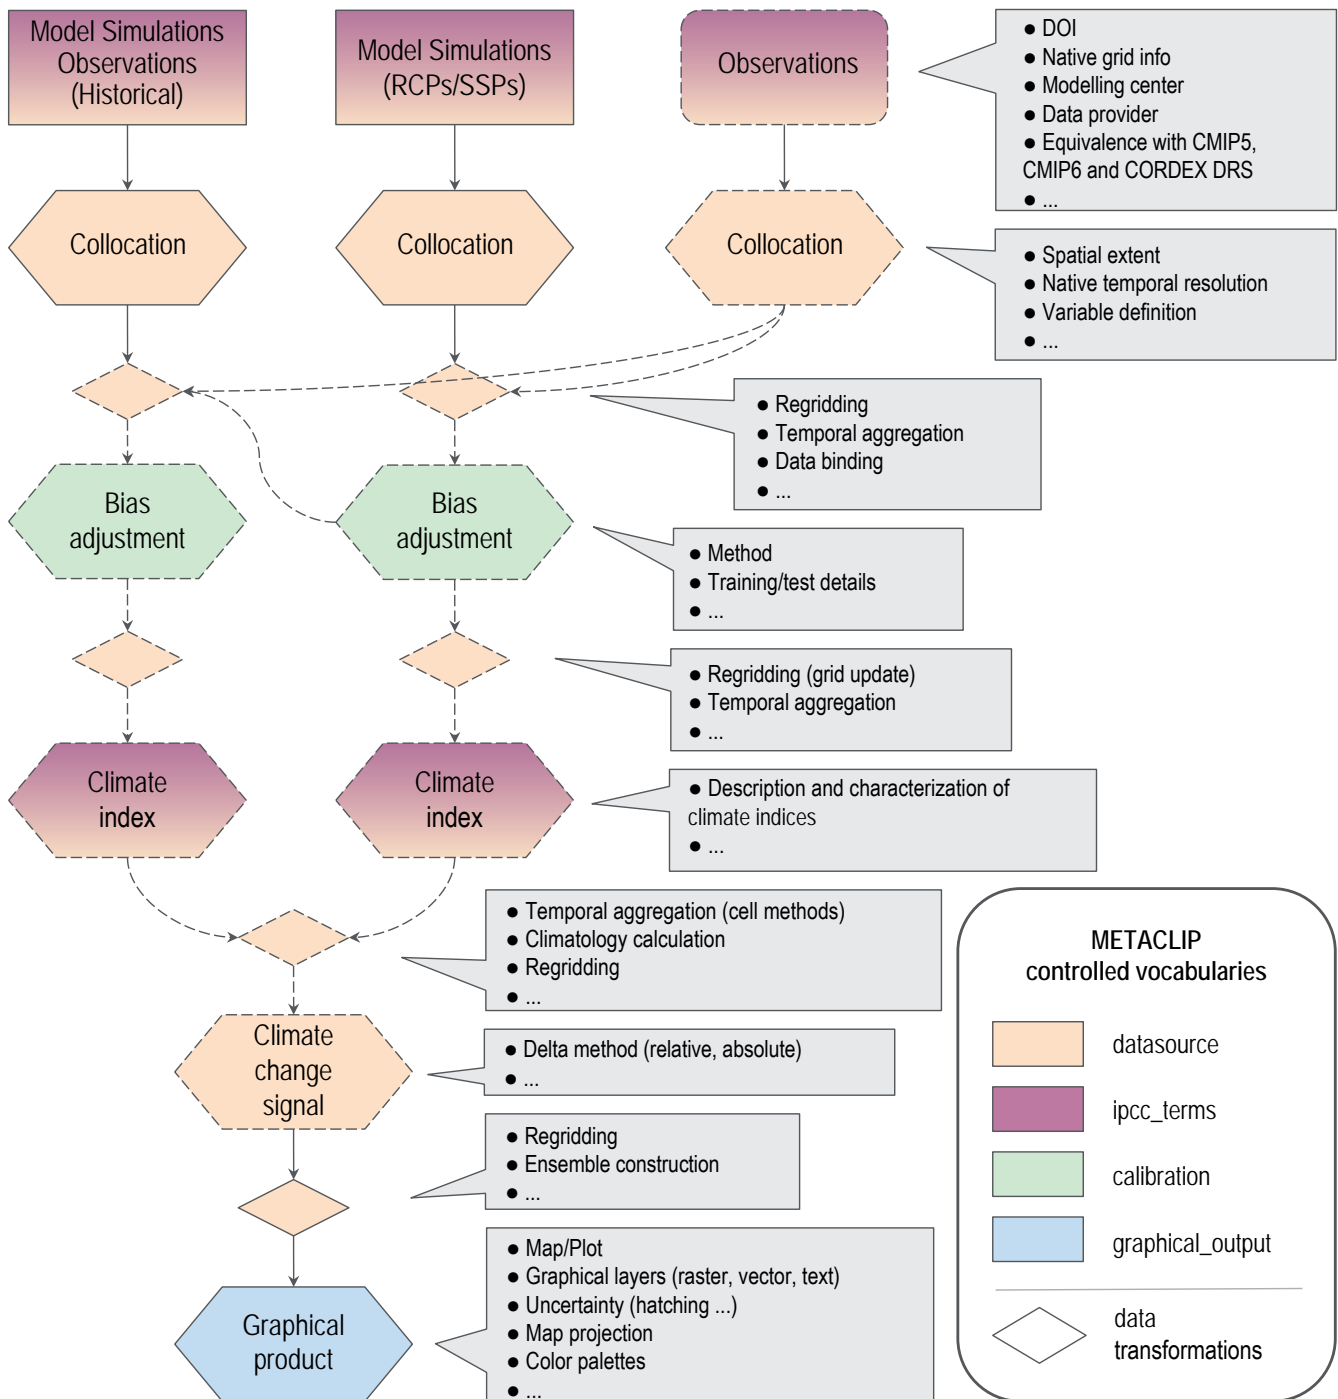

Figure Atlas.10 | Schematic representation of the Interactive Atlas workflow, from database description, subsetting and data transformation to final graphical product generation (maps and plots). Product-dependent workflow steps are depicted with dashed borders. METACLIP specifically considers the different intermediate steps consisting of various data transformations, bias adjustment, climate index calculation and graphical product generation, providing a semantic description of each stage and the different elements involved. The different controlled vocabularies describing each stage are indicated by the colours, with gradients indicating several vocabularies involved, usually meaning that specific individual instances are defined in 'ipcc_terms' extending generic classes of 'datasource'. These two vocabularies, dealing with the primary data sources have specific annotation properties linking their own features with the CMIP5, CMIP6 and CORDEX Data Reference Syntax, taking as reference their respective controlled vocabularies. All products generated by the Interactive Atlas provide a METACLIP provenance description, including a persistent link to a reproducible source code under version control.

(Candan et al., 2001). It is an abstract model that has become a general method for conceptual description of information for the Web, using a variety of syntax notations and serialization formats. METACLIP (Bedia et al., 2019) exploits RDF through specific vocabularies, written in the Web Ontology Language (OWL), describing different aspects involved in climate product generation, from the data source to the post-processing workflow, extending international standard vocabularies such as PROV-O (Moreau et al., 2015). The METACLIP vocabularies are publicly available in the METACLIP repository (Bedia and Martin, 2021).

METACLIP emphasizes the delivery of ‘final products’ (understood as any piece of information that is stored in a file, such as a plot or a map) with a full semantic description of its origin and meaning attached. METACLIP ensures ‘machine readability’ through reuse of well-defined, standard metadata vocabularies, providing semantic interoperability and the possibility of developing database engines supporting advanced provenance analytics. Therefore, this framework has been adopted to generate provenance information and attach it as metadata to the products generated by the Interactive Atlas. A specific vocabulary (‘ipcc_terms’) is created alongside the inclusion of new products in the Interactive Atlas and uses the controlled vocabularies existing from CMIP and CORDEX experiments. As an example, Figure Atlas.10 shows the semantic vocabularies needed to encode the information of the typical workflow for computing (from bias-adjusted data) any of the climate indices (extreme or CIDs) included in the Interactive Atlas.

Atlas.2.4 Guidance for Users

Atlas.2.4.1 Purpose of the Interactive Atlas

The primary purpose of the IPCC is to provide a policy-relevant, non-prescriptive assessment of the state of knowledge on climate change and its impacts. This purpose is different from the provision of information targeted to implement climate policies, which is the focus of climate services and national climate change assessment communities. IPCC assessments are based on quantitative observational and model-generated data that are also used in many activities supporting the development of climate policies. However, the functionality of the Interactive Atlas is primarily aimed at supporting the knowledge assessment.

Much of the assessment in this report is based on multiple lines of evidence (Cross-Chapter Box 10.3). The Interactive Atlas facilitates combining multiple observational and model-generated datasets and spatial and temporal analyses that combine to support statements on the characteristics of the climate system. The use of predefined spatial and temporal aggregations imposes constraints on the ability to make specific or tailored assessments but does provide essential background and uncertainty information to generate broad findings and provide confidence statements on these. Also, the inclusion of a selection of extremes and climatic impact-drivers (CIDs) is a new element in the Interactive Atlas and facilitates broader application, including the handshake with WGII. Below, some guidelines on the use, interpretation and limitations of the Interactive Atlas are given.

Atlas.2.4.2 Guidelines for the Interactive Atlas

Atlas.2.4.2.1 Quantitative Support for Assessments

Many assessment statements make use of evidence derived from observed changes, model projections, and process-oriented attribution of changes to human interventions. The Interactive Atlas shows a small subset of available observations that document climate change, namely surface air temperature and total precipitation (and thus not including observations of other atmospheric and Earth system components used as part of the evidence base for the report). Only datasets that have (near) global or large regional gridded spatial coverage and go back multiple decades are used. For each variable multiple datasets are included, but some of these have overlapping native ground-station observations and so are not independent (Atlas.1.4.1). The datasets show patterns of substantial spatial and temporal variability, and the empirical evidence of a non-stationary climatology needs to be filtered from this information. Issues with quality, representativity and mutual consistency lead to constraints on their use for attribution of causes of trends (see Section 10.4.1.2 for examples). The practice of attributing trends and extreme events to human causes gives confidence that these trends are expected to continue in the (near) future, provided the human drivers of climate change remain unchanged. However, large internal variability at decadal time scales can be misinterpreted as an anthropogenic influence on the likelihood of extreme events, and in that case extrapolation of trends cannot be expected to be a reliable predictor for the future (Schiermeier, 2018).

The Interactive Atlas gives access to a specific set of climate variables from a large number of climate model simulations, particularly the (global) CMIP5, CMIP6 and (regional) CORDEX archives. The global model outputs generally give a relatively coarse picture of climate change, which is an important line of evidence for the detection and attribution of climate change, but is rarely directly applicable for local climate change assessment or support of policy design (van den Hurk et al., 2018). To provide additional detail, downscaling global projections with regional climate models (RCMs) or statistical downscaling can be undertaken but also adds a source of uncertainty as it involves additional modelling (Section 10.3).

The information displayed in the Interactive Atlas allows a number of sources of uncertainty to be quantified. ‘Observational uncertainty’ is represented by the use of multiple (albeit often not completely independent) observational datasets. ‘Uncertainty due to internal variability’ cannot be quantified directly since multiple realizations from historic and future projections are not accessible (the Interactive Atlas uses a single realization of each model). The use of a large collection of model systems allows for an elaborate quantification of ‘model uncertainty’. In addition, a comparison of CMIP5 and CMIP6 supports evidence of progress in model quality since AR5, while the evaluation of the added value of RCMs reveals model uncertainty related to spatial resolution (Section 10.3). Finally, the assessment of ‘scenario uncertainty’ is supported by the inclusion of multiple emissions scenarios for both CMIP5, CORDEX and CMIP6.

The communication of uncertainty has a profound influence on the perception of information that is exchanged during the communication process. An assessment of uncertainty communication and the barriers to climate information construction is given in Section 10.5.4.

Atlas.2.4.2.2 Insights From Physical Understanding

The detailed technical findings in IPCC reports also serve as an important benchmark resource for the research community. The Interactive Atlas complements the IPCC assessment report as a repository of scientific information on global and regional climate and its representation in coordinated model ensemble experiments. Regional climate is governed by a mixture of drivers, such as circulation patterns, seasonal monsoons, annual cycles of snow and regional land–atmosphere feedbacks. Global warming may affect regional climate characteristics by altering the dynamics of their drivers. The Interactive Atlas allows the comparison of different levels of global warming on specific regional climate features but is not designed for advanced analysis of the relationship between drivers and regional climate characteristics. For this, tailored analysis protocols need to be applied, such as the aggregation of climate change information from ensembles of regional climate projections, and stratification according to drivers of regional climate such as patterns of atmospheric circulation (Lenderink et al., 2014). The analysis of complex regional climate characteristics resulting from compound drivers also require additional expert knowledge and data processing (Thompson et al., 2016). Section 12.6.2 assesses various categories of climate services, including tailored analysis of regional climate processes.

Atlas.2.4.2.3 Construction of Storylines

Communicating the full extent of available information on future climate for a region, including a quantification of uncertainties, can act as a barrier to the uptake and use of such information (Lemos et al., 2012; Daron et al., 2018). To address the need to simplify and increase the relevance of information for specific contexts, recent studies have adopted narrative and storyline approaches (see Sections 1.4.4 and 10.5.3 for definitions and further discussion on these concepts; Hazeleger et al., 2015; Shepherd et al., 2018). The use of region-specific climate storylines, including a role for local mechanisms, drivers and societal impacts generally requires detailed information that is typically not provided by the Interactive Atlas. However, background information and basic (scenario) assumptions can be derived from the Interactive Atlas which can be considered to provide an expert knowledge base from which to build targeted storylines and climate information.

Atlas.2.4.2.4 Visual Information

The visual communication of climate information can take many forms. Besides the standard visual products typically used for communicating global and regional climate information to practitioners (e.g., maps, time series or scatter plots), the Interactive Atlas incorporates new visuals, for example, ‘stripes’ (RMetS, 2019), facilitating the communication of key messages (e.g., warming and consistency across models) to a less technical audience. The various

tabular and graphical representation alternatives included as options in the Interactive Atlas (Figure Atlas.8) facilitate exploring the information interactively from different perspectives and in different levels of detail, thus favouring communication with the large and diverse audience of IPCC products.

To support the use of visuals provided in the Interactive Atlas for application to different audiences, new insights since AR5 have emerged from a range of scientific disciplines, including the cognitive and psychological sciences (Harold et al., 2016). Studies have used interviews and online surveys to assess interpretations of visuals used to communicate climate information and uncertainties (Daron et al., 2015; Lorenz et al., 2015; McMahon et al., 2015; Retchless and Brewer, 2016). They commonly find wide-ranging interpretations and varied understandings of climate information amongst respondents due to the choice of visuals. In addition, Taylor et al. (2015) found that preferences for a particular visualization approach do not always align with the approaches that achieve greatest accuracy in interpretation. Choosing appropriate visuals for a particular purpose and audience can be informed by testing and evaluation with target groups.

Atlas.2.4.2.5 Dedicated Climate Change Assessment Programmes

Communication aimed at informing the general public about assessed scientific findings on climate change have a different purpose and format than if intended to inform a specific target audience to support adaptation or mitigation policies (Whetton et al., 2016). The growing societal engagement with climate change means IPCC reports are increasingly used directly by businesses, the financial sector, health practitioners, civil society, the media, and educators at all levels. The IPCC reports could effectively be considered a tiered set of products with information relevant to a range of audiences.

The Interactive Atlas does provide access to a collection of observational and modelling datasets, presented in a form that supports the distillation of information on observed and projected climate trends at the regional scale. Access to the repository of underlying datasets enables further processing for particular purposes. As noted above, it is not the intention nor the ambition of this IPCC assessment and the Interactive Atlas component to provide a climate service for supporting targeted policies. For this an increasing number of dedicated climate change assessment programmes have been carried out, aiming at mapping climate change information relevant for adaptation and mitigation decision support.

For instance, EEA (2018) provides an overview of European national climate change scenario programmes. Most of these use CMIP5 (or earlier) global climate change ensembles driven by an agreed set of greenhouse gas (GHG) emissions scenarios, followed by downscaling using RCMs and/or statistical methods, in order to generate regionally representative hydro-meteorological indicators of climate change. In some cases, output of selected downscaled global and regional models is provided to users (Whetton et al., 2012; Daron et al., 2018). Uptake by users is strongly dependent on providing justification of the selection or for the downscaling procedure and if further steps are needed to tailor the information to local scales (Lemos et al., 2012).

More comprehensive programmes provide probabilistic climate information by careful analysis and interpretation of ensembles of model outputs (Lowe et al., 2018). The information is generally tailored to professional practitioners with expertise to interpret and process this probabilistic data. This top-down probabilistic information chain is not always able to highlight the essential climate change information for users, and alternative bottom-up approaches are encouraged (Frigg et al., 2013). Section 12.6.2 assesses climate services including the national climate assessments and user uptake.

Atlas.3 Global Synthesis

Most other chapters in WGI assess past or future behaviour of specific aspects of the global climate system and this section introduces some of the key results, specifically from Chapters 2, 4 and 9. This provides a global overview on observations and information from the CMIP5 and CMIP6 ensembles to underpin the regional assessments in the rest of the Atlas Chapter and the results displayed in the Interactive Atlas. Thus, its aim is not to generate an assessment of regional climate change directly but to provide the global context for this information derived later in the Atlas. Atlas.3.1 considers global atmospheric and land surface information with global ocean information in Atlas.3.2.

Atlas.3.1 Global Atmosphere and Land Surface

The principal atmospheric quantities of interest for understanding how climate change may impact human and ecological systems, as well as being key global indicators of change, are surface air temperature and precipitation. They are therefore a significant focus of the regional climate assessments in the following regional sections of the chapter (Atlas.4 to Atlas.11) and of the Interactive Atlas. Changes in these variables over land during the recent past (1961–2015) are shown in Figure Atlas.11 using results from two global datasets (assessed in Chapter 2) to illustrate both where there is robust information on observed trends and observational uncertainty.

For temperature, a clear signal of warming is seen over most land areas with an amplification at high latitudes, though all continents apart from Africa also have regions where trends are not significant. Significant changes in annual mean precipitation are seen over much more limited areas though with consistent increasing trends over some northern high-latitude regions and decreasing trends over smaller regions in tropical Africa, the Americas and South West Asia. The information conveyed in Figure Atlas.11 on both consensus in the signal of change and on observational uncertainty is used in this chapter as a line of evidence to assess historical observed trends.

As an alternative way of viewing and summarizing information in the observational data, the panels (c) and (d) in Figure Atlas.11 show the time at which any significant temperature trends from the Berkeley Earth and CRUTEM5 datasets, averaged over the reference regions, emerged from interannual variability – with a signal-to-noise ratio greater than two (Hawkins et al., 2020). In the former, a regionally averaged warming signal has emerged over all of the land reference

regions. In the latter, emergence times are only calculated for those regions which have data available in more than 50% of the land area (unlike Berkeley Earth, CRUTEM does not include spatial interpolation, see Section 2.3.1.1.3) and these are similar for all but one of the regions indicating that observational uncertainty does not change the main conclusion of widespread emergence of surface temperature signals over land regions.

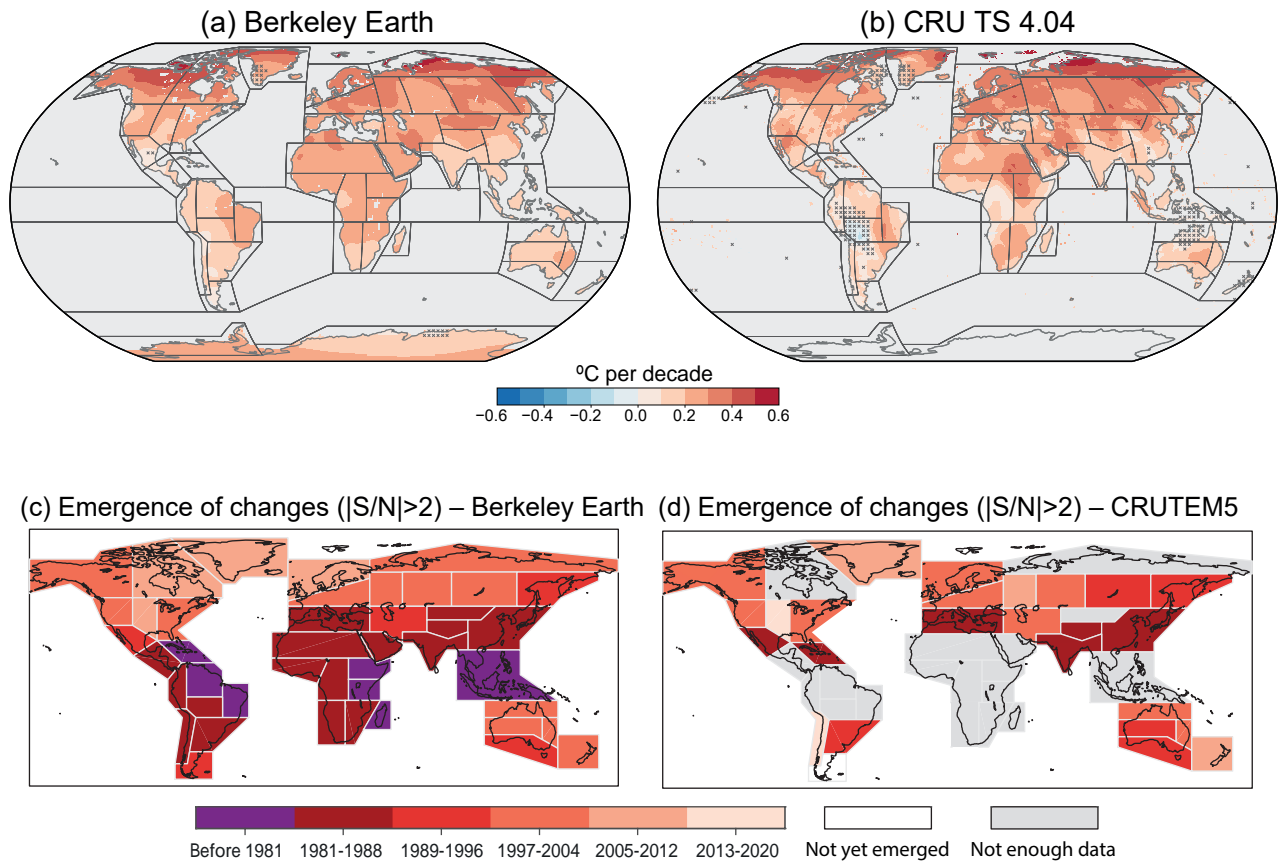

As described earlier, information on projected future changes is required both at different time periods in the future under a range of emissions scenarios but also for different global warming levels. Figure Atlas.12 shows the global surface air temperature (GSAT) change projection calculated from the CMIP6 ensemble mean for the middle of the century under the SSP1-2.6 and SSP3-7.0 emissions scenarios compared to the end-of-century warming under SSP3-7.0 and for a global warming level of 2°C. The patterns of changes are similar to the observed warming and there is a high level of consistency with CMIP5 in terms of both patterns and magnitude of change (Interactive Atlas). However, for the long-term future, warming in the CMIP6 ensemble is generally higher, reflecting the increase in the top end of the range of climate sensitivities amongst the CMIP6 GCMs (Figure Atlas.13).

Figure Atlas.12 demonstrates how temperature is projected to increase for all regions, and at a greater rate than the global average over many land regions, and with significant amplification in the Arctic. It also shows the higher mid-century warming and significantly higher end-of-century warming under the high-emissions SSP3-7.0 scenario compared to the low-emissions SSP1-2.6 scenario. Conversely, comparing the projected 2°C global warming level change with that projected additional warming compared to the recent past under the SSP1-2.6 scenario, demonstrates the much smaller additional warming projected under this low-emissions scenario. Finally, the maps display the CMIP6 ensemble mean projection, but it is important to explore the full range of outcomes from the ensemble, for example when undertaking a comprehensive risk assessment in which temperature is an important hazard. This can be explored regionally in the Interactive Atlas (Atlas.2) by viewing the time series of changes for all of the models within the ensemble over the AR6 WGI reference regions (Figure Atlas.2).

Changes in annual mean precipitation present a more complex picture with regions of decrease as well as increase, and areas where there is model disagreement on the sign of the change, even when the signal is strong in the long-term future period as shown in Cross-Chapter Box Atlas.1, Figure 1. However, as with the temperature changes, there is a high level of consistency in the patterns and magnitude of the precipitation changes, with changes in some areas being larger in the long-term future period. Considering changes over land, Cross-Chapter Box Atlas.1, Figure 1 also shows that at lower warming levels there are many regions, especially in the Southern Hemisphere, where there is no robust signal of change from the models.

In addition to displaying results from global model ensembles as maps of projected changes and their robustness or as time series of the projected temporal evolution of the median and

Trends of annual temperature (1961-2015)

Trends of annual precipitation (1961-2015)

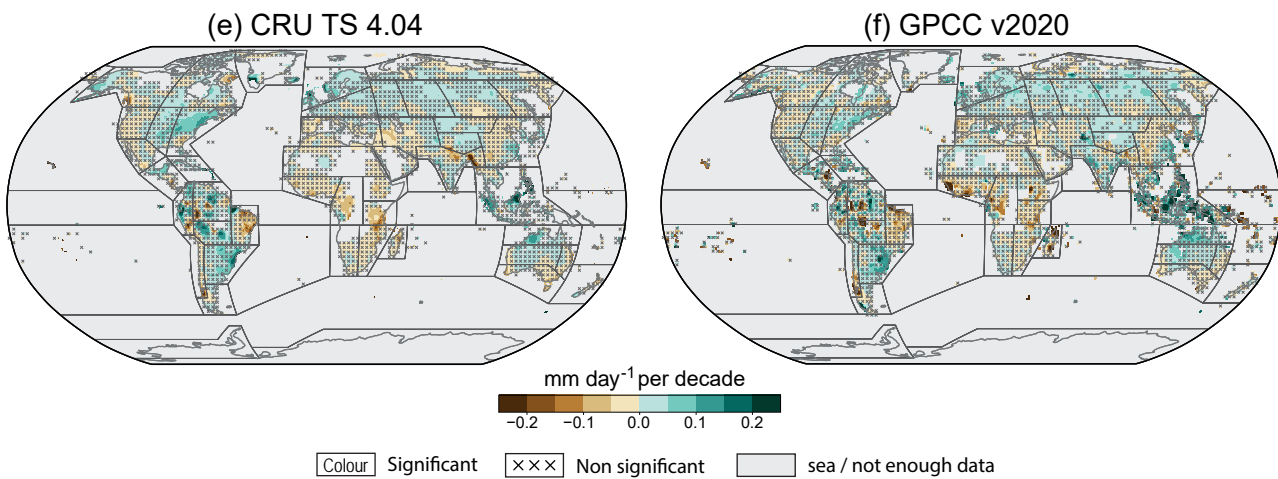

Figure Atlas.11 | Observed linear trends of signals in annual mean surface air temperature (a, b) and precipitation (e, f) in the Berkeley Earth, CRU TS and GPCC datasets (see Atlas.1 for dataset details). Trends are calculated for the common 1961–2015 period and are expressed as °C per decade for temperature and relative change (with respect to the climatological mean) per decade for precipitation. Crosses indicate regions where trends are not significant (at a 0.1 significance level) and the black lines mark out the reference regions defined in Atlas.1. Panels (c) and (d) display the period in which the signals of temperature change in data aggregated over the reference regions emerged from the noise of annual variability in the respective aggregated data. Emergence time is calculated for (c) Berkeley Earth (as used in (a)) and CRUTEM5. Regions in the CRUTEM5 map are shaded grey when data are available over less than 50% of the land area of the region. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

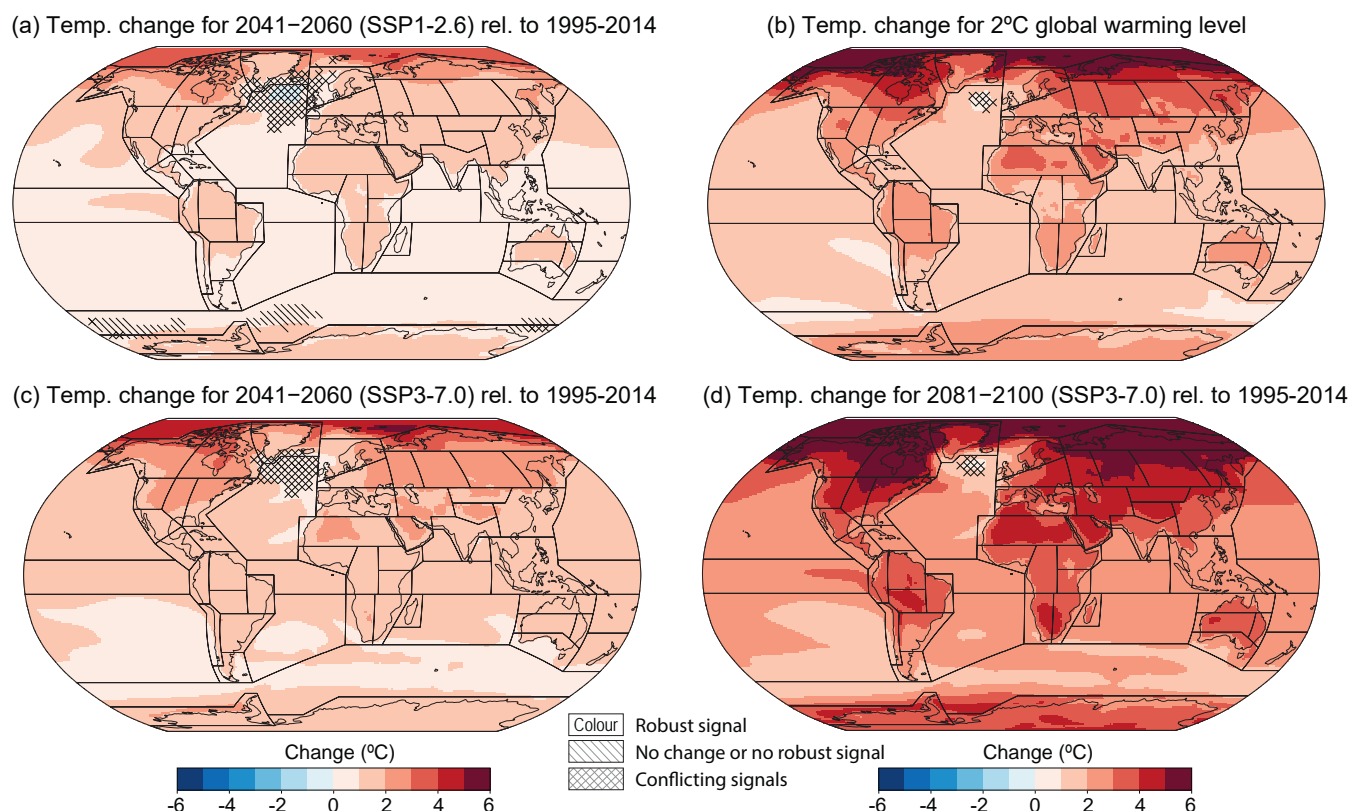

Figure Atlas.12 | Global temperature changes projected for mid-century under SSP1-2.6 (a) and SSP3-7.0 (c) compared with a 2°C global warming level (b) and the end of the century under SSP3-7.0 (d) from the CMIP6 ensemble. Note that the future period warmings are calculated against a baseline period of 1995–2014 whereas the global mean warming level is defined with respect to the baseline period of 1851–1900 used to define global warming levels. The other three SSP-based maps would show greater warmings with respect to this earlier baseline. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

range of a climate statistic, it is often useful to generate area-averaged summaries of these statistics under different future emissions scenarios or at specific global warming levels. This is demonstrated in Figure Atlas.13 and forms the basis of a common set of analyses, which are presented for the reference regions in the regional assessments in Atlas.4 to Atlas.11. It shows the range of projected changes compared to the 1850–1900 and recent past 1995–2014 baseline periods for the CMIP5 and CMIP6 ensembles. The first four panels show: annual mean changes in temperature globally and over land only for various global warming levels and emissions scenarios and time periods (left pair), and then again globally and for global land, changes in precipitation and temperature at the same global warming levels (right pair). The second four panels provide the same temperature and precipitation information globally and for global land only in the December–February and July–August seasons. These results demonstrate the consensus between the two ensembles for increased warming over land areas and increases in global precipitation at all warming levels, and that global land precipitation increases more. They also show the increased precipitation response in December–January–February (DJF), reflecting the large precipitation increases in the Northern

Hemisphere higher latitudes in winter. Finally, they demonstrate the greater warming projected by the CMIP6 ensemble, as an average over the ensemble and the upper end of the range. See Chapter 4 for an in-depth assessment of these results.

Global warming leads to systematic changes in regional climate variability via various mechanisms such as thermodynamic responses via altered lapse rates (Kröner et al., 2017; Brogli et al., 2019) and land–atmosphere feedbacks (Boé and Terray, 2014). These can modify temporal and spatial variability of temperature and precipitation, including an altered seasonal and diurnal cycle and return frequency of extremes. Regional influences from and feedbacks with sea surface, clouds, radiation and other processes also modulate the regional response to enhanced warming, both locally and, via teleconnections, remotely.

Given their potential to influence extremes in temperature, precipitation and other climatic impact-drivers and hazards, and thus risks to human and ecological systems, it is important to understand these links for developing adaptations in response to clear anthropogenic influences on individual hazards. This

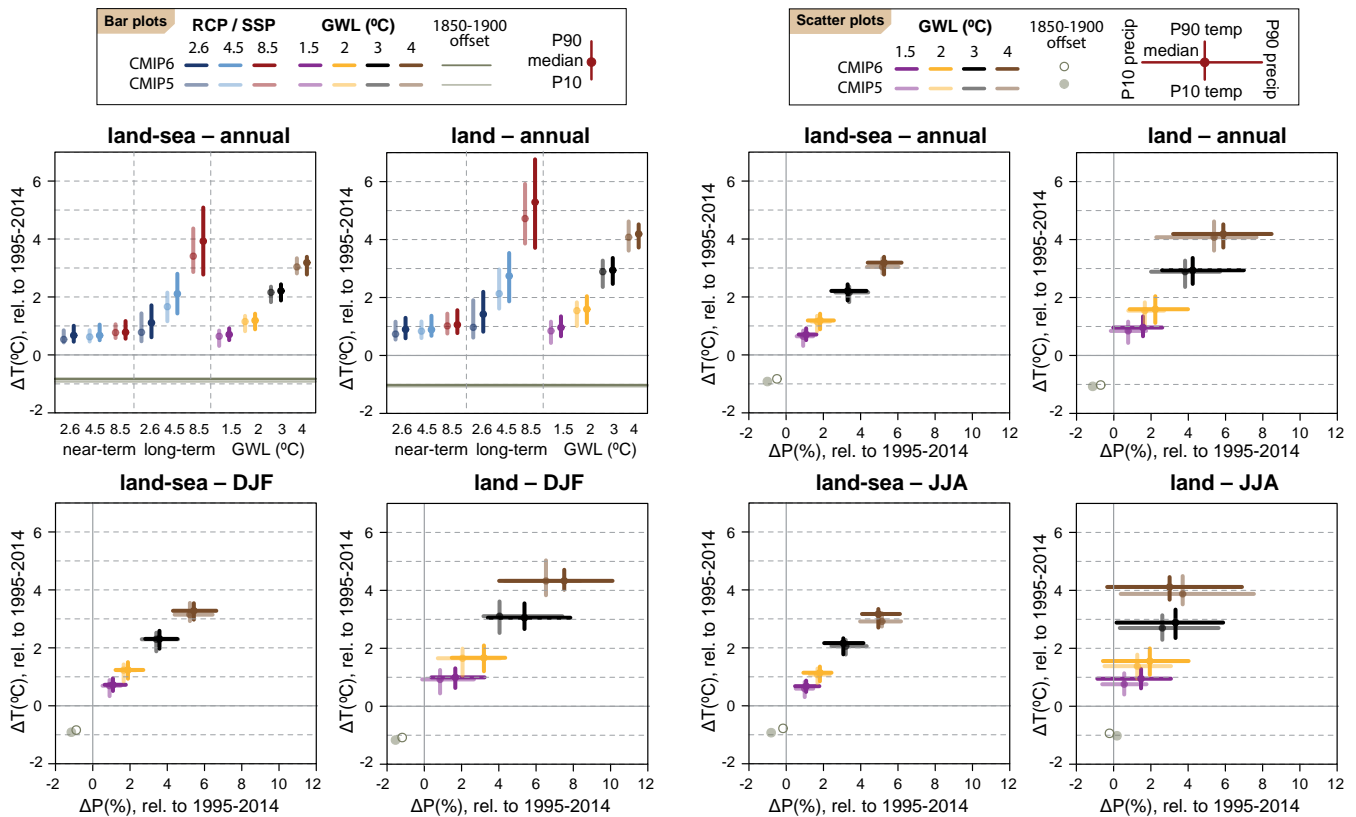

Figure Atlas.13 | Changes in annual mean surface air temperature and precipitation averaged over the global land–sea (left) and global land areas (right) in each horizontal pair of panels. The top-left two panels show the median (dots) and 10th–90th percentile range across each model ensemble for temperature change, for two datasets (CMIP5 and CMIP6) and two scenarios (SSP1-2.6/RCP2.6 and SSP5-8.5/RCP8.5). The first 12 bars represent the projected changes over three time periods (near-term 2021–2040, mid-term 2041–2060 and long-term 2081–2100) compared to the baseline period of 1995–2014, and the remaining four bars represent the additional warming projected relative to the same baseline to reach four global warming levels (GWLs; 1.5°C, 2°C, 3°C and 4°C). The top-right two panels show scatter diagrams of temperature against precipitation changes, displaying the median (dots) and 10th–90th percentile ranges for the same four GWLs, again representing the additional changes for the global temperature to reach the respective GWL from the baseline period of 1995–2014. In all panels the dark (light) grey lines or dots represent the CMIP6 (CMIP5) simulated changes in temperature and precipitation between the 1850–1900 baseline used for calculating GWLs and the recent-past baseline of 1995–2014 used to calculate the changes in the bar diagrams and scatter plots. Changes are absolute for temperature and relative for precipitation. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

will also support the related fields of disaster risk reduction and global sustainable development efforts (Stephens et al., 2018). They demonstrated that 15 regional hazards shared connections via the El Niño–Southern Oscillation (ENSO), with the Indian Ocean Dipole, North Atlantic Oscillation and the Southern Annular Mode (see Annex IV) being secondary sources of significant regional interconnectivity (Figure Atlas.14). Understanding these connections and quantifying the concurrence of resulting hazards can support adaptation planning as well as multi-hazard resilience and disaster risk reduction goals.

The main modes of variability influencing global and regional climate are comprehensively described in Annex IV. In the context of the assessment in the Atlas chapter, they are important because of their influence on the variability of temperature (Part A) and precipitation (Part B) in regions around the world. This is quantified in Table Atlas.1, which lists the fraction of interannual variance in seasonal mean temperature and precipitation explained by variability in these modes. The table provides information on the influence

of the teleconnections for selected seasons for the interannual to decadal modes and at an annual scale for the multi-decadal modes. The columns related to the interannual to decadal modes focus on the seasons where these connections are strongest but each mode of variability will often have influences in other seasons (for more details see Annex IV). The table shows that for many regions, seasonal temperature and precipitation is substantially modulated by these modes of variability – all regions feel some influence, and variability in ocean basins often has influence in multiple remote regions.

Figure Atlas.14 | Influence of major modes of variability (see Annex IV) on regional extreme events relevant to assessing multi-hazard resilience. Ribbon colours define the driver from which they originate and their width is proportional to the correlation. Crossed lines represent where there is conflicting evidence for a correlation or where the driver is not directly related to the hazard; dots represent drivers that have both a positive and negative correlation with the hazard. Figure is copied from Steptoe et al. (2018)/CCBY4.0.

Table Atlas.1 | Regional mapping of the teleconnections associated with the main modes of variability (Annex IV). Fraction of surface air temperature and precipitation variance explained at interannual time scale by each mode of variability (columns) for each AR6 region (rows) based on the coefficient of determination R^2 . Units are in percent and non-significant values based on t-statistics at the 95% level of confidence are indicated by a white cell with a diagonal line. Grey cells represent regions where there is insufficient data to calculate any teleconnection. HadCRUT (HAD), GISTEMP (GIS), Berkeley Earth (BE), and CRU-TS (CRU) observed datasets are used to assess the strength of the teleconnection for surface air temperature, and GPCC and CRU-TS are used for precipitation. The colour scale given on label bars shown at the bottom quantifies the values of the explained variance and also stands for the sign of the teleconnection for the positive phase of the mode. All data are linearly detrended prior to the computation of the regression. Note that results are sensitive to the choice of the detrending function (linear, loess filter, 3-order polynomial function) but by a few percent at most, which is well below the range of the observational uncertainty assessed here through the use of several observational products. Figure 1 is a horizontal stacked bar chart illustrating precipitation anomalies and explained variance for 10 regions. The x-axis represents 'Precipitation anomalies and explained variance (%)' ranging from -40 to 40. The y-axis lists the regions: 1. North America, 2. Europe, 3. Asia, 4. Africa, 5. Australia, 6. South America, 7. Antarctica, 8. Arctic, 9. Southern Ocean, and 10. Northern Ocean. The legend indicates that white bars represent 'Not significant in >50% of available data sets' and grey bars represent 'Data unavailable in >50% of data sets'. The bars show varying degrees of significance and data availability across regions.

Atlas.3.2 Global Ocean

As with the atmosphere, there are several key ocean-related quantities which are relevant for understanding how climate change may impact human and ecological systems and/or key global indicators of change. These include ocean surface temperature and heat content, sea surface height, sea ice cover and thickness, and certain chemical properties such as ocean acidity and oxygen concentration. For example, there is growing awareness of the threat presented by ocean acidification to ecosystem services and its socio-economic consequences are becoming increasingly apparent and quantifiable (Hurd et al., 2018), and SR1.5 (IPCC, 2018c) noted a significant impact of low levels of global warming on the state of the global oceanic ecosystems and food security. For instance, 70–90% of coral reefs are projected to decline at a warming level of 1.5°C, with larger losses at 2°C.

Thus, because of their importance to coastal populations and infrastructure and ocean ecosystems, the Interactive Atlas focuses on change in sea-surface temperature, sea level and pH. Figure Atlas.15 shows projected changes to sea surface temperature (SST) and sea level at the end of the century under SSP1-2.6 and SSP5-8.5

emissions, demonstrating the much larger changes seen with the higher-emissions scenario. The projected changes in sea level show the significantly greater increases, of up to 1 m locally, under a high-emissions future. Regional details of these projected changes under a range of emissions scenarios and time periods can be explored in the Interactive Atlas. An in-depth assessment of these changes is presented in Section 5.3 and Chapter 9.

(a) SST for 2081-2100 (SSP1-2.6) rel. to 1995-2014

(b) SST for 2081-2100 (SSP5-8.5) rel. to 1995-2014

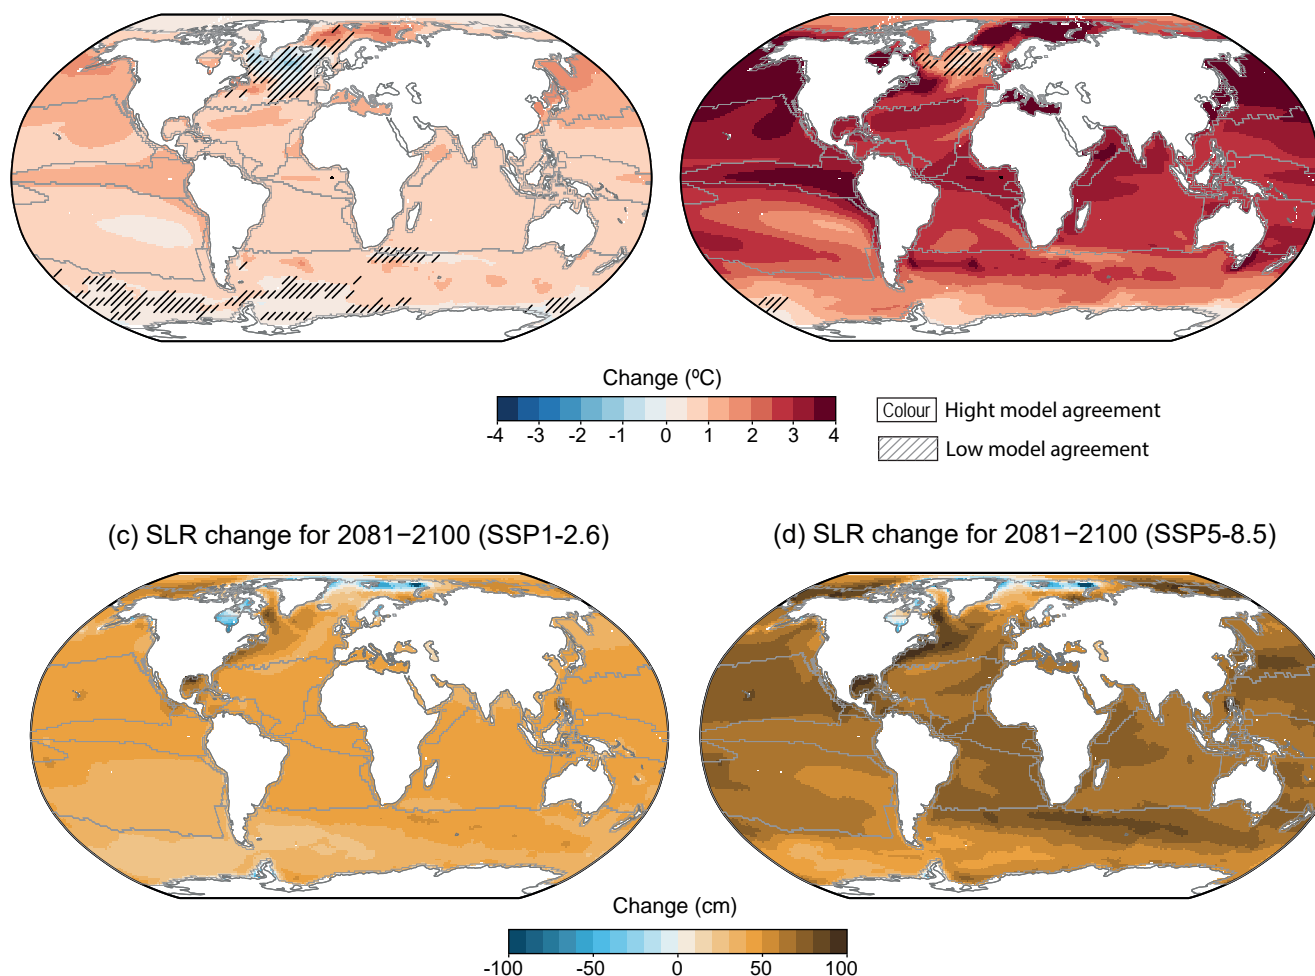

Figure Atlas.15 | Projected changes in sea surface temperature (a,b), sea level rise (c,d) for 2081–2100 under SSP1-2.6 (a,c) and SSP5-8.5 (b,d) emissions scenarios compared to a 1995–2014 baseline period from the CMIP6 ensemble. For sea surface temperature, diagonal lines indicate regions where 80% of the models do not agree on the sign of the projected changes. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Atlas.4 Africa

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Tables 11.4–11.6) and climatic impact-drivers in Chapter 12 (Tables 12.1–12.12).

Atlas.4.1 Key Features of the Regional Climate and Findings from Previous IPCC Assessments

Atlas.4.1.1 Key Features of the Regional Climate

Africa has many varied climates which can be categorized as dry regime in the Saharan region, tropical humid regime in West and East Africa except for parts of the Greater Horn of Africa (alpine) and the Sahel (semi-arid), and a dry/wet season regime in the northern and

southern African region including the Namib and Kalahari deserts; each climate region has its local variations resulting in very high spatial and temporal variations (Peel et al., 2007). Based on the varied climates, nine sub-regions are defined for Africa (Figure Atlas.16): the Mediterranean region (MED) including North Africa, Sahara including parts of the Sahel (SAH), West Africa (WAF), Central Africa (CAF), North Eastern Africa (NEAF), South Eastern Africa (SEAF), West Southern Africa (WSAF), East Southern Africa (ESAF) and Madagascar (MDG).

The climatic features that characterize the intra-seasonal and interannual variability of Africa are mainly the Madden–Julian Oscillation (MJO), which is confined to the deep tropics during boreal winter, Pacific Decadal Variability (PDV), and the shift of the Atlantic Inter-tropical Convergence Zone in response to changes in the meridional SST gradient. A positive phase of PDV weakens African monsoons (Figure AIV.8d; Meehl and Hu, 2006), and MJO phase 4 suppresses convection over equatorial Africa (Figure AIV.10a; see Annex IV). Other features influence specific sub-regions. For instance, El Niño events increase precipitation in eastern Africa and

decrease precipitation in southern Africa. Over southern Africa there is a strong link between ENSO and droughts (Meque and Abiodun, 2015). The positive phase of the Indian Ocean Dipole (IOD) increases rainfall in eastern tropical Africa in boreal autumn to early winter (Figure AIV.5d), while the negative phase induces the reduction in rainfall. The West African Monsoon is influenced by Atlantic Zonal Mode (AZM) with decreased rainfall over the Sahel and increased rainfall over Guinea (Losada et al., 2010). Positive Atlantic Multi-decadal Variability (AMV) influences positive anomalies all year round over a broad Mediterranean region, including North Africa.

Atlas.4.1.2 Findings From Previous IPCC Assessments

The most recent IPCC reports, AR5 and SR1.5 (Christensen et al., 2013; Hoegh-Guldberg et al., 2018), state that over most parts of Africa, minimum temperatures have warmed more rapidly than maximum temperatures during the last 50 to 100 years (*medium confidence*). In the same period, minimum and maximum temperatures have increased by more than 0.5°C relative to 1850–1900 (*high confidence*). While the quality of ground observational temperature measurements tends to be high compared to that of measurements for other climate variables, Africa remains an under-represented region as reported in SR1.5 (Hoegh-Guldberg et al., 2018; IPCC, 2018c). Based on the Coupled Model Intercomparison Project Phase 5 (CMIP5) ensemble and reported in IPCC AR5 and SR1.5, surface air temperatures in Africa are projected to rise faster than the global average increase and are *likely* to increase by more than 2°C and up to 6°C by the end of the century, relative to the late 20th century, if global warming reaches 2°C (Bindoff et al., 2013; Niang et al., 2014; Hoegh-Guldberg et al., 2018). The higher temperature magnitudes are projected during boreal summer. Southern Africa is *likely* to exceed the global mean land surface temperature increase in all seasons by the end of the century. Temperature projections for East Africa indicate considerable warming under RCP8.5 where average warming across all models is approximately 4°C by the end of the century. According to SROCC, eastern Africa like other regions with smaller glaciers is projected to lose more than 80% of its glaciers by 2100 under RCP8.5 (*medium confidence*) (Hock et al., 2019b).

West Africa has also experienced an overall reduction of rainfall over the 20th century, with a recovery towards the last 20 years of the century (Christensen et al., 2013). Over the last three decades rainfall has decreased over East Africa, especially between March and May/June. Projected rainfall changes over Africa in the mid- and late 21st century is uncertain. In regions of high or complex topography such as the Ethiopian Highlands, downscaled projections indicate *likely* increases in rainfall and extreme rainfall by the end of the 21st century. However, North Africa and the south-western parts of South Africa are *likely* to have a reduction in precipitation.

The consequence of increased temperature and evapotranspiration, and decreased precipitation amount, in interaction with climate variability and human activities, have contributed to desertification in dryland areas in sub-Saharan Africa (*medium confidence*) as reported in SRCLL (Mirzabaev et al., 2019).

Atlas.4.2 Assessment and Synthesis of Observations, Trends and Attribution

Figure Atlas.11 shows observed trends in annual mean surface temperature and indicates it has been rising rapidly over Africa from 1961 to 2015 and with significant increases in all regions of 0.1°C–0.2°C per decade and higher over some northern, eastern and south-western regions (*high confidence*) (see also Interactive Atlas). This is confirmed by an independent analysis performed for a longer period (1961–2018) over areas where long-term homogeneous temperature time series are available (Engelbrecht et al., 2015). More specifically over the Horn of East Africa, the long-term mean annual temperature change between 1930 and 2014 showed two distinct but contrary trends: significant decreases between 1930 and 1969 and increases from 1970 to 2014 (Ghebregabher et al., 2016). North Africa has an overall warming in observed seasonal temperature (Barkhordarian et al., 2012; Lelieveld et al., 2016) with positive trends in annual minimum and maximum temperatures (Vizy and Cook, 2012). Temperatures over West Africa have increased over the last 50 years (Mouhamed et al., 2013; Niang et al., 2014) with a spatially variable warming reaching 0.5°C per decade from 1983 to 2010 (Sylla et al., 2016). West Africa has also experienced a decrease in the number of cool nights, as well as more frequent warm days and warm spells (Mouhamed et al., 2013; Ringard et al., 2016). Similarly, East Africa has experienced a significant increase in temperature since the beginning of the early 1980s (Anyah and Qiu, 2012) with an increase in seasonal mean temperature. Over South Africa, positive trends were found in the annual mean, maximum and minimum temperatures for 1960–2003 in all seasons, except for the central interior (Kruger and Shongwe, 2004; Zhou et al., 2010; Collins, 2011; Kruger and Sekele, 2013; MacKellar et al., 2014), where minimum temperatures have decreased significantly (MacKellar et al., 2014). Within inland southern Africa, minimum temperatures have increased more rapidly than maximum temperatures (New et al., 2006).

Most areas lack enough observational data to draw conclusions about trends in annual precipitation over the past century. In addition, many regions of Africa have discrepancies between different observed precipitation datasets (Sylla et al., 2013; Panitz et al., 2014). A statistically significant (95% confidence level) decrease in rainfall and the number of rainy days is reported in autumn over the eastern, central and north-eastern parts of South Africa in spring and summer during 1960–2010 (MacKellar et al., 2014; Kruger and Nxumalo, 2017). Central Africa has experienced a significant decrease in total precipitation, which is likely associated with a significant decrease of the length of the maximum number of consecutive wet days (Aguilar et al., 2009). Furthermore, rainfall decreased significantly in the Horn of Africa (Tierney et al., 2015) with the largest reductions during the long rains season from March to May (Lyon and DeWitt, 2012; Viste et al., 2013; Rowell et al., 2015). Over mountainous areas significant increases are found in the number of rain days around the southern Drakensberg in spring and summer during the period 1960–2010 (MacKellar et al., 2014). Similarly, southern West Africa is observed to have had more intense rainfall from 1950 to 2014 during the second rainy season of September to November (Nkrumah et al., 2019). The Sahel region also had more intense rainfall throughout the rainy season (Panthou et al., 2014, 2018a, b; Sanogo et al., 2015;

Gaetani et al., 2017; Taylor et al., 2017; Biasutti, 2019) during the period 1980–2010. Southern African rainfall shows a significant downtrend of $-0.013 \text{ mm day}^{-1} \text{ year}^{-1}$ in recent decades and $-0.003 \text{ mm day}^{-1} \text{ year}^{-1}$ for longer periods during 1900–2010 (*low confidence*) (Jury, 2013).

Temperature increases over Africa in the 20th century can be attributed to the strong evidence of a continent-wide anthropogenic signal in the warming (Figure 3.9; Hoerling et al., 2006; Min and Hense, 2007; Stott et al., 2010, 2011; Niang et al., 2014). More specifically over West Africa, the clear emergence of temperature change (Figure Atlas.11) is due to the relatively small natural climate variability in the region which generates narrow climate bounds that can be easily surpassed by relatively small climate changes (Niang et al., 2014). Warming over North Africa is largely due to anthropogenic climate forcing (Knippertz et al., 2003; Barkhordarian et al., 2012; Diffenbaugh et al., 2017).

The drying observed over the Sahel in the 1960s to 1970s has been attributed to warming of the South Atlantic SST and southern African drying as a response to Indian Ocean warming (Hoerling et al., 2006; Dai, 2011). Enhanced rainfall intensity since the mid-1980s over the Sahel (Maidment et al., 2015; Sanogo et al., 2015) is associated with increased greenhouse gases suggesting an anthropogenic influence (*medium confidence*) (Biasutti, 2019). In the last decade, the changes in the timing of onset and cessation of rainfall over Africa have been linked to changes in the progression of the tropical rainband and the Saharan heat low (Dunning et al., 2018; Wainwright et al., 2019). Moreover, later onset and earlier cessation of eastern Africa rainfall is associated with a delayed and then faster movement of the tropical rainband northwards during the boreal spring and northward shift of the Saharan heat low (Wainwright et al., 2019), driven by anthropogenic carbon emissions and changing aerosol forcings (*medium confidence*). Over East Africa, the drying trend is associated with an anthropogenic-forced relatively rapid warming of Indian Ocean SSTs (Williams and Funk, 2011; Hoell et al., 2017); a shift to warmer SSTs over the western tropical Pacific and cooler SSTs over the central and eastern tropical Pacific (Lyon and DeWitt, 2012); multi-decadal variability of SSTs in the tropical Pacific, with cooling in the east and warming in the west (Lyon, 2014); and the strengthening of the 200-mb easterlies (Liebmann et al., 2017). However, decadal natural variability from SST variations over the Pacific Ocean has also been associated with the drying trend of East Africa (Wang et al., 2014; Hoell et al., 2017) with an anthropogenic-forced rapid warming of Indian Ocean SSTs (*medium confidence*).

Atlas.4.3 Assessment of Model Performance

Model development has advanced in the world, but Africa still lags as a focus and in its contribution (James et al., 2018). None of the current generation of global climate models (GCMs) was developed in Africa (Watterson et al., 2014), and the relevant processes in the continent have not been the priority for model development but treated in a one-size-fit-all approach (James et al., 2018) except for a few studies that focused on convective-permitting climate projections (Stratton et al., 2018; Kendon et al., 2019). However,

there are growing efforts to boost African climate science by running and evaluating climate models over Africa (Endris et al., 2013; Kalognomou et al., 2013; Gbobaniyi et al., 2014; Engelbrecht et al., 2015; Klutse et al., 2016; Gibba et al., 2019).

The CMIP project previously did not result in improved performance for Africa (Flato et al., 2013; Rowell, 2013; Whittleston et al., 2017) and culling ensembles based on existing metrics for Africa fails to reduce the range of uncertainty in precipitation projections (Roehrig et al., 2013; Yang et al., 2015; Rowell et al., 2016), but biases over Africa are lower in CMIP6 compared to CMIP5 (Almazroui et al., 2020c). Nonetheless, the CMIP5 ensemble has been evaluated over Africa to advance its application for climate research (Biasutti, 2013; Rowell, 2013; Dike et al., 2015; McSweeney and Jones, 2016; Onyutha et al., 2016; Wainwright et al., 2019) as has, more recently, the CMIP6 ensemble (Almazroui et al., 2020c).

Coordinated Regional Downscaling Experiment (CORDEX) regional climate models have been widely evaluated over Africa. They capture the occurrence of the West African Monsoon jump and the timing and amplitude of the mean annual cycle of precipitation and temperature over the homogeneous sub-regions of West Africa (Gbobaniyi et al., 2014), simulate eastern Africa rainfall adequately (Endris et al., 2013), and over southern Africa capture the observed climatological spatial patterns of extreme precipitation (Pinto et al., 2016). They also effectively simulate the phasing and amplitude of monthly rainfall evolution and the spatial progression of the wet season onset over southern Africa (Shongwe et al., 2015). However, discrepancies and biases in present-day rainfall are reported over Uganda from the RCM-simulated rainfall compared to three gridded observational datasets (Kisembe et al., 2019). Specifically, they reported that the CORDEX models underestimate the annual rainfall in Uganda and struggle to reproduce the variability of the long and short rainy seasons.

Atlas.4.4 Assessment and Synthesis of Projections

Research over Africa has improved since AR5, and although SR1.5 (de Coninck et al., 2018) has synthesized new information for the continent, there is still not enough literature on specific areas for assessment. CMIP5 and CMIP6 projections (Figure Atlas.16) are for continued warming, with median projected regional warming for 2080–2100 compared to 1995–2014 of between 1°C and 2°C under SSP1-2.6/RCP2.6 emissions and exceeding 4°C and in some regions 5°C under SSP5-8.5/RCP8.5 emissions. The central interiors of southern and northern Africa are *likely* to warm faster than equatorial and tropical regions (Interactive Atlas). Projections from CMIP5 show that East Africa is *likely* to warm by 1.7°C – 2.8°C and 2.2°C – 5.4°C under the RCP4.5 and RCP8.5 scenarios respectively in the period 2071–2100 relative to 1961–1990 (Ongoma et al., 2018). Over southern Africa, areas in the south-western region of the sub-continent, covering South Africa and parts of Namibia and Botswana, are projected to experience the largest increase in temperature, which are expected to be greater than the global mean warming (Maure et al., 2018). A large ensemble of CORDEX Africa simulations have been used to project the impact of 1.5°C

and 2°C GWLs (Klutse et al., 2018; Lennard et al., 2018; Maure et al., 2018; Mba et al., 2018; Nikulin et al., 2018; Osima et al., 2018). While a few studies addressed the whole African continent (Lennard et al., 2018; Nikulin et al., 2018), some focused on specific regions of Africa (Diedhiou et al., 2018; Klutse et al., 2018; Kumi and Abiodun, 2018; Maure et al., 2018; Mba et al., 2018). CORDEX simulations project robust warming over Africa in excess of the global mean

(Lennard et al., 2018; Nikulin et al., 2018), and over West Africa the magnitude of regional warming reaches the 2080–2100 global warming level one to two decades earlier (Mora et al., 2013; Niang et al., 2014; Sylla et al., 2016; Klutse et al., 2018). Temperature increases projected under RCP8.5 over Sudan and northern Ethiopia imply that the Greater Horn of Africa would warm faster than the global mean relative to 1971–2000 (Osima et al., 2018). Over North

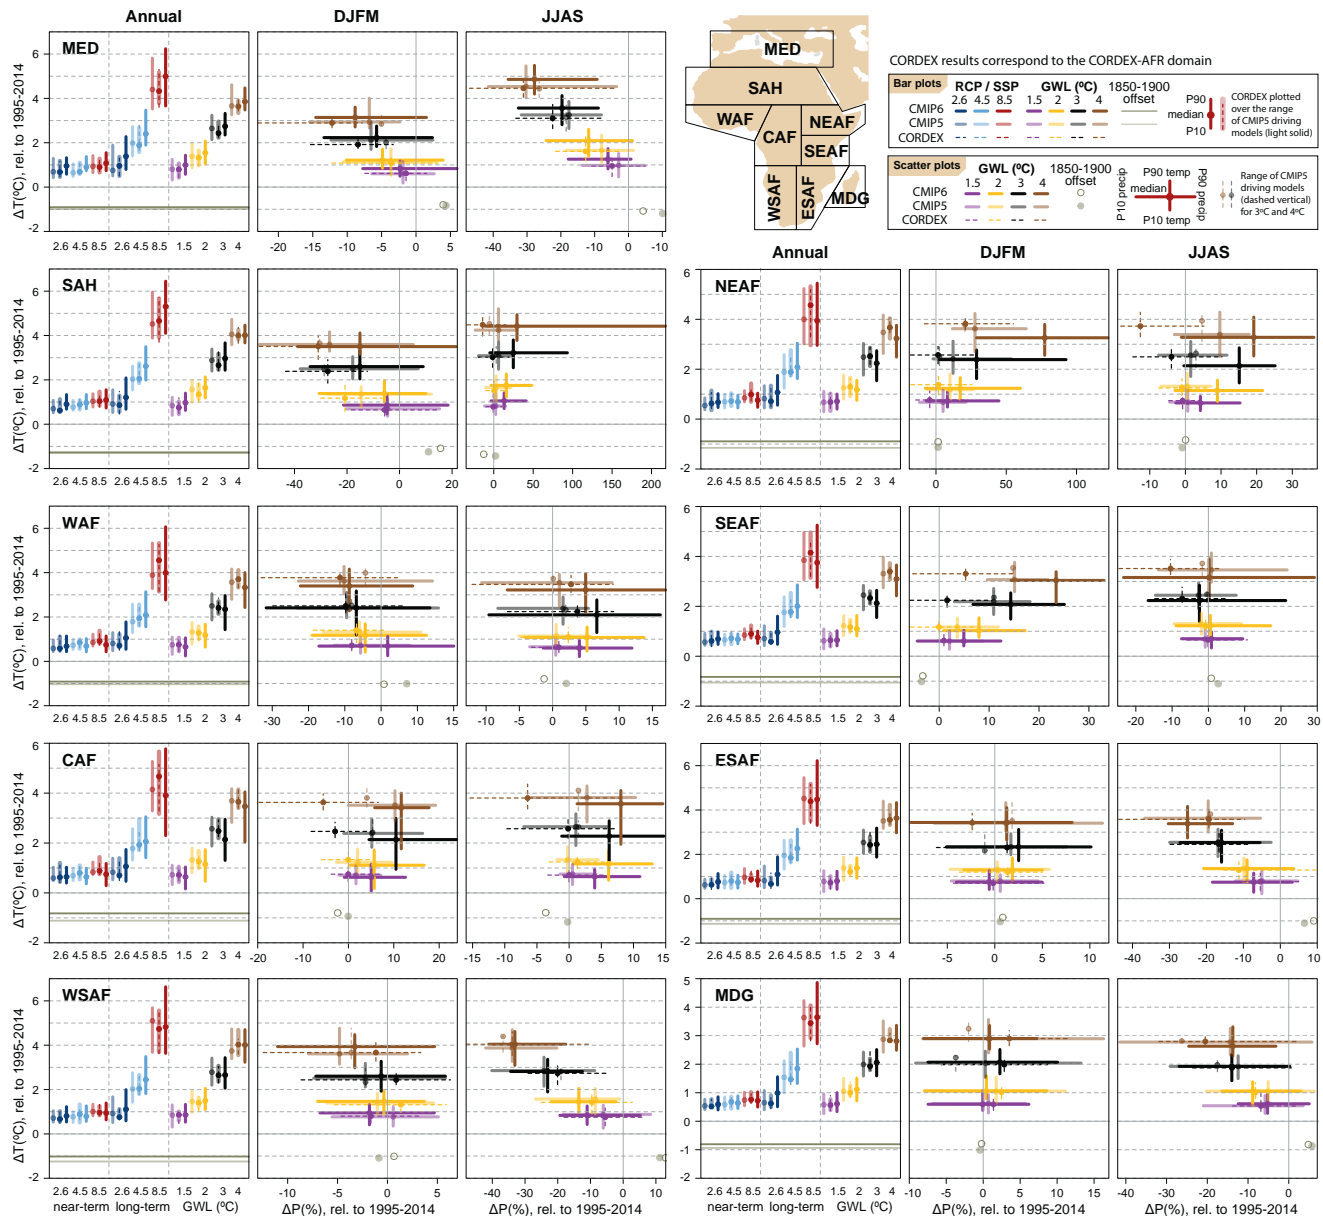

Figure Atlas.16 | Regional changes over land in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Africa (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWLs: 1.5°C, 2°C, 3°C and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February–March (DJFM; middle panel) and June–July–August–September (JJAS; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in $^{\circ}\text{C}$) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Africa, summer mean temperatures from CORDEX, CMIP5 (RCP8.5) and CMIP6 (SSP5-8.5) are projected to increase beyond 6°C by the end of the century with respect to the period 1970–2000 (Schilling et al., 2012; Ozturk et al., 2018; Almazroui et al., 2020c), see also the Interactive Atlas. Note that results for the CORDEX-AFR over the Mediterranean (MED) are consistent with those reported from the CORDEX-EUR dataset (Figure Atlas.24; Section Atlas.1.3), in agreement with Legasa et al. (2020).

Projected rainfall changes over Africa in the mid- and late 21st century are uncertain in many regions, highly variable spatially and with differing levels of model agreements (Figure Atlas.16) though with robust projections of decreases in MED and WSAF and increases in NEAF and SEAF by 2080–2100 under high emissions (Interactive Atlas). Some uncertainties are reported over parts of Africa from CORDEX projections (Dosio and Panitz, 2016; Endris et al., 2016; Klutse et al., 2018). For example, large uncertainties are associated with projections at 1.5°C and 2°C of global warming over Central Africa (Mba et al., 2018) and over the Sahel (Gbobaniyi et al., 2014; Sylla et al., 2016). Over southern Africa, enhanced warming is projected to result in a reduction in mean rainfall across the region (Maure et al., 2018), and in particular over the Limpopo basin and smaller areas of the Zambezi basin in Zambia, and also in parts of the Western Cape in South Africa, under a global warming of 2°C. The projections of reduced precipitation in summer rainfall regions of southern Africa are associated with delayed wet season onset in spring (Dunning et al., 2018) due to a northward shift and delayed breakdown of the Congo Air Boundary (Howard and Washington, 2020). However, projected rainfall intensity over southern Africa is *likely* to increase and be magnified under RCP8.5 compared with RCP4.5 for the period 2069–2098 relative to the reference period 1976–2005 (Pinto et al., 2018). For West Africa, rainfall projection is uncertain because of the contrasting signals from models (Dosio et al., 2019). Nonetheless, West Africa river basin-scale irrigation potential would decline under 2°C of global warming even for areas where water availability increases (Sylla et al., 2018). The western and eastern Sahel are projected as hotspots for delayed rainfall onset dates of about four days and six days causing reduced length of rainy season in the 1.5°C–2°C warmer climates under RCP4.5 and RCP8.5 scenarios (Kumi and Abiodun, 2018). Projected delay in rainfall cessation dates and a longer length of rainy season over the western part of the Guinea coast is *likely* under the same scenarios (Figure Atlas.16; Sellami et al., 2016; Kumi and Abiodun, 2018). There is a tendency towards an increase in annual mean precipitation over central Sahel and eastern Africa (Interactive Atlas, Figure Atlas.16, (Nikulin et al., 2018), especially over the Ethiopian Highlands with up to 0.5 mm day⁻¹ (Osima et al., 2018).

Atlas.4.5 Summary

The rate of surface temperature increase has generally been more rapid in Africa than the global average and by at least 0.1°C–0.2°C during 1961–2015 (*high confidence*). Minimum temperatures have increased more rapidly than maximum temperatures over inland southern Africa (*medium confidence*). Since 1970, mean temperature over East Africa has shown an increasing trend but showed a decreasing trend in the previous 40 years (*medium confidence*).

The Horn of Africa has experienced significantly decreased rainfall during the long rains season from March to May (*high confidence*) and drying trends in this and other parts of Africa are attributable to oceanic influences (*high confidence*), resulting from both internal variability and anthropogenic causes. Drying over the Sahel in the last century was attributed to an increase in the South Atlantic SST and more recently over southern African as a response to anthropogenic-forced Indian Ocean warming. Drying over East Africa is associated with decadal natural variability in SSTs over the Pacific Ocean. The enhanced rainfall intensity over the Sahel in the last two decades is associated with increased greenhouse gases indicating an anthropogenic influence (*medium confidence*).

Relative to the late 20th century, annual mean temperature over Africa is projected to rise faster than the global average (*very high confidence*) with the increase *likely* to exceed 4°C by the end of the century under RCP8.5 emissions. The central interiors of southern and northern Africa are *likely* to warm faster than equatorial and tropical regions (*high confidence*).

There are contrasting signals in the projections of rainfall over some parts of Africa until the end of the 21st century (*high confidence*) though changes in any given region are generally projected with *medium confidence*. In regions of high or complex topography such as the Ethiopian Highlands, downscaled projections indicate increases in rainfall by the end of the 21st century. However, northern Africa and the south-western parts of South Africa are *likely* to have a reduction in precipitation under higher warming levels (*high confidence*). Over Western Africa, rainfall is projected to decrease in the western Sahel sub-region (*medium confidence*) and increase in the central Sahel sub-region (*low confidence*) and along the Guinea coast sub-region (*medium confidence*). Rainfall amounts are projected to increase over Eastern Africa (*medium confidence*). Southern Africa is projected to have a reduction in annual mean rainfall but increases in rainfall intensity by 2100 (*medium confidence*).

Atlas.5 Asia

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes is in Chapter 11 (Tables 11.7–11.9) and climatic impact-drivers in Chapter 12 (Table 12.4). It covers most Asian territories of the region (Figure Atlas.17) with the exception of the Russian Arctic (RAR), which is assessed as part of the Arctic in Section 11.2. These include West and East Siberia (WSB, ESB) and the Russian Far East (RFE) in the north; West and East Central Asia (WCA, ECA), the Tibetan Plateau (TIB) and East Asia (EAS); and the Arabian Peninsula (ARP), South and South East Asia (SAS, SEA) in the south. Figure Atlas.17 supports the assessment of regional mean changes in annual mean surface air temperature and precipitation over Asia. Due to the high climatological and geographical heterogeneity of Asia, the assessment is performed over five sub-continental areas: East Asia (EAS and ECA), North Asia (WSB, ESB and RFE), South Asia (SAS),

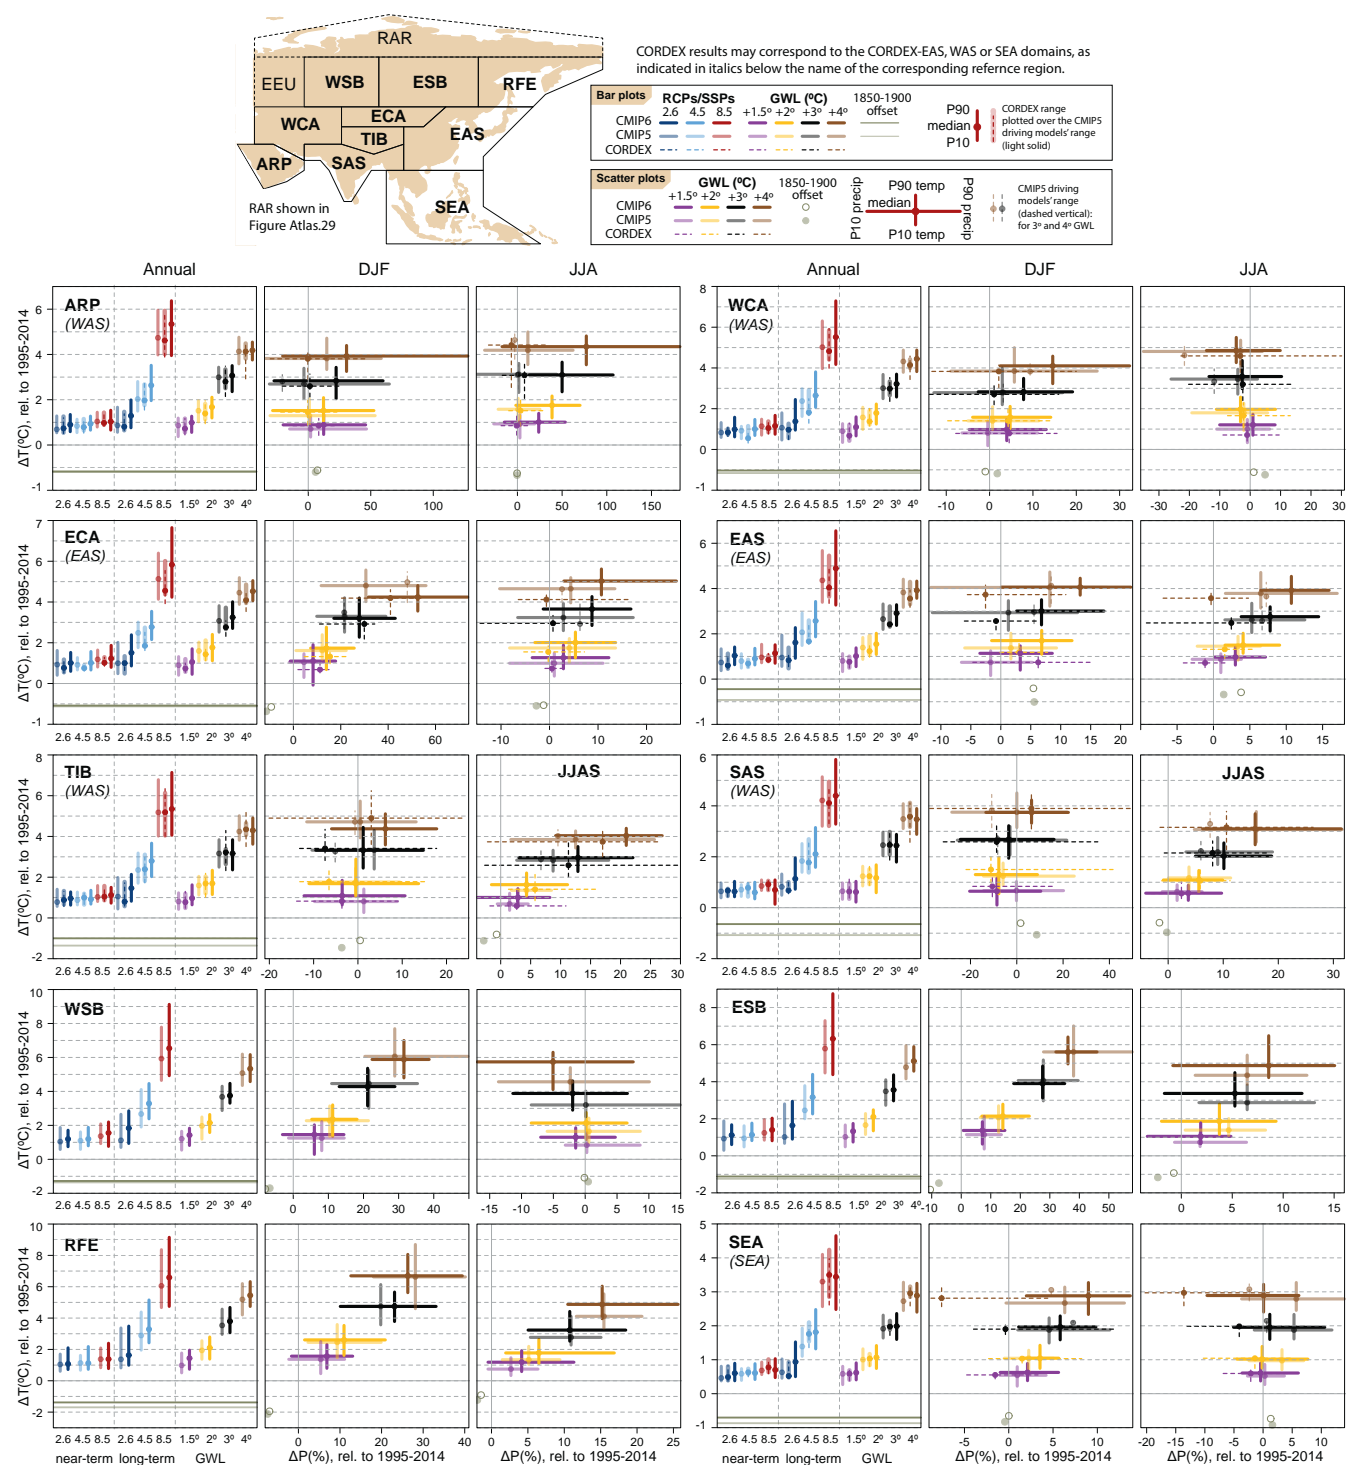

Figure Atlas.17 | Regional changes over land in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Asia (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; a subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5 and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWs: 1.5°C, 2°C, 3°C and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December–January–February (DJF; middle panel) and June–July–August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWs. Changes are absolute for temperature (in $^{\circ}\text{C}$) and relative (as %) for precipitation. See Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

South East Asia (SEA) and South West Asia (ARP and WCA) with the Tibetan Plateau (TIB) being relevant and thus referred to in both the East and South Asia assessments. Note also TIB forms a major part of the Hindu Kush Himalaya region, which is assessed in Cross-Chapter Box 10.4, and relevant findings are summarized and cross-referenced in the East and South Asia sections below.

Atlas.5.1 East Asia

Atlas.5.1.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.5.1.1.1 Key Features of the Regional Climate

The climatic regions defined for East Asia include central and eastern China, Japan and the Korea Peninsula (regions ECA and EAS in Figure Atlas.17). East Asia is significantly influenced by monsoon systems (Section 8.3.2.4.2). The seasonal advance or retreat of the East Asian summer monsoon (EASM) rainband is crucial to local climate. The East Asian winter monsoon (EAWM) has significant influence on the weather and climate over East Asia and plays an important role in regulating winter temperatures including strong cold events and snowstorms (Wang and Chen, 2014; Wang and Lu, 2016). The East Asian monsoons exhibit considerable variability on a wide range of time scales, including notable interannual variabilities that includes an effect of the El Niño–Southern Oscillation (ENSO; Wang et al., 2000) and the Indian Ocean Dipole (IOD; Takaya et al., 2020), and significant inter-decadal variabilities in the 20th century resulted from the effect of Pacific Decadal Variability (PDV; Zhou et al., 2009), see also Annex IV and Table Atlas.1. The thermal conditions of both the Tibetan Plateau and related ocean regions play key roles in modulating the intensity of the monsoon circulation. The East Asian monsoons are mainly driven by land–sea thermal contrast and, thus, are deeply affected by global climate change (Ding et al., 2014; Gong et al., 2018).

Atlas.5.1.1.2 Findings From Previous IPCC Assessments

The findings of the IPCC AR5 (Christensen et al., 2013) stated that the EASM and EAWM circulations have experienced an inter-decadal scale weakening since the 1970s, leading to a warmer climate in winter and enhanced mean precipitation along the Yangtze River Valley (30°N) but deficient mean precipitation in northern China in summer. Since the middle of the 20th century, it is *likely* that there has been an increasing trend in winter temperatures across much of Asia (Christensen et al., 2013). The numbers of cold days and nights have decreased and the numbers of warm days and nights have increased over Asia (Hartmann et al., 2013). It is *likely* that there are decreasing numbers of snowfall events where increased winter temperatures have been observed (Hartmann et al., 2013). The SRCCL reports a land-use-change-induced cooling as large as -1.5°C in eastern China between 1871 and 2007 (Hartmann et al., 2013). The summer rainfall amount over East Asia shows no clear trend during the 20th century.

The IPCC AR5 (Christensen et al., 2013) reports a significant increase in mean temperatures in south-eastern China, associated with a decrease in the number of frost days under the SRES A2 emissions scenario.

The CMIP5 model projections indicate an increase of temperature in both boreal winter and summer over East Asia for RCP4.5. Based on CMIP5 model projections, there is *medium confidence* in an intensified EASM and increased summer precipitation over East Asia. More than 85% of CMIP5 models show an increase in mean precipitation of the EASM, while more than 95% of models project an increase in heavy precipitation events (Christensen et al., 2013). The SROCC states that future projections of annual precipitation indicate increases of the order of 5–20% over the 21st century in many mountain regions, including the Himalaya and East Asia (Hock et al., 2019b). The SR1.5 reports that statistically significant changes in heavy precipitation between 1.5°C and 2°C of global warming are found in East Asia (Hoegh-Guldberg et al., 2018).

Atlas.5.1.2 Assessment and Synthesis of Observations, Trends and Attribution

Summer (June–August) mean temperature in eastern China has increased by 0.82°C since reliable observations were established in the 1950s (Sun et al., 2014). Based on historical meteorological observations, the best estimate of the linear trend of annual mean surface air temperature (SAT) for China with 95% uncertainty ranges is $0.38^{\circ}\text{C} \pm 0.05^{\circ}\text{C}$ per decade for 1979–2015 (Li et al., 2017). From 1960 to 2010, the increasing trend of temperature was about 0.34°C per decade in the arid region of north-west China, higher than the average over China (B. Li et al., 2012; Xu et al., 2015). Over South Korea, warming is 1.4–2.6 times larger than global trends. The increase is 1.90°C during 1912–2014 and 0.99°C during 1973–2014 (Park et al., 2017) with a 25–45% urbanization contribution. The annual temperature increased in large cities at a rate of $0.29^{\circ}\text{C} \pm 0.08^{\circ}\text{C}$ per decade compared with $0.11^{\circ}\text{C} \pm 0.08^{\circ}\text{C}$ per decade in other stations in South Korea from 1960 to 2010 (H.-S. Kim et al., 2016). A relatively high increase in annual mean temperature at the rate of 3.0°C per century was detected in the Tokyo metropolitan area for the period 1901–2015 (Matsumoto et al., 2017). Trends of annual temperature for the period of 1961–2015 are shown in Figure Atlas.11. Most areas of East Asia have significant warming trends exceeding 0.1°C per decade, and the strongest warming (0.3°C – 0.4°C per decade) occurs in northern China.

Observational studies indicated significant decadal variations in the EAWM (Wang and Lu, 2016; He et al., 2017). It weakened significantly around the late 1980s, being relatively strong during 1976–1987 and weaker during 1988–2001. The EAWM has recovered in intensity after 2004 and caused frequent and prevalent severe cold spells, as well as a number of unusually harsh cold winters in many parts of East Asia during the period 2004–2012 (Wang and Chen, 2014; Kug et al., 2015; Ge et al., 2016; Gong et al., 2018). Negative zonal mean winter SAT anomalies were observed over the whole of East Asia from 1980 to 1988, with positive anomalies observed over high and low latitudes from 1988 to 2010 (Miao and Wang, 2020).

Precipitation trends over East Asia show considerable regional differences (*medium confidence*). Mean precipitation has shown negligible sensitivity to the warming trend with consequently limited overall trends in China though summer rainfall daily frequency and intensity show respectively decreasing and increasing trends from

1961 to 2014 (Zhou and Wang, 2017). The summer precipitation trends over eastern China display a dipole pattern, characterized by positive anomalies in central-eastern China along the Yangtze River Valley and negative anomalies in north China since the 1950s (Section 8.3.2.4.2). This pattern has changed with the enhanced rainfall in the Huaihe River Valley and decreased in the regions south of the middle and lower reaches of the Yangtze River Valley since the 2000s (Liu et al., 2012; Zhao et al., 2015). The climate in north-west China changed from 'warm-dry' to 'warm-wet' condition in the mid-1980s (Peng and Zhou, 2017; Wang et al., 2020), with an increased rate of annual precipitation of about 3.7% per decade from 1961 to 2015 (P. Wu et al., 2019) and 11.2 mm per decade between 1960 and 2011 in northern Xinjiang (Xu et al., 2015). Mean rainfall and the number of rainy days during the Meiyu-Baiu-Changma period from June to September have increased during 1973–2015 in Korea (Lee et al., 2017). The precipitation trend has caused a large increase in summer precipitation at a rate of 40.6 ± 4.3 mm per decade, resulting in an increase of annual precipitation of 27.7 ± 5.5 mm per decade in South Korea from 1960 to 2010 (H.-S. Kim et al., 2016). Precipitation amounts exhibited a slight decrease at both the annual and seasonal scales in Japan for the period 1901–2012 (Duan et al., 2015).

Agriculture intensification through oasis expansion in Xinjiang region has increased summer precipitation in the Tian Shan mountains (*high confidence from medium evidence with high agreement*) (Zhang et al., 2009, 2019b; Deng et al., 2015; Guo and Li, 2015; Yao et al., 2016; Xu et al., 2018; Cai et al., 2019). However, there is *very low confidence* of the effect of oasis expansion on the temperature warming trend (Han and Yang, 2013; Li et al., 2013; Yuan et al., 2017).

In the context of climate warming, intense snowfalls have hit China frequently in recent winters and have caused severe damages to the sustainability of society (Sun et al., 2019). Observations generally show a decrease in the frequency and an increase in the mean intensity of snowfalls in north-western, north-eastern and south-eastern China and the eastern Tibetan Plateau since the 1960s (Zhou et al., 2018), but the results may depend on the objective criteria for identifying winter snowfall (J. Luo et al., 2020).

Atlas.5.1.3 Assessment of Model Performance

Current climate models perform poorly in simulating the mean precipitation in East Asia, including the phase of the northward progression of the seasonal rainband (M. Zhang et al., 2018). Although there has been an improvement in the simulation of mean states, interannual variability and past climate changes in the progression from CMIP3 to CMIP5, some previously documented biases (such as the ridge position of the western North Pacific Subtropical High and the associated rainfall bias) are still evident in CMIP5 models (Sperber et al., 2013; Zhou et al., 2017). Most models capture the main characteristics of the winter mean circulation over East Asia reasonably well, but they still suffer from difficulty in predicting the interannual variability of the EAWM (Shin and Moon, 2018). Models have improved from CMIP5 to CMIP6 for climatological temperature and EAWM (D. Jiang et al., 2020). Some CMIP6 models also show improvements in simulating the annual mean and interannual variation of precipitation (Sellar et al., 2019; Tatebe et al., 2019;

T. Wu et al., 2019). The performance of models is sensitive to cumulus convection schemes and horizontal resolution (Haarsma et al., 2016; Wu et al., 2017; Kusunoki, 2018b). High-resolution atmospheric global climate models (AGCM) successfully reproduce the intensity and the spatial pattern of the EASM rainfall (Li et al., 2015; Yao et al., 2017; Ito et al., 2020a) and improve the simulation of the diurnal cycle of precipitation rates and the probability density distributions of daily precipitation over Korea, Japan and northern China (Lin et al., 2019), but increasing horizontal resolution (at the typical scales used in GCMs) is not always a panacea for solving model biases (Roberts et al., 2018).

Recent studies using CORDEX-EA models with resolution of about 12–25 km showed that the RCMs produce relatively more detailed regional features of the temperature distribution compared with the driving GCMs (Tang et al., 2016). Over China, RCMs provide more spatial details and in general reduce the biases of their driving GCMs, in particular in DJF (December–January–February) and over areas with complex topography (Wu and Gao, 2020). However, RCMs also show biases in simulating East Asian precipitation and its variability (Park et al., 2016; Zhou et al., 2016; Zou and Zhou, 2016), and do not always show added value compared to the driving GCMs (Li et al., 2018b). For example, by comparing inter-GCM and inter-RCM differences around the Japan archipelago, it was found that RCM generate relatively large differences in precipitation (Suzuki-Parker et al., 2018). The RCM multi-model ensemble produces superior simulation compared to that of a single model (Jin et al., 2016; D.-L. Guo et al., 2018). A comparative study of RCMs at different spatial resolutions showed that with coarse resolution they present some limitations and high-resolution RCMs offer added value for several evaluation metrics (Park et al., 2020).

Atlas.5.1.4 Assessment and Synthesis of Projections

The development of climate models provides a solid basis for projection of future monsoon changes under different global warming scenarios. Coupled model simulations indicate that East Asia and the Tibetan Plateau will *likely* experience higher warming than the global mean conditions across all global warming levels (Figure Atlas.17) and with the projected warming greater in ECA and TIB than EAS. Also, in the CMIP6 ensemble, the multi-model mean and 90th percentile warming for a given period and emissions scenario are consistently greater than in the CMIP5 ensemble. Larger warming magnitudes are projected to occur in the southern, north-western, and north-eastern regions of China, parts of Mongolia, the Korean Peninsula, and Japan than in other regions (Li et al., 2018a). Projections indicate winter increases in SAT over the East Asian continent and in precipitation over the northern East Asian continent with 1.5°C and 2.0°C global warming under the RCP4.5 and RCP8.5 scenarios (Miao et al., 2020).

Projected annual precipitation changes in the CMIP5 and CMIP6 ensembles are positive for all warming levels in ECA and TIB and for the higher warming levels in EAS. Changes in precipitation per degree Celsius global warming are larger in DJF than in JJA in ECA but show smaller seasonal difference in EAS (Figure Atlas.17). The EASM precipitation is projected to increase but with a complex spatial structure (Kitoh, 2017; Moon and Ha, 2017). Simulations

from CMIP5 models show that compared with the current summer climate, both SAT and precipitation increase significantly over the East Asian continent during the 1.5°C warming period (L. Chen et al., 2019) and that the main mode of EASM precipitation changes from tripolar to dipolar (Wang et al., 2018). The increase in precipitable water in the wet EASM region is only slightly greater than the global average but the increase in precipitation is much greater (Z. Li et al., 2019). The monsoon circulation in the lower troposphere is projected to strengthen due to the enhanced thermal forcing by the Tibetan Plateau (He et al., 2019; He and Zhou, 2020), which causes the increased summer precipitation over the East Asian continent. Precipitation over eastern China increases for almost all months under global warming in projections from GCMs with different horizontal resolutions (Kusunoki, 2018a). Also, under RCP scenarios, in the 21st century, mean precipitation is projected to increase (Kim et al., 2020), especially in the late afternoons (Oh and Suh, 2018), over the Korean Peninsula due to global warming and associated changes in EASM. Increase in JJA mean precipitation is projected in northern East Asia consistently among the CMIP models, while northward migration of early summer East Asian rainbands such as the Meiyu-Baiu-Changma is delayed along with that of the mid-latitude westerly jet in the future (Horinouchi et al., 2019). However, the geographical distribution of precipitation change tends to depend more on the cumulus convection scheme (Ose, 2017) and horizontal resolution of models rather than on SST distributions. Under the RCP4.5 and the RCP8.5 scenarios, the interannual variability in EASM rainfall is projected by the multi-model ensemble mean to increase in the 21st century (Ren et al., 2017). Further studies show a projected increase in heavy rainfall together with increases in rainfall intensity (Endo et al., 2017). Multi-model intercomparison indicates significant uncertainties in future projections of climate change in East Asia, although precipitation increases consistently across models (Zhou et al., 2017). Simulations under the RCP4.5 scenario project that the number of snow days will be reduced by the end of the 21st century relative to 1986–2005, primarily owing to the decline of light snowfall events. The total amount is projected to increase in north-western China but decrease in the other sub-regions (Zhou et al., 2018).

The increasing temperature trends under RCP scenarios were consistently reproduced in projections using CORDEX-EA models (Y. Kim et al., 2016) as reported in AR5 using GCMs. However, changes in annual and seasonal mean precipitation exhibit significant inter-RCM differences with larger magnitudes and variability than in the GCMs (Ham et al., 2016; Ozturk et al., 2017; H. Sun et al., 2018; D. Zhang et al., 2018). RCM simulations project that the Meiyu-Baiu-Changma heavy rainfall will significantly increase in northern Japan at the end of the 21st century under the RCP8.5 scenario (Osakada and Nakakita, 2018), but projected precipitation amount and the number of precipitation days in summer around and over Japan differ as a result of RCM uncertainty (Suzuki-Parker et al., 2018). Annual total snowfall is projected to decrease in most parts of Japan except for Japan's northern island under RCP2.6 (Kawase et al., 2021).

Projections based on statistical downscaling of 37 CMIP5 GCMs for Xinjiang, China, show pronounced temperature increases of 0.27°C to 0.51°C per decade from 2021 to 2060 while precipitation changes were projected to be between –1.7% to 6.8% per decade

and varying seasonally and spatially (Luo et al., 2018). A decrease of precipitation was projected in the western region of Xinjiang during summer. More extreme rainfall events were projected to occur during summer and autumn.

Atlas.5.1.5 Summary

In East Asia annual mean temperature has been increasing since the 1950s (*high confidence*). The linear trend of annual mean surface air temperature *likely* exceeded 0.1°C per decade over most of East Asia from 1961 to 2015. Trends of annual precipitation show considerable regional differences with areas of both increases and decreases (*medium confidence*), and with increases over north-west China and South Korea (*high confidence*). Agricultural intensification through oasis expansion in Xinjiang region has increased summer precipitation in the Tian Shan mountains (*high confidence*).

GCMs still show poor performance in simulating the mean rainfall and its variability over East Asia, especially over regions characterized by complex topography. The CMIP6 models have improved from CMIP5 for climatological temperature and winter monsoon but show little improvements for the summer monsoon. The RCMs produce relatively more detailed regional features, but do not always produce superior simulations compared with the driving GCMs.

The annual mean surface temperature over East Asia and the Tibetan Plateau will *very likely* increase under all emissions scenarios and GWLs. Larger warming magnitudes will *likely* occur in the northern part of EAS and in ECA and TIB. Precipitation is *likely* to increase over land in most of EAS at the end of the 21st century under higher-emissions scenarios (SSP3-7.0, RCP8.5 and SSP5-8.5) and global warming levels, and in ECA and TIB under all emissions scenarios and global warming levels. Summer precipitation increase is *likely* to occur in East Asia, corresponding to the strengthened summer monsoon circulation.

Atlas.5.2 North Asia

Atlas.5.2.1 Key Features of the Regional Climate and Findings From Previous IPCC Assessments

Atlas.5.2.1.1 Key Features of the Regional Climate

North Asia extends from the Ural Mountains in the west to the Pacific Ocean in the east and from the Russian Arctic in the north to West and East Central Asia and East Asia in the south. Its most recognizable features are boreal forests and permafrost. In AR6 North Asia is divided into three reference regions (Figure Atlas.17): West Siberia (WSB) with a continental climate, warm summers and cold winters, many waterlogged areas and several natural zones due to a large extent from south to north and heterogeneity in regional climates; East Siberia (ESB) which is mainly highland with extensive permafrost and a more severe continental climate characterized by harsh, long winters and short, hot summers, and by less precipitation and snow cover than in neighbouring regions; and the Russian Far East (RFE) with a monsoon-influenced climate, cold winters and wet

summers in the south, and cold winters and cool summers almost without precipitation in the north. WSB and ESB are mainly influenced by NAO and NAM (Annex IV.2.1) and the Arctic Oscillation (AO) with associated atmospheric blocking by the Siberian High (SH) that exhibits a pronounced decadal-to-multi-decadal variability (see also Table Atlas.1). RFE is under the influence of the ENSO (Annex IV.2.3) and the PDV (Annex IV.2.6) that mostly affect rainfall variability.

Atlas.5.2.1.2 Findings From Previous IPCC Assessments

In the previous IPCC assessment cycles, the three sub-regions comprising North Asia in this section, along with Eastern Europe and the Asian Arctic, were considered as either Northern Eurasia or Russia in AR4 and AR5. The AR5 WGI stated that for North and Central Asia CMIP5 models had difficulty in representing climatological means of both temperature and precipitation, which is partly related to the scarceness of observational data in northern parts of the region and to issues related to the estimation of biases with coarse-resolution models (Christensen et al., 2013). In CMIP5 projections under different RCP scenarios, North Asian temperatures increase more in winter (DJF) than summer (JJA; Seneviratne et al., 2012). With most models projecting increased precipitation significantly above the 20-year natural variability, it was concluded that precipitation in North Asia will *very likely* increase (Christensen et al., 2013).

The SRCCL identified aridification of the climate in southern East Siberia between 1976 and 2016 as causing an extension of the steppes polewards whilst climate change also extended the vegetation season, increasing forest productivity in most of boreal Siberia, but increasing risk of wildfire and tree mortality (Mirzabaev et al., 2019). The SROCC noted the warming climate has caused permafrost thaw and loss of ground ice, and thus land subsidence and collapse, disturbing ecosystems and human infrastructure. Permafrost stability, hydrology and vegetation were also impacted by recent extensive fires burning into the organic soil layer (Meredith et al., 2019). The SR1.5 noted that future, higher levels of warming lead to greater impacts in key systems such as the Siberian ecosystems, identified as one of the threatened systems ('Reason for Concern 1 – RFC1'; Hoegh-Guldberg et al., 2018) with impacts at 2°C expected to be greater than those at 1.5°C (*medium confidence*).

Atlas.5.2.2 Assessment and Synthesis of Observations, Trends and Attribution

Increases in surface air temperature (SAT) have been observed since the mid-1970s over the whole of North Asia (Frolov et al., 2014), and particularly over the north-eastern part (Figure Atlas.11; Gruza et al., 2015). Trends of annual SAT in the northern part of the region during the last decades were *very likely* twice as strong as the global average (Figure Atlas.11; Frolov et al., 2014; Mokhov, 2015; Sherstyukov, 2016) with trends in RFE of 0.8°C–1.2°C per decade for the 1976–2014 period and more intense warming strengthening from south to north observed in spring in ESB (Frolov et al., 2014; Ippolotov et al., 2014; Kokorev and Sherstiukov, 2015).

Recent strong warming in polar regions (Section Atlas.11.2) was accompanied by cooling in winter in mid-latitude regions particularly

in the southern part of WSB and ESB (Cohen et al., 2014; Ippolotov et al., 2014; Gruza et al., 2015; Kharyutkina et al., 2016; Overland et al., 2016; Perevedentsev et al., 2017; Wegmann et al., 2018). These temperature decreases were strongly correlated with significant warming over the Barents-Kara Sea (greater than 2.5°C per decade during 2003–2017) and sea ice loss, suggesting a causal link (Outten and Esau, 2012; Semenov et al., 2012; Overland et al., 2016; Semenov, 2016; Wegmann et al., 2018; Meleshko et al., 2019; Susskind et al., 2019), though recent studies (Blackport et al., 2019; Clark and Lee, 2019) have shown that both phenomena result from mid-latitude circulation variability (see also Cross-Chapter Box 10.1). In addition, significant warming in the last decade has halved the cooling trend in southern WSB from –0.6°C per decade during 1976–2012 to –0.3°C per decade during 1976–2018 (*high confidence*) (Frolov et al., 2014; Roshdyromet, 2019).

Annual precipitation totals *very likely* increased over North Asia in the last half century along with more heavy and less light precipitation, more freezing rain and less freezing drizzle (Figure Atlas.11 and the Interactive Atlas; Wen et al., 2014; Groisman et al., 2016; Ye et al., 2017; Chernokulsky et al., 2019). The highest increase was observed over regions of Siberia and RFE with estimated trends of 10–25 mm per decade for the 1976–2014 period (Kokorev and Sherstiukov, 2015) or 5% per decade for the 1976–2018 period (Roshdyromet, 2019). Increases over southern RFE are the largest (over 50 mm per decade)

(a) Linear trend of Jul–Dec snow duration (days/decade)

(b) Linear trend of Jan–Jun snow duration (days/decade)

(c) Linear trend of the maximum yearly snow height (mm/decade)

Colour Significant ××× Non significant

Figure Atlas.18 | Linear trends for the 1980–2015 period based on station data from the World Data Centre of the Russian Institute for Hydrometeorological Information (RIHMI-WDC; Bulygina et al., 2014). (a) Snow-season duration from 1 July to 31 December (days per decade); (b) snow-season duration from 1 January to 30 June (days per decade); (c) maximum annual height of snow cover (mm per decade). Trends have been calculated using ordinary least squares regression and the crosses indicate non-significant trend values (at the 0.1 level) following the method of Santer et al. (2008) to account for serial correlation. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

and are mostly due to positive changes in convective precipitation intensity in the region in the summer season (JJA) during 1966–2016 (*medium confidence*) (Chernokulsky et al., 2019). A decreasing trend was observed in central WSB, northern ESB, the Baikal and Transbaikalian regions, the Amur River region, and Primorie territories of RFE (the Kamchatka and Chukchi peninsulas) with up to –20 mm per decade for the 1976–2014 period (Kokorev and Sherstiukov, 2015) or 15–20% per decade for the 1976–2018 period (Roshydromet, 2019). Overall, solid precipitation predominantly decreased in North Asia and *very likely* caused both less snow cover extent (SCE) and snow water equivalent (SWE), attributable to the anthropogenic influence with *high confidence* (Sections 2.3.2.2 and 3.4.2).

Snow characteristics depend on both temperature and precipitation, and observed trends over North Asia show large spatial heterogeneity and interannual variability (Figure Atlas.18) leading to *medium confidence* that maximum snow depth has increased over Siberia, the Okhotsk Sea coast and in southern RFE since the 1960s (Callaghan et al., 2011; Loginov et al., 2014), with trends during 1976–2016 of 1.8 cm (in WBS), 1.1 cm (in ESB), and 4.6 cm (in RFE) per decade (Bulygina et al., 2017). Snow cover duration increased in Yakutia, Sakhalin Island and some other coastal areas of the Pacific Ocean in RFE during 1980–2009 (Callaghan et al., 2011), and decreased in WSB and ESB (Bulygina et al., 2017; Roshydromet, 2019). However, Gorbatenko et al. (2019) reported that in south-eastern WSB maximal snow depth has increased by 5–20 cm and duration of steady snow cover by between 4 and 10 days during 1989–2016 (Figure Atlas.18).

Atlas.5.2.3 Assessment of Model Performance

Temperature trends and means derived from reanalysis datasets (JRA-25 and MERRA) correctly represented temperature variability shown in observational data over the Asian territory of Russia for the 1976–2010 period (Loginov et al., 2014). Assessment of CRU TS 3.22, CRUTEMP4, ERA-Interim and NCEP2 datasets against station data over North Asia for annual and seasonal air temperature has shown that the ERA-Interim reanalysis outperforms others for the 1981–2005 period (Kokorev and Sherstiukov, 2015). The latter reanalysis also underestimates summer precipitation and shows large wet biases over north-east Asia during spring and underestimates mean seasonal temperature over north-east Asia in spring (MAM), autumn (SON), and winter (DJF), but overestimates it in summer (JJA) compared with the CRU dataset (*medium confidence*) (Ozturk et al., 2017; Top et al., 2021).

GCMs capture the main synoptic processes affecting North Asia and the CMIP5 ensemble simulates the temporal evolution of the magnitude and position of the Siberian High (SH) over the period 1872–2005 (Fei and Yong-Qi, 2015). CMIP5 models simulate a weakened intensity of the winter SH and a strengthened interannual variability compared to observations (Fei and Yong-Qi, 2015). The characteristics of blocking events over the region (number, duration, intensity and frequency) were reasonably well reproduced by GCMs (Mokhov et al., 2014), and most overestimate the annual mean temperature over northern Eurasia (Interactive Atlas). Biases in simulated annual surface air temperature simulation primarily come from the winter (DJF) season and are relatively smaller in other

seasons (Miao et al., 2014; Peng et al., 2019). Most GCMs capture the main decadal SAT trend (Miao et al., 2014), though CMIP5 GCMs fail to capture the decreasing temperature trend over East Siberia (Fei and Yong-Qi, 2015). Possible causes of GCMs' inability to represent the recent slowdown of warming is further discussed in Cross-Chapter Box 3.1. For CMIP5, models with higher resolution do not always perform better than those with lower resolutions (*medium confidence*) (Miao et al., 2014).

Sixteen CMIP5 model simulations of SAT variability over Eurasia were evaluated against CRU observations for permafrost sub-regions (Peng et al., 2019), showing a warm bias in north-west Eurasia, capturing the climate warming over the 20th century and its acceleration during the late 20th century. CMIP5 GCMs generally underestimate daily temperature range compared with observations over north-eastern Russia (Sillmann et al., 2013; Lindvall and Svensson, 2015). Currently there is no literature on the CMIP6 ensemble over the region though a few single-model studies are available (Voldoire et al., 2019; T. Wu et al., 2019).

There is very limited use of RCMs for North Asia. CORDEX-CAS covers North Asia, except parts of RFE, and ARCTIC-CORDEX covers the northern regions (Figure Atlas.6). For CORDEX-CAS three RCMs (REMO, ALARO-0 and CLMcom) have been used and have warm biases for maximum temperatures, cold biases for minimum temperatures and a wet bias in the north during the winter (Top et al., 2021). Rain gauges, however, are known to have problems in terms of measuring properly solid precipitation (e.g., due to drifting snow) which can greatly affect the accuracy of precipitation observations over North Asia (Harris et al., 2014).

Atlas.5.2.4 Assessment and Synthesis of Projections

CMIP5 and CMIP6 projections are consistent in the direction and ranges of surface temperature change which are higher than the global average and with ensemble-mean warming of around 6°C for the 4°C GWL. Projected precipitation changes are also consistent with significant increases in winter, of up to 40% in the ensemble mean for the highest warming levels, and lower increases in summer except for WSB where changes are small and suggest drying at the 4°C GWL (Figure Atlas.17 and the Interactive Atlas).

The CMIP5 ensemble projects a warming of the annual mean SAT over northern Eurasia in the 21st century, *likely* in the range of 0.8°C–1.0°C (RCP2.6), 2.3°C–3.1°C (RCP4.5) and up to 7.2°C (RCP8.5) (Miao et al., 2014; Peng et al., 2019). Mid-latitude permafrost sub-regions in Eurasia are projected to warm more than the global mean and non-permafrost territories, with ensemble area-averaged changes of 1.7°C (RCP2.6), 3.2°C (RCP4.5) or 6.4°C (RCP8.5) in 2081–2100 relative to 1986–2005 (Peng et al., 2019).

Over the Central Asia CORDEX domain, RegCM4.3.5 simulations driven by two different CMIP5 GCMs (HadGEM2-ES and MPI-ESM-MR) project SAT warming for 2071–2100 relative to 1971–2000 of about 3°C–4°C during the summer for RCP4.5 to over 7°C for all seasons for RCP8.5. Projected warming is most evident on the large continental Siberian Plateau with boreal and sub-boreal climates and biomes

(i.e., taiga forests and tundra) during the winter season (Ozturk et al., 2017). The Voeikov Main Geophysical Observatory (MGO) RCM, driven by five CMIP5 GCMs for the RCP8.5 scenario, projects a faster increase in annual minimum temperature as compared with maximum temperature over the whole territory of Russia (Kattsov et al., 2017), and the smallest change in growing season lengths (i.e., periods with daily temperatures over 5°C, 10°C and 15°C) in the area of northern taiga in WSB and ESB comparable with other territories of Russia during the 21st century (Torzhkov et al., 2019).

For precipitation, MGO RCM projects for the Arctic-CORDEX domain under the RCP8.5 scenario increases in annual totals for northern North Asia, a decrease in summer over ESB for 2006–2100 relative to 1951–2005 and significant increases in the upper limit of intense precipitation over most of the region in winter (Kattsov et al., 2017; Khlebnikova et al., 2018). Other RCM projections show that in most seasons and for all future periods, precipitation in Siberia is not projected to change with respect to the 1971–2000 period, except under the RCP8.5 scenario for the winter and autumn (Ozturk et al., 2017). This very limited and controversial evidence leads to *low confidence* in RCM precipitation projections for North Asia and since the projections of GCMs and ESMs are more physically consistent, assessment of future precipitation changes is based on CMIP5/CMIP6 presented in Figure Atlas.17 and the Interactive Atlas.

Atlas.5.2.5 Summary
