Snow: The snow season length in Australia has decreased by 5% during 2000-2013 relative to 1954-1999, especially in spring (Pepler et al., 2015). A shift in the date of peak snowfall has also been observed with an 11 day advance over the same period (Pepler et al., 2015). A decreasing trend in maximum snow depth has been observed for Australian alpine regions since the late 1950s, with the largest declines during spring and at lower altitudes. Maximum snow depth is highly variable and is strongly influenced by rare heavy snowfall days, which have no observed trends in frequency (CSIRO and BOM, 2020).

Projections for Southern Australia and New Zealand show a continuing reduction in snowfall during the 21st century (high confidence). The magnitude of decrease varies with the altitude of the region and the emission scenario. At elevations lower than 1,500 m, years without snowfall are projected from 2030 in some models. By 2090, and under RCP8.5, such years are projected to become common (CSIRO and BOM, 2015). The number of annual snow days in New Zealand is projected to decrease under all RCP’s, by up to 30 days or more by 2090 under RCP8.5, relative to 1986 – 2005 (MIE, 2018).

Glacier: Glacier mass and areal extent in New Zealand is projected to continue to decrease over the 21st century (high confidence) (Section 9.5.1.3). Glacier ice volume from 1977 to 2018 in New Zealand has decreased from 26.6 km$^3$ to 17.9 km$^3$ (a loss of 33%) (Salinger et al., 2019). Relative to 2015, glaciers in New Zealand are projected to lose 36 ± 44%, 53 ± 33%, and 77 ± 27% of their mass by the end of the century under RCP2.6, RCP4.5, and RCP8.5, respectively, with the loss rates decreasing over time under RCP2.6 and increasing under RCP8.5 (Marzeion et al., 2020).

In summary, snowfall is expected to decrease throughout the region at high altitudes in both Australia (high confidence) and New Zealand (medium confidence). In New Zealand, glacier ice mass and extent are expected to decrease over the 21st century for all scenarios (high confidence).

12.4.3.5 Coastal and Oceanic

Relative sea level: Around Australasia, over 1900-2018, a new tide-gauge based reconstruction finds a regional-mean RSL change of 1.33 [0.80-1.86] mm yr$^{-1}$ in the Indian ocean - South Pacific region (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr$^{-1}$ (Section 2.3.3.3; Table 9.5). For the period 1993-2018, the RSLR rates, based on satellite altimetry, increased to 3.65 [3.23-4.08] mm yr$^{-1}$ (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr$^{-1}$ (Section 2.3.3.3; Table 9.5).
Relative sea level is virtually certain to increase throughout the region over the 21st century (Section 9.6.3, Figure 9.28). Regional-mean RSLR projections for the oceans around Australasia range from 0.4 m–0.5 m under SSP1-RCP2.6 to 0.7 m–0.9 m under SSP5-RCP8.5 for 2081–2100 relative to 1995–2014 (median values), which means local RSL change falls within the range of mean projected GMSL change (Section 9.6.3.3). However, these RSLR projections may be underestimated due to potential partial representation of land subsidence (Section 9.6.3.2).

Coastal flood: The most commonly used index for episodic coastal inundation in Australia is the summation of a high end SLR and the 1:100 yr storm tide level (the combined sea level due to storm surge and tide) (CSIRO and BOM, 2016; McInnes et al., 2016). However, episodic coastal flooding is caused by Extreme Total Water Levels (ETWL), which is the combination of SLR, tides, surge and wave setup (12.3.5.2). The present day 1:100 yr ETWL is between 0.5 m – 2.5 m around most of Australia, except the northwestern coast where 1:100 yr ETWL can be as large as 6 m–7 m (Vousdoukas et al., 2018; O’Grady et al., 2019; Kirezci et al., 2020).

Extreme total water level magnitude and occurrence frequency are expected to increase throughout the region (high confidence) (see Figure 12.4p-r and Figure SM 12.6). Across the region, the 5th – 95th percentile range of the 1:100 yr ETWL is projected increase (relative to 1980 – 2014) by 5 cm – 35 cm and by 10 cm – 40 cm by 2050 under RCP4.5 and RCP8.5, respectively (Figure 12.4q). By 2100 (Figure 12.4p-r), this range is projected to be 25 cm – 80 cm and 50 cm – 190 cm under RCP4.5 and RCP8.5, respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, the present day 1:100 yr ETWL is projected to have median return periods of around 1:20 yrs by 2050 and 1:1 yrs by 2100 in SAU and NZ and return periods of around 1:50 yrs by 2050 and 1:20 yrs by 2100 in NAU under RCP4.5 (Vousdoukas et al., 2018), while the present day 1:50 yr ETWL is projected to occur around 3 times a year by 2100 with a SLR of 1 m around Australasia (Vitousek et al., 2017).

Coastal erosion: Satellite derived shoreline retreat rates for the period between 1984 – 2015 show retreat rates between 0.5 m yr⁻¹ and 1 m yr⁻¹ around the region, except in SAU where a shoreline progradation rate of 0.1 m yr⁻¹ has been observed (Luijendijk et al., 2018; Mentaschi et al., 2018). Mentaschi et al. (2018) report a coastal area loss of 350 km² over the same period in West Australia from satellite observations.

Projections indicate that a majority of sandy coasts in the region will experience shoreline retreat, throughout the 21st century (high confidence) (Figure 12.7b,d). Median shoreline change projections (CMIP5) under both RCP4.5 and RCP8.5 presented by Vousdoukas et al. (2020) show that, by mid-century, sandy shorelines will retreat (relative to 2010) by between 50 m and 80 m all around Australasia, except in SAU and NZ where the projected retreat (relative to 2010) is between 35 m and 50 m. By 2100, median shoreline retreats exceeding 100 m (relative to 2010) are projected along the sandy coasts of NAU (~ 150 m), CAU (~ 160 m), and EAU (~ 110 m) under RCP4.5m, while projections for SAU and NZ are around 80 m – 90 m. Under RCP8.5, shoreline retreat exceeding 100 m is projected all around the region by 2100 (relative to 2010) with retreats as high as 220 m in NAU and CAU (~ 170 m in EAU and around 130 m in SAU and NZ) (Figure 12.7b, d). The total length of sandy coasts in Australasia that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 12,500 km and 16,000 km respectively, an increase of approximately 30%.

Distinct from long term coastline recession, storms and storm surges also result in episodic coastal erosion. In general, the historically measured maximum episodic coastal erosion (either eroded volume or coastline retreat distance) or that due to a 1:100 yr return period storm wave height is used as a design criterion for coastal zone management and planning in Australia (Wainwright et al., 2014; Mortlock et al., 2017).

While there is wide recognition in Australia that the combined effect of SLR, changing storm surge and wave climates will directly affect future episodic coastal erosion (Harley et al., 2017; McInnes et al., 2016; Ranasinghe, 2016) only a few projections of how this hazard may evolve are available for Australia. In one such study, Jongejan et al. (2016) provide projections of how the full exceedance probability curve of the maximum erosion per year may evolve over the 21st century (due to the combined action of SLR, storm surge and storm waves). Their results show that, for example, the 0.01 exceedance probability maximum
coastline retreat in 2025 will have an exceedance probability of 0.015 by 2050 and 0.07 by 2100.

**Marine heatwave:** The mean SST of the ocean around Australia and east of New Zealand has warmed at a rate of about 0.22°C per decade between 1992 and 2016 (Wijffels et al., 2018), which is higher than the global average SST increase of 0.16°C per decade (Oliver et al., 2018). This mean ocean surface warming is connected to longer and more frequent marine heatwaves in the region (Oliver et al., 2018). Over the period 1982-2016, the coastal ocean of Australia experienced on average more than 1.5 MHW per year, with the north coast of Western Australia and the Tasman Sea experiencing on average 2.5-3 MHW per year. The average duration was between 10 and 15 days, with somewhat longer and hotter MHWs in the Tasman Sea. In New Zealand, the SE coast of the South Island experiences the most MHWs (2.5-3.0 per year). The duration of MHW in New Zealand is on average 10-15 days (Oliver et al., 2018). Changes over the 20th century, derived from MHW proxies, show an increase in frequency between 0.3 and 1.5 MHW per decade, except along the south east coast of New Zealand (Box 9.1), an increase in duration per event; and the total number of MHW days per decade, with the change being stronger in the Tasman Sea than elsewhere (Oliver et al., 2018).

There is high confidence that MHWs will increase around most of Australasia. Under RCP4.5 and RCP8.5 respectively, mean SST is projected to increase by 1°C and 2°C around Australia by 2100, with a hotspot of around 2°C for RCP4.5 and of 4°C for RCP8.5 along the southeast coast between Sydney and Tasmania (see Interactive Atlas). Under all RCPs, the mean SST around Australia is expected to increase in the future, with median values of around 0.4-1.0°C by 2030 under RCP4.5, and 2-4°C by 2090 under RCP8.5 (CSIRO and BOM, 2015). Warming is expected to be largest along the north-west coast of Australia, southern Western Australia, and along the east coast of Tasmania (CSIRO and BOM, 2018). More frequent, extensive, intense and longer-lasting MHWs are projected around Australia and New Zealand for GWLs of 1.5°C, 2°C and 3.5°C relative to the modelled reference value for 1861-1880 (Frölicher et al., 2018) Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Australasia by 2081-2100, relative to 1985-2014 (Box 9.2, Figure 1).

In general, there is high confidence that most coastal/ocean related hazards in Australasia will increase over the 21st century. Relative sea-level rise is virtually certain to continue in the oceans around Australasia, contributing to increased coastal flooding in low-lying areas (high confidence) and shoreline retreat along most sandy coasts (high confidence). Marine heatwaves are also expected to increase around the region over the 21st century (high confidence).

The assessed direction of change in climatic impact-drivers for Australasia and associated confidence levels are illustrated in Table 12.5, together with emergence time information (see Section 12.5.2). No assessable literature could be found for Hail and Snow avalanches, although these phenomena may be relevant in parts of the region.

**[START TABLE 12.5 HERE]**

Table 12.5: Summary of confidence in direction of projected change in climatic impact-drivers in Australasia, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP3-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea-level rise) to global warming levels between 2°C and 2.4°C (see 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural inter-annual variability if found with at least medium confidence in Section 12.5.2.
12.4.4 Central and South America

For the purpose of this assessment, Central and South America is sub-divided into eight sub-regions, as defined in Chapter 1: southern Central America (SCA), north western South America (NWS), northern South America (NSA), South American Monsoon (SAM), north eastern South America (NES), south western South America (SWS), south eastern South America (SES), and southern South America (SSA). The Caribbean is placed under the Small Islands section (12.4.7) of this chapter.

Previous assessments have documented ongoing and projected changes in several CIDs. IPCC AR5 projections (IPCC, 2014b) pointed to increases in mean temperature between 2-6°C by end of the century (high confidence) and increases in the occurrence of warm days and nights under various future climate scenarios (medium confidence). AR5 also pointed to patterns of changes in precipitation (medium confidence), changes in the duration of dry spells (medium confidence), and decreases in water supply (high confidence). IPCC SR1.5 projections indicated expected increases in river flooding and extreme runoff at 2°C warming in parts of South America, and decreases in runoff in Central America, central and southern South America, and the Amazon basin. The IPCC SROCC reported an increased number of landslides, a decreased volume of lahars from ice and snow-clad volcanoes, and increased frequency of Glacier Lake Outburst Floods. SROCC also indicated that regional and local-scale projections point to decreasing trends in glacier runoff.

New literature is now available for the regional climate as a result of observational research and coordinated modelling outputs of CORDEX South America (Solman, 2013; Sánchez et al., 2015) and CORDEX-CORE (Giorgi et al., 2018; Teichmann et al., 2019; Coppola et al., 2021b). Of particular interest are the new projections of both mean climate and extremes. This new regional climate information is key to main sectors sensitive to climate change in Central and South America such as water resources, infrastructure, agriculture, livestock, forestry, silviculture, and fisheries (Magrin, 2015; López Feldman and Hernández Cortés, 2016), human health (changes in morbidity and mortality, and emergence of diseases in previously non-endemic areas; (Núñez et al., 2016)) and biodiversity (Uribe Botero, 2015), urban planning, navigation and tourism.
Figure 12.8: Projected changes in selected climatic impact-driver indices for Central and South America. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m$^3$ s$^{-1}$ km$^{-2}$) from CORDEX models for 2041-2060 relative to 1995-2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 (meters; negative values indicate shoreline retreat) from the CMIP5 based data set presented by Voudoukas et al. (2020). (c) Bar plots for Q100 (m$^3$ s$^{-1}$ km$^{-2}$) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5 based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Voudoukas et al. (2020). Dots indicate regional mean change estimates and bars the 5th-95th percentiles ranges of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

[END FIGURE 12.8 HERE]

12.4.4.1 Heat and cold

Mean air temperature: New literature confirms a continuous warming since the beginning of the 20th century in the majority of the eight sub-regions (Atlas 7). However, observational datasets in several areas are still short and trend estimation is hindered by year-to-year and interannual variability. Atlas projections point to a virtually certain warming across all sub-regions, with the largest increases taking place in the Amazon Basin (NSA and SAM) (Atlas 7.2.4). A consistent increase in temperature-related indices linked to several climate-sensitive sectors (GDD, CDD) is found across CMIP5, CMIP6 and CORDEX-CORE projections, with lesser increase for CDD in medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5 based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Voudoukas et al. (2020). Dots indicate regional mean change estimates and bars the 5th-95th percentiles ranges of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

Extreme heat: Chapter 11 found high confidence of increased heat waves in all regions but SSA over the past decades. There is evidence of increasing heat stress over summertime in much of SES and SWS using the WBGST index for the period 1973-2012, and this has been attributed to human influence on the climate system (Knutson and Ploshay, 2016). Climate change projections point to major increases in several heat indices across the region for all scenarios (high confidence). Largest increases in the frequency of hot days (maximum temperatures, Tx > 35°C) are projected for the Amazon basin under SSP5-8.5 with more than 200 days per year at the end of the century under SSP5-8.5, while such increases remain moderate (50-100 days) in SSP1-2.6. For the dangerous heat threshold of HI>41°C, increases in frequency are similar to that in Tx>35°C (Figure 12.4 and Figure SM 1.1 and 1.2) (Coppola et al., 2021b; Schwingshackl et al., 2021).

Cold spell and frost: A decreasing frequency of cold days and nights has been observed in many sub-regions (Chapter 11). There is medium confidence (limited agreement) of a decrease in frost days in SWS, SES and SSA. Projections consistently suggest a general decrease in the frequency of cold spells and frost days in all sub-regions as indicated by several indices based on minimum temperature (Chou et al., 2014; López-Franca et al., 2016; Li et al., 2020b). Heating Degree Days are consistently projected to decrease by 5 degree days per year in the Amazon region, and up to 20-30 degree days in NSA, SWS and SES, under future RCP8.5/SSP5-8.5 (Coppola et al., 2021b).
In conclusion, it is virtually certain that warming will continue everywhere in Central and South America and there is high confidence that by the end of century most regions will undergo extreme heat stress conditions much more often than in recent past (e.g., increase of dangerous heat HI>41°C, or T<35°C) with more than 200 additional days per year under SSP5-8.5, while such conditions will be met up typically 50-100 more days per year under SSP1-2.6 over the same regions. Cold spells and frost days will have a decreasing trend (high confidence).

12.4.4.2 Wet and dry

Mean precipitation: The Atlas documents diverse historical precipitation trends in the region, including: a small but not significant increasing trend in SCA, a decreasing trend in south-eastern and north-eastern Brazil, and an increasing trend in SSA. Projections indicate a drying signal for SCA (medium confidence) (Coppola et al., 2014; Nakaegawa et al., 2014), NES and SWS (high confidence) (Atlas 7.2.5) and the well-known dipole for South America, meaning increasing precipitation over subtropical regions like the Río de La Plata basin (SES) (high confidence) and decreased precipitation in the Amazon (NSA) (medium confidence) (Chou et al., 2014; Llopart et al., 2014; Reboita et al., 2014; Sánchez et al., 2015b; Teichmann et al., 2019). These features are consistent among observations (Sena et al., 2018) and are consistently evident in regional and global model projections by mid- and end-of-century for both RCP4.5 and RCP8.5 (Jones and Carvalho, 2013).

River flood: Emerging literature in the region documents ongoing changes in river floods. (Mermild et al., 2018) report decreases and increases in annual runoff on the west of the Andes Cordillera's continental divide, with the greatest decreases in the number of low (<10th percentile) runoff and the greatest increases in high (>90th percentile) runoff conditions. In coastal northeast Peru, extreme precipitation events recently caused devastating river floods and landslides (Son et al., 2020). In Brazil, floods are becoming more (less) frequent and intense in wet (drier) regions (Bartiko et al., 2019; Borges de Amorim and Chaffe, 2019), with higher propagation of hydrological changes through anthropogenically-modified agricultural basins (Chagas and Chaffe, 2018). Record, catastrophic, unprecedented, and once-in-a-century flooding events have also been reported in recent decades in the tributaries of the Amazon river or along its mainstream (Sena et al., 2012; Espinoza et al., 2013; Marengo et al., 2013; Filizola et al., 2014), in Argentinean rural and urban areas (Barros et al., 2015), in the lower reaches of the Atrato, Cauca and Magdalena rivers in Colombia (Hoyos et al., 2013; Ávila et al., 2019), in basins whose mainstreams flow through important metropolitan areas such as Concepción, Chile (Rojas et al., 2017), and even in one of Earth's driest regions, the Atacama Desert (Wilcox et al., 2016). In the Amazon basin, the significant increase in extreme flow was associated with the strengthening of the Walker circulation (Barichivich et al., 2018).

Emerging literature in the region documents projected increases for river floods in SES and SAM (medium confidence). Projections indicate that SES and the coasts of Ecuador and Peru will experience a tendency toward wetter conditions that can be a proxy for longer periods of flooding and enhanced river discharges (Zaninelli et al., 2019). CORDEX models project the strongest changes for the peak flow with a return period of 100 years in SES by mid-century and under RCP8.5. (Figure 12.8). At the continental scale, on the contrary, (Alfieri et al., 2017) suggest that 100-yr river floods are projected to decrease under RCP8.5. Regional projections of river floods have high uncertainty, however; owing to differences in hydrological models (Reyer et al., 2017a) (low confidence). Fábrega et al. (2013) projected increases in surface runoff for Panamá, while Zulkaflı et al. (2016) identified increases in 100-yr floods of 7.5% and 12.0% in projections for the Peruvian Amazon wet season under RCPs 4.5 and 8.5, respectively. Wetter conditions and ±20% variations in annual mean streamflow are also projected for the Río de La Plata under the warming levels of 1.5°C, 2°C and 3°C above pre-industrial conditions (Montroull et al., 2018). In central Chile, 50-yr peak flows are expected to be greater by mid-century than 100-yr peak flows observed over the reference period (Bozkurt et al., 2018).

Heavy precipitation and pluvial flood: Chapter 11 indicated that there is low confidence due to limited evidence of extreme precipitation trends in almost all Central and South America, except in SES where increases in the magnitude and frequency of heavy precipitation have been observed (high confidence). In
general, data scarcity persists for a representative continental assessment. Chapter 11 projections indicate 

low confidence of increase, compared to the modern period, in the intensity and frequency of heavy 

precipitation in SCA and SWS for all GWLs, a medium confidence of increase in NSA, NES, SSA, SAM and 

SES for GWL of 4°C. In NWS, a wide range of changes is projected (low confidence).

Landslide: Several regions in Central America, as well as Colombia and southeastern Brazil, are considered 

areas of high incidence of fatal landslides. In these areas, ENSO-driven fluctuations in rainfall 

amounts (Sepúlveda and Petley, 2015) and climate change (Nehren et al., 2019) seem to be key factors. Rock 

falls, ice- and rock-ice avalanches, lahars, and landslides have been reported in frequent number in the 

southern, extratropical Andes in the last decades (Gariano and Guzzetti, 2016). A large number of ice- and 
moraine-dammed lakes have consequently failed, causing floods that rank amongst the largest events ever 

recorded (Iribarren Anacona et al., 2015). However, due to research deficit, evidence is largely missing for a 

reliable assessment of past and future trends of such hazards.

Aridity: Several regional studies suggest positive trends in the frequency and length of droughts in the 

region, such as: over NWS (Domínguez-Castro et al., 2018), NSA (Marengo and Espinoza, 2016; Cunha et al., 2019) and NES (Marengo and Bernasconi, 2015), over southern Amazonia (Fu et al., 2013; Boisser et al., 2015), in the São Francisco River Basin and the capital city Distrito Federal in Brazil (Borges et al., 2018; Bezerra et al., 2019), in the southern Andes (Vera and Díaz, 2015), in central southern Chile (Boisser et al., 2018), in SES (Rivera and Penalba, 2014), and during recent years in SSA (Rivera and Penalba, 2014). 

Chapter 8 indicated medium confidence of anthropogenic forcing on observed drying trends in central Chile. 

Additional discussion on droughts and aridity trends in South America is presented in Chapter 8 (Sections 

8.3.1.6, 8.4.1.6, 8.6.2.1).

Chapter 8 projections point to two important drying hotspots in South America with long-term soil moisture 

decline and precipitation declines, namely the Amazon basin (SAM and NSA) and SWS (medium 

confidence) (see also Figure 12.4). End-of-century RCP8.5 projections show a longer dry season in the 

central part of South America and decreased precipitation over the Amazon and central Brazil (Coppola et al., 2014; Giorgi et al., 2014b; Llopast et al., 2014; Teichmann et al. 2013) (Atlas.7). Seasonal changes are 

also apparent, with decreases in June-July-August rainfall projected for NSA, the coastal region of SES, 

SAM and the southern portion of the SWS (Marengo et al., 2016). Decreases in December-January-February 

rainfall are projected for the central part of South America in the near term (Kitoh et al., 2011; Chou et al., 

2014; Cabrè et al., 2016). Regional projections for Central and South America also indicate an increase in 

dryness in SCA and NES by mid to end of the century (medium confidence) (Chou et al., 2014; Marengo and 

Bernasconi, 2015).

Hydrological drought: Chapter 11 assessed mostly low confidence in observed changes in hydrological 
droughts given a lack of studies and clear evidence, with medium confidence only for a streamflow decrease 
in subregions of SWS. Some trends are becoming more clear, such as the ones reported for Colombia (NWS) 
by Carmona and Poveda (2014), who indicated that 62% of the 25- to 50-year long monthly average 
streamflow time series exhibited significant decreasing trends. However, studies of discharge changes 
indicate that uncertainty is still large, as argued by Pabón-Caicedo et al. (2020) for the full extent of the 
Andes.

A number of studies project decreases in runoff and river discharge for SCA, Colombia, Brazil and the 
southern part of South America by the end of this century (Nakaegawa and Vergara, 2010; Arnell and 
Gosling, 2013; van Vliet et al., 2013). Section 11.9 assessed high confidence in projections of increases in 
hydrological droughts in NSA, SAM, SWS, and SSA under a +4°C GWL, medium confidence in SCA, and 
low confidence in the rest of the sub-regions given insufficient evidence, lack of signal or mixed signals 
among the available studies. Signals are much more uncertain for the middle of the century (or for a 2°C 
GWL), with only SAM projected to have increased hydrological droughts with medium confidence.

Agricultural and ecological drought: Section 11.9 assessed low confidence in observed changes to 
agricultural and ecological drought across Central and South America due to regional heterogeneity and 
differences depending on the drought metrics used, except in NES which has seen a dominant increase in
drought severity (medium confidence).

NSA and SAM are the two regions where the strongest signal of increasing number of dry days (NDD) and drought frequency (DF) is projected compared to other regions of the world (Coppola et al., 2021b). By the end of this century and under RCP8.5, the NSA area average value for NDD reaches 43, 32 and 27, within the CORDEX-CORE, CMIP5 and CMIP6 ensembles, respectively. For the frequency of droughts, the NSA area average value is of about 4.6, 3.4 and 3.8. The SAM region shows NDD and DF values of 29, 20 and 21, and of 4, 3 and 3.5, respectively (see also Figure 12.4j). In Central America, a significantly drier northern region and a wetter southern region were projected for mid-century by (Hidalgo et al., 2017), whilst Fuentes-Franco et al. (2015) pointed to more pronounced dry periods during the rainy season in SCA by the end of this century under RCP8.5. Increases in the frequency of meteorological droughts that may initiate other drought types are projected for the eastern part of the Amazon and the opposite for the west under RCP8.5 (Duffy et al., 2015). In central Chile, the occurrence of extended droughts, such as the recently-experienced 2010-2015 mega-drought (which is still driving impacts), is projected to increase from one to up to five events per 100 years under RCP8.5 (Bozkurt et al., 2018). Section 11.9 highlights change in confidence in increases in drought severity in SCA, NSA, NES, SAM, SWS, and SSA from low to high under the three GWLs of +1.5°C, +2°C and +4°C. NES and SES change from low confidence to medium confidence increases in agricultural and ecological drought severity by +4°C GWL with different metrics and high agreement between studies. Only SAM and SSA have projections of agricultural and ecological drought increasing with high confidence for the middle of the century, or for a +2°C GWL, and NSA, NES and SCA are increasing with medium confidence.

**Fire weather:** There is evidence of increases in forest fire activity (number of fires, burned area and fire duration) such as in central and south-central Chile, where more conducive fire weather conditions have been proposed as the main driver (González et al., 2018; Urrutia-Jalabert et al., 2018). Projections indicate that the Amazon is one of the regions in the world with the highest increase in fire weather indices over the 21st century and under all RCPs (high confidence) (Betts et al., 2015; Abatzoglou et al., 2019; Sun et al., 2019b). This is consistent with the large increase in the frequency of joint occurrence of extreme hot and dry days for a 2°C warming level or more (Vogel et al., 2020). Projections of fire weather indices also show an increased risk in SWS (high confidence), SSA and SCA (medium confidence). However, wildfires highly depend on land-use and appropriate management may help mitigate future increases in fire risk (Fonseca et al., 2019).

Mean precipitation is projected to change in a dipole pattern with increases in NWS and SES and decreases in NES and SWS (high confidence) with further decreases in NSA and SCA (medium confidence). There is medium confidence of an increase in river floods in SAM and SES. There is high confidence of a dominant increase in drought duration in NES, an in the number of dry days and drought frequency in NSA and SAM. Dry climatic impact-drivers have more prevalent regional increases with higher global warming levels, with strongest projections of agricultural and ecological drought (high confidence) and aridity and fire changes (medium confidence) over the Amazon and with both drought types increasing over the SWS (medium confidence).

### 12.4.4.3 Wind

**Mean wind speed:** Due to the lack of long-term homogeneous records or limited observations in the region, past wind speed trends are difficult to establish. Global climate models project an increase in wind speeds, under all future scenarios, augmenting wind power potential in most parts of Central and South America, especially in NES where changes lie in the range 0-20% by 2050 under RCP8.5 and 0-40% under RCP8.5 (medium confidence) (Karnauskas et al., 2018a; Reboita et al., 2018; Jung and Schindler, 2019). In Patagonia, wind speeds are projected to decrease. For RCP4.5 changes remain marginal and have low confidence (low agreement). Further information in (Figure 12.4m-o).

**Severe wind storm:** Similar observational limitations inhibit an assessment of long-term extreme wind trends. However, (Pes et al., 2017) found extreme wind increases in most of Brazil over the past decades. Future projections indicate a slight decrease in the number of extra-tropical cyclones in mid latitudes (limited confidence).
Tropical cyclone: CMIP5 and CMIP6 simulations, including the new HighResMIP, project a decrease in the frequency of tropical cyclones in the Atlantic and Pacific coasts of Central America for the mid-century or under a 2°C global warming level, accompanied with an increased frequency of intense cyclones (medium confidence) (Diro et al., 2014; Knutson et al., 2020; Roberts et al., 2020) (Chapter 11).

In summary, there is limited evidence of current trends in observed wind speed and wind storms in South America. Climate projections indicate a decrease in frequency of tropical cyclones in Central America accompanied with an increased frequency of intense cyclones, and an increase in mean wind speed and wind power potential in NES, NSA and SAM (medium confidence).

12.4.4.4 Snow and ice

Snow: Studies on seasonal snow cover are limited and restricted to the Andes Cordillera. Mernild et al. (2017) indicated that much of the area north of 23°S experienced a decrease in the number of snow cover days, while the southern half experienced the opposite. A reduction in snow cover of about 15% was simulated for areas in the range [3000-5000 m], whereas in regions with altitude below 1000 m (Patagonia) snow cover extent increased. The reduced snowfall over the Chilean and Argentinean Andes mountains, which has resulted in unprecedented reductions in river flow, reservoir volumes and groundwater levels, led to the most severe and long-lasting hydrological drought (2010-2015) reported in the adjacent semi-arid foothills of the central Andes (Garreaud et al., 2017; Rivera et al., 2017; Masiokas et al., 2020). Projections (based on process understanding) in Chapter 9 point to decreases in seasonal snow cover extent and duration across South America as global climate continues to warm (high confidence).

Glacier: Observation and future projection of Central and South America glacier mass changes are assessed in Section 9.5.1, grouped in two main regions: Low Latitude region (98% of which is glaciers in the Andes) and the Southern Andes region. An increase in the number and areal extent of glacial lakes in the Southern Andes was reported for the period 1986-2016 (Wilson et al., 2018). Similar changes are being observed in the central Andes (Colonia et al., 2017). Since 1800 at least 15 ice-dammed lakes and 16 moraine-dammed lakes have failed in the extratropical Andes, causing high-magnitude Glacial Lake Outburst Floods (Rojas et al., 2014; Cook et al., 2016; Wilson et al., 2018; Drenkhan et al., 2019). Partially due to glaciers shrinkage and lake growth, the frequency of outburst floods has increased in the last 30-40 years (Carey et al., 2012; Iribarren Anacona et al., 2015).

Glaciers across South America are expected to continue to lose mass and glacier area in the coming century (high confidence) (Section 9.5). In term of their mass, glaciers in the Low Latitude region are projected by GlacierMIP to lose 67 ± 42%, 86 ± 24% and 94 ± 13%, of their 2015 baseline by the end of the century under RCP2.6, RCP4.5 and RCP8.5 scenarios, respectively (Marzeion et al., 2020). Glaciers in the Southern Andes show decreasing mass loss rates for RCP2.6, and increasing rates for RCP8.5, which peak in the mid to late 21st century. Glaciers in the Southern Andes are projected to lose 26 ± 27%, 33 ± 26%, and 47 ± 26% of their mass in 2050 by the end of the century under RCP2.6, RCP4.5 and RCP8.5 scenarios, respectively. Details in (Section 9.5.1.3).

Permafrost: There is limited information on the ongoing changes and projections of permafrost conditions in the region. Based on model projections under the IPCC A1B scenario, permafrost areas in the Bolivian Andes will eventually be lost, but this could take years to decades or longer depending on permafrost thickness (Rangecroft et al., 2016). The central Andes will experience the highest disturbance to the thermal regime of the twenty-first century. As a consequence, in the Argentinian Andes up to 95% of rock glaciers in the southern Desert Andes and in the central Andes will rest in areas above 0 °C under the worst case
scenario of warming (the freezing level might move up more than twice as much as during the entire Holocene) (Drewes et al., 2018).

In conclusion, glacier volume loss and permafrost thawing will likely continue in the Andes Cordillera under all climate scenarios, causing important reductions in river flow and potentially high-magnitude Glacial Lake Outburst Floods.

12.4.4.5 Coastal and oceanic

Relative sea level: Around Central and South America, over 1900-2018, a new tide-gauge based reconstruction finds a regional-mean relative sea level (RSL) change of 2.07 [1.36 to 2.77] mm yr⁻¹ in the South Atlantic, 2.49 [1.89 to 3.06] mm yr⁻¹ in the subtropical North Atlantic and 1.20 [0.76 to 1.62] mm yr⁻¹ in the East Pacific (Frederikse et al., 2020), compared to a global mean sea level (GMSL) change of around 1.7 mm yr⁻¹ (Section 2.3.3.3; Table 9.5). For the period 1993-2018, these RSLR rates, based on satellite altimetry, increased to 3.45 [3.04 to 3.86] mm yr⁻¹, 4.04 [2.77 to 5.24] mm yr⁻¹ and 2.85 [0.70 to 4.06] mm yr⁻¹, respectively (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3; Table 9.5).

Relative sea-level rise is extremely likely to continue in the oceans around CSA. Regional-mean RSLR projections for the oceans around Central and South America range from 0.3 m–0.5 m under SSP1-RCP2.6 to 0.5 m–0.9 m under SSP5-RCP8.5 for 2081-2100 relative to 1995-2014 (median values), which is around the projected GMSL change (Section 9.6.3.3). These RSLR projections may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

Coastal flood: Present day 1:100 yr Extreme Total Water Level (ETWL) ranges from 0.5 to 2.5 m around most of Central and South America, except in SSA and SWS subregions where 1:100 yr ETWLs can be as large as 5 to 6 m (Vousdoukas et al., 2018). ETWL magnitude and occurrence frequency are expected to increase throughout the region (high confidence) (see Figure 12.4 p. and Figure SM 12.6). Across the region, the 5th – 95th percentile range of the 1:100 yr ETWL is projected increase (relative to 1980 – 2014) by 8 cm – 34 cm and by 10 cm – 43 cm by 2050 under RCP4.5 and RCP8.5; respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). By 2100, this range is projected to be 31 cm – 93 cm and 34 cm – 190 cm under RCP4.5 and RCP8.5, respectively (Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, under RCP4.5, the present day 1:100 yr ETWL is projected to have median return periods of 1:10 yrs – 1:50 yrs by 2050 and 1:1 yr by 2100 in SES, SSA and SWS. In other regions of Central and South America, the present day 1:100 yr ETWL is projected to occur once per year or more by both 2050 and 2100 under RCP4.5. The present day 1:50 yr ETWL is projected to occur around 3 times a year by 2100 with a SLR of 1 m (Vitousek et al., 2017).

Coastal erosion: According to satellite data, shoreline retreat rates of around 1 m yr⁻¹ have been observed along the sandy coasts of SCA, SES and SSA over the period 1984-2015, while shoreline progradation rates of around 0.25 m /yr has been observed in NWS and NSA. The sandy shorelines in NES and SWS have remained more or less stable over the same period (Luijendijk et al., 2018; Mentaschi et al., 2018). Using satellite observations, Mentaschi et al. (2018) report a coastal area loss of 250 km² over a 30-year period (1984-2015) along the Pacific coast of South America, and of 780 km² along the Atlantic coastlines.

Projections indicate that a majority of sandy coasts in the region will experience shoreline retreat throughout the 21st century (high confidence). Median shoreline change projections (CMIP5) for the mid-century period show that, relative to 2010, presented by Vousdoukas et al. (2020) show that sandy shorelines will retreat by between 30 m and 75 m in SCA, NES, SES and SSA under both RCP4.5 and RCP8.5, while the projected mid-century retreats are less than 30 m in NSA, NWS and SWS for both RCPs (Vousdoukas et al., 2020). Parts of the coastline in these latter three regions projected to prograde over the 21st century, if present ambient shoreline change trends continue (Vousdoukas et al., 2020). By 2100, median retreats of more than 100 m are projected in SCA, NES, SES and SSA under both RCPs, while retreats between 50 m – 100 m are projected for NSA, NWS, and SWS under both RCPs (Figure 12.8). Notably, the projected shoreline retreats
in SCA and SES approach 150 m by 2100 under RCP4.5 and 200 m under RCP8.5. The total length of sandy
coasts in Central and South America that is projected to retreat by more than a median of 100 m by 2100
under RCP4.5 and RCP8.5 is about 15,000 km and 12,000 km respectively, an increase of approximately
30%.

**Marine heatwave**: The mean sea surface temperature (SST) of the Atlantic Ocean and the Caribbean around
Central and South America increased from 0.25°C to 1°C over the period 1982-1998 (Oliver et al., 2018).
This mean ocean surface warming is connected to longer and more frequent marine heatwaves (MHW) in the
region (Oliver et al., 2018). Over the period 1982-2016, the coastlines experienced on average more than 1.0
MHW per year, with the Pacific coast of North Central America and the coast of SES (Atlantic) experiencing
an average 2.5-3.0 MHWs per year. The average duration was between 10 and 15 days, with the notable
exception of the Equatorial Pacific coastline, which experiences MHWs with >30 days average duration
related to ENSO conditions. In the Southwestern Atlantic shelf (32-38°S), more than half of the days with
MHWs have occurred since 2014, and the most intense event (1.7°C above previous maximum) took place
in the austral summer of 2017 (Manta et al., 2018). Changes over the 20th century, derived from MHW
proxies, show an increase in frequency between 0.5 and 2.0 MHW per decade in the South Atlantic, the
Caribbean and the Pacific coast of North Central America, an increase in intensity per event in the South
Atlantic, and a decrease along the Equatorial Pacific coastline. The total number of MHW days per year
increases around Central and South America, with the exception of the Equatorial Pacific coastline (Oliver et
al., 2018).

There is ***high confidence*** that MHWs will increase around Central and South America. Mean SST is
projected to increase by 1°C (2°C) by 2100, with a hotspot of about 2°C (4°C) along the coast of South East
South America and North West South America under RCP4.5 (RCP8.5). (See Interactive Atlas). More
frequent, MHWs are projected around the region for GWLs of 1.5 °C, 2 °C and 3.5 °C relative to the
modelled reference value for 1861-1880 (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both
show an increase in MHWs around Central and South America by 2081–2100, relative to 1985 – 2014 (Box
9.2, Figure 1).

**In summary**, relative sea-level rise is **extremely likely** to continue in the oceans around Central and
South America, contributing to increased coastal flooding in low-lying areas (**high confidence**) and
shoreline retreat along most sandy coasts (**high confidence**). Marine heatwaves are also expected to
increase around the region over the 21st century (**high confidence**).

The assessed direction of change in climatic impact-drivers for Central and South America and associated
confidence levels are illustrated in Table 12.6. No assortable literature could be found for sand and dust
storm, lake and sea ice, heavy snowfall and ice storms, hail, and snow avalanches, although these
phenomena may be relevant in parts of the region.

---

**Table 12.6**: Summary of confidence in direction of projected change in climatic impact-drivers in Central and South
America, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP3-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding
(for CID s that are independent of sea-level rise) to global warming levels between 2°C and 2.4°C (see 12.4
for more details of the assessment method). The table also includes the assessment of observed or projected
time-of-emergence of the CID change signal from the natural inter-annual variability if found with at least
**medium confidence** in Section 12.5.2.
1. Increase in extreme flow in the Amazon basin.
2. Tropical cyclones decrease in number but increase in intensity.
3. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.
4. Substantial parts of the NWS, NSA and NES coasts are projected to prograde if present-day ambient shoreline change rates continue.

- Already emerged in the historical period (medium to high confidence)
- Emerging by 2050 at least in Scenarios RCP8.5/SSP5-8.5 (medium to high confidence)
- Emerging after 2050 and by 2100 at least in Scenarios RCP8.5/SSP5-8.5 (medium to high confidence)

**[END TABLE 12.6 HERE]**

### 12.4.5 Europe

The regional European climate and main hazards have been previously assessed in SREX, AR5 (WGII), SR1.5, SROCC and SRCCL and a summary of key findings can be found in the Europe section of the Atlas 8.1. For the purpose of these assessment Europe is divided in four climatic regions North Europe (NEU), Western and Central Europe (WCE), Eastern Europe (EE) and Mediterranean (MED) (see Figure Atlas.27).

Since AR5 and SR1.5, a large body of literature that uses the EURO-CORDEX and MED-CORDEX ensembles of high-resolution simulations (Jacob et al., 2014; Ruti et al., 2016; Kjellström et al., 2018; Vautard et al., 2020; Coppola et al., 2021a) to assess signals of climate change in Europe has emerged. These scenario simulations have been the basis of a number of impact studies (see e.g., Jacob et al., 2014b, 2018; Somot et al., 2018; Faggian and Decimi, 2019) highlighting the use of the climatic impact-drivers. The development of the science of attribution of weather events (Stott et al., 2016) has provided evidence of links between climate change and hazard changes such as the 2017 Mediterranean heat wave (Kew et al., 2019) and many others (see Chapter 11).

The ability of global and regional models to reproduce the observed changes in mean and extreme temperature and precipitation in Europe is assessed in the literature (see Atlas 8.3). In summary, both GCMs and RCMs have their limitations but, in general, the increased resolution of RCMs is shown to clearly add valued in terms of resolving spatial patterns and seasonal cycles of precipitation and precipitation extremes in many European regions, especially in regions of complex topography such as the Alps and for quantities such as snowmelt driven runoff, regional winds and Mediterranean hurricanes (Medicanes).

Examples of projected hazard thresholds are illustrated in Figures 12.4 and 12.9 based on the most recently updated Euro-CORDEX RCM projections, CMIP5 and CMIP6 GCMs for comparison. For a more comprehensive representation of other hazard index trends assessed in this section the reader is referred to the interactive Atlas.
Figure 12.9: Projected changes in selected climatic impact-driver indices for Europe. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m³ s⁻¹ km⁻²), and (b) median change in the number of days with snow water equivalent (SWE) over 100 mm (from November to March), from EURO-CORDEX models for 2041-2060 relative to 1995-2014 and RCP8.5. Diagonal lines indicate where less than 80% of models agree on the sign of change. (c) Bar plots for Q100 (m³ s⁻¹ km⁻²) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) As for (c) but showing absolute values for number of days with SWE > 100mm, masked to grid cells with at least 14 such days in the recent past. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

12.4.5.1 Heat and Cold

Mean air temperature: Since AR5, studies have confirmed that the mean warming trend in Europe is increasing (Atlas 8.2). The observed warming trend patterns are largely consistent with those simulated by global and regional climate models and it is very likely that such trends are, in large part, due to human influence on climate (Chapter 3).

All temperature trends are very likely to continue for a global warming of 1.5°C or 2°C and 3°C (Atlas 8.4). Future warming leads to the exceedance of different temperature thresholds relevant for vector-borne diseases (medium confidence) (Caminade et al., 2012; Medlock et al., 2013), invasive allergens (medium confidence) (Storkey et al., 2014; Hamaoui-Laguel et al., 2015), SST thresholds in the Mediterranean (likely to exceed 20°C), or relevant for the vibrio bacteria development (Vezzulli et al., 2015). Future warming is also projected to lead to the exceedance of cooling degree-day index (>22°C) thresholds, characterizing a potential increase in energy demand for cooling in Southern Europe with increases likely exceeding 40% in some areas (Spinoni et al., 2015) by 2050 under RCP8.5 (high confidence) (Coppola et al., 2021a) (see also Atlas and Section 12.3).

Extreme heat: The frequency of heat waves observed in Europe has very likely increased in recent decades due to human-induced change in atmospheric composition (see Chapter 11) and a detectable anthropogenic increase in a summertime heat stress index over all regions of Europe has been identified based on wet bulb globe temperature (WBGT) index trends for 1973-2012 (medium confidence, limited evidence) (Knutson and Ploshay, 2016).

It is very likely that the frequency of heat waves will increase during the 21st century regardless of the emission scenario in each European region, and for 1.5°C and 2°C global warming levels (GWLs) (Chapter 11). Heat stress due to both high temperature and humidity, affecting morbidity, mortality and labor capacity (see Section 12.3) is projected to increase under all emission scenarios and GWLs by the middle of the century (Figure 12.4a-f). Under RCP8.5, the expected number of days with WBGT larger than 31°C of about 25, 30 and 40 days per year, projected by EURO-CORDEX, CMIP5 and CMIP6 respectively on average over the Mediterranean region, and specifically of 30, 40 and 60 days per year in low coastal plain areas such as the Po Valley, the Italian, Greek and Spanish coasts and the Mediterranean islands in (Coppola et al., 2021a). An average increase of a few days per year of maximum daily temperature exceeding 35°C, a typical critical threshold for crop productivity, is expected by the mid-century in Central Europe, and a further increase of 10-20 days is expected for the Mediterranean areas (see Figure 12.4b) (Coppola et al., 2021a). By
contrast, under SSP1-2.6, the increase in this number of days remain limited to less than about 10 days, and
confined to the Mediterranean regions. Mitigation is expected to have a strong effect: by the end of century,
and under SSP5-8.5, dangerous heat threshold of HI>41°C is projected to be crossed 5-10 days more per
year in the Mediterranean regions and a few days per year more in WCE and EEU while these increases
would virtually be absent under SSP1-2.6 (Figure 12.4d-f).

Cold spell and frost: Temperature observations for winter cold spells in Europe show a long-term
decreasing frequency (Brunner et al., 2018), with their probability of occurrence projected to decrease in the
future (high confidence) and virtually disappear by the end of the century (Chapter 11). The frequency of
frost days will very likely decrease for all scenario and all time horizons (Lindner et al., 2014; Coppola et al,
2021) with consequences on agriculture and forests. A simple heating degree-day index, characterizing
heating demand, shows a large observed decreasing trend for winter heating energy demand in Europe
(Spinoni et al., 2015). This trend is very likely to continue through the 21st century, with decreases in the
range of 20-30% for Northern Europe, about 20% for Central Europe and 35% for Southern Europe, by mid-
century under RCP8.5 (Spinoni et al., 2018b; Coppola et al., 2021a) (See also the interactive Atlas).

In summary, irrespective of the scenario, it is virtually certain that warming will continue in Europe,
and there is high confidence that the observed increase in heat extremes is due to human activities. It is
very likely that the frequency of heat extremes will increase over the 21st century with an increasing
gradient toward the Southern regions. Extreme heat will exceed critical thresholds for health,
agriculture and other sectors more frequently (high confidence), with strong differences between
mitigation scenarios. It is very likely that the frequency of cold spells and frost days will keep
decreasing over the course of this century and it is likely that cold spells will virtually disappear
towards the end of the century.

12.4.5.2 Wet and Dry

Mean precipitation: Precipitation has generally increased in Northern Europe and decreased in Southern
Europe, especially in winter (Fischer and Knutti, 2016; Knutson and Zeng, 2018) but in the latter
precipitation trends are strongly dependent on the examined period (Chapter 11). The trend in precipitation
increase in the north and decreasing in the south is also represented by global and regional climate
simulations (Jacob et al., 2014; Rajczak and Schär, 2017; Lionello and Scarascia, 2018; Coppola et al,
2021a) (see Atlas.8.2) and has been attributed to climate change (Chapter 3, Chapter 8).

Studies since AR5, together with EURO-CORDEX and MED-CORDEX experiments and the latest CMIP6
ensemble, have increased confidence in regional projections of mean and extreme precipitation (Prein et al,
2016) despite their wet bias, and show that it is very likely that precipitation will increase in Northern Europe
in DJF and decrease in the Mediterranean in JJA under all climate scenarios except RCP2.6/SSP1-2.6 and
for both mid and end century periods (Coppola et al., 2021a). (Atlas 8.5).

River flood: There is high confidence of an observed increasing trend of river floods in Central and Western
Europe (WCE) and medium confidence of a decrease in northern (NEU) and Southern Europe (MED).

SR1.5 shows evidence of an increase in reported floods in the UK over the period 1884-2013, and increasing
trends in annual maximum daily streamflow data over 1966–2005 in parts of Europe. Although, high flow
does not show uniform trends for the entire region (Hall et al., 2014; Mediero et al., 2015) or specific region
(Mudersbach et al., 2017; Tramblay et al., 2019; Vicente-Serrano et al., 2017), regional patterns of
significant flood trends do exist. Based on the most extended river flow database spanning the period 1960-
2010, an increase in floods frequency in northwestern Europe, decreasing in medium and large catchments
in southern Europe and decreasing floods in eastern Europe has been detected (Blöschl et al., 2019) in line
with (Mediero et al., 2014; Arheimer and Lindström, 2015; Gudmundsson et al., 2017; Krysanova et al.,
2017; Kundzewicz et al., 2018; Mangini et al., 2018)

There is high confidence of river floods increasing in Central and Western Europe (WCE) and medium
confidently of a decrease in northern (NEU) Eastern (EE) and Southern Europe (MED) for mid and end of century under RCP8.5 and low confidence under RCP2.6. The projected increase in WCE is roughly 10% (18% by end of century) and the projected decrease in NEU is of 5% (11% by end of century) for the peak flow with a return period of 100 years for mid-century, under RCP8.5 (Di Sante et al., 2021) (See Figure 12.9a for mid of century Q(100) projections of flood discharges per unit catchment area (Blöschl et al., 2019) based on EURO-CORDEX models).

Using frequency analysis of extreme peak flow events above a 100-year return period as a threshold, which is the average protection level of the European river network (Rojas et al., 2013), Alfieri et al. (2017) and Alfieri et al. (2015) show that Europe is likely to be one of the regions where the largest increases in flood risk may occur, with only few countries in Eastern Europe showing a decrease (Poland Lithuania, Belarus) (Osuch et al., 2017). They find a significant increase of events with peak discharge above 100-year return period (Q100) in most of Europe in line with (Rojas et al., 2012; Hirabayashi et al., 2013; Dankers et al., 2014; Forzieri et al., 2016; Roudier et al., 2016; Thober et al., 2018) and an increase in the magnitude of floods in southern Europe, although (Giuntoli et al., 2015) projects no change. A modest but significant decrease in the 100-year return period river flood is projected for Southern (due to reduction of precipitation) and north Eastern European regions the latter because of the strong reduction in snowmelt induced river floods (Thober et al., 2018; Di Sante et al., 2021).

Heavy precipitation and pluvial floods: Heavy precipitation frequency trends have been detected in Europe with high confidence for the NEU and Alpine regions and with medium confidence in WCE, and also attributed to climate change with high confidence in NEU (Section 11.9).

Projections based on multiple lines of evidence from global to convective permitting model scales show high confidence in extreme precipitation increase in the northern, central and eastern European regions (NEU, WCE, EEU and in the Alpine area. Increases with medium confidence are projected for the Mediterranean basin (with a negative gradient toward the south) for mid and end of century under RCP8.5, RCP4.5, and SSP5-8.5 (Section 11.9) (MedECC, 2020). Guerreiro et al. (2017), based on observations, showed that 20% of city areas in WCE and MED regions is affected by pluvial flooding, and less than 10% of city areas in the Northern and Western coastal cities.

Landslide: Increase of rainfall periods connected to landslides are projected to increase in central Europe by up to 1 more period per year in flat areas in low altitudes and by up to 14 more periods per year at higher altitudes by mid-century, becoming even more evident by end of the century (Schlögl and Matulla, 2018). An increase of landslides by up to +45.7% and +21.2% is also projected for Southern Italy (Calabria region) by mid of century under both RCP4.5 and RCP8.5 (Garani and Guzzetti, 2016) and by up to 40% in Central Italy (Umbria) during the winter season (Ciabatta et al., 2016). A decrease of landslides is projected in the Peloritani Mountains in Southern Italy (RCP4.5 and 8.5) by mid of the century (Peres and Cancelliere, 2018). A slight increase (10 year return period) in landslides is projected in the Eastern Carpathians, the Moldavian Subcarpathian and the northern part of the Moldavian Tableland and higher increase in the western hilly and plateau areas of Romania (100 year return period) (Jurchescu et al., 2017).

Aridity: The Mediterranean region shows evidence of large-scale decreasing precipitation trends over 1901-2010, which are at least partly attributable to anthropogenic forcing according to CMIP5 models (Knutson and Zeng, 2018). Nevertheless, there is low agreement among studies on observed precipitation trend in the Mediterranean region. (Chapter 11; Atlas 8.2).

The precipitation is projected to decrease by mid end of century for the RCP8.5 and SSP5-85 with strong agreement among CMIP5, CMIP6 and CORDEX regional climate ensemble models on the direction of change. With both temperature increase and precipitation decrease there is high confidence on increase aridity in the MED region. (Coppola et al., 2021 Atlas.8.2; Chapter 4; Chapter 8).

Hydrological drought: There is high confidence that hydrological droughts have increased in the Mediterranean basin with medium confidence in anthropogenic attribution of the signal, and high confidence that they will continue to increase through the 21st century for 2°C GWL and higher and all scenarios.
Streamflow droughts are projected become more severe and persistent in Mediterranean and Western Europe (current 100-year events could occur approximately every 2 to 5 years by 2080) (Forzieri et al., 2016).

The opposite tendency is projected in Northern, Eastern, and Central Europe where higher precipitation that outweigh the effects of increased evapotranspiration is expected to result in a decrease in streamflow drought frequency (Forzieri et al. 2014). For a 2°C GWL droughts will become more intense in the MED and in France and longer mainly due to less rainfall and higher evapotranspiration. A reduction of drought length and magnitude is projected for NEU and EEU (Roudier et al., 2016). In the Southern Alps, both winter and summer low flows are projected to be more severe, with a 25% decrease in the 2050s (Vidal et al., 2016).

Agricultural and ecological drought: There is medium confidence that agricultural and ecological droughts have increased in Western and Central Europe and in the Mediterranean region, and medium confidence that anthropogenic drivers contributed to the Mediterranean increase (Section 11.9. Chapter 8).

Chapter 11 assesses that agricultural and ecological droughts will increase in the Mediterranean regions (high confidence) and Western and Central Europe (medium confidence) by mid-century with high confidence by the end of the century for the MED for 2°C GWL and higher and all scenarios. Low confidence in direction of change is assessed for EEU and NEU (see Figure 12.4k).

Recent local studies provide additional risk-relevant context to changes in European drought. Agricultural and ecological drought conditions are expected to intensify in Southern Europe by end-of-century based on the 12-month rainfall Drought Severity Index (a soil moisture indicator), precipitation deficit SPI and SPEI indices. There will be regions in Southern Europe where this type of drought could be up to 14 times worse than the worst drought in the historical period (Guerreiro et al., 2018). One-in-10 year drought events are projected to happen every second year (Mora et al., 2018; Ruosteenoja et al., 2018). The Mediterranean region will have 100 additional stress years (years with three consecutive months of precipitation deficits greater than 25%) (Giorgi et al., 2018), an increase of both drought frequency (up to 2 events per decade) and severity (Spinoni et al., 2014, 2019a) and an increase of consecutive dry day (CDD) in the southern part of the MED region (Lionello and Scarascia, 2020). In contrast, droughts are expected to decrease in winter in Northern Europe (Spinoni et al., 2018a; Section 11.9). These findings are confirmed by the EURO-CORDEX, CMIP5 and CMIP6 ensemble that show a change of frequency of drought events in the MED between 2 and 3 events per decade for mid of the century RCP8.5 scenario (Coppola et al., 2021a) (see also Figure SM 1.3)

Fire weather: Fire weather conditions have been increasing since about 1980 over a few regions in Europe including Mediterranean areas (low confidence) (Venäläinen et al., 2014; Urbiet a et al., 2019; Barbero et al., 2020; Giannaros et al., 2021). However beyond a few studies, evidence is largely missing about attribution of these trends to anthropogenic climate change (Forzieri et al., 2016). An increase in fire weather is projected for most of Europe, especially Western, Eastern and Central regions, by 2080 (current 100-yr. events will occur every 5 to 50 years), with a progressive increase in confidence and model agreement along the 21st century (medium confidence) (Forzieri et al., 2016; Abatzoglou et al., 2019). With increased drying and heat combined, in Mediterranean areas, an increase in fire weather indices is projected under RCP4.5 and RCP8.5, or SRES A1B, as early as by the mid century (Bedia et al., 2014; Abatzoglou et al., 2019; Dupuy et al., 2020; Fargeon et al., 2020; Ruffault et al., 2020) (high confidence) and an increase in burned area of 40% and 100% for a 2°C and 3°C respectively (Turco et al., 2018).

In summary, there is high confidence that river floods will increase in Central and Western Europe and medium confidence that they will decrease in Northern, Eastern and Southern Europe, for mid and end of century under RCP8.5 and with low confidence under RCP2.6. There is high confidence that aridity will increase by mid and end of century for the RCP8.5 and SSP5-85, and high confidence that agricultural, ecological and hydrological droughts will increase in the Mediterranean region by mid and far end of century under all RCPs except RCP2.6/SSP1-2.6 and also for 2°C and higher.
GWLs. There is high confidence in fire weather increase in the Mediterranean region.

12.4.5.3 Wind

Mean wind speed: Mean surface wind speeds have decreased in Europe as in many other areas of the Northern Hemisphere over the past four decades (AR5, WGI) (medium confidence), with a reversal to an increasing trend in the last decade (low confidence) that is however not fully consistent across studies (Tian et al., 2019; Zeng et al., 2019; Zhang et al., 2019d; Deng et al., 2021) (Chapter 2). Reanalyses also show declining winds in Europe (Deng et al., 2021) with large interdecadal variability (Laurila et al., 2020). The declining trend has induced a corresponding decline in wind power potential indices across Europe (low confidence) (Tian et al., 2019). However, there is low agreement and low evidence that climate model historical trends are consistent with observed trends (Tian et al., 2019; Deng et al., 2021). Several factors have been attributed to these trends, including forest growth, urbanization, local changes in wind measurement exposure and aerosols (Bichet et al., 2012), as well as natural variability (Zeng et al., 2019).

Due to changes in mean surface wind speed patterns (Li et al., 2018a) and the poleward shift of the North Atlantic jet stream exit, mean surface wind speeds are projected to decrease in the Mediterranean areas under RCP4.5 and RCP8.5 by the middle of the century and beyond, or for global warming levels of 2 degrees and higher (high confidence), with a subsequent decrease in wind power potential (medium confidence) (Hueting et al., 2013; Tobin et al., 2015, 2018; Davy et al., 2018; Karnauskas et al., 2018a; Björk et al., 2018; Moemken et al., 2018) (see also Fig. 12.4). However, subregional patterns of change are present from regional climate models such as an increase in wind speeds in the Aegean Sea and in the northern Adriatic Sea where a reduction of Bora events and an increase of Scirocco events are projected for mid-century and beyond under RCP4.5 and RCP8.5 (medium confidence) (Tobin et al., 2016; Davy et al., 2018; Belušić Vozila et al., 2019). Projections (as cited above) also indicate a decrease in mean wind speed in Northern Europe (medium confidence, medium agreement) (Karnauskas et al., 2018a; Tobin et al., 2018; Jung and Schindler, 2019). Daily and interannual wind variability is projected to increase under RCP8.5 (only) Northern Europe (Moemken et al., 2018) (low confidence), which can influence electrical grid management and wind energy production (low confidence). Wind speeds are projected to shift towards more frequent occurrences below thresholds inhibiting wind power production (Weber et al., 2018). Wind stagnation events may become more frequent in future climate scenarios in some areas of Europe in the second half of the 21st century (Horton et al., 2014; Vautard et al., 2018), with potential consequences on air quality (low confidence).

Severe wind storm: There are large uncertainties in past evolutions of windstorms and extreme winds in Europe. Extreme near-surface winds have been decreasing in the past decades (Smits et al., 2005; Tian et al., 2019; Vautard et al., 2019) according to near-surface observations. Significant negative trends of cyclone frequency in spring and positive trends in summer have been found in the Mediterranean basin for the period 1979-2008 (Lionello et al., 2016). By contrast increasing trends have been found in Arctic ocean areas (Wickström et al., 2020). These trends are not associated with significant trends in extratropical cyclones (Chapter 2), and are consistent with the mean wind decreasing trends.

There is medium confidence that serial clustering of storms, inducing cumulated economic losses, in future climate will increase in many areas in Europe under climate projections over Europe (Karrenmann et al., 2014; Economou et al., 2015). Strong winds and extra-tropical storms are projected to have a slightly increasing frequency and amplitude in the future in Northern, Western and central Europe (Outten and Esau, 2013; Feser et al., 2015; Forzieri et al., 2016; Möltjer et al., 2016; Ruosteenoja et al., 2019b; Vautard et al., 2019) in RCP8.5 and SRES A1B by the end of the century (medium confidence), as well as off the European coasts (Martinez-Alvarado et al., 2018) due to the increase of intensity of extratropical storms at a 2°C global warming level or above (Zappa et al., 2013) in these areas. The frequency of storms, including Medicanes, is projected to decrease in Mediterranean regions, and their intensities are projected to increase, by the middle of the century and beyond for SRES A1B, A2 and RCP8.5 (medium confidence) (Nissen et al., 2014; Feser et al., 2015; Forzieri et al., 2016; Möltjer et al., 2016; Tous et al., 2016; Romera et al., 2017; González-Alemán et al., 2019) (MedECC, 2020) (Chapter 11).

Do Not Cite, Quote or Distribute
Projections of smaller-scale hazard phenomena such as tornadoes, wind gusts, hailstorms, and lightning are currently not directly available partly due to the inability of climate models to simulate such phenomena. Observational networks for such phenomena usually lack homogeneity over long climate periods, hindering clear trends to be detected. For instance, while no robust trends have been identified (Hermida et al., 2015; Mohr et al., 2015a; Burcea et al., 2016; Ćurić and Janc, 2016), hailstorm environments (favourable atmospheric configurations) have increased in frequency (Sanchez et al., 2017) (low confidence, low evidence). In future climate periods it is more likely than not that severe convection environments will become more frequent by the end of the century under scenario RCP8.5 (Mohr et al., 2015b; Püčík et al., 2017), and there is medium confidence that such environments become more frequent by the 2050s in scenario RCP4.5. There is no evidence for changes in tornado frequencies in Europe in the observations (Gronemeyer and Kühne, 2014) as well as in future climate projections. Insufficient observational record length for lightning numbers does not allow an assessment of trends.

There is high confidence that mean wind speeds will decrease in Mediterranean areas and medium confidence of such decreases in Northern Europe for global warming levels of 2°C or more and beyond the middle of the century. A slightly increased frequency and amplitude of extratropical cyclones, strong winds and extra-tropical storms is projected for Northern, Central and Western Europe by the middle of the century and beyond and for global warming levels of 2°C or more (medium confidence). The frequency of Medicanes is projected to decrease (medium confidence), but their intensity is projected to increase. Proxies of intense convection indicate that the large-scale conditions conducive to severe convection will tend to increase in the future climate (low confidence).

12.4.5.4 Snow and ice

Snow: Widespread and accelerated declines of snow depth are currently observed in Europe (Fontrodona Bach et al., 2018) and snow water equivalent (Marty et al., 2017b) (see also Figures 12.9b) for a typical range of altitudes of higher settlement elevation and ski resorts. In the Pyrenees a slow snow cover decline has been observed starting from the industrial period with a sharp increase since 1955 (López- Moreno et al., 2020). Under the RCP2.6, RCP4.5 and RCP8.5 scenario the reliability elevation using snowmaking will rise of 200-300 m in the Alps and 400-600 in the Pyrenees by mid-century. By end of century projections are highly dependent from the scenario being stationary for the RCP2.6 and continuously decreasing under the RCP8.5 up to not have anymore natural snow conditions for any of the locations in the French Alps and Pyrenees (Spandre et al., 2019). Similarly also Norway and Austria will see a rising of the natural snow elevation with consequences for the ski season (Scott et al., 2020; Steiger and Scott, 2020). In the Alps, recent simulations project a reduction in Snow Water Equivalent (SWE) at 1500 m a.s.l. of 80–90% by 2100 under the A1B scenario and a snow season that would start 2-4 weeks later and end 5-10 weeks earlier than in the 1992-2012 average (Schmucki et al., 2015), which is equivalent to a shift in elevation of about 700 m (Marty et al., 2017a). For elevations above 3000 m a.s.l., a decline in SWE of at least 10% is expected by the end of the century even when assuming the largest projected precipitation increase. Similar trends are observed for the Pyrenees and Scandinavia (López-Moreno et al., 2009; Räisänen and Eklund, 2012). For the Northern French Alps above 1500 m and the Ötztal locations in the Austrian Alps SWE has a similar decreasing trend altitudinal dependent for all 3 scenarios (RCP2.6, RCP4.5 and RCP8.5) until mid of century and with significant differentiation among them in the second half of the century up to free snow condition for the RCP8.5 scenario (Hanzer et al., 2018; Verfaillie et al., 2018).

Glacier: Observation and future projections of European glacier mass changes are assessed in Section 9.5.1 grouped in two main regions: Scandinavia and Central Europe regions. It is virtually certain that glaciers will shrink in the future and there is medium confidence in the timing and mass change rates (Chapter 9). Central Europe is one of the regions where glaciers are projected to lose substantial mass even under low-emission scenarios (Section 9.5.1.3) (MedECC, 2020). GlacierMIP projections indicate that glaciers in the Central Europe region lose 63 ± 31%, 80 ± 22% and 93 ± 13% of their 2015 mass by the end of the century for RCP2.6, RCP4.5 and RCP8.5, respectively (Marzeion et al., 2020). In those same scenarios, glaciers in Scandinavia are projected to lose 55 ± 33%, 66 ± 34% and 82 ± 24% of their 2015 mass. The virtually certain shrink in glaciers is bolstered by RCM simulations from the EURO-CORDEX ensemble, with the
Global Glacier Evolution Model (GloGEM) indicating a substantial reduction of glacier ice volumes in the European Alps by 2050 (47–52% with respect to 2017 for RCP2.6, 4.5 and 8.5). Under RCP2.6, about two-thirds (63 ± 11%) of the present-day (2017) ice volume is projected to be lost by 2100. In contrast, under the strong warming of RCP8.5, glaciers in the European Alps are projected to largely disappear by 2100 (94 ± 4% volume loss compared to 2017; Zekollari et al., 2019).

**Permafrost:** In Europe, permafrost is found in high mountains and in Scandinavia, as well as in Arctic Islands (e.g., Iceland, Novaya Zemlia or Svalbard). In recent decade permafrost has been lost (Chapter 9) and accelerated warming at high altitudes and latitudes has favored an increase of permafrost temperatures in the order of 0.2 ± 0.1°C between 2007 and 2016 (Romanovsky et al., 2018; Noetzli et al., 2019). Over the 21st century, permafrost is very likely to undergo increasing thaw and degradation (Hock et al., 2019) and it is virtually certain that permafrost extent and volume with decrease with increase of global warming (Chapter 9).

Permafrost thawing is projected to affect the frequency and magnitude of high-mountain mass wasting processes (Stoffel and Huggel, 2012). The temporal frequency of periglacial debris flows in the Alps is unlikely to change significantly by the mid-21st century but is likely to decrease during the second part of the century, especially in summer (Stoffel et al., 2011, 2014; Lane et al., 2017). There is medium confidence that most of the Northern Europe periglacial processes will disappear by the end of the century, even in the RCP2.6 scenario (Aalto et al., 2017). The magnitude of debris flow events might increase (Lugon and Stoffel, 2010) (low confidence) and the debris-flow season may last longer in a warming climate (Stoffel and Corona, 2018) (medium confidence). Quantitative data for the European Alps is highly site dependent (Haebler, 2013).

**Heavy Snowfall, ice storms and hail:** There is low confidence that climate change will affect ice and snow episodic hazards (limited evidence). The change in snowpack in the Alps is expected to lead to a possible reduction in overall avalanche activity (low confidence), except possibly in winter and at high altitudes (Castebrunet et al., 2014).

For ice storms, or freezing rainstorms, there is also limited evidence due to a limited number of studies. Heavy snowfalls have decreased in frequency in the past decades and this is expected to continue in the future climate (Beniston et al., 2018) (low confidence). Freezing rain is projected to increase in western, central and southern Europe (Kääräinen et al., 2018) (low confidence). Rain-on-snow events, are decreasing in northern regions (Fall et al., 2019) and by 48% on average in southern Scandinavia (Poschlod et al., 2020) due to decreases in snowfall.

In summary, in the future snow cover extent and seasonal duration will reduce (high confidence) and it is virtually certain that glaciers will continue to shrink. A reduction of glacier ice volume is projected in the European Alps and Scandinavia (high confidence). There is high confidence that permafrost will undergo increasing thaw and degradation over the 21st century. Most of the Northern Europe periglacial will disappear by the end of the century even for a lower emissions scenario (medium confidence) and the debris-flow season may last longer in a warming climate (medium confidence).

12.4.5.5 Coastal and Oceanic

**Relative sea level:** Around Europe, over 1900-2018, a new tide-gauge based reconstruction finds a regional-mean RSL change of 1.08 [0.79 to 1.38] mm yr⁻¹ in the subpolar North Atlantic (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3; Table 9.5). For the period 1993-2018, the RSLR rates, based on satellite altimetry, increased to 2.17 [1.66 to 2.66] mm yr⁻¹ (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3; Table 9.5).

Relative sea level rise is extremely likely to continue in the oceans around Europe. Regional-mean RSLR projections for the oceans around Europe range from 0.4 m–0.5 m under SSP1-RCP2.6 to 0.7 m–0.8 m under SSP5-RCP8.5 for 2081-2100 relative to 1995-2014 (median values), which means that there are locally large

Do Not Cite, Quote or Distribute 12-73 Total pages: 227
deviations from the projected GMSL change {Section 9.6.3.3}. These RSLR projections may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2). The signal is strongest for the North Sea and Atlantic coasts, followed by the Black Sea. The Baltic Sea on the contrary shows the lowest increase due to land uplift (Vousdoukas et al., 2017). The model agreement is higher for the Mediterranean and in line with the previous findings by Gualdi et al. (2013).

Coastal flood: The present day 1:100 yr ETWL is between 0.5-1.5m in the MED basin and 2.5-5.0 m in the western Atlantic European coasts, around the UK and along the North Sea coast, and lower at 1.5-2.5m along the Baltic Sea coast. (Kirezci et al 2020). Similar values are reported by Vousdoukas et al., (2018).

There is high confidence that extreme total water level (ETWL) magnitude and occurrence frequency will increase throughout Europe (see Figure 12.4p-r), except in the northern Baltic Sea. Across the region, the 5th–95th percentile range of the 1:100 yr ETWL is projected to increase (relative to 1980–2014) by 4 cm – 40 cm and by 6 cm – 47 cm by 2050 under RCP4.5 and RCP8.5, respectively. By 2100, this range is projected to be 6 cm – 88 cm and 25 cm – 186 cm under RCP4.5 and RCP8.5, respectively (Vousdoukas et al., 2018; Kirezci et al., 2020) (see Figure SM 12.6). Mass addition across the Gibraltar Strait may play a role even if this is quite unclear to which extent (Lionello et al., 2017). Furthermore, under RCP4.5, the present day 1:100 yr ETWL is projected to have median return periods of between 1:5 and 1:20 yrs by 2050 and occur once per year or more by 2100 in the Mediterranean and Black Sea, while in the rest of Europe it is mostly projected to have median return periods of between 1:20 yrs and 1:50 yrs by 2050 and between 1:5 yrs and 1:20 yrs by 2100 (Vousdoukas et al., 2018). Under RCP8.5, occurrence of the present day 1:100 yr ETWL is projected to increase further to median return periods of 1:1 yr to 1:5 yrs by 2050 and occur more than once per year by 2100 in the Mediterranean and Black Sea, while in the rest of Europe it is mostly projected to have median return periods between 1:5 yrs and more than once per year by 2100.

Coastal erosion: Satellite derived shoreline change estimates over 1984 – 2015 indicate shoreline retreat rates of around 0.5 m yr⁻¹ along the sandy coasts of CEU and MED, around 4 m yr⁻¹ in EEU (Caspian Sea region) and more or less stable shorelines in NEU (Luijendijk et al., 2018; Mentaschi et al., 2018). Mentaschi et al. (2018) report a coastal area loss of 270 km² over a 30 year period (1984-2015) along the Atlantic coastlines of Europe.

Projections indicate that sandy coasts throughout the continent (except those bordering the northern Baltic Sea) will experience shoreline retreat through the 21st century (high confidence). Median shoreline change projections (CMIP5) relative to 2010, show that, by mid-century, shorelines will retreat by between 25 m and 60 m along sandy coasts in CEU and MED under both RCP4.5 and RCP8.5 (Vousdoukas et al., 2020; Athanasiou et al., 2020). Mid-century median projections for NEU indicate virtually no shoreline retreat under RCP4.5, but a retreat of around 40 m under RCP8.5. By 2100, median shoreline retreats of around 50 m are projected in NEU and MED under RCP4.5, increasing to around 80 m under RCP8.5. End century median projections for CEU are far higher at 100 m (RCP4.5) and 160 m (RCP8.5). The total length of sandy coasts in Europe that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 12,000 km and 18,000 km respectively, an increase of approximately 54% (Vousdoukas et al., 2020)

Local assessments of both long term shoreline retreat and episodic coastal erosion are given by (Li et al., 2013a; Toimil et al., 2017; Bon de Sousa et al., 2018; Le Cozannet et al., 2019). In terms of episodic coastal erosion, 31%–88% of all Aegean beaches are projected to experience complete erosion, with a RCP4.5 sea level rise of 0.5 m and a surge of 0.6 m, but with substantial uncertainty (Monioudi et al., 2017).

Marine heatwave: The mean SST of the Atlantic Ocean and the Mediterranean has increased between 0.25°C and 1°C since 1982-1998. This mean ocean surface warming is correlated to longer and more frequent marine heatwaves in the region (Oliver et al., 2018). Over the period 1982-2016, the coastlines of Europe experienced on average more than 2.0 MHW per year, with the eastern Mediterranean and Scandinavia experiencing 2.5–3 MHWs per year. The average duration was between 10 and 15 days. Changes over the 20th century, derived from MHW proxies, show an increase in frequency of between 1.0 and 2.0 MHWs per decade in Europe, although the trend is not statistically significant; with an increase in
intensity per event in the North Atlantic and the Mediterranean, and a decrease in the Atlantic off the British Isles. The total number of MHW days per decade has increased in the Mediterranean (Oliver et al., 2018).

Mean SST is projected to increase by 1 °C to 3°C around Europe by 2100, with a hotspot of around 4 °C to 5 °C along the Arctic coastline of Europe under RCP4.5 and RCP8.5 scenarios (see Interactive Atlas), leading to a continued increase in MHW frequency, magnitude and duration (Oliver et al., 2018; MedECC, 2020). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around Europe by 2081 – 2100, relative to 1985 – 2014 (Box 9.2, Figure 1). Darmaraki et al. (2019) project that, by the end of the 21st century and under RCP8.5, there will be one MHW occurring every year in the Northern Mediterranean sea, and that these MHWs would be 3 months longer, 4 times more intense, and 42 times more severe than present day MHWs in the region. Frölicher et al. (2018) show that, in Europe, the change in the probability for the number of days of MHWs exceeding the 99th percentile of the pre-industrial level is 4%, 15% and 30% for global warming levels of 1°C, 2°C and 3.5°C, respectively. MHW increase in the Mediterranean will impact on many species that live in shallow waters and have reduced motility, with consequences for the related economic activities (Galli et al., 2017).

In general, there is high confidence that most coastal/ocean related climatic impact-drivers in Europe will increase over the 21st century for all scenarios and time horizons. Relative sea level rise is extremely likely to continue around Europe (except in the northern Baltic Sea), contributing to increased coastal flooding in low-lying areas and shoreline retreat along most sandy coasts (high confidence). Marine Heatwaves are also expected to increase around the region over the 21st century (high confidence).

12.4.5.6 Other events

Compound events. One typical compound event that is observed in the European area is compound flooding due to the combination of extreme sea level events and extreme precipitation events associated with high level of runoff. In the present climate, the Mediterranean coasts are exposed to a higher probability of this type of compound flooding events (Bevacqua et al., 2019). Under RCP8.5, the probability of these events are projected to increase along northern European coasts (west coast of UK, northern France, the east and south coast of the North Sea, and the eastern half of the Black Sea) with the percentage of coastline currently experiencing such events with a return period lower than 6 years will increasing from 3% to 11% by the end of the 21st century (Bevacqua et al., 2019).

Under RCP8.5, regions in Russia, France and Germany are projected to experience an increase in the frequency and the length of wet and cold compound events, while Spain and Bulgaria are projected to stay longer in the hot and dry state by mid-century (Sedlmeier et al., 2016).

Compound events of dry and hot summers have increased in Europe. (Manning et al., 2019) found that the probability of such compound events has increased across much of Europe between 1950–1979 and 1984–2013, notably in southern, eastern and western Europe. Compound hot and dry extremes are projected to increase in Europe by mid-century for the SRES A1B and RCP8.5 but a particularly strong signal is projected in southern and eastern Germany and the Czech Republic (Sedlmeier et al., 2016).

The assessed direction of change in climatic impact-drivers for Europe and associated confidence levels are illustrated in Table 12.7, together with emergence time information (see Section 12.5.2). No assessable literature could be found for Sand and dust storms, although these phenomena may be relevant in parts of the region.
### Table 12.7: Summary of confidence in direction of projected change in climatic impact-drivers in Europe, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP3-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea-level rise) to global warming levels between 2°C and 2.4°C (see 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural inter-annual variability if found with at least medium confidence in Section 12.5.2.

1. Excluding southern UK.
2. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat.
3. The Baltic sea shoreline is projected prograde if present-day ambient shoreline change rates continue.
4. For the Alps landslide risk is likely to increase.
5. Low confidence of decrease in the southernmost part of the region.
7. Medium confidence of decrease in frequency and increase in intensities.
8. Except in the Northern Baltic Sea region.

- Already emerged in the historical period (medium to high confidence)
- Emerging by 2050 at least in Scenarios RCP8.5/SSP5-8.5 (medium to high confidence)
- Emerging after 2050 and by 2100 at least in Scenarios RCP8.5/SSP5-8.5 (medium to high confidence)

### 12.4.6 North America

Major changes in North American CIDs were assessed in WGII AR5 Chapter 26 (Romero-Lankao et al., 2014), with additional detail on connections to warming levels provided by SR1.5 (IPCC, 2018), and climate information related to land degradation and land use suitability in SRCCl (IPCC, 2019c), and ocean and coastal hazards in the SROCC (IPCC, 2019b). Recent national assessments in the United States (USGCRP, 2017, 2018) and Canada (Bush and Lemmen, 2019) enhance the local perspective and assessments across a number of CIDs and their sectoral connections. For the purpose of this assessment, North America is subdivided into six sub-regions as defined in Chapter 1: Central North America (CNA), Western North America (WNA), Central North America (CAN), Eastern North America (ENA), Northeast North America (NEN), and Northwest North America (NWN). Greenland and Arctic regions of Northeast and Northwest North America are further assessed in 12.4.9, and the Caribbean and Hawaiian Islands are assessed in 12.4.7.

### Figure 12.10: Projected changes in selected climatic impact-driver indices for North America.

(a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m³ s⁻¹ km⁻²), and (b) median change in the...
number of days with snow water equivalent (SWE) over 100 mm (from November to March), from
CORDEX-North America models for 2041-2060 relative to 1995-2014 and RCP8.5. Diagonal lines
indicate where less than 80% of models agree on the sign of change. (c) Bar plots for Q100 (m$^3$s$^{-1}$km$^{-2}$)
averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column
within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute
values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes
relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for
three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C
(yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model
ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by
medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) As
for (c) but showing absolute values for number of days with SWE > 100mm, masked to grid cells with at
least 14 such days in the recent-past. See Technical Annex VI for details of indices. A Caribbean Q100
bar plot is included here but assessed in the Small islands section (12.4.7). Further details on data sources
and processing are available in the chapter data table (Table 12.SM.1).

[END FIGURE 12.10 HERE]

12.4.6.1 Heat and cold

Mean air temperature: Section Atlas.9.2 assessed very likely mean warming in observations across North
America with highest increases at higher latitudes and in the winter season. Section Atlas.9.4 assessed very
likely mean warming in future decades in all North American regions, with CMIP and CORDEX models
showing median increases exceeding 2°C in much of the continental interior under RCP8.5 (2041-2060
compared to 1995-2014) and higher increases toward the north. Mean temperatures at the end of century
show strong scenario dependence, rising between 1°C and 2.5°C in RCP2.6 and about 4 to 8°C in RCP8.5
(Figures Atlas.15, Atlas.32, Atlas.33). Warming also raises stream temperatures across the continent (DOE,
2015; Trtanj et al., 2016; van Vliet et al., 2016; Chapra et al., 2017), and Hill et al. (2014) projected US
stream warming by 0.6°C (+0.3°C) per 1°C increase in local air temperature. Mean warming drives shifts in
the seasonal timing of temperature thresholds, including increasing growing degree-days (Mu et al., 2017),
longer growing seasons (Gowda et al., 2018; Li et al., 2018b; Vincent et al., 2018c), reduced chill hours
(Luedeling, 2012; Lee and Sumner, 2015; Xie et al., 2015; Parker and Abatzoglou, 2019), and longer pollen
and allergy seasons (Fann et al., 2016; Anenberg et al., 2017; Sapkota et al., 2019). Warmer temperatures
will very likely reduce heating degree days and increase cooling degree days (Bartos et al., 2016; US EPA,
2016; Craig et al., 2018; Zhang et al., 2019c; Coppola et al., 2021b).

Extreme heat: Section 11.9 assessed that extreme temperatures in North America have increased in recent
decades (medium evidence, medium agreement) other than Central and Eastern North America (low
confidence), and extreme heat in all regions is projected to increase with climate change (high confidence).
Observed trends in extreme heat are more positive for heat extreme indices that include temperature and
humidity given historical expansion of irrigation and intensification of agriculture (Mueller et al., 2017;
Grotjahn and Huyhn, 2018; Thiery et al., 2020). Several studies noted statistically significant increases in
intensity and particularly the frequency, duration, and seasonal length of the physiologically-hazardous
extreme heat conditions across North American (Grineski et al., 2015; Habeeb et al., 2015; Martinez-Austria
et al., 2016; Pettitt et al., 2016; Vincent et al., 2018c; Garcia-Cueto et al., 2019).

Figure 12.4b shows over a month of additional days at CMIP6 SSP5-8.5 mid-century where temperatures
exceed 85°C across much of southern Mexico and regions near the US-Mexico border and these extreme
temperatures occur at least once per year up to southern Canada. (Coppola et al., 2021b) found similar
patterns in CMIP5 and CORDEX-Core. Using locally-tailored heat thresholds, Maxwell et al. (2018) found
that “very hot” days in 5 US cities will occur a median of 3 to 5 times more often by RCP8.5 2036-2065 (2
to 3.5x in RCP4.5), Oleson et al. (2018) projected that annual heatwave duration will exceed one month in
Houston in RCP8.5 2061-2080, and Anderson et al. (2018) projected 7 to 12 times more exceedances of
thresholds associated with high-mortality in RCP8.5 2061-2080 (6 to 7x in RCP4.5). (Schwingshackl et al.,
2021) found that Central and North Eastern North America are among the regions with the strongest trend in heat
stress indicators. Studies also project increasingly surpassed heat extreme thresholds for North American
crops (Gourdji et al., 2013), airplane weight restrictions (Coffel et al., 2017), and peak load energy systems
(Auffhammer et al., 2017).

The number of days crossing dangerous heat thresholds such as HI>41°C will be very sensitive to the
mitigation scenario at the end of century (Wuebbles et al., 2014; Zhao et al., 2015; Dahl et al., 2019;
Schwingshackl et al., 2021). At the end of the century under SSP5-8.5, a CMIP6 median increase of
exceedances of 75-150 days per year is projected over much of North Central America, Central North
America and the U.S. Southwest while this increase is projected to remain limited below 60 days under
SSP1-2.6 (Figure 12.4d,f and Figure SM 1.2). Steinberg et al. (2018) also projected more frequent and longer
‘heat-health’ events in California extending into October.

**Cold spell:** Chapter 11 assessed high confidence in decreasing frequency and intensity of cold spells over
North America (Section 11.9). The number of days with extreme wind chill hours (humidex < -30) decreased
at 76% of examined Canadian stations from 1953-2012 (Mekis et al., 2015) and cold days and coldest nights
decreased in Mexico from 1980-2010 (Garcia-Cueto et al., 2019).

Cold spells are projected to decrease over North America under climate change, with the largest decreases
most common in the winter season (high confidence) (Section 11.9). Minimum winter temperatures are
projected to rise faster than the mean wintertime temperature (Underwood et al., 2017) and alter cold
hardiness zones used to determine agricultural suitability (Parker and Abatzoglou, 2016). Wuebbles et al.
(2014) projections for RCP8.5 end-of-century found that the 4-day cold spell that happens on average once
every 5 years is projected to warm by more than 10°C and CMIP5 models do not project current 1-in-20
year annual minimum temperature extremes to recur over much of the continent. Multiple studies have
shown that Arctic warming can alter large-scale variability and change the frequency and duration of mid-
latitude cold air outbreaks, potentially leading to increasing cold hazards in some regions (Barcikowska et
al., 2019; Cohen et al., 2019; Zhou et al., 2021) (low agreement).

**Frost:** An expansion of the frost-free season is underway and projections for North America indicate a
continuation of this trend in the future (high confidence). Significant decreases in frost days, consecutive
frost days, and ice days were identified in 1948-2016 station observations across Canada, along with a
resulting lengthening of the frost-free season by more than a month in many regions (Vincent et al., 2018c).
Frost days also declined in nearly all Mexican cities from 1980-2010 (Garcia-Cueto et al., 2019), and a 1917-
2016 decline of about 3 weeks in frigid winter conditions challenges ecosystems in the Northeast US and
Southeast Canada (Contosta et al., 2020). Studies connect projections of a longer frost-free season in North
America to a longer outdoor construction season, orchard production, and weight restrictions on runways
(Daniel et al., 2018; DeGaetano, 2018; Jacobs et al., 2018). Frosts are projected to persist as an episodic
hazard in many regions given natural variability and cold air outbreaks even as mean temperature rises (high
confidence).

Climate change is virtually certain to shift the balance of temperature toward warming trends and
away from cold extremes, with increases in the magnitude, frequency, duration and seasonal and
spatial extent of heat extremes driving impacts across North America. There is a particular sensitivity
to scenario pathway in resulting changes to the frequency of exceeding dangerous heat thresholds such
as HI>41°C in NCA, CNA and the US Southwest, with 75-150 days more under SSP5-8.5 but less than
60 days more under SSP1-2.6 in the end of the century.

12.4.6.2 Wet and dry

**Mean precipitation:** Atlas.9.2 found that trends in annual precipitation over 1960–2015 are generally non-
significant though there are consistent positive trends over parts of ENA and CNA, together with significant
decreases in precipitation in parts of south-western US and north-western Mexico.

Atlas.9.4 assessed very high confidence in increases in precipitation over most of Northern and Eastern

Do Not Cite, Quote or Distribute 12-78

Total pages: 227
North America, with medium confidence of decrease over Northern Central America and low confidence elsewhere (see Figure Atlas.33, Cross-Chapter Box Atlas.1 Figure 1). Changes are most dramatic in the Spring and Winter, when wet conditions are projected to extend from the northern portions of the continent as far south as the central Great Plains while Mexico becomes drier; in contrast, summertime changes are uncertain across most of the continent other than wetter conditions in Northern Canada (Easterling et al., 2017; Bukovsky and Mearns, 2020; Teichmann et al., 2020; Almazroui et al., 2021).

River flood: There is limited evidence and low agreement on observed climate change influences for river floods in North America (see also Section 11.5). Trends in streamflow indices are mixed and difficult to separate from river engineering influences, with large changes but little spatial coherence across the US, making it difficult to identify trends with confidence (Villarini and Slater; Peterson et al., 2013; Mallakpour and Villarini, 2015; Archfield et al., 2016; Wehner et al., 2017; Hodgkins et al., 2019; Neri et al., 2019).

There is high confidence in historical shifts in the timing of peak streamflow toward higher winter and earlier spring flows in snowmelt-driven basins in Canada (Burn and Whitfield, 2016; Bonsal et al., 2019) and the United States (Dudley et al., 2017; Wehner et al., 2017). Some rivers show ice-jam floods occurring a week earlier, but changes are mixed given localized positive and negative changes across the continent (Rokaya et al., 2018). There is medium confidence that climate change will increase river floods over the United States and Canada but low confidence for changes in Mexico. Wobus et al. (2017a) used a regional hydrologic model for 57000 streams to project more than a doubling in the frequency of current 100 yr flow events in many portions of the United States for RCP8.5 2050 with additional contributions from earlier snowmelt. CMIP6 projections for SSP5-8.5 2065-2099 show strongest peak United States runoff increases in the East (Villarini and Zhang, 2020); however, several studies applying global hydrological models disagree with regional streamflow projections, indicating a decrease in the magnitude or frequency of floods over a large portion of North America (e.g., Hirabayashi et al., 2013; Arnell and Gosling, 2016) (Figure 12.10a,c).

Heavy precipitation and pluvial flood: Section 11.4 assessed high confidence in observed increases in extreme precipitation events (including hourly totals) in Central and Eastern North America with low confidence in broad trends elsewhere in the continent despite observational increases in some portions of each region (Vincent et al., 2018c; García-Cueto et al., 2019; Zhang et al., 2019c).

Section 11.4 found that high precipitation is projected to increase across North America (high confidence) except for portions of Western North America where projections are mixed (medium confidence of increase). Maxwell et al. (2018) identified regional “heavy precipitation day” thresholds for 5 cities across the US and projected that a tripling (or more) of these events is possible by RCP8.5 mid-century. Projections indicate changes to intensity-duration-frequency (IDF) curves typically used for construction design and automobile hazards, as well as increases in the 10 year recurrence level of 24 hour rainfall intensities that challenge storm water drainage systems (Hambly et al., 2013; Cheng and AghaKouchak, 2015; Neumann et al., 2015b; Prein et al., 2017b; Hettiarachchi et al., 2018; Ragno et al., 2018). Precise levels of regional IDF characteristics may still depend substantially on the method and resolution of downscaling applied (DeGaetano and Castellano, 2017; Cook et al., 2020b).

Landslide: There is growing but yet limited evidence for unique climate-driven changes in landslide and rockfall hazards in North America, even as theory suggests decreases in slope and rockface stability due to more intense rainfall, snow-on-snow events, mean warming, permafrost thaw, glacier retreat, and coastal erosion (Cloutier et al., 2017; Coe et al., 2018; Handwerger et al., 2019; Hock et al., 2019; Patton et al., 2019) although dry trends can decelerate mass movements (Bennett et al., 2016). Landslide frequency has likely increased in British Columbia (Geertsema et al., 2006) and is expected to increase in Northwest North America given the combination of these factors (medium confidence) (Gariano and Guzzetti, 2016). Cloutier et al. (2017) projected an increase in landslides in Western Canada due to wetter overall conditions and reduced return period for extreme rainfall. Robinson et al. (2017) used scenarios based upon projection of 50 yr recurrence of 7 d precipitation periods to highlight the potential for increased landslide hazards near Seattle. Broad US projections are more uncertain given increases in evapotranspiration that will counteract precipitation changes over much of the country (Coe, 2016).

Aridity: Chapter 8 showed that aridity in North America generally moves opposite to mean precipitation.
change with an added evaporative demand from warmer temperatures (high confidence in aridity increase for North Central America, medium confidence increase in Central North America; high confidence decrease in Northeast North America, medium confidence decrease in Eastern and Northwest North America; see also Section 11.9). Projected soil moisture declines (Figure 12.4j-l) are most widespread across North America during the summertime, with largest declines in Mexico and the southern Great Plains but also extending into Canada (Section 8.4.1.6; Swain and Hayhoe, 2015; Easterling et al., 2017; Bonsal et al., 2019; Lu et al., 2019). Yoon et al. (2018) found net reduction in southern Great Plains groundwater storage in RCP8.5 mid-century projections despite increases in mean precipitation and both wet and dry extremes. Soil moisture drying could reach unprecedented levels by the CMIP6 RCP8.5 end of century, even when evaluating deeper soil columns relevant for crop rooting depth (Cook et al., 2020a). Projected changes in the aridity index portray a shift the geographic range of temperate drylands northward and eastward in Central and Western North America (Schlaepfer et al., 2017; Seager et al., 2018) which also diminishes aquifer recharge rates in the southern Great Plains and in some Western regions where snowpack is reduced (Mekemser et al., 2016).

**Hydrological drought**: Section 11.9 assessed low confidence of significant observational trends and projected future changes in the characteristics of episodic hydrological drought in North America given limited evidence and low agreement in modeled changes. Zhao et al. (2020) found that increases in hydrological drought frequency (particularly the 100 yr drought) were far more prevalent than for meteorological drought across 5797 watersheds in the US and Canada, indicating a strong influence of evaporative demand. Reductions in the overall supply of meltwater from a declining snowpack also increase the potential for intermittent hydrological droughts in the Western US (Mote et al., 2018; Livneh and Badger, 2020).

**Agricultural and ecological drought**: Section 11.9 assessed medium confidence for an increase in agricultural and ecological drought in Western North America but otherwise found limited evidence for broadly observed changes in North American agricultural and ecological drought even as increasing evaporative demand intensified vegetation stress and soil moisture deficits in recent events (Sections 11.6, 11.9). Section 11.9 assessed medium confidence for more intense agricultural and ecological drought conditions over North Central America, Western North America and Central North America in a 2°C global warming level (about mid-century), with medium confidence extending to Eastern North America and high confidence for North Central America and Central North America under a 4°C global warming level associated with higher emissions scenarios past 2050. Figure 12.4g-i shows that the frequency of meteorological droughts (which often initiate hydrological, agricultural and ecological drought) is largely projected to increase in North American areas where total precipitation decreases (and vice versa; see Section 11.9 and Coppola et al., 2021b), and higher evaporative demand will extend the regions where more intense ecological and agricultural droughts develop when meteorological droughts occur (Wehner et al., 2017; Cook et al., 2019). Studies utilizing a variety of drought indices and soil moisture projections consistently project increased drought extending from Mexico into the southern Canadian Plains during the summer (Swain and Hayhoe, 2015; Ahmadalipour et al., 2017; Feng et al., 2017; Bonsal et al., 2019; Tam et al., 2019; Cook et al., 2020a).

**Fire weather**: Climatic conditions conducive to wildfire have increased in Mexico, Western and Northwest North America, essentially due to warming (high confidence). Abatzoglou and Williams (2016) found climate changes led to higher values for 8 fuel aridity indices over the Western US in recent decades, with 2000-2015 changes exposing 75% more forested area to high fuel aridity and adding 9 more high fire potential days each year, similar to 1979-2013 Western US and Mexico fire season expansion in Jolly et al., 2015). Increases in lightning-initiated fires have been distinguished from trends in man-made fire in Western Canada and the United States (Balch et al., 2017; Hanes et al., 2019). Jain et al. (2017) identified a 1979-2015 expansion in fire weather season in Eastern Canada and the southwestern United States (with a smaller reduction in the northern mountain West) along with regional shifts in the 99th percentile Canadian Fire Weather Index (FWI) and potential fire spread days. Girardin and Wotton (2009) noted that 1951-2002 trends in the Monthly Drought Code fire index in Eastern Canada could hardly be distinguished from decadal variability.

Climate change drives future increases in North American fire weather, particularly in the Southwest (high confidence assessed extending to Eastern North America and high confidence for North Central America and Central North America under a 4°C global warming level). Sections 11.6, 11.9 assessed medium confidence for an increase in agricultural and ecological drought in Western North America but otherwise found limited evidence for broadly observed changes in North American agricultural and ecological drought even as increasing evaporative demand intensified vegetation stress and soil moisture deficits in recent events (Sections 11.6, 11.9). Section 11.9 assessed medium confidence for more intense agricultural and ecological drought conditions over North Central America, Western North America and Central North America in a 2°C global warming level (about mid-century), with medium confidence extending to Eastern North America and high confidence for North Central America and Central North America under a 4°C global warming level associated with higher emissions scenarios past 2050. Figure 12.4g-i shows that the frequency of meteorological droughts (which often initiate hydrological, agricultural and ecological drought) is largely projected to increase in North American areas where total precipitation decreases (and vice versa; see Section 11.9 and Coppola et al., 2021b), and higher evaporative demand will extend the regions where more intense ecological and agricultural droughts develop when meteorological droughts occur (Wehner et al., 2017; Cook et al., 2019). Studies utilizing a variety of drought indices and soil moisture projections consistently project increased drought extending from Mexico into the southern Canadian Plains during the summer (Swain and Hayhoe, 2015; Ahmadalipour et al., 2017; Feng et al., 2017; Bonsal et al., 2019; Tam et al., 2019; Cook et al., 2020a).
Changes in North American wet and dry climatic impact-drivers are largely organized by the northeast (more wet) to southwest (more dry) pattern of mean precipitation change, although heavy precipitation increases are widespread and increasing evaporative demand expands aridity, agricultural and ecological drought, and fire weather (particularly in summertime) (high confidence).

### 12.4.6.3 Wind

**Mean wind speed:** Mean wind speeds have declined in past decades in North America as in other Northern Hemisphere areas over the past four decades (AR5, WGI) (medium confidence) with a reversal in the last decade (low confidence) not fully consistent across studies (Tian et al., 2019; Zeng et al., 2019; Zhang et al., 2019d) (Chapter 2). Tian et al. (2019) found a corresponding reduction in the wind power potential across the eastern parts of North America.

Mean wind speeds are expected to decline over much of North America (Figure 12.4m-o), but the only broad signal of consistent change across model types is a reduction in wind speed in Western North America (high confidence). These declines reduce wind power endowment by 2050 and as early as the 2020-2040 near-term period in the US Mountain West, while there is disagreement between global and regional model change projections in the upper and lower Great Plains, Ohio River Valley, Mexico and Eastern Canada (Karnauskas et al., 2018a; Jung and Schindler, 2019; Chen, 2020).

**Severe wind storm:** There is limited evidence and low agreement in observed changes in North American CID indices associated with extratropical cyclones (Chapter 11), severe thunderstorms, severe wind bursts (derechos), tornadoes, or lightning strikes (Vose et al., 2014; Easterling et al., 2017; Kossin et al., 2017). Observational studies have indicated a reduction in the number of tornado days in the US, but increases in outbreaks with 30 or more tornadoes in one day (Brooks et al., 2014), the density of tornado clusters (Elsner et al., 2015), and overall tornado power (Elsner et al., 2019).

There is medium confidence of a general decrease in the number of extratropical cyclones producing high wind speeds in North America, except over northernmost parts, for a global warming level of 2ºC or by the end of the century in under RCP4.5 and RCP8.5 (Kumar et al., 2015; Jeong and Sushama, 2018; Li et al., 2018a). GCMs cannot directly resolve tornadoes and severe thunderstorms, however projections of favorable environments for severe storms (based on convective available potential energy and wind shear) indicate medium confidence for more severe storms and a longer convective storm season in the United States weaker increases extending north and east (Seeley and Romps, 2015; Glazer et al., 2020) and a corresponding increase in fall and winter tornadic storms (Brooks, 2013a; Diffenbaugh et al., 2013; Brooks et al., 2014) (see also Section 11.7.1). Prein et al. (2017a) used a convection-permitting model to project a tripling of mesoscale convective systems over the United States for end-of-century RCP8.5.

**Tropical cyclone:** Section 11.7.1 identified recent reductions in tropical cyclone translation speed and higher tropical cyclone rainfall totals over the North Atlantic as well as substantial natural variability. Projections indicate low confidence in change in North Atlantic tropical cyclone numbers, but medium confidence in...
Mexico and the US Gulf and Atlantic coasts for more intense storms with higher wind, precipitation, and storm surge totals when they do occur (Diro et al., 2014; DOE, 2015; Walsh et al., 2016a; Kossin et al., 2017; Marsooli et al., 2019; Ting et al., 2019; Knutson et al., 2020) (see Section 11.7.1). A more rapid intensification of tropical cyclone winds and destructive power also heightens the tropical cyclone hazard (Bhatai et al., 2019). Greenhouse gas forcing is projected to shift tropical cyclones poleward (Kossin et al., 2016), while also holding the potential for higher precipitation totals (Risser and Wehner, 2017; Knutson et al., 2020) particularly given evidence that storms increasingly stall near North American coastlines (Hall and Kossin, 2019).

**Sand and dust storm:** Land use change has increased dust emission in the western U.S. in the past 200 years (Neft et al., 2008). However, there is medium confidence for observed increases in Western North American sand and dust storm activity since 1980. In their study of Valley Fever spread, Tong et al. (2017) identified a rapid intensification of dust storm activity using PM10 and PM2.5 observations from 1980-2011 across 29 monitoring sites in the Southwestern US, similar to contiguous US observations by Braheyn et al. (2013). Hand et al. (2016) attributed the earlier onset of spring dusts in the Southwest in large part to the Pacific Decadal Oscillation, however. The increasing trend in dust since the 1990s in the southwest US can be explained by precipitation deficit and surface bareness (Pu and Ginoux, 2018). Projections of future sand and dust storms over North America are based on aridity as a primary proxy for conducive conditions which lends medium confidence of an increase over Mexico and the Southwest US. Pu and Ginoux (2017) project about 5 more dusty days in spring and summer in the southern Great Plains under RCP8.5 at the end of the century, while dusty days decrease in northern regions where mean precipitation tends toward wetter conditions.

Tropical cyclones, severe wind and dust storms in North America are shifting toward more extreme characteristics, with a stronger signal toward heightened intensity than increased frequency, although specific regional patterns are more uncertain (medium confidence). Mean wind speed and wind power potential are projected to decrease in Western North America (medium confidence) with differences between global and regional models lending low confidence elsewhere.

### 12.4.6.4 Snow and ice

**Snow:** The seasonal extent of snow cover has reduced over North America in recent decades (robust evidence, high agreement) (see also Section 2.3.2.2, Section 9.5.3 and Atlas). The average North America area covered by snow decreased at a rate of about 8500 km² per year over the 1972-2015 period, reducing the average snow cover season by two weeks primarily due to earlier spring melt (US EPA, 2016).

Observations indicate earlier spring snowpack melting (Dudley et al., 2017) and a reduction in end-of-season snowpack metrics important to water resources over the Rockies (particularly since 1980) and Pacific Northwest (Pederson et al., 2013; Kormos et al., 2016; Kunkel et al., 2016; Fyfe et al., 2017; Mote et al., 2018). In situ measurements in Canada show more heterogenous trends in snow amount and density (Brown et al., 2019).

Climate change is expected to reduce the total snow amount and the length of the snow cover season over most of North America, with a corresponding decrease in the proportion of total precipitation falling as snow and a reduction in end-of-season snowpack (high confidence) (see Atlas.9). Changes include a reduction in days with snowfall in all but Northern Canada (Danco et al., 2016; McCrory and Mearns, 2019), a delay of about a week in first snowfall in the US West in RCP8.5 2050 (Pierce and Cayan, 2013), and more prominent reductions in Canadian snow cover in the October-December period (Mudryk et al., 2018). Reduced total snowpack and earlier snowmelt lower dry season streamflow (Kormos et al., 2016; Rhoades et al., 2018). Figure 12.10b shows a reduction in days suitable for skiing (SWE>10 cm; Wobus et al., 2017b) across the US and Southern Canada, although some portions of Northern Central Canada see an increase.

**Glacier:** Section 9.5.1 assessed that glaciers in Alaska, Western Canada and the Western United States are expected to continue to lose mass and areal extent (high confidence). Compared to their 2015 state, glaciers in the Western Canada and the United States region will lose 62 ± 30%, 75 ± 29% and 85 ± 23%, of their
mass by the end of the century for RCP2.6, RCP4.5 and RCP8.5 scenarios, respectively (Marzeion et al., 2020). Meanwhile glaciers in Alaska will lose $26 \pm 21\%$, $31 \pm 24\%$ and $44 \pm 27\%$, of their mass in 2015 under the same scenarios. The overall loss of glacial mass can act as a meltwater supply for freshwater resources, although this is expected to peak in the middle of the century and then fade as glaciers disappear (Fyfe et al., 2017; Derksen et al., 2018). Continued shrinkage of glaciers is projected to create further glacial lakes (medium confidence) similar to those that have led to outburst floods in Alaska and Canada (Carrivick and Tweed, 2016; Harrison et al., 2018).

Permafrost: Warmer ground temperatures are expected to extend the geographical extent and depth of permafrost thaw across northern North America (very high confidence) (see also Section 9.5.2). Observations across Canada show that permafrost temperature is increasing and the active layer is getting thicker (Chapter 2.3.2.5; Biskaborn et al., 2019; Derksen et al., 2019; Romanovsky et al., 2020). Slater and Lawrence (2013) note that end-of-century RCP8.5 in North America only has shallow permafrost as the most probable condition in the Canadian Archipelago. Melvin et al. (2017) noted the loss of shallow permafrost in 5 RCP8.5 CMIP5 models across a wide swath of southern Alaska by 2050 along with increases of active layer thickness. There is high confidence in continued reductions in mountain near-surface permafrost area with high spatial variability given local snow and temperature changes (Chapter 9.5.2; Peng et al., 2018; Hock et al., 2019).

Lake, river and sea ice: Anthropogenic warming reduces the seasonal extent of lake and river ice over many North American freshwater systems, with ice-free winter conditions pushing further north with rising temperatures (high confidence). Observations in Central and Eastern North America show reduced average seasonal lake ice cover duration (Benson et al., 2012; Mason et al., 2016; US EPA, 2016). Satellite observations show declines in lake ice (Du et al., 2017) and loss of more than 20% of winter river ice length in much of Alaska (2008-2018 compared to 1984-1994; Yang et al., 2020). Spring lake and river ice in Canada is projected to break up 10-25 days earlier while fall freeze-up occurs 5-15 days later by mid-century, with larger declines in lake ice season by the coasts (Dibike et al., 2012) and for rivers in the Rockies and Northeastern United States (Yang et al., 2020a) although global models have difficulty with frozen freshwater system dynamics (Derksen et al., 2018). Substantial ice loss is projected over the Laurentian Great Lakes (Hewer and Gough, 2019; Matsumoto et al., 2019). The southern extent of lakes experiencing intermittent winter ice cover moves northward with rising temperature, pushing nearly out of the continental United States at low elevations when GMT increases by 4.5°C (Sharma et al., 2019). Higher spring flows and the potential for winter thaws are also projected to heighten the threat of ice jams (Rokaya et al., 2018; Bonsal et al., 2019) while reducing the seasonal viability of ice roads and recreational use (Pendakur, 2016; Mullan et al., 2017; Knoll et al., 2019).

Seasonal sea ice coverage along the majority of Canadian and Alaskan coastlines is declining (robust evidence, high agreement) and there is high confidence that hazards associated with a loss of sea ice increase under climate change, as further assessed in Section 12.4.9.

Heavy snowfall: There is low agreement (limited evidence) for observed changes in heavy snowfall in North America. Kluver and Leathers (2015) noted a 1930-2008 frequency increase for all snow intensities in the Northern Great Plains but declines in heavier snow events in the Pacific Northwest and declines in the Southeastern US. Changnon (2018) found that most extreme 30-day high snowfall periods in the 1900-2016 record over the Eastern US occurred in the 1959-1987 period that lies between the Dust Bowl and recent warming. There is low agreement and medium evidence for broad projected changes to heavy snowfall over North America given increased heavy precipitation and warmer winter temperatures. Several recent regional studies have projected that low-intensity events decrease more rapidly than heavy snowfall events, resulting in an increase in the snowfall proportion from heavy snowfall events even as the number of such events decreases (O’Gorman, 2014; Lute et al., 2015; Zarzycki, 2016; Janoski et al., 2018; Ashley et al., 2020).

Ice storm: There is limited evidence in the literature of unique changes in ice storms observed or projected over North America. Groisman et al. (2016) examined 40 years of observations and found weak decreases in freezing rain events over the Southeastern US in the most recent decade. Ning and Bradley (2015) project that the average snow-rain transition line, which is associated with mixed precipitation, moves 2° latitude
northward over Eastern North America by the end of the 21st century under RCP4.5 (4° under RCP8.5) (see also Klima and Morgan, 2015).

**Hail:** There is limited evidence and low agreement for observed changes in the frequency or intensity of North American hail storms. Allen et al., (2015) and Allen (2018) found that temporal inconsistencies in the US and Canadian hail records made long-term climate analysis difficult, although Tang et al. (2019) identified increasing environments conducive for hail ≥ 5 cm over the Central and Eastern United States. There is limited evidence and medium agreement in projections of increased hail damage potential over North America. Some regional and convective-permitting model projections indicate a longer hail season with fewer events and larger hail sizes that result in higher hail damage potential (Brimelow et al., 2017; Trapp et al., 2019).

**Snow avalanche:** There is limited evidence of directional changes in snow avalanches over North America. Mock and Birkeland (2000) identified a 1969-1995 decrease in snow avalanches over the Western United States, although they note the heavy influence of natural variability. A similar decline was observed over Western Canada (Bellaire et al., 2016; Sinickas et al., 2016), but clear trends are difficult to discern given sparse observations and shifts in avalanche management. We concur with the SROCC assessment of medium confidence and high agreement that snow avalanche hazards generally decrease at low elevations given lower snowpack even as high elevations are increasingly susceptible to wet snow avalanches (Hock et al., 2019; see also Lazar and Williams, 2008).

Observations and projections agree that snow and ice CIDs over North America are characterized by reduction in glaciers and the seasonality of snow and ice formation, loss of shallow permafrost, and shifts in the rain/snow transition line that alters the seasonal and geographic range of snow and ice conditions in the coming decades (very high confidence).

### 12.4.6.5 Coastal and oceanic

**Relative sea level:** Chapter 9 found that observations indicate increasing sea levels along most North American coasts (robust evidence, high agreement), although there is substantial regional variation in relative sea level rise (robust evidence, high agreement). Around North America, over 1900-2018, a new tide-gauge based reconstruction finds a regional-mean RSL change of 1.08 [0.79,1.38] mm yr⁻¹ in the subpolar North Atlantic, 2.49 [1.89-3.06] mm yr⁻¹ in the subtropical North Atlantic, and 1.20 [0.76-1.62] in the East Pacific (Frederikse et al., 2020), compared to a GMSL change of around 1.7 mm yr⁻¹ (Section 2.3.3.3; Table 9.5). For the period 1993-2018, these RSLR rates, based on satellite altimetry, increased to 2.17 [1.66-2.66] mm yr⁻¹, 4.04 [2.77-5.24] mm yr⁻¹ and 2.35 [0.70-4.06] mm yr⁻¹, respectively (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr⁻¹ (Section 2.3.3.3; Table 9.5). Relative sea level (RSL) is falling in portions of southern Alaska (Sweet et al., 2018) and much of northern Northeastern Canada and around Hudson Bay (where land is rising by >10 mm/year; Greenan et al., 2019).

Relative sea-level rise is virtually certain to continue in the oceans around North America, except in northern Northeastern Canada and portions of Southern Alaska. Regional-mean RSLR projections for the oceans around North America range from 0.4 m -1.0 m under SSP1- RCP2.6 to 0.7 m -1.4 m under SSP5-RCP8.5 for 2081-2100 relative to 1995-2014 (median values), which means that there are locally large deviations from the projected GMSL change (Section 9.6.3.3), including decreases in RSL in northern Northeastern Canada from land uplift (see also Sweet et al., 2017; Greenan et al., 2019; Oppenheimer et al., 2019). The RSLR projections here may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

**Coastal flood:** Observations indicate that episodic coastal flooding is increasing along many coastlines in North America (robust evidence, high agreement), and this episodic coastal flooding will increase in many North American regions under future climate change (high confidence) although land uplift from glacial isostatic adjustment in northern and Hudson Bay portions of Northeast North America leads to only medium confidence of coastal flood increases in that region. Sweet et al. (2018) found 2000-2015 observed increases...
of about 125% in high tide flooding frequencies along the southern Atlantic US coastline, with 75%
increases along the US Gulf Coast and US northern Atlantic coastlines. That same study noted that a GMSL
of 0.5m in 2100 would increase high tide (‘nuisance’) flooding from current rates of about once a month for
most coastal regions to about once every other day along the US Atlantic and Gulf Coasts and smaller
frequency increases along the Pacific coast, and Dahl et al. (2017) found similar trends on the US East Coast
prior to mid-century (see also. The present day 1:50 yr ETWL is projected to occur around 3 times a year by
2100 with a SLR of 1 m all around the region, except in most of Eastern North America where it is expected
to have return periods of 1:1 yr – 1:2 yrs (Vitousek et al., 2017). Ghanbari et al. (2019) projected
corresponding shifts toward higher frequencies of major flooding events for 20 US cities. Figure 12.4 and
Figure SM.12.6 show increases of 70 cm or more in the 100-yr return period extreme total water level
(ETWL) over much of the US East Coast, British Columbia, Alaska, and the Hudson Bay under RCP8.5 by
2100 (relative to 1980–2014), with lower increases in Northern Mexico, Northern Canada, Labrador, and the
Pacific and Gulf Coasts of the US (Vousdoukas et al., 2018). Projected coastal flooding increases generally
follow patterns of RSL change although sea ice loss in the north also increases open water storm surge
(Greeman et al., 2019).

Coastal erosion: There is limited evidence of changes in North American episodic storm erosion caused by
waves and storm surges. Observations show increased extreme wave energy on the Pacific coast, but no clear
trend on other US coasts given substantial natural variability (Bromirski et al., 2013; Vose et al., 2014). In
terms of long term erosion, shoreline retreat rates of around 1 m yr⁻¹ have been observed during
1984-2015 along the sandy coasts of NWN and NCA while portions of the US Gulf Coast have seen a retreat
rate approaching 2.5 m yr⁻¹ (Luijendijk et al., 2018; Mentaschi et al., 2018). Sandy shorelines along ENA and
WNA have remained more or less stable during 1984 – 2014, but a shoreline progradation rate of around 0.5
m yr⁻¹ has been observed in NEN (Mentaschi et al. (2018) report 1984-2015 coastal area land losses of 630
km² and 1,260 km² along the Pacific and Atlantic coasts of USA, respectively.

Projections indicate that sandy coasts in most of the region will experience shoreline retreat through the 21st
century (high confidence). Median shoreline change projections presented by Vousdoukas et al. (2020)
compared CMIP5 projections show that sandy shorelines in NWN, ENA, and NCA will retreat by between
40 m – 80 m by mid-century (relative to 2010) under both RCP4.5 and RCP8.5. Projections for NEN and
WNA are lower at 20 m – 30 m under the same RCPs. The highest median mid-century projection in the
region is for CNA at around 125 m under both RCPs. RCP4.5 projections for 2100 show shoreline retreats of
100 m or more along the sandy coasts of NWN, CNA, and NCA, while retreats of between 40 m – 80 m are
projected in other regions. Under RCP8.5, retreats exceeding 100 m are projected in all regions except NEN
and WNA (approximately 80 m) by 2100, with particularly high retreats in NWN (160 m), CNA (330 m) and
SCA (200 m). The total length of sandy coasts in North America that are projected to retreat by more than a
median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 15,000 km and 25,000 km respectively, an
increase of approximately 70%.

Marine heatwave: There is high confidence in observed increases in marine heatwave frequency and future
increases in marine heatwaves are very likely around North America (Box 9.2). The total number of MHW
days per decade increased in the North American coastal zone, albeit somewhat more in the Pacific (Oliver
et al., 2018; Smale et al., 2019). Projected increases in degree heating weeks (Herson et al., 2016) and degree
heating months (Frieler et al., 2013) indicate increasing bleaching-level and mortality-level heating stress
threshold events for reefs in Florida and Mexico.

Mean SST is projected to increase by 1 °C (3 °C) around North America by 2100, with a hotspot of around 4
°C (5 °C) off the North America Atlantic coastline under RCP4.5 (RCP8.5) conditions (see Interactive Atlas).
Frölicher et al. (2018) projected increasing MHW frequency and spatial extent at a 2°C global warming level
with the largest increases in the Gulf of Mexico and off the southern US East Coast (>20x) as well as off the
coast of the Pacific Northwest (>15x). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in
MHWs around North America by 2081 – 2100, relative to 1985 – 2014 (Box 9.2, Figure 1).

There is high confidence that most coastal CIDs in North America will continue to increase in the
future with climate change. An observed increase in relative sea level rise is virtually certain to
continue in North America (other than around the Hudson Bay and Southern Alaska) contributing to more frequent and severe coastal flooding in low-lying areas (high confidence) and shoreline retreat along most sandy coasts (high confidence). Marine heatwaves are also expected to increase all around the region over the 21st century (high confidence).

The assessed direction of change in climatic impact-drivers for North America and associated confidence levels are illustrated in Table 12.8.

1. Snow may increase in some high elevations and during the cold season and decrease in other seasons and at lower elevations.
2. Along sandy coasts and in the absence of additional sediment sinks or any physical barriers to shoreline retreat.
3. Increasing in northern regions and decreasing toward south.
4. Decreasing in northern regions and increasing toward south.
5. Higher confidence in northern regions and lower toward south.
6. Higher confidence in southern regions and lower toward north.
7. Higher confidence to increase for some climatic impact drivers during summertime.
8. Increase in extreme temperature but decrease in winter extratropical cyclones.

### END TABLE 12.8 HERE

#### 12.4.7 Small islands

This section covers the climatic impact-drivers affecting small islands around the world (see definition of SIDS in the Glossary; Cross-Chapter Box Atlas.2) with a particular focus on small islands in the Caribbean (CAR) Sea and the Pacific Ocean. Caribbean and Pacific small islands have mostly tropical climates and local conditions are also influenced by diverse topography ranging from low-lying islands and atolls to volcanic and mountainous terrain. Climate variability in these islands is influenced by the trade winds, the
easterly waves, tropical cyclones (TC), and the migrations of the Inter-Tropical Convergence Zone (ITCZ),
the North Atlantic Subtropical High, and the South Pacific Convergence Zone (SPCZ), and other modes of
climate variability as discussed in Cross-Chapter Box Atlas.2. Furthermore, changes in the ocean
temperature and chemistry, and relative sea level have strong impacts on these small islands given their
geographical location and dependence on coastal and marine ecosystem services.

IPCC AR5 recognized the heterogeneity in these small islands in terms of physical geography, socio-
-economic and cultural backgrounds, as well as their vulnerability to the impacts of climate change. Similar to
previous reports, these regions have been assessed together in this section given similarities in the challenges
they face in addressing climate change impacts and risk, which was thought to be dominated by sea level rise
until IPCC AR4 (Nurse et al., 2014; Betzold, 2015). Since then there has been a substantial increase in the
number and complexity of the literature on the drivers and impacts of climate change on small islands (BOM
and CSIRO, 2011, 2014; Nurse et al., 2014; Gould et al., 2018; Keener et al., 2018). There are also
increasing efforts in producing higher resolution climate projections for the small islands through
downscaling methods (Elison Timm et al., 2015; McLean et al., 2015; Khalyani et al., 2016; Zhang et al.,
2016a; Stennett-Brown et al., 2017; Bhardwaj et al., 2018; Bowden et al., 2021).

IPCC AR5 identified the key climate and ocean-related hazards affecting the small islands, which occur at
different timescales and have diverse impacts on multiple sectors (Christensen et al., 2013; Nurse et al.,
2014). Recent findings from IPCC SR1.5 and IPCC SROCC emphasize that the multiple interrelated climate
hazards currently faced by low-lying islands and coastal areas will be amplified in the future, especially at
higher global warming levels (Hoegh-Guldberg et al., 2018; IPCC, 2019b).

12.4.7.1 Heat and Cold

Mean air temperature: Significant warming trends are clearly evident in the small islands, such as those in
the Pacific, CAR, and Western Indian Ocean, particularly over the latter half of the 20th century (see Figure
Atlas.11; Section Atlas.10.2; Cross-Chapter Box Atlas.2, Table 1). This observed warming signal in the
tropical western Pacific has been attributed to anthropogenic forcing (Wang et al., 2016). There is high
confidence of warming over small islands even at 1.5°C global warming level (GWL) (Section Atlas.10.4;
Figure Atlas.31) (Hoegh-Guldberg et al., 2018). Mean temperature is very likely to increase by 1°C–2°C
(2°C–4°C) by 2041–2060 (2081–2100) under RCP8.5 (BOM and CSIRO, 2014) and SSP3-7.0 (Figure 4.19
and Figure Atlas.13) (Section Atlas.10.4) (Almazroui et al., 2021).

Extreme heat: Observation records indicate warming trends in the temperature extremes since the 1950s in
CAR and the Pacific small islands (high confidence) (Section 11.3.2; Section 11.9, Table 11.7). A detectable
anthropogenic increase in summertime heat stress index has been identified over a number of island regions
in CAR, western tropical Pacific, and tropical Indian Ocean, based on wet bulb globe temperature (WBGT)
index trends for 1973–2012 (medium confidence) (Knutson and Ploshay, 2016). An increasing trend in the
maximum daytime heat index is also noted in CAR during the 1980–2014 period, as well as more extreme
heat events since 1991 (Ramirez-Beltran et al., 2017).

Compared with the recent past, it is likely that the intensity and frequency of hot (cold) temperature extremes
will increase (decrease) in the small islands (Section 11.9, Table 11.7) (BOM and CSIRO, 2014). Warm
spell conditions will occur up to half the year in CAR at 1.5°C GWL with an additional 70 days at 2°C
(Taylor et al., 2018), with livestock temperature-humidity tolerance thresholds increasingly surpassed (Lallo
et al., 2018). In CAR, a median increase of almost a month where temperatures exceed 35°C is projected by
end of the 21st century under SSP5-8.5 (Figure 12.4a.e and Figure SM 12.1). Heat waves are projected to
increase in CAR by the mid- and end of the 21st century under RCP8.5 (Section 11.3.5; Section 11.9, Table
11.7). Figure 12.4d-f and Figure SM 12.2 also show an increase of about 30-60 days with HI exceeding 41°C
by 2041-2060 under SSP5-8.5 relative to 1995-2014 in CAR, with an additional increase of about days by
end of the 21st century for RCP8.5/SSP5-8.5, but this increase remains below 50 days for RCP2.6/SSP1-2.6.
The Pacific Islands is also among regions projected to have an increase in number of days with mean HI
exceeding 41°C by 2091-2100 under RCP8.5/SSP5-8.5, increasing the risk of heat stress in the region
It is very likely that the significant recent warming trends observed in the small islands will continue in the 21st century, which will likely further increase heat stress in these regions.

### 12.4.7.2 Wet and Dry

#### Mean precipitation:
Observational datasets have generally revealed no significant long-term trends in rainfall in the Caribbean over the 20th century when analysed at seasonal and inter-decadal timescales, except for some areas where there is evidence for decreasing trends for the period 1901-2010 but not for the period 1951-2010 (Knutson and Zeng, 2018; Section Atlas.10.2; Cross-Chapter Box Atlas.2, Table 1). Although there are spatial variations, annual rainfall trends in the Western Indian Ocean are mostly decreasing, with generally non-significant trends in the Western tropical Pacific since the 1950s (low confidence). Significant drying trends are noted in the southern Pacific subtropics and southwestern French Polynesia during the 1951-2015 period (McGree et al., 2019), and in some areas of Hawaii during the 1920-2012 period (medium confidence) (Section Atlas.10.2; Cross-Chapter Box Atlas.2, Table 1).

Atlas.10.4 projects precipitation reduction over the Caribbean (high confidence) and parts of the Atlantic and Indian Oceans, particularly in June to August by end of 21st century. Precipitation is generally projected to increase in the small islands in parts of the western and equatorial Pacific, but there is low confidence in broad changes given drier conditions projected for the southern sub-tropical and eastern Pacific Ocean (limited agreement given spatial and seasonal variability; Section Atlas.10.4; Figure Atlas.31) (Almazroui et al., 2021).

#### River flood:
There is limited evidence on observed changes in river flooding in small islands. Long-term records in Hawaii indicate no clear trends in peak flow, except for the significant decrease in peak streamflow in Hawaii Island over the period 1967-2016 (Bassoum and Oki, 2013; Clilverd et al., 2019). Similarly, there is no significant trend in the frequency and height (after adjusting for average sea level rise) of river flood in Fiji over the period 1892-2013 (McAneney et al., 2017). There is low confidence on the direction of future change of river flooding in the small islands due to the limited currently available literature. In Oahu, Hawaii, extreme peak flow events with high return periods are projected to increase by end of 21st century under RCP8.5, but there is also high uncertainty in these projections (Leta et al., 2018).

#### Heavy precipitation and pluvial flood:
Heavy precipitation days in CAR have increased in magnitude, and have been more frequent in the northern part during the latter part of the 20th century (low confidence) (Section 11.4.2; Table 11.7). The direction of change in extreme precipitation varies across the Pacific and depends on the season (low confidence) (Section 11.4.2; Cross-Chapter Box Atlas.2, Table 1). Although pluvial flooding events have been observed in some islands, there is limited evidence for an assessment on past changes in pluvial flooding unlike in other regions. There is low confidence in the projected increase in magnitude of very heavy precipitation days in CAR across different GWLs (Table 11.7). On the other hand, there is high confidence in the increase in frequency and intensity of extreme rainfall events (i.e. 1-in-20 year rainfall events) in the western tropical Pacific in the 21st century even for RCP2.6 scenario based on model agreement and mechanistic understanding but low confidence in the magnitude of change in extreme rainfall due to model bias (BOM and CSIRO, 2014).

#### Landslide:
Heavy rainfall, such as from tropical cyclones, can trigger landslides over steep terrain in the small islands (Bessette-Kirton et al., 2019). There is limited evidence to determine long-term trends in rainfall-induced landslides in the small islands (Kirschbaum et al., 2015; Sepúlveda and Petley, 2015; Froude and Petley, 2018; Bessette-Kirton et al., 2019). There is low confidence in the future change in landslides in the small islands. The direction of change may depend on future changes in precipitation, tropical cyclones, climate modes (e.g., El Niño-Southern Oscillation (ENSO)), as well as human disturbance, but more data and understanding of the complexity of these relationships are needed, especially in these vulnerable areas (Sepúlveda and Petley, 2015; Gariano and Guzzetti, 2016; Froude and Petley, 2018).
Aridity: Current estimates identify many small islands as being under water stress and thus particularly sensitive to variations in rainfall and groundwater, population growth and demand, land use change, among others (Holding et al., 2016) (Cross-Chapter Box Atlas.2). From 1950 to 2016, a heterogeneous but prevalent drying trend is found in CAR (medium confidence), where drought variability is modulated by the tropical Pacific and North Atlantic oceans (Herrera and Ault, 2017) (Table 11.7, Cross-Chapter Box Atlas.2, Table 1). In the future, increased aridity and decreased freshwater availability are projected in many small islands due to higher evapotranspiration in a warmer climate that partially offsets increases or exacerbates reductions in precipitation (Karnauskas et al., 2016, 2018b; Hoegh-Guldberg et al., 2018). Increased aridity is projected for the majority of the small islands, such as in CAR, southern Pacific and Western Indian Ocean, by 2041-2059 relative to 1981-1999, and at 1.5°C and 2.0°C GWLs, under RCP8.5, which will further intensify by 2081-2099 (Karnauskas et al., 2016, 2018b) (medium confidence). Groundwater recharge is projected to increase in Maui, Hawaii except on the leeward sides of the island, which underscores the importance of topography and elevation on freshwater availability in different island microclimates (Brewington et al., 2019; Mair et al., 2019).

Hydrological drought: There is low confidence of widespread changes to hydrological drought in the Caribbean or Pacific small islands in recent decades, although an increasing number of studies document local changes. Records in Hawaii indicate downward trends in low streamflow and base flow from 1973 to 2008 (Bassiouni and Oki, 2013). Decadal variability of Hawaiian streamflow coincides with rainfall fluctuations associated with the Pacific Decadal Variability although significant average declines in surface and baseflow runoff of about 8% and 11% per decade, respectively, have been noted during the 1987-2016 period (Clilverd et al., 2019).

There is low confidence in hydrological drought change projections given low signal to noise ratios and the challenge in representing island scales in global analyses. Prudhomme et al. (2014) recognized the Caribbean as one of the regions with highest increase in regional deficit index (RDI; a measure of the fraction of area in hydrological drought conditions) by end of the 21st century under RCP8.5. Daily streamflow and extreme low flows in two watersheds in Oahu, Hawaii are projected to decline by mid-and end of the 21st century under RCP4.5 and RCP8.5, which would result in more frequent hydrological droughts in this area (Leta et al., 2018).

Agricultural and ecological drought: Recent trends toward more frequent and severe droughts have been noted in the small islands but only generate low confidence in broad trend patterns given high spatial variability including heightened drought on the leeward side of islands (e.g., Frazier and Giambelluca, 2017; Herrera and Ault, 2017; McGree et al., 2019; Table 11.7, Cross-Chapter Box Atlas.2, Table 1). There is medium confidence that agricultural and ecological droughts will increase in frequency, duration, magnitude, and extent in the small islands, such as in CAR and parts of the Pacific, particularly where there are future declines in precipitation compounded by higher evapotranspiration, under increasing levels of warming (Naumann et al., 2018; Taylor et al., 2018; Vichot-Llano et al., 2021). Relative to the period 1985-2014, decreases in annual surface and total column soil moisture becomes more robust in more areas in CAR by 2071-2100 under SSP3-7.0 and SSP5-8.5 scenarios (Cook et al., 2020a), but global simulations are challenged to represent drought features in small island domains (see also Section 11.9).

Fire weather: There is limited evidence on trends in wildfire in CAR and the Pacific. Records of wildfire in Hawaii from 2005-2011 indicate a peak in area burned during the hot and dry summer months, but Trauernicht et al. (2015) note the difficulty in establishing the link between past climate and wildfire trends due to human activities and vegetation changes. Availability of literature limits assessment on future fire weather in the small islands (low confidence). Drying and warming trends tend to increase fire probability aside from the climate impact on fuel loading, e.g., grassland fires in Hawaii (Trauernicht, 2019), and wildfires in Puerto Rico (Van Beusekom et al., 2018).

Observed and projected rainfall trends vary spatially across the small islands. Higher evapotranspiration under a warming climate can partially offset future increases or amplify future reductions in rainfall resulting in drier conditions and increase water stress in the small islands (medium confidence).
12.4.7.3 Wind

**Mean wind speed**: Scarcity of observations limits assessment of long-term changes in winds over the small islands in the Pacific and CAR. Records indicate that average daily wind speeds have slowly declined in Hawaii, but trends have remained constant across western and south Pacific sites since the mid-20th century (Marra and Kruk, 2017). Recent studies of reanalyses and hindcast simulations indicate an intensification of the Pacific trade winds during the 1992-2011 period, which contributed to the ocean cooling in the tropical central and eastern Pacific (England et al., 2014; Takahashi and Watanabe, 2016). Projections estimate up to 0.4 m s\(^{-1}\) (8%) increase in annual winds in CAR under RCP8.5, which is associated with changes in the extension of the North Atlantic Subtropical High that enhances the Caribbean low-level jet during the wet season, and stronger local easterlies due to enhanced land-ocean temperature differences in the dry season (Costoya et al., 2019) (*low confidence*).

**Tropical cyclone**: Tropical cyclones have devastating impacts on the small islands due to intense winds, storm surge, and rainfall, although the associated rainfall can also be beneficial for freshwater resources. It is likely that tropical cyclone intensity and intensification rates at a global scale have increased in the past 40 years but it is not clear if regional-scale changes are basin-wide or due to shifts in tracks (Section 11.7.1.2). Other features are less sensitive to these issues, such as the poleward migration where tropical cyclones reach peak intensity in the western North Pacific and the slowdown in tropical cyclone translational speed in most basins in the latter half of the 20th century (*low confidence*), which can enhance rainfall and flooding events, including over small islands in CAR and the Pacific (Section 11.7.1.2).

Future global changes in tropical cyclones include more frequent Category 4-5 storms (*high confidence*) and increased rain rates (*very high confidence*) (Knutson et al., 2020), with relative sea level rise exacerbating storm surge potential but large differences per region depending also on changes to future storm tracks (Section 11.7.1.5). By the late 21st century, tropical cyclones are projected to be less frequent in the basins of the western and eastern North Pacific, Bay of Bengal, Caribbean Sea and in the Southern Hemisphere, but will be more frequent in the subtropical central Pacific (Murakami et al., 2014; Yoshida et al., 2017; Bell et al., 2019; Knutson et al., 2020). Over CAR, tropical cyclone intensity is expected to increase due to higher sea surface temperatures but can be inhibited by increases in vertical wind shear in the region (*medium confidence*) (Kossin, 2017; Ting et al., 2019). The poleward movement of the area where tropical cyclones reach peak intensity in the western North Pacific is likely to continue, which affects the tropical cyclone frequency over the small islands in the area (Kossin et al., 2016) (Section 11.7.1.5). Projections also indicate an increase (decrease) in the tropical cyclone frequency during El Niño (La Niña) events in the Pacific at the end of the 21st century (Chand et al., 2017). RCP8.5 2080-2099 projections indicate an increase in tropical cyclone number by 2% in the North Central Pacific relative to 1980-1999, with tracks shifting northward towards Hawaii (Li et al., 2018d). Given projected reductions to the overall number of storms but increases in storm intensity, total rainfall and storm surge potential, we assess *medium confidence* of overall changes to tropical cyclones affecting the Caribbean and Pacific small islands.

**Global changes**: Global changes indicate that small islands will generally face fewer but more intense tropical cyclones (*medium confidence*) although there is substantial variability across small island regions given projected regional shifts in storm tracks.

12.4.7.4 Coastal and Oceanic

**Relative sea level**: Relative sea level rise (SLR) continues to be a major threat to small islands and atolls, since it can exacerbate the impacts of other climate hazards on low-lying coastal communities and infrastructures, ecosystems, and freshwater resources (Nurse et al., 2014; Hoegh-Guldberg et al., 2018). In the Indian Ocean- South Pacific region, a new tide-gauge based reconstruction finds a regional-mean RSL change of 1.33 [0.80 to 1.86] mm yr\(^{-1}\) over 1900-2018 (Frederikse et al., 2020) compared to a GMSL change of around 1.7 mm yr\(^{-1}\) (Section 2.3.3.3; Table 9.5). RSLR rates based on satellite altimetry for the period 1993-2018 increased to 3.65 [3.23 to 4.08] mm yr\(^{-1}\) (Frederikse et al., 2020), compared to a GMSL change of 3.25 mm yr\(^{-1}\) (Section 2.3.3.3; Table 9.5).
Relative sea-level rise is very likely to continue in the oceans in the Small Island States. Around the small islands, regional-mean RSLR projections vary widely, from 0.4 m–0.6 m under SSP1-RCP2.6 to 0.7 m–1.6 m under SSP5-RCP8.5 for 2081–2100 relative to 1995–2014 (median values), but in general they are situated in areas with RSL changes ranging from the mean projected GMSL change to above-average values (Section 9.6.3.3). These RSLR projections may however be underestimated due to potential partial representation of land subsidence in their assessment (Section 9.6.3.2).

Coastal flood: Relative sea-level rise, storm surges, and swells contribute to coastal inundation in the small islands, where studies on historical trends in coastal flooding are currently limited. For example, a swell event due to distant extra-tropical cyclones in December 2008 raised extreme water levels leading to flooding affecting five Pacific island nations: Marshall Islands, Micronesia, Papua New Guinea, Kiribati and Solomon Islands (Hoek et al., 2013; Merrifield et al., 2014). Over low-lying atoll islands in the northwest tropical Pacific, potential increases in the areal extent in coastal flooding with reduced return periods, especially at higher SLR scenarios, are expected to have negative consequences on freshwater resources and island habitability (Storlazzi et al., 2015, 2018). Select tide gauges across the Pacific also indicate increasing trends in the frequency of minor flooding since the 1960s (Marra and Kruk, 2017).

As relative sea levels increase, the potential for coastal flooding increases in the small islands (high confidence). Across the Pacific and CAR small islands, the 5th – 95th percentile range of the 1:100 yr ETWL is projected to increase (relative to 1980 – 2014) by 10 cm – 35 cm and by 14 cm – 41 cm by 2050 under RCP4.5 and RCP8.5, respectively (Figure 12.4q). By 2100, this range is projected to be 27 cm – 81 cm and 44 cm – 188 cm under RCP4.5 and RCP8.5, respectively (Figure 12.4p,r) (Vousdoukas et al., 2018; Kirezci et al., 2020). Furthermore, by 2050, the present day 1:100 yr ETWL is projected to have median return periods of between 1:1 yr and 1:50 yr in both the Pacific and CAR small islands, with some Pacific islands projected to experience the present day 1:100 yr ETWL more than once a year (Vousdoukas et al., 2018; Oppenheimer et al., 2019). By 2100, the present day 1:50 yr ETWL is projected to occur around 3 times a year by 2100 with a SLR of 1 m at Pacific and CAR small islands (Vitousek et al., 2017). In the Western Tropical Pacific, the magnitude and frequency of coastal flooding due to SLR can be modulated by changes in the wave climate (Shope et al., 2016).

Coastal erosion: Recent studies have indicated variable and dynamic changes in shorelines of reef islands (medium confidence), including both erosion and accretion, which suggest factors other than SLR affecting shoreline changes, such as in the central and western Pacific within the past 50 to 60 year timeframe (Webb and Kench, 2010; Le Cozannet et al., 2014; Ford and Kench, 2015; Duvat and Pillet, 2017). For example, islands on atolls in the central and western Pacific have not substantially eroded or reduced in size in the past decades when sea level has increased but rather have changed their position and morphology due to anthropogenic factors (e.g., seawalls, reclamation) and climate-ocean processes (Biribo and Woodroffe, 2013; McLean and Kench, 2015). Analysis of aerial and satellite imagery revealed severe shoreline retreat in six islands and the disappearance of five vegetated reef islands in Solomon Islands in the western Pacific between 1947 to 2014, which may be due to the interaction between SLR and waves (Albert et al., 2016). In French Polynesia, changes in shoreline and island area have been observed since the 1960s, partly due to the effect of TCs on sediment changes and human activities (Duvat and Pillet, 2017; Duvat et al., 2017). Coastal erosion have also been noted over the small, low-lying, sandy islands, such as in French Polynesia and Solomon Islands, among others, due to high relative sea level rise and storms (Luijendijk et al., 2018a; Mentaschi et al., 2018). Average shoreline retreat rates between 1 m yr$^{-1}$ and 2 m yr$^{-1}$ are estimated for the islands in the Equatorial Pacific and in CAR, while a retreat rate of 0.5 m is estimated for islands in the south Pacific, based on satellite observations from 1984-2016 (Luijendijk et al., 2018a; Mentaschi et al., 2018). There was also a loss of 610 km$^2$ vs. a gain of 520 km$^2$ in coastal area in Oceania during the 1984-2015 period (Mentaschi et al., 2018).

Projections indicate that shoreline retreat will occur over most of the small islands in the Pacific and CAR throughout the 21st century with spatial variability (high confidence). Median shoreline change projections (CMIP5), relative to 2010, presented by Vousdoukas et al. (2020) show that, by mid-century, shorelines in the islands in the equatorial Pacific and south Pacific will retreat by around 40 m, under both RCP4.5 and RCP8.5. In CAR islands, sandy shorelines are projected to retreat by about 80 m by mid-century under both
RCPs. By 2100, more than 100 m of median shoreline retreat is projected for all small islands under both RCPs; notably in CAR where retreats approaching 200 m (relative to 2010) are projected under both RCPs. The total length of sandy coasts in CAR and Pacific small islands that is projected to retreat by more than a median of 100 m by 2100 under RCP4.5 and RCP8.5 is about 1,100 km and 1,200 km respectively, an increase of approximately 14%.

Marine heatwave: Ocean temperatures from satellite observations noted a moderate increase of 1–4 annual marine heat wave (MHW) events between 1982–1988 and 2000–2016 over some areas in the Indian Ocean, subtropical parts of the North and South Atlantic, and central and western parts of the North and South Pacific, but a decrease in frequency (2 annual events) over the eastern Pacific Ocean (Oliver et al., 2018) (see Box 9.2). The intensity of MHWs has also increased between 0.2°C and 0.5°C over the equatorial portions of the North Atlantic, and the South Pacific. Over the eastern tropical Pacific, the decrease in intensity and duration of MHW is between 0.5–1.0 °C and between 30–75 days, respectively (Oliver et al., 2018) (see Box 9.2). There is high confidence that MHWs will increase around all small island nations.

Marine heatwaves are projected to be more intense and prolonged where the largest changes are noted in the equatorial region with maximum annual intensities up to 1.2°C (1.8°C) and annual mean duration reaching 100 days (200 days) at 1.5°C (2.0 °C) warming levels (Frölicher et al., 2018). Projections for SSP1-2.6 and SSP5-8.5 both show an increase in MHWs around all small island nations by 2081–2100, relative to 1985–2014 (Box 9.2, Figure 1).

In summary, relative sea level rise is very likely in the oceans around small islands, and along with storm surges and waves will exacerbate coastal inundation in small islands. Shoreline retreat is projected along sandy coasts of most small islands (high confidence). There is high confidence that MHWs will increase around all small island nations.

The assessed direction of change in climatic impact-drivers for CAR and Pacific small islands and associated confidence levels are illustrated in Table 12.9. Cold, Snow, Ice related climatic impact-drivers, and sand and dust storms are not broadly relevant in small islands.

[START TABLE 12.9 HERE]
12.4.8 Open and deep ocean

Oceans face challenges from anthropogenic perturbations to the global Earth system, which cause increasing ocean warming, carbon dioxide induced acidification and oxygen loss (Bindoff et al., 2019). Climate change will affect the major oceanic CIDs described in Section 12.2; mean ocean temperature, marine heatwaves, ocean acidity, ocean salinity, dissolved oxygen (O₂), severe wind storms and sea ice melting. These changes result in a shifting profile of hazards relevant to impact and risk assessments (Section 12.3). New evidence, the IPCC (2019b) and advances in the new CMIP6 climate simulations reinforce confidence in projected changes in climate impact drivers in the global oceans. As the ocean has taken up about 90% of the global warming for the period 1971-2018 (Section 7.2.2.2), the emergence of the sea surface temperature increase signal has already been observed in global oceans over the last century (Hawkins et al., 2020). The emergence signal in sea ice extent decrease has already emerged in the Arctic Ocean (Landrum and Holland, 2020), while ocean acidification and low oxygen have also already emerged in many oceanic regions and will emerge in all global oceans by 2050 under RCP8.5 (see Section 12.5.2; Table 12.10). This section assesses key hazards that can be linked with sectoral and regional vulnerability and exposure in open and deep oceans, drawing from previous Chapters (2, 3, 4, 5, and 9).

**Mean ocean temperature:** It is very likely that global mean sea surface temperature global mean SST has increased by 0.88°C [0.68 to 1.01°C] from 1850-1900 to 2011-2020, and 0.60°C [0.44 to 0.74°C] from 1980-2020 (Section 2.3.1.1.6; Table 2.4). There is very high confidence that the Indian Ocean, western equatorial the Pacific Ocean, and western boundary currents have warmed faster than the global average, while the Southern Ocean, the eastern equatorial Pacific, and the North Atlantic Ocean have warmed more slowly or slightly cooled (Section 9.2.1.1). It is virtually certain that SST will continue to increase in the 21st century at a rate depending on future emission scenario, while the global mean ocean surface temperature will continue to increase throughout the 21st century (very high confidence), with CMIP6 projections indicating an increase of 0.86°C (likely range: 0.43-1.47°C) under SSP1-2.6 and 2.89°C (2.01-4.07°C) under SSP5-8.5, by 2081-2100, relative to 1995-2014 (Section 9.2.1.1). Global warming of 2°C above pre-industrial levels is projected to increase sea surface temperature, resulting in the exceedance of numerous hazard thresholds for pathogens, seagrasses, mangroves, kelp forests, rocky shores, coral reefs and other marine ecosystems (Poloczanska et al., 2013b, 2016, 2013a; Pörtner et al., 2014; Liu et al., 2014; Graham et
al., 2015; Schoepf et al., 2015; Gobler et al., 2017; Henson et al., 2017; Hoegh-Guldberg et al., 2017; Krueger et al., 2017; Hughes et al., 2018b, 2018a; Perry et al., 2018) (medium confidence). It is virtually certain that upper ocean stratification has increased at a rate of 4.9±1.5% during 1970-2018 and that this will continue to increase in the 21st century (Section 9.2.1.3), potentially leading to reduced nutrient supply and total productivity (Moore et al., 2018) (low confidence).

Marine heatwaves: Marine heatwaves have increased in frequency over the 20th century, with an approximate doubling since the 1980s (high confidence), and their intensity and duration have also increased (medium confidence) (Box 9.2). Projections show that this increasing trend likely continues with 2-9 times more frequent marine heatwaves (at global scale) projected by 2081-2100, relative to 1995-2014 under SSP1-2.6, and 4-18 times more frequent under SSP5-8.5. The largest changes in MHW frequency likely to occur in the tropical ocean and the Arctic, while there is medium confidence of moderate increases in the mid-latitudes, and of small increases in the Southern Ocean (Box 9.2). Permanent MHWs (more than 360 days per year, relative to the historical climate conditions) are projected to occur in the 21st century in parts of the tropical ocean, in the Arctic Ocean and around latitude 45ºS, under SSP5-8.5 (Box 9.2). The occurrence of such permanent MHWs can be largely avoided under SSP1-2.6 scenario (Box 9.2). MHW can have devastating and long-term impacts on ecosystems (Oliver et al., 2018), making them an emerging hazard for marine ecosystems (Frölicher and Laufkötter, 2018; Smale et al., 2019). A series of marine heatwaves that occurred in 2010-2011 had consequences for seagrass in Western Australia (Wernberg et al., 2013; Arias-Ortiz et al., 2018), and for lower fishery in the Gulf of Maine (Pershing et al., 2018). The MHWs that occurred Western Australia in 2015/2016 lead to the third highest mass bleaching globally (Le Nohaïc et al., 2017).

Ocean acidity: With the increasing CO₂ concentration, the global mean ocean surface pH is decreasing and is now the lowest it has been for at least a thousand years (very high confidence) (Section 2.3.3.5). It is very likely that, since the 1980s, ocean surface pH has changed at a rate of -0.016 to -0.019 per decade in the subtropical open oceans, at -0.010 to -0.026 per decade in the tropical Pacific, and at -0.003 to -0.026 per decade in open subpolar and polar zones (Section 2.3.3.5; Section 5.3.3.2). Over the period 1870–1899 to 2080–2099, ocean surface pH is projected to decline by -0.16 ± 0.002 under SSP1-2.6, and by -0.44 ± 0.005 under SSP5–8.5 (Section 4.3.2.5; Section 5.3.4.1). Declining ocean pH will exacerbate negative impacts on marine species (Albright et al., 2016; Kwiatkowski et al., 2016; Watson et al., 2017) (medium confidence).

Ocean salinity: Salinity contrasts have increased since the 1950s, near the ocean surface (virtually certain) and in the sub-surface (very likely), with high salinity regions becoming more saline and low salinity regions becoming fresher (Section 2.3.3.2). At the basin scale, it is very likely that the Pacific and the Southern Oceans have freshened, and the Atlantic has become more saline (Section 2.3.3.2). The IPCC (2019) assessment that fresh ocean regions get fresher and salty ocean regions get saltier will continue in the 21st century is confirmed in Section 9.2.2.2.

At the regional scale, by 2100, the average Arctic surface salinity is projected to decrease by 1.5 ± 1.1 psu, and the liquid freshwater column in the Arctic Ocean is projected increase by 5.4 ± 3.8 m under RCP8.5, (Shu et al., 2018). In the Indian Ocean, sea surface salinity is projected to decrease by 0.49 psu and 0.75 psu by 2080, compared to 2015, under RCP2.6 and RCP2.6, respectively (Akhiljith et al., 2019). Projections for the North and South Atlantic Oceans indicate increasing salinity in the upper layer (0 – 500 m) under both RCP4.5 and RCP8.5, due to the decreasing freshwater input from the Equator and increasing net evaporation (Skliris et al., 2020). There is medium confidence that fresh ocean regions (Pacific, Southern and Indian oceans) will get fresher and salty ocean regions (Atlantic ocean) will get saltier over the 21st century (IPCC, 2019; Section 9.2.2.2). Ocean warming and high-latitude surface freshening is projected to continue to increase upper ocean stratification in the 21st century (Section 9.2.1.3).

Dissolved oxygen: Since the middle of the last century, oxygen concentrations of open and coastal waters have been declining, and such deoxygenation affects biological and biogeochemical processes in the ocean (Schmidttdk et al., 2017). In recent decades, low oxygen zones in ocean ecosystems have expanded, and projections indicate an acceleration with global warming (Diaz and Rosenberg, 2008; Gilly et al., 2013; Gobler et al., 2014) (medium confidence). A 2% loss (4.8 ± 2.1 Pmoles O₂) in total dissolved oxygen in the
upper ocean layer (100–600 m) has been observed during 1970–2010 (Section 2.3.4.2), with the highest
oxygen loss of up to 30 mol m⁻² per decade in the equatorial and North Pacific, the Southern Ocean and the
South Atlantic Ocean (Section 5.3.3.2). Global mean ocean oxygen concentration is projected to decrease by
6.36 ± 2.92 mmol m⁻³ under SSP1-2.6 and by 13.27 ± 5.28 mmol m⁻³ under SSP5-8.5 in the subsurface (100-
600 m) by 2080–2099, compared to 1870–1899, which is respectively 71% and 40% greater than previous
estimates based on CMIP5 models (Section 5.3.3.2). In the benthic ocean, projected future losses of
dissolved oxygen concentration by 2080–2099, compared to 1870–1899, are −5.14 ± 2.04 mmol m⁻³ under
SSP1-2.6 and −6.04 ± 2.19 mmol m⁻³ under SSP5-8.5 (Kwiatkowski et al., 2020). Section 5.3.3.2 assessed
very likely global decreases in ocean oxygen concentrations although there is medium confidence in specific
regional declines that are expected to expand both anoxic and hypoxic zones, with such reductions of oxygen
expected to persist for thousands of years (Yamamoto et al., 2015; Frölicher et al., 2020).

Sea ice: The Arctic sea ice area for September has decreased from 6.23 to 3.76 million km² and for March
from 14.52 to 13.42 million km² between 1979-1988 and 2010-19 (Section 2.3.2.1.1). There is high
confidence that sea ice in the Arctic will further decrease in the future under all emission scenarios (Section
9.3.1.1). In contrast, there is no clear observed trend in the Antarctic sea ice area over the past few decades
and there is low confidence of future changes therein (Section 9.3.1.1). The duration of the summer season in
the Arctic has increased by 5 to 20 weeks between 1979 and 2013, with a significant trend ranging from 5 to
17 days/decade for earlier spring retreat and from 5 to 25 days/decade for later fall advance, with
consequences for Arctic marine mammals (AMMs) due to sea ice habitat loss (Laidre et al., 2015). The
Arctic is projected to be ice-free more often during summer under 2°C global warming compared to 1.5°C
global warming (Section 9.3.1.1; see also Section 12.4.9 and Section 4.4.2.1), opening new shipping lanes
for international commerce (Valsson and Ulfarsson, 2011) and lengthening the season for offshore resource
extraction (Schaeffer et al., 2012). Iceberg numbers are expected to increase as a result of global warming,
forming an elevated hazard to shipping and offshore facilities (Bigg et al., 2018).

It is virtually certain that global mean SST will continue to increase throughout the 21st century,
resulting in the exceedance of numerous hazard thresholds relevant to marine ecosystems (medium
confidence). Marine heatwaves day are projected to increase in global oceans with a larger increase in
the tropical ocean and Arctic Ocean (high confidence). It is virtually certain that upper ocean
stratification will continue to increase in the 21st century. Future Ocean warming will very likely assist
the development of both anoxic and hypoxic zones, with such reductions of oxygen expected to persist
for thousands of years. Future projections also indicate freshening of the Pacific, Southern and Indian
Oceans and a saltier Atlantic Ocean (medium confidence).

The assessed direction of change in climatic impact-drivers for open and deep ocean regions and associated
confidence levels are illustrated in Table 12.10, following the AR6 WGI ocean reference regions as proposed
by the Atlas (Figure Atlas.2b).

[START TABLE 12.10 HERE]

Table 12.10: Summary of confidence in direction of projected change in climatic impact-drivers in open and deep
ocean regions, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5,
SSP3-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately
corresponding (for CIDs that are independent of sea-level rise) to global warming levels between 2°C and
2.4°C (see 12.4 for more details of the assessment method). The table also includes the assessment of
observed or projected time-of-emergence of the CID change signal from the natural inter-annual
variability if found with at least medium confidence in Section 12.5.2.
### 12.4.9 Polar terrestrial regions

Several recent climate assessments on polar regions describe robust patterns of recent and future climatic changes driving impacts and risk for polar environmental, societal, and economic assets, including the IPCC SROCC (Meredith et al., 2019), the Report on Snow, Water, Ice and Permafrost in the Arctic (AMAP, 2017b), and national assessments for the United States (Markon et al., 2018) and Canada (Derksen et al., 2018). This section examines Greenland and Iceland, the Russian Arctic, Antarctica, and the arctic portions of Northern Europe and North America (Figure 1.18c).

#### 12.4.9.1 Heat and cold

**Mean air temperature:** Atlas.11.2 shows *high confidence* in warming of the Arctic in observations and projections, measuring among the fastest-warming places at more than twice the global mean, with substantially higher temperature increases in the cold season (see also AMAP, 2017; Meredith et al., 2019). Atlas.11.1 assessed *very likely* warming in observations of West Antarctica from 1957-2016, but *limited evidence* of mean air temperature change across East Antarctica even as there is *high confidence* in future warming across the continent (Meredith et al., 2019) (Figures Atlas.32, Atlas.33).

**Extreme heat, cold spell and frost:** Ecosystem and societal temperature thresholds in polar regions often reflect lower tolerance to heat and higher tolerance to cold. Extreme heat events have increased around the Arctic and Iceland since 1979, including increases in cold season warm days and nights, melt days, and Arctic winter warm events (T>10°C) as well as decreases in cold days and nights (Mernild et al., 2014; Matthes et al., 2015; Vikhamar-Schuler et al., 2016; Graham et al., 2017; Sui et al., 2017; Dobricic et al., 2020; Peña-Angulo et al., 2020). Heatwaves causing high temperature records have been recently documented in West and East Antarctica (Wille et al., 2019; Robinson et al., 2020). There is *high confidence* that polar amplification will drive increases in Arctic heat extremes as well as continuing declines in the...
magnitude and frequency of cold extremes (Matthes et al., 2015; Karin et al., 2018), although dynamical
effects will still bring substantial cold air anomalies over the Arctic (Wu and Francis, 2019). There is
medium confidence for equivalent changes in extreme heat in Antarctica based primarily on higher mean
temperatures, with Lee et al. (2017) projecting more than 50 additional degree days above freezing (2098
RCP8.5 vs. 2014) over parts of the Antarctic Peninsula but smaller changes over mainland Antarctica.

12.4.9.2 Wet and dry

Mean precipitation: Atlas.11.2 indicated medium confidence in observed increases in Arctic precipitation
with the largest rises in the cold season. Antarctic precipitation showed no significant overall trend since the
1970s, with a positive trend over the 20th century (Atlas.11.1, 9.4.2.1). Increases in Arctic and Antarctic
precipitation during the 21st century are very likely with projected percentage increases that are much higher
than most sub-polar regions of the world (Figure Atlas.32).

Floods and heavy precipitation: Observations and model projections indicate high confidence in
increasing Arctic river runoff in response to increasing total precipitation (Box et al., 2019; Durocher et al.,
2019; Meredith et al., 2019) with a shift toward earlier meltwater flooding (AMAP, 2017b). Higher Arctic
precipitable water totals are also connected with observed increases in heavy precipitation and convective
activity (high confidence) (Ye et al., 2015; Karin et al., 2018; Chernokulsky et al., 2019). Higher flood
magnitudes are also driven by future increases in rain-on-snow event days, amounts, and runoff, which are
more significant in the Arctic than in mid-latitudes (where seasonal snow cover is often further reduced)
(AMAP, 2017b; Il Jeong and Sushama, 2018).

Landslide and snow avalanche: There is a growing number of studies on mass movements in polar
regions. Although there is low confidence in widespread observational trends for landslides or snow
avalanches, a rise in the number of future landslides is supported by strong links to increases in heavy
precipitation, glacier retreat, and thawing of ice-rich permafrost that can lead to retrogressive thaw slumps in
Arctic regions (Kokelj et al., 2015; Derksen et al., 2018; Lewkowicz and Way, 2019; Patton et al., 2019;
Ward Jones et al., 2019) (Section 2.3.2.5).

Aridity and drought: Recent decades have seen a general decrease in Arctic aridity with projections
indicating a continuing trend toward reduced aridity (high confidence) as increased moisture transport leads
to higher precipitation, humidity and streamflow (Meredith et al., 2019) and a corresponding decrease in dry
days (Khlebnikova et al., 2019b). There is low confidence overall of recent or projected drought changes in
polar regions (Section 11.9) even as increasing evidence shows that drainage from permafrost thaw, higher
potential evapotranspiration, and changing seasonal patterns of melt have caused lake reduction and soil
moisture deficits in several areas that match with projections of future drought increase despite overall
precipitation increases (Andresen and Lougheed, 2015; Bring et al., 2016; Spinoni et al., 2018a; Feng et al.,
2019; Finger Higgen et al., 2019).

Fire weather: Fire season lengthened from 1979-2015 over Arctic portions of North America (Jain et al.,
2017), corresponding also to a 1975-2015 increase in lightning-ignited fires in Northwestern North America
(Girardin et al., 2013; Veraverbeke et al., 2017). Abatzoglou et al. (2019) climate model simulations project
significant fire weather index increases in boreal forests of Arctic Europe, Arctic Russia and Northeast North
America (medium confidence). Trends toward more frequent fires in tundra regions are expected to continue,
driven in particular by increasing potential evapotranspiration and changes in vegetation (high confidence)
(Hu et al., 2015; AMAP, 2017b; Young et al., 2017).

12.4.9.3 Wind

Mean wind speed and severe storm: There is medium confidence of mean wind decrease over the Russian
Arctic, Greenland and Iceland and Arctic Northeast North America (Karnauskas et al., 2018a; Jung and
Schindler, 2019), but low confidence of changes in the other Arctic regions and Antarctica. Bintanja et al.
(2014) projected that a strengthening of the Southern Annular Mode would decrease easterlies along
Antarctica’s coasts with only small changes in katabatic winds (although this effect may diminish with
stratospheric ozone recovery). In contrast, Gorter et al. (2014) regional climate model projections indicated a
reduction in mean winds over the interior of Greenland by RCP4.5 2100 while coastal winds increase.
Reanalysis data and climate models indicate few coherent regional trends of polar cyclone frequency or
relationships with cyclone depth and size (Akperov et al., 2018, 2019; Day and Hodges, 2018; Zahn et al.,
2018).

12.4.9.4 Snow and ice

Snow: Atlas.11.1 identified likely increases in surface mass balance (driven by snowfall) across Antarctica in
the 20th century (medium confidence). In the Arctic, overall snow extent and seasonal duration are projected
to continue recent declines (high confidence), although mid-winter snowpack increases in some of the
coldest and high-elevation locations given higher precipitation totals (medium confidence) (Bring et al.,
2016; Danco et al., 2016; AMAP, 2017; Meredith et al., 2019) (9.5.3; Atlas.11.2; Atlas.9). Higher
temperatures result in a higher percentage of Arctic precipitation falling as rain (particularly in fall and
spring) (high confidence), with most land regions (outside of Greenland and Antarctica) becoming
dominated by rainfall (more than 50% of total precipitation) by RCP8.5 2100 (Bintanja and Andry, 2017;
Irannezhad et al., 2017).

Glacier and ice sheet: Section 9.5.1 and Section 2.3.2.3 found that glaciers have lost mass in all polar
regions since 2000 (high confidence), and Section 9.4 assessed high confidence in Greenland ice sheet mass
losses since 1980 and Antarctic Ice Sheet losses since 1992 (dominated by West Antarctica with losses in
parts of East Antarctica in the past two decades). New simulations from GlacierMIP (Marzeion et al., 2020)
indicate glaciers in Iceland will lose 31 ± 35%, 41 ± 46% and 53 ± 45% of their mass in 2015 by the end of
the century for RCP2.6, RCP4.5 and RCP8.5 scenarios, respectively. Marzeion et al. (2020) projected mass
losses (high confidence) for those same scenarios in the Greenland Periphery: 22 ± 23%, 29 ± 26%, and 42 ±
28%; Svalbard: 35 ± 34%, 50 ± 36%, and 66 ± 35%; Russian Arctic: 26 ± 26%, 38 ± 28%, and 52 ± 30%;
Northern Arctic Canada: 12 ± 13%, 18 ± 12%, and 27 ± 18%; Southern Arctic Canada: 23 ± 27%, 33 ± 29%,
and 48 ± 32%; and Antarctic Periphery: 7 ± 12%, 13 ± 10%, and 16 ± 19%. Areas with receding glaciers are
also potentially vulnerable to glacial lake outburst floods (Harrison et al., 2018).

Permafrost: Observations from recent decades (assessed in Section 9.5.2 and Section 2.3.2.5) show
increases in permafrost temperature (very high confidence) and active layer thickness (medium confidence)
across the Arctic (AMAP, 2017; Markon et al., 2018; Biskaborn et al., 2019; Derksen et al., 2019;
Farquharson et al., 2019; Meredith et al., 2019; Romanovsky et al., 2020). Section 9.5.2 noted that
observations of active layer thickness in Antarctica are too limited to assess long-term trends (see also
Biskaborn et al., 2019; Hrbáček et al., 2018). Future projections indicate continuing increases in permafrost
temperature and active layer thickness with loss of permafrost across the Arctic (Section 9.5.2). Streletskiy et
al. (2019) noted that changes to Russian permafrost temperature and active layer thickness are most
pronounced in areas where permafrost is continuous (underlying >90% of landmass). CMIP5 analyses by
Slater and Lawrence (2013) projected that, by RCP8.5 2100, shallow (<3 m) permafrost would be most
probable only in portions of the Canadian Arctic Archipelago and the Russian Arctic coastal and eastern
upland regions.

Sea ice: Consistent with the SROCC (Meredith et al., 2019), Section 9.3.1 and Section 2.3.2.1.1 assess very
high confidence that Arctic sea ice thickness, extent, and average age have significantly decreased over the
past four decades with largest declines in September (when sea ice is at an annual minimum). Declines in
landfast ice are most rapid in the Laptev Sea (Selyuzhenok et al., 2015), are breaking perennial landfast ice
blocking ocean channels (‘ice plugs’) in the Canadian Archipelago (Pope et al., 2017), and declining in the
cold season by 7% decade−1 across the Arctic (1976–2007) (Yu et al., 2014). Observed trends and projections
suggest that perennial sea ice is being replaced by thin, seasonal ice, although multi-year ice will persist
above the Canadian Archipelago and drift into sea transportation lanes (Howell et al., 2016; Derksen et al.,
2018). Trends from 1979–2013 show slightly earlier spring melt for Arctic sea ice, but substantially-delayed
fall freeze up and a melt season lengthened by more than 3 days decade$^{-1}$ off northern Alaska and Canada with the exception of portions of the Bering Sea (Parkinson, 2014; Stroeve et al., 2014). Section 9.3.2 assessed low confidence in long-term trends in sea ice extent or thickness near Antarctica.

Future declines in Arctic sea ice are virtually certain, although there is low confidence in declines of Antarctic sea ice given dynamical processes in the Southern Ocean and the recovery of stratospheric ozone (Section 9.3; Meredith et al., 2019). Projections of an ‘ice-free’ Arctic vary depending on definitions representing transportation needs, however Laliberté et al. (2016) noted that the median of 42 CMIP5 models projected <5% sea ice for the month of September by 2050, with equivalent conditions for the entirety of the August-October period by 2090. Section 9.3.1 assessed high confidence that practically ice-free conditions (<1 million km$^2$ in the September mean) would likely first appear before 2050 even under strong mitigation scenarios (Simond et al., 2018; Stroeve and Notz, 2018; Notz and SIMIP, 2020).

Lake and river ice: There is high confidence in observations of significant declines in seasonal ice cover thickness and duration over most Arctic lakes, with many lakes projected to lose more than month of ice cover by mid-century (medium confidence) (Meredith et al., 2019; Sharma et al., 2019). Some lakes that previously froze to the bottom (‘bedfast’) now maintain liquid bottom water year round, and others shift from perennial to seasonal ice cover (Surdu et al., 2016; Engram et al., 2018). Yang et al. (2020) identified a decline in Arctic cold-season river ice extent in satellite observations (particularly in Alaska) and projected reductions in average Northern Hemisphere seasonal river ice duration of 6.10 ± 0.08 days per degree global surface air temperature.

Heavy snowfall and ice storm: There is limited evidence of changes in heavy snowfall due to competing influences of shortened snowfall seasonality with more intense (and larger overall) precipitation in the Arctic. Episodic heavy snowfall trends in Antarctica are difficult to separate from large interannual variability (limited evidence) (Gorodetskaya et al., 2014, Turner et al., 2020). Limited evidence also hinders clear signals in ice storms, although warming shifts the freezing line (around which ice storms occur) poleward and upslope (Bintanja and Andry, 2017). Groisman et al. (2016) used 40 years of observations to identify an increase of freezing rain events in Norway, North America, and Eastern and Western Russia. Increases in wintertime rainfall have led to more frequent development of difficult wildlife and livestock grazing conditions as basal ice conditions coat the ground below snowpack (Peeters et al., 2019).

12.4.9.5 Coastal and oceanic

Relative sea level: Satellite altimetry and tide data show that relative sea levels (with glacial isostatic adjustment) are rising in Arctic Europe and Northwest North America, declining in portions of Southern Alaska and Arctic Northeast North America and no clear trend in Greenland and Arctic Russia (Sweet et al., 2018; Rose et al., 2019), which is broadly consistent with findings in Oppenheimer et al. (2019). Areas with low or negative change have substantial land uplift counteracting the global mean sea level trend (Greenan et al., 2018; Sweet et al., 2018; Madson et al., 2019). SROCC projections indicate high confidence in future rises in relative sea level for all Arctic regions other than areas of substantial land uplift in Northeastern Canada, the west coast of Greenland, and narrow portions of West Antarctica (Oppenheimer et al., 2019).

Coastal flooding and erosion: Higher sea levels and reduced coastal sea ice protection will increase future extreme sea levels in the Arctic (high confidence for Arctic NEU, RAR, and Arctic NWN; medium confidence for GIC and Arctic NEN given glacial isostatic adjustment). Vousdoukas et al. (2018) project that the current 1:100 yr extreme total water level would have median return periods of 1:20 yrs – 1:50 yrs by 2050, increasing to 1:5 yrs – 1:20 yrs by 2100 under RCP4.5 along nearly the entire Arctic coastline by 2100 (excluding GIC for which projections are not available). Projections for RCP8.5 indicate that the present day 1:100 yr ETWL would have median return periods of 1:10 yrs – 1:50 yrs 2050 and would occur once every 5 years (or more frequently). Arctic coastal erosion is also expected to increase with climate change (medium confidence; high agreement but limited evidence of projections), accelerated in some regions by subsurface permafrost thaw and increased wave energy (Gibbs and Richmond, 2015; Fritz et al., 2017; Oppenheimer et al., 2019; Casas-Prat and Wang, 2020). A longer ice-free season for the RCP8.5
2080s is projected to help drive more than 100 m of shoreline retreat in Northwest North America Arctic coastal communities (Melvin et al., 2017; Greenan et al., 2019; Magnan et al., 2019). Assessment of coastal flooding and erosion changes in Antarctica are limited by a lack of studies.

**Marine heatwave:** Recent years have seen marine heatwaves and increasing extreme coastal SSTs in Arctic systems (Lima and Wethey, 2012; Collins et al., 2019; Frölicher, 2019). Projections show increases in marine heatwave intensity, frequency, and duration will be larger over the Arctic Ocean than mid-latitude oceans due in part to low interannual variability under current sea ice (*high confidence*). Frölicher et al. (2018) used 12 CMIP5 models to project median MHW days increasing about 25-fold and 50-fold at the 2°C and 3.5°C GWLs in response to mean ocean warming and sea ice loss, and the smallest global changes still being increases in the Southern Ocean around Antarctica (see also Cross-chapter Box 9.1).

Climate change has caused and will continue to induce enhanced warming trend, increasing heat-related extremes and decreasing cold spells and frosts in the Arctic (*high confidence*), with similar changes in Antarctica but *medium confidence* for extreme heat increases and West Antarctic frost change decreases and *low confidence* for cold spell changes and East Antarctica frost. The water cycle is projected to intensify in polar regions, leading to more rainfall, higher river flood potential and more intense precipitation (*high confidence*). Projections indicate reductions in glaciers and sea ice at both poles, with enhanced permafrost warming, decreasing permafrost extent, and decreasing seasonal duration and extent of snow cover in the Arctic (*high confidence*) even as some of the coldest regions will see higher total snowfall given increased precipitation (*medium confidence*). Projections indicate relative sea level rises in Polar regions (*high confidence*), with the exception of regions with substantial land uplift including Northeast North America (*high confidence*), Western Greenland, the Northern Baltic Sea, and portions of West Antarctica. Higher sea levels also contribute to *high confidence* for projected increases of Arctic coastal flooding and higher coastal erosion (aided by sea ice loss) (*medium confidence*) with lower confidence for those CIDs in regions with substantial land uplift (Arctic Northeast North America and Greenland).

[START TABLE 12.11 HERE]

**Table 12.11:** Summary of confidence in direction of projected change in climatic impact-drivers in the polar regions, representing their aggregate characteristic changes for mid-century for scenarios RCP4.5, SSP3-4.5, SRES A1B, or above within each AR6 region (defined in Chapter 1), approximately corresponding (for CIDs that are independent of sea-level rise) to global warming levels between 2°C and 2.4°C (see 12.4 for more details of the assessment method). The table also includes the assessment of observed or projected time-of-emergence of the CID change signal from the natural inter-annual variability if found with at least *medium confidence* in Section 12.5.2. Note that the Arctic portions of the NEU, NEN, and NWN differ from the full AR6 regions assessed in the Europe and North America sections above (see also Figure 1.18c).
1. Snow may increase in some high elevations and during the cold season and decrease in other seasons and at lower elevations
2. Higher confidence in southern regions and lower toward north
3. Higher confidence in increase for some climatic impact-driver indices during summertime
4. Glaciers decline even as some regional snow climatic impact-driver indices increase
5. Decreasing as wet and increasing in east
6. Except for Northern Baltic Sea coasts where relative sea levels fall
7. Along sandy coasts and in the absence of additional sediment sinks/sources or any physical barriers to shoreline retreat
8. Already emerged in the historical period (medium to high confidence)
9. Emerging by 2050 at least in Scenarios RCP8.5/SSPS-8.5 (medium to high confidence)
10. Emerging after 2050 and by 2100 at least in Scenarios RCP8.5/SSPS-8.5 (medium to high confidence)

### 12.4.10 Specific zones and hotspots

This section focuses on CIDs affecting specific zones heightened vulnerability and coherent characteristics that cut across traditional continental regions (see also Section 12.3). It is designed to match the structure of the cross-chapter papers in the WGII report, although polar regions were addressed in more extensive detail in 12.4.8 and 12.4.9 and the Mediterranean Region will not be handled separately given that its climatic impact-drivers are discussed in Sections 12.4.1 and 12.4.5 as well as in Cross-Chapter Box 10.3.

#### 12.4.10.1 Hotspots of biodiversity (land, coasts and oceans)

Hotspots of biodiversity are defined by the AR6 WGII as “geographic areas with exceptionally high richness of species, including rare (endemic) species” (WGII Cross-Chapter Paper 1). The AR6 assessment is based on 238 distinctive regions often called the “Global 200 ecoregions” (Olson and Dinerstein, 2002).

Mean temperature increase is a major climatic impact-driver for biodiversity hotspots, and it is very likely that it will affect all hotspot areas identified in the literature, at various rates in all climate scenarios, except those located in the North Atlantic where warming is uncertain (see Chapter 4). Terrestrial ecosystems will experience an enhanced warming compared to ocean ecosystems, because land temperatures are warming faster than ocean temperatures (Chapter 4). Marine ecoregions will experience ocean acidification and temperatures that increase faster in high latitudes (high confidence), but critical temperature and oxygen thresholds are projected to be crossed earlier (by mid-century RCP8.5) in tropical areas (Hughes et al., 2017a; Bruno et al., 2018). A warming trend is also expected for freshwater ecosystems, with different local magnitudes due to combined effects of groundwater system inertia as well as hydrology changes (Knouft and Ficklin, 2017). In tropical land areas, because interannual temperature variability is weak compared to changes, the temperature distribution range is likely to be shifted to a very different range in all projection scenarios, with unprecedented values relative to preindustrial. High climate velocities are particularly
noteworthy for biodiversity hotspots given complex ecosystem dynamics and niche climates not easily
replicated under shifted geographies (Burrows et al., 2014; Halpern et al., 2015; Dobrowski and Parks,
2016). In some regions (Central Africa, Amazon, South East Asia) the mean temperature change is already
beyond the normal range of variations as it has reached levels higher than 3 (and up to 6) times larger than
the standard deviation of the interannual variations (Hawkins et al., 2020). Together with global warming,
land and marine heat waves are very likely to increase in the future climate in biodiversity hotspots (Sections
12.4.1-12.4.7).

There is low confidence in broad patterns of future drying or wet trends across the land and freshwater
biodiversity hotspots from the humid tropics, although drying trends have been detected and predicted in
parts of the Amazon (Fu et al., 2013; Boisier et al., 2015). There is medium confidence (limited evidence,
high agreement) that in several regions the length of the dry season has already increased and is projected to
further increase in some parts of the Mediterranean, Amazonia and sub-Saharan Africa (S. Debor
tolli et al., 2015; Dunning et al., 2018; Hochman et al., 2018; Saeed et al., 2018). Longer dry seasons also extend the
seasonal length and geographical extent of fire weather in all future scenarios (medium confidence) (Jolly et
al., 2015; Abatzoglou et al., 2019).

In conclusion, biodiversity hotspots located around the world will each face unique challenges in
climatic impact-drivers changes. However, heat, drought and length of dry season, wildfire weather,
sea surface temperature and deoxygenation are relevant drivers to terrestrial and freshwater
ecosystems, and have marked increasing trends.

12.4.10.2 Cities and settlements by the sea

Cities and settlements (C&S) by the sea are exposed to specific climate and climate change patterns and to
compound coastal hazard risks (AR6 WGII Cross-chapter paper 2). AR5 WGII found that, in general, “urban
climate change-related risks are increasing (including rising sea levels and storm surges, heat stress, extreme
precipitation, inland and coastal flooding, landslides, drought, increased aridity, water scarcity, and air
pollution)”. Since AR5 a number of studies have been carried out to understand urban climate and its
change. Box 10.3 identified a continuing strong role of the urban heat island in amplifying heat extremes in
cities, although changes in the urban heat island are an order of magnitude smaller than projected localized
warming trends (very high confidence).

Coastal cities’ proximity to the sea somewhat mitigates the effect of urban heat islands (high confidence)
(Salvati et al., 2017; Santamouris et al., 2017; Wang et al., 2018b; Martinelli et al., 2020). Cities and
settlements by the sea typically experience higher humidity levels than inland regions, combining with heat
to enhance heat stress and reduce exceedance of critical heat stress thresholds for outdoor activities, with
potential enhanced exposure to heat for informal settlements (Wang et al., 2019b). Such threshold
exceedances are projected to increase for many coastal areas (high confidence), including the Persian Gulf
where heat stress is projected to be extreme (Pal and Eltahir, 2016; Ahmadalipour and Moradkhani, 2018),
and some low-lying areas in Europe such as the Po Valley and coastal Mediterranean areas (Coppola et al.,
2021a) (Schwinghacker et al., 2021) (see also the heat stress index shown in Figure 12.4d-f).

Climate change related variations in oceanic drivers (e.g., relative sea level, storm surge, ocean waves),
combined with tropical cyclones, extreme precipitation and river flooding, are expected to lead to more
frequent and more intense coastal flooding and erosion (very high confidence) impacting C&S located
especially in low elevation coastal zones and mega-deltas (Chan et al., 2012, 2018; Karymbalis et al., 2012;
Hemer et al., 2013; Aerts et al., 2014; Neumann et al., 2015a; Ranasinghe, 2016; Hauer et al., 2016; Hinkel
et al., 2018; Mavromatidi et al., 2018; Marcos et al., 2019) (See also Sections 12.3, 12.4.1-12.4.7 and
12.4.9). Coastal erosion and flooding also pose challenges to critical infrastructure such as roads, subway
tunnels, electricity and phone networks, wastewater management plants and buildings (Grahn and Nyberg,
2017; Pregnolato et al., 2017). Compound flooding due to simultaneous storm surges and high river flows
have been found to be increasingly frequent in several cities and/or low-lying areas in Europe and the U.S.A.
(Wahl et al., 2015; Paprotny et al., 2018; Bevacqua et al., 2019; Ganguli and Merz, 2019) (high confidence).
Chapter 11 found that the frequency of such compound flood events is projected to increase \textit{(high confidence)}. In addition to sea level rise induced changes, many C&S by the sea are in regions where tropical cyclones are projected to become more intense and frequent \textit{(high confidence)} (Section 11.7).

The SROCC report highlighted coastal settlements in the Arctic as being particularly exposed to several CID changes (Magnan et al., 2019). Enhanced waves due to extended season of sea ice retreat are projected to foster coastal flooding and erosion (Gudmestad, 2018; Casas-Prat and Wang, 2020) (Section 12.4.9). Climate change is also affecting sea ice quality and season length along coasts of the Arctic ocean where populations depend on sea ice for hunting or transportation (Pearce et al., 2015) (Section 12.4.9).

In summary, coastal cities and settlements are particularly affected by a number of climatic impact-drivers that have already changed and will continue to change whatever the emission scenario. These include increases in extreme heat, pluvial floods, coastal erosion and coastal flood \textit{(high confidence)}. Increasing relative sea level compounding with increasing tropical cyclone storm surge and rainfall intensity will increase the probability of coastal city flooding \textit{(high confidence)}. Arctic coastal settlements are particularly exposed to climate change due to sea ice retreat \textit{(high confidence)}.

\subsection*{12.4.10.3 Deserts and semi-arid areas}

Drylands, which include hyper arid, arid, semi-arid and dry sub-humid areas (IPCC, 2019c), lie on all continents and cover 46\% of the global land area and host over a third of the current population (Olsson et al., 2019). Huang et al. (2016) found that aridity changes have helped expand dryland area by \textasciitilde 4\% from 1948 to 2004, with the largest expansion of drylands occurring in semi-arid regions since the early 1960s. Section 4.5.1 assessed \textit{high confidence} of a future poleward expansion of the Hadley cell, leading to a poleward shift of dryland areas in all scenarios considered. There is no evidence of a future global trend in aridification of drylands (IPCC, 2019a), but \textit{high confidence} of aridification in some areas (Mediterranean, Central America, South Africa) (IPCC, 2019a) (see also Figure 12.4j-l). However, drivers of desertification largely include land cover changes and land use management, along with climate change (IPCC, 2019a).

Warming temperatures and extreme heat are major climatic impact-drivers with multiple potential impacts on societies, health, and habitat in semi-arid and arid regions that are already near physiological limits for outdoor activities. Semi-arid regions will \textit{very likely} undergo a warming in all future scenarios (Chapter 4; Atlas) and \textit{likely} undergo an increase in duration, magnitude and frequency of heatwaves (Chapter 11) (see also Figure 12.4a-c). It is \textit{likely} that heat stress will be much more intense by the end of the century in many areas under all scenarios, such as deserts and semi-arid zones in Asia (Murari et al., 2015; Mishra et al., 2017b), Australia and Africa (Dosio et al., 2018; Guo et al., 2017; Schwingshackl et al., 2021; Xia et al., 2016; Zhao et al., 2015a), with consequences on labour productivity with respect to very heat-humidity conditions (see also Figure 12.4d-f).

Drought is another major climatic impact-driver for semi-arid areas, imposing major challenges on agriculture given existing water availability constraints (Kusunose and Lybbert, 2014; Barlow et al., 2016; Wolski et al., 2018). Over the period 1961-2013, the annual area of drylands in drought has increased, on average by slightly more than 1\% per year, with large inter-annual variability (Olsson et al., 2019). In general, droughts have increased in several arid and semi-arid areas over the last decades \textit{(medium confidence)}, and \textit{are likely} to increase in the future as indicated by a number of indices calculated from climate (Liu et al., 2018b; Zkhiri et al., 2019; Coppola et al., 2021b; Driouech et al., 2021)(see also Figure 12.4j-l).

Deserts and semi-arid areas are prone to dust storms, which can drive impacts on health and several other sectors (Zhang et al., 2016b; Tong et al., 2017). SRCCl indicated that the evolution of dust under climate change is uncertain (Mirzabaev et al., 2019), and there is a lack of evidence and agreement of a change in their frequency or intensity so far in most regions (Sections 12.4.1-12.4.9). Model projections of future changes in dust are hindered by the uncertainties in future regional wind and precipitation as the climate warms (Evan et al., 2016), in the effect of CO$_2$ fertilization on source extent (Huang et al., 2017), and in the
impact of human activities upon the land surface (Ginoux et al., 2012) (see Chapter 10). Projected trends on
dust storms and dust loads in deserts and semi-arid areas vary from region to region. Dust loadings are
expected to decrease over most of the Sahara and Sahel (low confidence) (Section 12.4.1), increase over
Mexico and Southwestern U.S. (medium confidence) (Section 12.4.6), and there is low confidence of a future
trend due to climate change in other continents (Sections 12.4.2-12.4.5).

In conclusion, desert and semi-arid areas are strongly affected by climatic impact-drivers such as
extreme heat, drought and dust storms. Heat hazards are very likely increasing in all future climate
scenarios, but broadly consistent desert and semi-arid region changes for other climatic impact-
drivers' future evolution remains uncertain.

12.4.10.4 Mountains

Mountains cover about 30% of the land areas on Earth (not counting Antarctica) and deliver a number of
vital services to humanity (IPCC, 2019b) (WGII Cross-chapter paper 5). Climate change in high mountains
was addressed in the SROCC, which emphasized changes in several climatic impact-drivers, such as: an
observed general decline in low-elevation snow cover, glaciers and permafrost (high confidence), which
induced changes in natural hazards such as decrease in slope stability (high confidence), changes to the
frequency of glacial lake outbursts (limited evidence), and climate effects on other hazards (avalanche, rain-
on-snow floods) with various degrees of confidence (Hock et al., 2019).

There is a growing body of literature indicating elevation-dependent warming (EDW; different rates of
warming by altitude although not necessarily increasing with altitude) in several mountain regions but not
globally (Hock et al., 2019; Pepin et al., 2019; Ahmed et al., 2020; Li et al., 2020a; Williamson et al., 2020;
You et al., 2020; Micu et al., 2021). Statistically significant elevational enhancement to long-term trends in
maximum near-surface air temperatures and diurnal temperature range were observed in southern central
Himalaya and in the Swiss Alps (Rottler et al., 2019; Thakuri et al., 2019). Aguilar-Lome et al. (2019)
reported that winter daytime land surface temperatures in the Andean region between 7°S and 20°S show the
strongest trends at higher elevations: +1.7°C per decade above 5000 masl. Palazzi et al. (2019) identified
changes in albedo and downward thermal radiation as key drivers of EDW according to the simulation
outputs of a high-spatial resolution model in three important mountainous areas: the Colorado Rocky
Mountains, the Greater Alpine Region and the Himalayas-Tibetan Plateau, but mechanisms for EDW remain
complex (Hock et al., 2019). Warming is also affecting mountain lake surface temperatures, increasing
probabilities of ice-free winters and the frequency and duration of “lake heatwaves” (O’Reilly et al., 2015;
Woolway et al., 2020, 2021) (high confidence) with a high variability from lake to lake.

EDW could speed up the observed, rapid upward shifts of the Freezing Level Height (FLH) in several
mountainous regions of the world and lead to faster changes in the snowline, the glacier equilibrium-line
altitude and the snow/rain transition height (high confidence). In the Indus, Ganges and Brahmaputra basins
in Asia, the FLH is projected to rise at a rate of 4.4 to 10.0 m yr⁻¹ under RCP8.5 (Viste and Sorteberg, 2015).
In the Argentinian Andes, FLH is projected under RCP8.5 to move up more than twice as much by 2070 as
during the entire Holocene under the worst case scenario (Drewes et al., 2018). On the western slope of the
subtropical Andes (30°-38°S) in central Chile, the mean value of the free tropospheric height of the 0°C
isotherm under wet conditions is projected to be close to or higher than the upper quartile of the distribution
in the current climate, towards the end of the century and under RCP8.5 (Mardones and Garreaud, 2020). In
the Alps and the Pyrenees, Spandre et al. (2019) projected a rise in the natural snow elevation of 200 to 300
m and 400 to 600 m by mid-century under RCP2.6 and RCP8.5, respectively. In the same region, the
environmental equilibrium-line altitude is projected to exceed the maximum elevation of 69%, 81% and 92%
of the glaciers by the end of the century under RCPs 2.6, 4.5 and 8.5, respectively (Žebre et al., 2021).

Orographic effects enhance convection and stratiform heavy precipitation (due to uplift) and make
mountains prone to extreme precipitation events. These events are projected to increase in major
mountainous regions (Alps, parts of the Andes, British Columbia, Northwest North America, Calabria,
Carpathian, Hindu-Kush-Himalaya, Rockies, Umbria; medium to high confidence depending on location),
with potential cascading consequences of floods, landslides and lake outbursts in mountainous areas in all scenarios (medium confidence) (Geeritsema et al., 2006; Kim et al., 2015; Gaire et al., 2015; Kharku et al., 2016; Syed and Al Amin, 2016; Ciabatta et al., 2016; Gariano and Guzzetti, 2016; Jurisch et al., 2017; Rajczak and Schär, 2017; Cloutier et al., 2017; Gajděk et al., 2017; Alvioli et al., 2018; Schloegl and Matulla, 2018; Coe et al., 2018; Chen et al., 2019a; Handwerger et al., 2019; Hock et al., 2019; Patton et al., 2019; Vaidya et al., 2019; Kirschbaum et al., 2020; Coppola et al., 2021b) (Sections 12.4.1-12.4.9, Chapter 11).

Declines in low-elevation snow depth and seasonal extent are projected for all SSP-RCPs (see Sections 12.4.1-6), along with reductions in mountain glacier surface area, increases in permafrost temperature, decreases in permafrost thickness, changes in lake and river ice, changes in the amount and seasonality of streamflows and hydrologic droughts in snow-dominated and glacier-fed river basins (e.g., in Central Asia; Sorg et al., 2014; Reyner et al., 2017) (medium confidence), and decreases in the stability of mountain slopes and snowfields. Glacier recession could lead to the creation of new glacial lakes in places like the Himalaya-Karakoram region; (Linsbauer et al., 2016) and in Alaska and Canada (Carrivick and Tweed, 2016; Harrison et al., 2018) (medium confidence). With increasing temperature and precipitation these can increase the occurrence of glacier lake outburst floods and landslides over moraine-dammed lakes (Carey et al., 2012; Rojas et al., 2014; Iribarren Anacona et al., 2015; Cook et al., 2016; Haebeli et al., 2017a; Kapitsa et al., 2017; Narama et al., 2018; Wilson et al., 2018; Drenkhan et al., 2019; Wang et al., 2020a) (high confidence).

In conclusion, mountains face complex challenges from specific climatic impact-drivers drastically influenced by climate change: regional elevation-dependent warming (high confidence), low-to-mid-altitude snow cover and snow-season decrease even as some high elevations see more snow (high confidence), glacier mass reduction and permafrost thawing (high confidence), and increases in extreme precipitation and floods in most parts of major mountain ranges (medium confidence).

12.4.10.5 Tropical forests

Tropical forests, which are among the world’s most biologically diverse ecosystems, are essentially located in Central and South America, Africa and South-East Asia. AR5 and SR1.5 indicated several specific climatic impact-driver changes that are particularly important to tropical forests: mean temperature increase, long-term drying trends (including shifts in the length of the dry season), prolonged drought, wildfires and surface CO₂ increase for inland forests (IPCC, 2013, 2018). SRCCL assessed an enhanced risk and severity of wildfires in tropical rainforests (high confidence), but fires are not only natural and also due to deforestation and other human influences (IPCC, 2019a).

Temperature is rising in all tropical regions covered with forests and will very likely continue to rise, reaching levels unprecedented in recent decades as the temperature trends rapidly emerge from weak historical interannual variability (12.4.1-4; 12.5.2) (see Chapter 4, Atlas).

Regional patterns of increasing drought or unusual wet and dry periods are predicted with agreement over many climate models such as over the Amazon basin (Boisier et al., 2015; Duffy et al., 2015; Zulkafl et al., 2016; Coppola et al., 2021b). There is medium confidence (limited evidence, high agreement) that in several tropical-forest regions the dry season length has increased (Amazonia, West Africa) (Fu et al., 2013; S. Deborjoli et al., 2015; Saced et al., 2017; Dunning et al., 2018; Wadsworth et al., 2019), and low confidence (limited evidence) that deforestation influences the shift in the onset of the wet season in South Amazonia (Lêitê-Filho et al., 2019). In contrast, the wet season is increasing in Northern Australia Tropical Forests (Catto et al., 2012).

Tropical forests typically reach peak fire weather conditions in the dry season (Taufik et al., 2017), in particular during long-lived droughts (Brando et al., 2014; Marengo et al., 2018), with consequences on tree mortality, forest and carbon sink loss (Brando et al., 2019), and on the hydrological cycle in South America (Martinez and Dominguez, 2014; Espinoza et al., 2020). Observations and reanalyses over the past 3-4 decades, combined into fire risk indices, show that the fire weather season length has been increasing by about 20% globally (Jolly et al., 2015), and this index exhibits particularly high trend values over tropical...
forest areas of South and Central America and Africa. There is generally low confidence in future projections of general fire weather risk evolution in tropical forests and evolutions depend on the region (Abatzoglou et al., 2019). Over the Amazon basin the fire risk increase is emerging well before 2050 while for other equatorial forests no significant evolution is found. In Savanna areas the risk increase is found to be more general.

In conclusion, most tropical forests are challenged by a mix of emerging warming trends that are particularly large in comparison to historical variability (medium confidence). Water cycle changes bring prolonged drought, longer dry seasons, and increased fire weather to many tropical forests, with plants also responding to CO₂ increases (medium confidence).

12.5 Global perspective on climatic impact-drivers

12.5.1 A global synthesis

Section 12.4 assessed changes in climatic impact-drivers by region, primarily based on a large number of local, regional-scale studies (even though global studies are also used). This section presents an assessment of changes in CID at the global scale. It is based on both a bottom-up synthesis of the results in 12.4, and a top-down assessment from global-scale studies undertaken here. Box 12.1 summarizes global-scale CIDs with levels of warming.

Global-scale studies use similar indices of climatic impact-drivers across space, although these indices may not be always those used at the local or regional scale. Most published global-scale studies concentrate on single sectors or climatic impact-drivers, but some take a multi-sectoral perspective (e.g., Warszawski et al., 2014; Arnell et al., 2016; Mitchell et al., 2017; O’Neill et al., 2018; Arnell et al., 2019a; Schleussner et al., 2016; Betts et al., 2018; Byers et al., 2018; Mora et al., 2018; O’Neill et al., 2018; Zscheischler et al., 2018). Only a few published global-scale studies (e.g., Coppola et al., 2021; Schingshackl et al., 2021) have used CMIP6 scenarios to date. Box 12.1 summarizes global-scale CIDs with levels of warming.

All regions will experience, before 2050, increased warming, an increase of extreme heat and a decrease in cold spells, regardless of the emissions trajectory (high confidence). Tropical regions, but also mid latitude regions to a lesser extent, will experience an increasing number of days with heat indices crossing dangerous thresholds used to characterize heat stress, such as HI>41°C (Figure 12.4). The increase, by the end of this century, exceeds 100 days per year in most tropical areas under SSP5-8.5 but remains much more limited to almost half under SSP1-2.6. Several global-scale studies have shown that high temperature extremes will increase everywhere (high confidence) (Gourdji et al., 2013; Perkins-Kirkpatrick and Gibson, 2017; Harrington et al., 2018; Jones et al., 2018; Lehner et al., 2018; Shi et al., 2018; Tebaldi and Wehner, 2018; Arnell et al., 2019; Russo et al., 2019; Schlingshackl et al., 2021), although the change depends on the indicator (see also Chapter 1). For example, by 2080, at least 80% of the land surface is expected to experience average summer temperatures greater than the historical (1920-2014) maximum with high RCP8.5 emissions (Lehner et al., 2018). The areas of rice and maize cropland with damaging extreme temperatures during the reproductive season will increase by a factor of three under RCP8.5 (Gourdji et al., 2013). Heatwaves that are currently considered rare become the norm almost everywhere with high emissions by the end of the century (Russo et al., 2014). Heat stress as a combined function of temperature and humidity also increases at the global scale, especially with high emissions (e.g. Matthews et al., 2017). Growing degree-days and cooling degree-days also increase everywhere (Arnell et al., 2019) with the absolute and proportional changes depending on temperature threshold. Increases in temperatures will result in reductions in heating degree-days (Arnell et al., 2019; Coppola et al., 2021b) and a widespread reduced frequency of cold extremes (high confidence).

Integrating the results of the regional assessments in 12.4 shows that changes in CIDs linked with the water cycle or atmospheric dynamics (e.g. storms) vary more among regions, largely due to the spatial pattern of changes in atmospheric circulation and changes in precipitation and evaporation (Chapters 8 and 11). There is high confidence that heavy precipitation and pluvial floods will be increasing in a majority of land regions,
primarily due to the well-understood Clausius-Clapeyron relationship describing the increase in moisture content with air temperature (Chapters 8 and 11), but there is a large spatial variability in fluvial flood hazards. Top-down global-scale studies show that although fluvial flood hazards are projected to decrease in regions where there are large reductions in seasonal rainfall totals or where warmer temperatures mean less accumulated snow, at the global scale, fluvial flood hazard (characterized as the area affected, size of peak or likelihood of an event) is projected to increase substantially through the century (Giuntoli et al., 2015; Arnell and Gosling, 2016; Winsemius et al., 2016; Alfieri et al., 2017; Dottori et al., 2018; Arnell et al., 2019). Projected changes in agricultural and hydrological drought characteristics are dependent on the indicator used to define drought (Section 12.3; Chapter 11), but there is at least medium confidence of an increase in the drought hazard in many parts of the world. This is also reflected in global scale studies, with for example Naumann et al. (2018) showing that the global mean average drought duration (based on the SPEI index) which is calculated from the difference between precipitation and potential evaporation) increased from 7 months with the current climate to 18.5 months for a global warming level of 3°C. The apparent global increase in drought occurrence is greater when evaporation is captured in the drought indicator (e.g. SPEI) than when the indicator is based on precipitation alone (as in SPI) (Carrão et al., 2018). There is evidence that the likelihood of simultaneous events in several locations will increase: (Trnka et al., 2019) found that the proportion of wheat-growing areas experiencing simultaneous severe water stress events (based on SPEI) in a year increased from 15% under current conditions to up to 60% at the end of the 21st century under high emissions.

The regional assessment in 12.4 shows that fire weather is projected to increase with medium or high confidence in every continent of the world, including Arctic polar regions. Globally, fire weather is projected to increase in future, primarily due to higher temperatures and exacerbated where precipitation reduces. By 2050, 60% of the global land area would see a significant increase in fire weather under RCP8.5 (Abatzoglou et al., 2019). There is less confidence in the projected distribution of change in fire weather across regions in global scale studies. For example, (Morritz et al., 2012) projected an increase in fire weather in mid and high latitudes but a reduction in the tropics, whilst Yu et al. (2019) and Bedia et al. (2015) projected an increase in the tropics. These differences reflect differences in methodologies and fire weather indices adopted in different studies.

Integration of the results of 12.4 shows that the total number of tropical cyclones is projected to decrease through the 21st century, particularly with high emissions, but the number of very intense tropical cyclones is projected to increase in most areas (at least medium confidence) (e.g. Bacmeister et al., 2018) (Chapter 11). Furthermore, regions with glaciers will lose glacier mass and regions concerned with snow cover will see a reduction in snow depth, the duration, or extent of cover (medium confidence in Polar regions, high confidence elsewhere).

Relative sea-level rise is projected in all regions (excepting a few Arctic polar regions) with likelihoods varying from very likely to virtually certain depending on the region. This will increase the frequency of extreme sea levels and, depending on the level of coastal flood protection, coastal flooding (Vousdoukas et al., 2018; Kirezgi et al., 2020). In terms of globally averaged extreme total water level (ETWL) frequency changes, the present-day 1:100 yr event is projected to become 1:30 yr and 1:20 yr events by 2050 under RCP4.5 and RCP8.5 respectively. By 2100 the present day 1:100 yr ETWL is projected to become a 1:5 yr event under RCP4.5, while under RCP8.5, such events are projected to occur more than once a year (Vousdoukas et al., 2018).

There is high confidence that most of the world’s sandy coasts will experience shoreline retreat, in the absence of terrestrial or offshore sediment sources. Median projections presented by (Vousdoukas et al., 2020b) indicate that 13.6% (36,097 km) and 15.2% (40,511 km) of the world’s sandy beaches could retreat by more than 100 m by 2050 (relative to 2010) under RCP4.5 and RCP8.5 respectively, implying a 12% increase in severely threatened shoreline length under RCP8.5, relative to RCP4.5. These median projections increase to 35.7% (RCP4.5)–49.5% (RCP8.5) (or 95,061 km–131,745 km) by the end of the century, implying a 38% increase in severely threatened shoreline length under RCP8.5, relative to RCP4.5.

Figure 12.11 highlights that each region will, with high confidence, experience changes in multiple CIDs,
challenging the vulnerability of the region and its adaptation and mitigation capacity. All non-polar regions with a coastline will see an increase in relative sea level, extreme sea level and coastal erosion, and will also see an increase in hot extremes, a decrease in cold extremes, and many will experience an increase in heavy precipitation. One cluster of regions – South eastern and western Africa regions, the Mediterranean, North Central America, West North America, the Amazon regions, Western South America, and Australia – will experience, in addition to the aforementioned globally changing CIDs, increases in either drought/aridity or fire weather with high confidence. This will impact upon agricultural resources, infrastructure and health and ecosystems. A second cluster of regions including mountainous areas or regions with seasonal snow cover will experience (in addition to increases in heat extremes, more intense short-duration rainfall, and increases in coastal hazards where coasts exist) reductions in snow and ice cover and/or increases in river flooding in many cases (Western, Northwestern, Central and Eastern North America, Arctic regions, Andes regions, Europe, Siberia, central and East Asia, Southern Australia and New Zealand) (high confidence). These are places where energy production, ski tourism, river transportation, infrastructure could in particular face increased risks.

In a few other regions, only a few CIDs are projected to change with high confidence (e.g., Sahara, Central Africa, Western Africa, Madagascar, Arabian Peninsula, South eastern South America, New Zealand, Small Islands). The lower confidence levels associated with changes in CIDs in these regions can be due either to weaker change signals compared to natural variability, or due to limited evidence and model uncertainties leading to low agreement, and does not mean that climate change may affect these regions any less than in other regions.

In summary, there is high confidence that all regions of the world will experience changes in several climatic impact-drivers by mid-century, albeit at region specific rates of change and confidence levels per CID. Consequently, changing CIDs have the potential to affect climate-related risks in all regions of the world.

[START FIGURE 12.11 HERE]

Figure 12.11: Synthesis of the CID changes projected by 2050 (2041-2060) with high confidence, relative to reference period (1985-2014), together with the sign of change. Information is taken from the CID tables in Section 12.4. Some CIDs are grouped in order to streamline the information in order to fit in all information in the figure. Mean temperature, extreme heat, cold spells and frost are grouped under a single icon “heat”, as they are projected to change simultaneously, albeit heat and cold are changing in opposite directions. Coastal CIDs (relative sea level, coastal flooding and coastal erosion at sandy beaches) are also grouped. In the figure, the “coastal” icon indicates regions where at least two of the three individual coastal CIDs are projected to change with high confidence. Cases where only two of the three CIDs increase with high confidence are in Arctic North Europe, Russian Arctic and Arctic North West North America. A single icon is used for aridity, hydrological drought, and agricultural and ecological drought, and only the number of drought types that change is indicated. For the “Snow, ice” icon, information is taken from the evolution of the “Snow, Glacier and ice sheet” CID, and in most regions also have similar changes for “permafrost” and “lake, river and sea ice”. Exceptions are for NEN, RAR and Arctic NWN where snow is decreasing with medium confidence (thus not appearing in the figure), while permafrost and Lake, river and sea ice is decreasing with high confidence. The location of the icon within the regions is arbitrary. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1). [END FIGURE 12.11 HERE]

12.5.2 The emergence of climatic impact-drivers across time and scenarios

The emergence of a climate change signal occurs when that signal exceeds some critical threshold (usually taken to be a measure of natural variability, see e.g. Hawkins and Sutton, 2012) or when the probability distribution of an indicator becomes significantly different to that over a reference period (e.g. Chadwick et al., 2019) (see also Section 1.4.2, Chapter 10), in which case external anthropogenic forcings can be detected
as causal factors. The “time of emergence” (ToE) or “temperature of emergence” is the time or global warming level thresholds associated with this exceedance. Emergence is particularly relevant to impacts, risks assessment and adaptation because human and natural systems are largely adapted to natural variability but may be vulnerable if exposed to changes that go beyond this variability range; this is not to say that changes within natural variability have no impact, as occurrence of damaging extremes proves. Emergence also informs the timing of adaptation measures. The emergence of a change is always relative to a reference period (e.g. the pre-industrial period or a recent past), depending on the framing question. In the former case, the goal is to estimate the amplitude of an anthropogenically driven change while in the latter, it is to estimate the amplitude of change relative to a baseline that is familiar to stakeholders. Both questions are important for risk assessment, but the former may be more directly interpretable in a mitigation context. The variability also refers to a time scale, generally interannual to interdecadal. The reader is referred to Section 1.4.2 and Chapter 10 for more details about how emergence is defined and used in the literature.

Changes in climatic impact-drivers may remain within the range of natural variability or have a time of emergence that varies by region and scenario. This section assesses the evidence for the effects of anthropogenic climate change on the emergence of changes in CID index, past, resent and future, as evidenced by the literature assessed in other chapters, as well as additional literature assessed here, at both global and regional scales. In many cases, however, sufficient literature for a robust region by region assessment of times of emergence is lacking. The assessment herein is made by CID. Regional emergence assessment is reported in Tables 12.3-11 but is undertaken in this section.

ToE estimation must be done with caution given the many sources of inherent uncertainties, such as observations representing only a single realization of climate history, internal variability (whose frequency -- e.g., annual or decadal -- needs to be precisely defined), model biases, and potential low-frequency changes in variability (Chapter 10) (Lehner et al., 2017). In addition, a homogeneous interpretation of multiple studies is hampered by heterogeneous methodologies used to calculate emergence. In this section, we assess emergence and its confidence level based on such multiple methods as provided by the literature, and unless specified otherwise, emergence here refers to S/N>1 (S/N= signal to noise ratio) relative to a preindustrial baseline and interannual variability (the “noise”). Furthermore, observed trends and attribution are taken into account in combination with climate simulations (historical or projections) for assessing whether a trend has already emerged in the historical period.

**Mean air temperature**: Warming of mean annual temperatures has already emerged in all land regions as obtained from past observations and confirmed by historical simulations (high confidence) (King et al., 2015; Hawkins et al., 2020) (Figure 1.13), with S/N ratios larger than 2. In the current climate, the highest S/N ratios exceed 5 over Central Africa, Amazonia, East and South East Asia. Seasonal warming emergence depends on the season. Because the temperature variability in the mid-latitudes is higher in winter than in summer, the emergence of seasonal warming occurs for summer but not for winter in most of this part of the world. In Europe, summer warming has emerged in all regions (medium confidence, medium agreement), and in North America, it has emerged only over Eastern and Western regions while in winter there is low confidence of an emergence in warming in all regions for both Europe and North America (Lehner et al., 2017; Hawkins et al., 2020). When considering the climate of the end of the 20th century (i.e. recent past) as a baseline, the emergence of mean temperature is projected at very different times depending on the scenario. For instance, emergence is reached by 2050 under RCP8.5 in most areas of Europe, Australia or East Asia, but it does not occur within the 21st century under RCP2.6 (medium confidence) (Sui et al., 2014; Im et al., 2020). This means that RCP2.6 is efficient to keep mean temperatures within the recent climate range in the mid-latitudes. However, even under RCP2.6, mean temperatures in tropical regions that have not already emerged are projected to emerge before 2050 (medium confidence).

**Extreme heat and cold**: Increase in heat extremes have emerged or will emerge in the coming 3 decades in most land regions (high confidence) (King et al., 2015; Seneviratne and Hauser, 2020) (Chapter 11), relative to the pre-industrial period, as found by testing significance of differences in distributions of yearly temperature maxima in simulated 20-year periods. In tropical regions, wherever observed changes can be established with statistical significance, and in most mid-latitude regions, there is high confidence that hot and cold extremes have emerged in the historical period, but only medium confidence elsewhere. In other
regions emergence is projected at the latest in the first half of the 21st century (high confidence) under RCP8.5 at least (King et al., 2015; Seneviratne and Hauser, 2020). Relative to the end of 20th-century conditions, changes in humid heat stress as characterized by wet bulb temperature, indicates a ToE as early as in the first two decades of the 21st century in RCP8.5 at least in many tropical regions (most of Africa in the band [20°S-20°N], South Asia and South-East Asia) (Im et al., 2020) (medium confidence). By 2050 and under RCP8.5, wet bulb temperature is projected to emerge in many other areas such as South Africa, North Africa, Europe, and most of Central, Southern, Eastern Asia and Northern and Eastern Australia, while under RCP2.6, emergence is either reached later in the century (Europe, Central Asia, Northern Australia), or never reached in the century (Im et al., 2020). Decrease of cold spells has already emerged above the interannual variability in Australasia, Africa and most of northern South America, and they are projected to emerge before 2050 in the Northern mid-latitudes and in southern South America (King et al., 2015) under RCP8.5 (medium confidence, low evidence and high agreement).

Mean precipitation: Over only a few regions mean precipitation changes have emerged in the historical period (increase in Northern and Eastern European and decrease in West Africa, Amazonia) from observations with an S/N ratio larger than 1 (Hawkins et al., 2020) (low confidence). The emergence of increasing precipitation before the middle of the 21st century is found across scenarios in Siberian regions, Russian far east, northern Europe, Arctic regions and the northernmost parts of North America (high confidence) and later in other Northern mid-latitude areas, depending on the scenario, albeit with different methods and emergence definitions used in climate projections (Chapter 8) (Giorgi and Bi, 2009; Maraun, 2013; King et al., 2015; Akhter et al., 2018; Kumar and Ganguly, 2018; Nguyen et al., 2018; Barrow and Sauchyn, 2019; Rojas et al., 2019; Kusunoki et al., 2020; Pohl et al., 2020; Li et al., 2021). Decreases in mean precipitation are projected to emerge in parts of Africa by the middle of the century, and later in the Mediterranean and southern Australia, but the emergence depends on the scenario, and specific seasons for crop growth (Nguyen et al., 2018; Rojas et al., 2019). Mean precipitation does not emerge in any of these regions at anytime in the 21st century under RCP2.6, but emerges in all under RCP8.5. ToE under RCP4.5 is projected to be around 25 years later relative to RCP8.5 in many of the early emergence regions, highlighting the importance of mitigation to gain more time for adaptation.

Heavy precipitation and floods: There is low confidence in the emergence of heavy precipitation and pluvial and fluvial flood frequency in observations, despite trends that have been found in a few regions (Chapter 8, Chapter 11, and across Section 12.4). In climate projections, the emergence of increase in heavy precipitation strongly depends on the scale of aggregation (Kirchmeier-Young et al., 2019), with, in general, no emergence before a 1.5°C or 2°C warming level, and before the middle of the century (medium confidence), but results depend on the method used for the calculation of the ToE (Maraun, 2013; King et al., 2015; Kusunoki et al., 2020). Emergent increases in heavy precipitation are found in several regions when aggregated at a regional scale in Northern Europe, Northern Asia and East Asia, at latest by the end of the century in SRES A1B or RCP8.5 scenarios or when considering the decadal variability as a reference (medium confidence) (Maraun, 2013; Li et al., 2018e, 2021; Kusunoki et al., 2020). There have been few emergence studies for streamflow and flooding, although one study showed emergence of different hydrological regimes at different times during the 21st century across the United States (Leng et al., 2016). Variability in extreme streamflows from year to year can be high relative to a trend (Zhu et al., 2018). Given the heterogeneity of methods and results, there is only low confidence in the emergence of heavy precipitation and flood signals in any region when considering the S/N ratio.

Droughts, aridity and fire weather: There is low confidence in the emergence of drought frequency in observations, for any type of drought, in all regions. Even though significant drought trends are observed in several regions with at least medium confidence (Section 12.4), agricultural and ecological drought indices have interannual variability that dominates trends, as can be seen from their time series (Guo et al., 2018a; Spinoni et al., 2019b; Haile et al., 2020; Wu et al., 2020b) (medium confidence). Studies of the emergence of drought with systematic comparisons between trends and variability of indices are lacking, precluding a comprehensive assessment of future drought emergence. Historical climate simulations indicate that fire weather indices have already emerged in several regions (the Amazon basin, Mediterranean, Central America, West and South Africa) (low confidence, low evidence) (Abatzoglou et al., 2019), and emergence is projected with low confidence by the middle of the century in several other regions (Southern Australia, ...
Siberia, most of Northern America and Europe) when considering several indices together.

**Wind:** Observed mean surface wind speed trends are present in many areas (12.4), but the emergence of these trends from the interannual natural variability and their attribution to human-induced climate change remains of low confidence due to various factors such as changes in the type and exposure of recording instruments, and their relation to climate change is not established. For future conditions, there is limited evidence of the emergence of trends in mean wind speeds due to the lack of studies quantifying wind speed changes and their interannual variability. The same limitation also holds for wind extremes (severe storms, cyclones, dust and sandstorms).

**Snow and ice:** The decrease in the Northern Hemisphere snow cover extent in spring has already emerged from natural variability (Section 3.4.2). The snow cover duration period is projected to emerge over large parts of Eastern and Western North America and Europe by the mid-century both in spring and autumn, and emergence is expected in the second half of the 21st century in the Arctic regions in the high RCP8.5 scenario (Chapter 9, SROCC) (medium confidence). For snow depth or snow water equivalent, there is low confidence (limited evidence) of the emergence of a decrease before 2050 because climate change also increases the variability of the snow depth signal, in Europe (Willibald et al., 2020) (Section 3.4.2). Terrestrial permafrost is warming worldwide due to climate change (Sections 2.3.2.5, 9.5.2). Due to weak interannual variability of permafrost temperatures, terrestrial permafrost warming has emerged above natural variability in almost all observed time series of the Northern Hemisphere (Biskaborn et al., 2019) (medium confidence, limited evidence, high agreement), but the active layer thickness exhibits considerable interannual variability inhibiting evidence for emergence (Chapter 9).

**Sea ice:** Sea ice area decrease in the Arctic in all seasons has already emerged from the interannual variability (high confidence) (Chapter 9). By contrast, the Antarctic sea ice area shows no significant trend, and therefore no emergence.

For other snow and ice CIDs (heavy snowfall and ice storm, hail, snow avalanche), there is limited evidence of emerging signals.

**Relative sea level, coastal flood and coastal erosion:** Near-coast RSLR will emerge before 2050 for RCP4.5 along the coasts of all AR6 regions (with coasts) except EAS, RFE, MDG, the southern part of ENA and the Antarctic regions (9.6.1.4) (Bilbao et al., 2015) (medium confidence). Under RCP8.5, emergence of near-coast RSLR is projected by mid-century along the coasts of all AR6 regions (with coasts), except WAN where emergence is projected to occur before 2100 (Section 9.6.1.4) (Lyu et al., 2014) (medium confidence). Emergence studies for ETWL and coastal erosion are lacking and hence it is not currently possible to robustly assess emergence in these CIDs.

**Mean ocean temperature and marine heatwave:** The emergence of the sea surface temperature increase signal has been observed in global oceans over the last century, and the largest S/N values are found in the tropical Atlantic and tropical Indian Oceans (Hawkins et al., 2020). There is high confidence in the widespread occurrence of marine heatwaves in all basins and marginal seas over the last decades (Chapter 9), but the emergence of this signal above the natural variability has not yet been addressed in detail.

**Ocean acidity, ocean salinity and dissolved oxygen:** The global ocean pH has very likely emerged from natural variability for more than 95% of the global open ocean (SROCC, Chapter 2). The regional signals are more variable, but in all ocean basins, the signal of ocean acidification in the surface ocean is projected to emerge in the early 21st century (Chapter 5). The mean time of emergence for acidity in the coastal subtropical to temperate northeast Pacific and northwest Atlantic is above two decades (5.3.5.2) (high agreement, medium evidence). Salinity change signals have already emerged with 20–45% of the zonally averaged basin in the Atlantic, 20–55% in the Pacific and 25–50% in the Indian Oceans and will be reaching 35–55% in the Atlantic in 2050 to 55–65% in 2080; 45–65% to 60–75% in the Pacific; 45–65% to 60–80% in the Indian Oceans (Silvy et al., 2020) (Chapter 9). Deoxygenation has already emerged in many open oceans. The signal is most evident in the Pacific and Southern Oceans but not evident in the North Atlantic Ocean (Andrews et al., 2013; Levin, 2018). However, there is medium confidence in the emergence of the
There is high confidence that several CID changes have already emerged above natural variability in the historical period in many regions (e.g. mean temperature in most regions, heat extremes in tropical areas, sea ice, salinity). Heat and cold CIDs (excluding frost) that have not already emerged will emerge by 2050 whatever the scenario (medium confidence) in almost all land regions. The emergence of increasing precipitation before the middle of the century is also projected in Siberian regions, Russian far east, northern Europe and the northernmost parts of North America and Arctic regions across scenarios with the various methods and emergence definitions used (high confidence). Studies are missing to properly assess S/N emergence for droughts and for wind CIDs. Arctic sea ice extent declines have mostly emerged above noise level (medium to high confidence), and the emergence of declining snow cover is expected by the end of the century under RCP8.5. There is medium confidence that, under RCP8.5, the anthropogenic forced signal in near coast relative sea-level change will emerge by mid-century in all regions with coasts, except in the West Antarctic region where emergence is projected to occur before 2100. In all ocean basins, the signal of ocean acidification in the surface ocean is projected to emerge before 2050 (high confidence).

Cross-Chapter Box 12.1:  Projections by warming levels of hazards relevant to the assessment of Representative Key Risks and Reasons for Concern

Contributors:
Claudia Tebaldi (USA), Guofinna Aoalgeirsdottir (Iceland), Sybren Drijfhout (UK), John Dunne (USA), Tamsin Edwards (UK), Erich Fischer (Switzerland), John Fyfe (Canada), Richard Jones (UK), Robert Kopp (USA), Charles Koven (USA), Gerhard Krinner (France), Friederike Otto (UK/Germany), Alex C. Ruane (USA), Sonia I. Seneviratne (Switzerland), Jana Sillmann (Norway/Germany), Sophie Szopa (France), Prodromos Zanis (Greece).

A consistent risk framework (Reisinger et al., 2020) has been adopted across the three Working Groups (WG) in IPCC AR6 while recognizing the diversity of risk concepts across disciplines. WGI is assessing changes in climatic impact-drivers (CID), which are physical climate system conditions (e.g., means, events and extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions (Sections 12.1-12.3). In the assessment of Representative Key Risk (RKR) categories and Reasons for Concerns (RFCs) in WGII Chapter 16, the focus lies on the adverse consequences of climate change, for which many types of CIDs (i.e., ‘hazards’ in the context of identified risks) play a key role. This box synthesizes the assessment of such hazards according to global warming levels (GWLs) from various chapters of WGI to inform understanding of their potential changes and associated risks with temperature levels in general, and in particular to facilitate WGII integrated assessments of RKRs and RFCs. Another cross-chapter box, CCB 11.1, connects the organization of regional information according to GWLs to the other common dimension along which future projections are organized, i.e., scenarios. Section 1.6 describes all dimensions of integration adopted in this report, adding cumulative carbon emissions to GWLs and scenarios.

Eight RKRs are identified within WGII Chapter 16:
RKR-A: risk to the integrity of low-lying coastal socio-ecological systems;
RKR-B: risk to terrestrial and ocean ecosystems;
RKR-C: risk to critical infrastructure and networks;
RKR-D: risk to living standards;
RKR-E: risk to human health;
RKR-F: risk to food security;
RKR-G: risk to water security; and
RKR-H: risk to peace and migration.
RFCs further synthesize the landscape of risks from climatic changes into five categories (from IPCC TAR onward; Smith et al., 2001):

RFC1: Risks to unique and threatened systems;
RFC2: Risks associated with extreme weather events;
RFC3: Risks associated with the distribution of impacts;
RFC4: Risks associated with global aggregate impacts; and
RFC5: Risks associated with large-scale singular events.

Importantly, the assessment of risk in WGII considers hazards as only one component of an integrated assessment that involves their complex interaction with exposure and vulnerability of the systems at risk (Reisinger et al., 2020).

Hazards relevant to RKRs and RFCs are identified among aspects of the climate system that have an episodic, short term nature, like extreme events (particularly relevant to RFC2 but contributing to many other risk categories). Increasing GWLs translate into changing characteristics of frequency, duration, intensity, seasonality and spatial extent for many of these hazards also apparent in scenario-based results (Chapter 11, Chapter 12, Sections 12.4 and 12.5.1). Also, increasing GWLs increase the likelihood of compound temporal or spatial occurrence of similar or different hazards (Chapter 11, Section 11.8). Other relevant hazards coincide with long-term trends embodying a gradual change that may result in unfavorable environmental conditions. Furthermore, RFC5’s focus on singular events includes concern surrounding potential tipping points and irreversible behavior in the physical climate system.

Cross-Chapter Box 12.2 Table 1 organizes information by hazard and presents current state and future change assessments with increasing GWLs (defined by increasing GSAT, see CCB2.3). We draw on individual chapters across the WG1 report for the assessment of how these hazards vary with GWL. Hazards for which a relation to GWLs has not been assessed are not reported in the table.

[START CROSS-CHAPTER BOX 12.1, TABLE 1 HERE]

Cross-chapter Box 12.1 Table 1: Summary of CIDs/hazards that are identified as driving RKRs and RFCs. The behavior of each (in most cases considered at the global scale, but for some types in terms of spatially resolved patterns) as a function of GWLs is described and when possible quantified (in which case the cell is colored), together with the level of confidence of the assessment, to be found in more detail in the chapter/sections indicated in the corresponding column. For the relation with GSAT levels, two columns detail current state, which can be associated to ~1C of global warming, and future behavior. Tipping Points and Irreversibility is comprehensively assessed with CMIP6 models up to GWL = 3C with fewer studies and lower confidence at higher GWLs up to 5C.

<tr>
<td><strong>Extreme events</strong></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Hot and Cold extremes</td>
<td>All RKRs; RFC2, RFC3</td>
<td>Frequency and intensity of hot extremes increased and cold extremes decreased at the global scale and in most regions since 1950 (GSAT change ~0.6°C) (virtually certain). Number of warm days and nights increased; intensity and duration of heat waves increased; number of cold days and nights decreased (virtually certain). Regional-to-continental scale trends generally consistent global-scale trends (high confidence). Limited data in a few regions (esp. of Africa) hampers trend assessment.</td>
<td>Strong linear relation between magnitude and intensity of heat and cold extremes and GSAT, detectable from warming as low as 1.5°C; changes in the extreme metrics twice as large (in mid-latitude regions) or more (in high latitude regions) than GSAT warming (very likely); metrics related to frequency of exceedance may show stronger than linear relationships (exponential) (very likely). Compared to today, changes in extremes at +2°C are at least two times larger than at +1.5°C, and four times larger at +3°C.</td>
<td>Sections 11.3, 11.9, 12.4; Figures 11.4, 11.5, 11.9; Table 11.2.</td>
</tr>
<tr>
<td>Extreme precipitation events</td>
<td>All RKRs; RFC2, RFC3</td>
<td>Frequency and intensity of heavy precipitation events increased at the global scale over a majority of land regions with good observational coverage (high confidence) and at the continental scale in North America, Europe, and Asia. Larger percentage increases in heavy precipitation observed in the northern high latitudes in all seasons, and in the mid latitudes of the cold season (high confidence). Regional increases in the frequency and/or the intensity of heavy rainfall also observed in most parts of Asia, northwest Australia, northern Europe, southeastern South America, and most of the United States (high confidence), and west and southern Africa, central Europe, the eastern Mediterranean region, Mexico, and northwestern South America (medium confidence). GHGs likely the main cause.</td>
<td>Precipitation events - including those associated with Tropical Cyclones (TCs) - increase with GSAT. For GWLs &gt;2°C very rare (e.g., 1 in 10 or more years) heavy precipitation events more frequent and more intense over all continents (virtually certain) and nearly all AR6 regions (likely). Likelihood lower at lower GWLs and for less rare events. At the global scale, intensification of heavy precipitation generally follows Clausius-Clapeyron (~6-7% per degree C of GSAT warming; high confidence). Increase in frequency of heavy precipitation events accelerates with warming; higher for rarer events (high confidence), with approximately a doubling and tripling frequency of 10-year and 50-year events, respectively, at 4°C of global warming.</td>

### Ocean Acidification/pH

| Ocean Acidification/pH | RKR-A,B; RFC1, RFC4 | Virtually certain decline of surface pH globally over the last 40 years at a rate of 0.017–0.027 pH units per decade, decline also in the subsurface over the past 2-3 decades (medium confidence). Surface pH now the lowest of at least the last 26 thousand years (very high confidence). | Increase of net ocean carbon flux throughout the century irrespective of the emission scenario considered (high confidence). Decrease of ocean surface pH through the 21st century, except for SSP-1.9 and SSP-2.6 where values increase slightly starting from 2070 to 2100 (high confidence). | Sections 2.3.3.5, 4.3.2.4, 5.3.4, 5.4.2, 12.4, Figure 4.6. |

### SPEI index Global

| SPEI index Global | RKR-B,F,G,H; RFC3 | 9.4% chance of at least 3 months of drought in a year at current levels (~1°C) | Increase at the global scale in the chance of at least 3 months of drought in a year to about 20% (15-30%) at 1.5°C, 35% (20-45%) at 2°C to 60% (45-75%) at 4°C. | Sections 12.4, 12.5.1. |

### ENSO Variability

| ENSO Variability | RKR-B,D,F,G; RFC2,3,5 | Medium confidence that both ENSO amplitude and frequency of high-magnitude events since 1950 is higher than over the pre-industrial period (before 1850) but low confidence of this being outside the range of natural variability. No clear evidence shifts in ENSO or associated features or its teleconnections. | No change in the amplitude of ENSO variability (medium confidence); enhanced ENSO-related variability of precipitation under SSP2-4.5 and higher (high confidence). Likely shift eastward of the pattern of teleconnection over N.Pacific and N. America. | Sections 2.4.2, 4.3.3.1, 4.5.3.2; Figure 4.10. |

### Sea-Ice Loss

| Sea-Ice Loss | RKR-A, B, H; RFC1,3,5 | Arctic Sea Ice Area decreased for all months since 1970s; strongest decrease in summer (very high confidence). Arctic sea-ice younger, thinner and faster moving (very high confidence). Current pan-Arctic sea ice levels unprecedented since 1850 (high confidence). Low confidence in all aspects of Antarctic sea-ice prior to the satellite era. Antarctic SIA experienced little net change since 1979 (high confidence). | The Arctic Ocean will likely become sea-ice-free in September before 2050 in all considered SSP scenarios; such disappearance consistently occurring in most years at 2-3°C (medium confidence) and including several months in most years at 3.5°C (high confidence). | Sections 2.3.2, 4.3.2.1, 9.3.1, 9.3.2, 12.4; Figures 4.2c, 4.5. |

### Permafrost Thaw

| Permafrost Thaw | RKR-A,C; RFC3,5 | Increases in permafrost temperatures in the upper 30 m over the past three to four decades throughout the permafrost regions (high confidence). | Global permafrost volume in the top 3 m decreasing by about 25±5% per °C for GWLs < 4°C. Relative to 1995-2014: at 1.5 and 2°C decreasing by less than 40% (medium confidence), at 2 and 3°C by less than 75% (medium confidence), at 3 and 5°C by more than 60% loss (medium confidence). | Sections 2.3.2.5, 9.5.2, 12.4.9. |

### Sea-Level Change over the 21st century

| Sea-Level Change over the 21st century | RKR-A,C,D,E,F,G, H; RFC1,3,4 | GMSL is rising with accelerated rate since the 19th century (high confidence). Almost doubled during past 2 decades (about 0.1 mm yr⁻³). GMSL increase over the 20th century faster than over any preceding century in at least the last three millennia (high confidence). | Up to 2050, limited scenario/GWL dependency (likely SLR=0.15-0.30 m). By 2100, likely GMSS rise wrt 1995-2014 of 0.51 (0.40-0.69) m, 0.62 (0.50-0.81) m and 0.70 (0.58-0.91) m for, respectively, GWLs of 2.0°C, 3.0°C, and 4.0°C (medium confidence). Deep uncertainty in projections for GWLs > 3°C because of Ice Sheet behavior. For example, incorporation of low confidence ice-sheet processes under SSP5-8.5 (approximately 5°C) leads to a rise of 0.6-1.6 m rather than 0.7-1.1 m. | Sections 9.6.1.2, 9.6.3.3, 9.6.3.4, 12.4. |

### Sea-Level Change Commitment (2000 years after peak GWL)

| Sea-Level Change Commitment (2000 years after peak GWL) | RFC5 | Global Mean Sea Level commitment (over the 2000-year-long period following peak warming) of 2-6 m for 2°C peak warming, 4-10 m for 3°C peak warming, 12-16 m for 4°C peak warming, and 19-22 m for 5°C peak warming (medium agreement, limited evidence). | Global Mean Sea Level commitment (over the 2000-year-long period following peak warming) of 2-6 m for 2°C peak warming, 4-10 m for 3°C peak warming, 12-16 m for 4°C peak warming, and 19-22 m for 5°C peak warming (medium agreement, limited evidence). | Section 9.6.3.5. |

### Northern Hemisphere Spring Snow Cover

| Northern Hemisphere Spring Snow Cover | RKR-G, RFC1,3 | Substantial reductions in spring snow cover extent in the NH since 1978 (very high confidence). Since 1981, general decline in NH spring snow water equivalent (high confidence). | Linear change of NH snow cover in Spring of about 8% (area) per °C of for GWLs <4°C. Relative to 1995-2014: at 1.5-2°C NH spring snow cover extent likely decreases by less than 20% (medium confidence); at 2-3°C likely decreases by less than 30%; At 3-5°C, likely decreases by more than 25%. | Sections 2.3.2.2, 9.5.3, 12.4. |

### Mass Loss of Glaciers

<p>| Mass Loss of Glaciers | RKR-B,G; RFC1, RFC3 | Very high confidence global glaciers continuing retreat since ~1850. Current global glacier mass loss highly unusual over at least the last 2000 years (medium confidence). Increased rate of glacier mass loss over the last 3-4 decades (high confidence). Glaciers not in balance with respect to current climate conditions and will continue to lose mass for at least several decades. | For 1.5-2°C about 50-60% (low confidence) of glacier mass outside the two ice sheets and excluding peripheral glaciers in Antarctica remaining, predominantly in the polar regions. At 2-3°C about 40-50% (low confidence) of current glacier mass outside Antarctica remaining. At sustained 3-5°C 25-40% (low confidence) of current glacier mass outside Antarctica remaining. Likely nearly all glacier mass lost in low latitudes, Central Europe, Caucasus, Western Canada and USA, North Asia, Scandinavia and New Zealand. | Sections 2.3.2.3, 9.5.1.2, 12.4. |</p>

2. **[END CROSS-CHAPTER BOX 12.1]**
12.6 Climate change information in climate services

Climate services are a significantly evolving source for climate change information to support adaptation, mitigation and risk management decisions. As an evolving field, there are multiple definitions of climate services (cf. Brasseur and Gallardo, 2016). The Global Framework for Climate Services defines a climate service as the provision of climate information to assist decision-making. The service includes appropriate engagement from users and providers, is based on scientifically credible information and expertise, has an effective access mechanism, and responds to user needs (Hewitt et al., 2012).

IPCC AR5 WGII introduced climate services as bridging the generation and application of climate knowledge, also describing their history and concepts (Jones et al., 2014). Since then, this transdisciplinary field has been growing rapidly (Brasseur and Gallardo, 2016; Hewitt et al., 2020a) with the social sciences in particular pointing out knowledge requirements for co-design and co-development of climate services (Larosa and Mysiak, 2019; Daniels et al., 2020; Steynor et al., 2020). Climate services differ from more research-driven vulnerability, impacts, and adaptation research in their orientation toward decision support (Stone and Meinke, 2005; Ruane et al., 2016; Golding et al., 2019), but overlaps exist (Bruno Soares and Buontempo, 2019). Climate services are often targeted at building resilience to climate-related hazards from near real-time to seasonal and multi-decadal time horizons, to inform adaptation to climate variability and change (Hewitt et al., 2012), widely recognized as an important challenge for sustainable development and risk management (Moss et al., 2010; Jones et al., 2014; Vaughan et al., 2018). This section focuses largely on climate change timescales (past, present and future), which are the focus of AR6 WGI.

This section introduces the current climate services landscape, assesses climate services practices and products related to climate change information and associated challenges. Cross-chapter box 12.2 provides concrete examples of climate services. The section builds on the introduction to climate services in Section 1.6.1.4 and the assessment of regional climate information construction including storylines discussed in sections 10.3.4.2, 10.5.3 and Box 10.2. The Atlas supports the provision of climate information across WGs by providing interactive maps and further details to the material made publicly accessible for use in climate services. WGII (Chapter 17) further elaborates on climate services as enablers for climate risk management.

12.6.1 Context of climate services

The idea of climate services is not new and has its roots in meteorology and climatology (Larosa and Mysiak, 2019). It can be traced back to the late 1970s and the US National Climate Program Act of 1978 (Henderson et al., 2016). The development of the Global Framework for Climate Services (GFCS) after the World Climate Conference-3 in Geneva brought international attention and renewed impetus to the climate services field (Hewitt et al., 2012). As a result, large investments have been made globally and regionally in the development of user-driven climate services. WMO has created Regional Climate Centres (RCCs) to facilitate climate service development by regional and national providers (Hewitt et al., 2020a). The European Union declared its ambition to stimulate “the creation of a community of climate services application developers and users that matches supply and demand for climate information and prediction”, giving primacy to climate services that are user-driven and science-informed (Lourenço et al., 2016), thus embracing concepts of co-design, co-development and co-evaluation of climate services (Street, 2016). Diverse and action-driven international initiatives allowed climate services to progressively shift from mitigation towards adaptation (Larosa and Mysiak, 2019). Opportunities for the development of climate services have emerged through the 2015 Agendas (Paris Agreement, Sustainable Development Goals and Sendai Framework), Nationally Determined Contributions, National Adaptation Plans, Multilateral Development Banks and Task Force on Climate-related Financial Disclosure (see Chapter 1.2.2).

Scientific advancements in climate services related to meteorology and climatology are still closely linked to essential climate variables (Larosa and Mysiak, 2019) and benefit from consistently growing computational power, infrastructure and storage capacity to meet the demands of higher spatially and temporally resolved climate information (Buontempo et al., 2020). Climate services also focus on impact chains providing decision-makers with information on climate change with cross-sectoral impact assessments for adaptation.
Climate services are undertaken in public and private sectors at global, regional, national, and local scales (Hewitt et al., 2012, 2020b; Cortekar et al., 2020). Intermediaries such as private sector consulting companies, national climate service providers as well as research organizations, government agencies or academic institutions provide climate services that translate aspects of climate research to the specific context of decision-makers (see also Chapter 10.5). The EU Roadmap for Climate Services (an Commission, 2015; Street, 2016) focuses on developing a market for climate services comprising of both public and private domains. The GFCS, under the leadership of several United Nations Agencies, emphasizes the public domain by supporting national and regional capacity building and development of climate services mainly through National Meteorological and Hydrological Services (Hewitt et al., 2012, Domingos et al., 2016; Sivakumar and Lucio, 2018; WMO, 2018). There are on-going debates about the commercialization of climate services (Brooks, 2013b; WMO, 2015; Webber and Donner, 2017; Hoa, 2018; Troccoli et al., 2018; Bruno Soares and Buontempo, 2019; Hewitt et al., 2020a). Some argue that the commercialization of climate services is needed to meet the diverse needs of specific clients and to drive innovation in the field (Brooks, 2013b; Troccoli, 2018a). Others argue that if climate services shift incentives for climate science away from the public interest towards profit-seeking, this will result in less publicly accessible and transparent climate information and more private knowledge (Keele, 2019; Tart et al., 2020).

Some climate adaptation planning already use climate information as provided by the IPCC, however, depending on the decision context, this information may be too coarse, too broad or too disciplinary to directly inform decision-making at the scale where adaptation measures are taken (Howarth and Painter, 2016; Nissan et al., 2019). Thus, while the role of IPCC is clearly felt as a reference, authoritative, starting point, there is a need for complementary information to translate the assessments at the national, local or sectoral level (Howarth and Painter, 2016; Kjellström et al., 2016; van den Hurk et al., 2018; Vaughan et al., 2018). The AR6 Interactive Atlas (see section Atlas.2) does provide a collection of observational data and global and regional climate projections. It is designed as a climate service towards the WGI needs and beyond to assess the state of the climate by offering data, maps and a level of expert analysis by aggregation of results to regions, scenarios and warming levels.

12.6.2 Assessment of climate services practice and products related to climate change information

The climate services landscape is fast growing and very broad as reflected in the vast diversity of practices and products that can be found in the peer-reviewed literature (very high confidence). However, a large part of climate services practices and products is published in ‘grey’ literature (i.e. non-peer reviewed or non-academic) by private consultancy and non-scientific civil organizations of which many are not in the public domain. In addition, the respective climate service context of a specific stakeholder in a sector dictates what climate information is required and on what scales and in what format it is most usefully provided. The extent and type of engagement between scientists and users is another critical aspect of climate services (see Cross-chapter box 12.2 Fig 1, and section 10.5). The assessment here can thus only provide a partial and rather general representation of available practices and products of the evolving climate services field.

User needs and decision making contexts are very diverse and there is no “one size fits all” solution to climate services (very high confidence) (Hewitt et al., 2017a; Vincent et al., 2018b). In many cases this requires recognizing that stakeholders make decisions through a combination of scientific information and additional values (Vanderlinden et al., 2017; Parker and Lusk, 2019) (see also Section 1.2.3 and Section 10.5.4). The emerging climate service literature may clarify some features of climate information requested by users, for instance climatic impact-driver identification and prioritization through stakeholder
Do N

2019; Street et al., 2019)

energy

such as those described i

There are various types of providers and products of climate services related to the key sectors and regions

Climate services require user engagement and can take various forms in which climate information and data

is delivered or communicated to the users (very high confidence). Different levels of user engagement exist, which can range from passive engagement, interactive group activities to focused relationships between

climate service provider and users, and which result in different types of climate service products including

websites, capacity building, and co-design of tailored climate indices (Hewitt et al., 2017b) (see Cross-

Chapter 12.2, Figure 1). The fundamental basis for climate service development is the co-production

process between climate services provider and user (Valieva, 2006; Briley et al., 2015; Golding et al., 2017a;

Vincent et al., 2018a; Bruno Soares and Buontempo, 2019; Schipper et al., 2019), which can be very

resource intensive (Buontempo et al., 2018; Falloon et al., 2018; Kolstad et al., 2019) and varies strongly

from case to case (Reinecke, 2015; Bremer et al., 2019; Goodess et al., 2019; Jung and Schindler, 2019).

Climate services scholars and practitioners can better facilitate and embrace the knowledge co-production

process if it is recognized as a multi-faceted phenomenon with several dimensions (e.g., constitutive, interactional, institutional, pedagogical, empowerment) (Kruk et al., 2017; Knaggård et al., 2019;

Weichselgartner and Arheimer, 2019).

Information moves from useful to usable only when users effectively incorporate this information into a

decision process (Lemos et al., 2012; Bruno Soares and Dessai, 2016; Prokopy et al., 2017) (see also WGII, Chapter 17). Climate services include a range of knowledge brokerage activities such as: identify knowledge needs; dissemination of knowledge; coordinate and network; compile and translate; build capacity through

informed decision-making; analyse, evaluate and develop policy; and personal consultation (e.g., (De Bruin et al., 2020). When analysing four European climate services, (Reinecke, 2015) found that different climate services emphasized different knowledge brokerage activities.

There are various types of providers and products of climate services related to the key sectors and regions

such as those described in previous sections (Hewitt et al., 2017a). For instance, studies have described

sectoral climate services in support of agriculture (Falloon et al., 2018; Hansen et al., 2019), health (Jancoes et al., 2014; Lowe et al., 2017), tourism (Morin et al., 2018; Damm et al., 2019; Matthews et al., 2020), energy (Troccoli, 2018b; Goodess et al., 2019; Soret et al., 2019), disaster risk reduction (Golding et al., 2019; Street et al., 2019), water (van den Hurk et al., 2016; Vano et al., 2018), ocean and coastal ecosystems

(Weisse et al., 2015; Le Cozannet et al., 2017), cities (Rosenzweig and Solecki, 2014; Rosenzweig et al., 2015; Gidhagen et al., 2020), and cultural heritage (ICOMOS, 2019). Many countries (including almost
every country in Europe – see Atlas.5.6.3.4) have established a climate service centre, which follow different

practices of user engagement and provide different products (e.g., Kjellström et al., 2016; Kolstad, 2019;

Skelton et al., 2017). Climate services in other countries may be distributed across agencies and programs,

although these are often not centrally coordinated (Parris et al., 2016). One of the key pillars of the GFCS is

the Climate Services Information System (CSIS), which is the principal mechanism through which

information about past, present and future climate is archived, analysed, modelled, exchanged and processed

for users (Hewitt et al., 2020a). Some national governments also have organized national climate projections
to be used for official planning (e.g., (EEA, 2018). A list of available national products (e.g., observational

engagement; the specification of thresholds for various regions/sectors; the types of metrics

(magnitude/intensity, frequency, duration, timing, spatial extent) that are of primary interest; and decision

support systems where informatics allow stakeholders to custom-make impact-relevant thresholds and then

query databases to understand current and future characteristics (Bachmair et al., 2016; Buontempo et al.,

2020). However, users also ask for capacity building activities related to basic knowledge in climate change

sciences and climate-related risks (De Bruin et al., 2020; Sultan et al., 2020).

Since AR5 and SROCC (Chapter 2) there has been considerable progress in understanding climate

information user needs (Baztan et al., 2017; Golding et al., 2017b, 2017a, 2019; Bruno Soares et al., 2018a;

Hewitt and Golding, 2018; Singh et al., 2018; Sivakumar and Lucio, 2018; Bessembinder et al., 2019; Sultan
et al., 2020; Wang et al., 2020b; Hewitt et al., 2020b), better facilitation of user engagement (Buontempo et al., 2014, 2018; Buontempo and Hewitt, 2018) and an appreciation of climate scientists to involve

communication specialists and social scientists to support the co-design and co-development process that is

fundamental to a successful climate service (Buontempo et al., 2014; Gregow et al., 2016; Damm et al.,

2019).
datasets) and projections can be found in the Atlas (e.g., Section Atlas.1.1.3 and 2.3).

Figure 12.12 maps a general categorization of practices and products that have emerged from reviewing the climate service literature and user interviews (Visscher et al., 2020). The categories range from very generic products or expert analysis focused particularly on climate information (climate-centric approaches) to more integrated products that include shared open-source products and capacity building as well as tailored products that treat climate information as part of a larger decision-making context (climate-inclusive approaches). Three specific examples that elaborate in more detail on specific practices and products related to those general categories are provided in the Cross-chapter box 12.2.

[START FIGURE 12.12 HERE]

Figure 12.12: Illustration of different types of climate services. Products, for instance, can focus only on climate-related information or can be designed to integrate climate information with other decision-relevant context (vertical axis) and they can be very generic in terms of relevance to a wide range of sectors or stakeholders or customized to fit the needs of a specific sector or stakeholder (horizontal axis). Source: Adapted from (Visscher et al., 2020).

[END FIGURE 12.12 HERE]

12.6.3 Challenges

Climate services set new scientific challenges to physical climate research (high confidence). Over at least the last decade, for instance, many questions have appeared in terms of optimal estimation of changes and uncertainties from projections of model ensembles, ensemble optimization, or adjustment of model biases while preserving essential information on trends and cross-variable, time and space consistencies, downscaling information at the local scale (Benestad et al., 2017; Hewitt et al., 2017a; Marotzke et al., 2017; Hewitt and Lowe, 2018; Knutti, 2019) (see also Section 10.5). Other challenges related to climate services are the inter-operability of data (Giuliani et al., 2017), access to data (open/FAIR Guiding principles (Wilkinson et al., 2016; Georgezon et al., 2017)), format of data (including moving away from percentile-based probabilistic forecasts (e.g., Haines, 2019) and funding mechanisms (Bruno Soares and Buontempo, 2019).

Understanding and modeling of weather and climate extremes is of great relevance for climate services and is continuing to set challenges for research, such as modeling changes in impact-relevant threshold exceedance and return periods for a variety of extremes (Maraun et al., 2015; Sillmann et al., 2017; Hewitt et al., 2020c; Schwingshailek et al., 2021) (see also Chapter 11). Extreme event attribution has also been used in context of climate services (Philip et al., 2020) as it is of interest to some stakeholder groups (Sippel et al., 2015; Marjanac and Patton, 2018; Jézequel et al., 2019, 2020). The usefulness or applicability of available extreme event attribution methods (see Cross-chapter box 1.4 and section 11.2.4) for assessing climate-related risks remains subject to debate (Shepherd, 2016; Mann et al., 2017; Lloyd and Oreskes, 2018).

The design of climate services involves key challenges, such as a domain challenge where users, tasks and data may be unknown; and an informational challenge related to the use and adoption of novel and complex scientific data (Christel et al., 2018). This includes challenges in the uptake of climate information in terms of coordinated delivery of data, information, expertise and training by public research institutes, the inclusion of climate change adaptation in public and private regulation, and uncertainties and confidence in climate projections (Cavelier et al., 2017). Quality control and quality assurance are still weak elements in the development of climate service products (Jacob, 2020). Quality criteria or standards (that go beyond good practice) will have to be developed and agreed (cf. (Pacchetti et al., 2021). These challenges reflect the dilemma that exists at the interface between the climate modelling community and climate services regarding: 1) the purposes of the models for climate research versus service development; 2) the gap between the spatial and temporal scales of the models versus the scales needed in applications; and 3) tailoring
Climate services require a sustained engagement between scientists, service providers and users that is often hindered by limited resources for the co-design and co-production process (high confidence). There are recurring challenges related to successful climate service applications: 1) climate services are not visible and poorly understood by ‘end users’ (Weichselgartner and Arheimer, 2019); 2) data can be of unknown or poor quality, data formats can be hard to access or process, and it can be difficult to choose from large databases (e.g. Section 1.5.4) without appropriate user guidance; 3) users are unsure how to choose from available climate services to meet their needs (Rösässler et al., 2019); 4) building trust between climate service users and providers (Baztan et al., 2020); 5) the lack of understanding of users and their contexts by the climate science and service community (Porter and Dessai, 2017); 6) the difficulty in scaling up services (Tall et al., 2014; van Huysen et al., 2018); 7) the lack of trained scientists skilled at conducting societally-relevant research (Rozance et al., 2020).

Challenges also arise in determining the effectiveness and added value of climate services, particularly in terms of providing quantitative estimates of economic benefits and making a business case for climate services (Bruno Soares, 2017). The market for climate services is still in its infancy (Cavelier et al., 2017; Bruno Soares et al., 2018b; Tall et al., 2018; Damm et al., 2019). One form of value may be determined by a particular user community’s willingness to pay (Acquah and Onumah, 2011; Ouedraogo et al., 2018; Antwi-Agyei et al., 2021), which however cannot reflect the value of climate services as a public good and for society as a whole (Hewitt et al., 2012). Literature is only recently emerging on the socio-economic benefits of weather and climate services (Vaughan et al., 2019). Early studies and guidelines from the WMO focus on cost-benefit ratios (Perrels et al., 2013; WMO, 2015). Issues related to demand-driven versus supply-driven climate services (Lourenço et al., 2016; Street, 2016; Daniels et al., 2020), public versus private climate services (Hewitt et al., 2020a) and business models for climate services (Hoa, 2018) have been raised. A large share of climate services documented in peer-reviewed literature is currently provided in non-market frameworks (e.g., public service obligations and R&D grants) (Hoa, 2018; Kolstad et al., 2019; Cortekar et al., 2020).

Other challenges related to governance and dealing with complex systems are sometimes acknowledged but less well described in the climate services domain (Hewitt et al., 2020a). Importantly, decision contexts are strongly rooted in past practice (which often does not even make optimal use of past climate information), stakeholder experience and history. Even important emerging concepts of co-production, entry points, and champions do not always fall naturally into these realities without significant effort. The social sciences have an important role in helping understand and tackle these challenges (Bruno Soares and Buontempo, 2019).

Cross-Chapter Box 12.2: Climate services and climate change information

**Contributing Authors:**
Suraje Dessai (UK/Portugal), Jana Sillmann (Norway/Germany), Carlo Buontempo (UK/Italy), Cecilia Conde (Mexico), Aida Diongue-Niang (Senegal), Francisco J. Doblas-Reyes (Spain), Christopher Jack (South Africa), Richard Jones (UK), Benjamin Lampet (Niger/Ghana), Xianfu Lu (UK/China), Douglas Maraun (Austria/Germany), Ben Orlove (USA), Roshanka Ranasinghe (Netherlands/Sri Lanka/Australia), Alex C. Ruane (USA), Anna Steynor (South Africa), Bart van den Hurk (Netherlands), Robert Vautard (France)

Climate services involve the provision of climate information in such a way as to assist decision-making. The service needs to have appropriate engagement from users and providers, be based on scientifically credible information and expertise, have an effective access mechanism, and meet the users’ needs (Hewitt et al., 2012). Predominantly, climate services are targeted at informing and enabling risk management in adaptation to climate variability and change (Jones et al., 2014; Vaughan et al., 2018). Chapter 1 introduces
climate services in a broader context of interaction between science and society, including how climate
information can be tailored and co-produced for greatest utility in specific contexts. Chapter 10 assesses the
key foundations for the generation of climate information about regional climate change. Chapters 11, 12
and Atlas comprehensively assess regional climate change information. The Interactive Atlas gives access to
various repositories of quantitative climate information. In WG2, Chapter 17 assesses climate services in the
context of climate risk management.

Climate services contexts are diverse and complex. They can be characterised using different factors such as
sectors, regions, purposes, time horizons, data sources, level of processing of climate data, background
knowledge, type of climate services providers, as well as the nature of the interactions between providers,
users and other stakeholders (Bessembinder et al., 2019). To illustrate the wide diversity of climate change
information in climate services, a useful categorisation is by user-provider engagement of climate services
(Cross-Chapter Box 12.2, Figure 1). One broad category includes Websites and web tools which generally
focuses on data and information provision (Hewitson et al., 2017). Websites are generally able to reach many
users, but engagement is passive through one-way transfer of information. The second broad category
involves Interactive group activities, such as workshops, meetings and interactive forums, which create a
stronger dialogue between climate service providers and decision-makers. Multi-way communication and
regular interaction enable building of trust, co-learning and co-production of products and services. The third
broad category involves Focused relationships which are tailored, targeted and address very specific needs
of the user. Effective engagement arises from an iterative process between the provider and user to ensure
the user’s needs are being addressed appropriately (Hewitt et al., 2017b).

The diversity of climate services practices and products is illustrated here using three case studies that
represent each of the broad categories of provider-user engagement (Cross-chapter box Figure 1).

[START CROSS-CHAPTER BOX 12.2, FIGURE 1 HERE]

Cross-Chapter Box 12.2, Figure 1: Schematic of three broad categories of engagement between users and providers of
climate services (adapted from Hewitt et al., 2017b).

[END CROSS-CHAPTER BOX 12.2, FIGURE 1 HERE]

Case study 1 – Websites and web tools. TheCopernicus Climate Change Service (C3S) provides free and
open access to climate data, tools and information through a website. It also includes demonstration projects
that show how C3S data can be used in practice through case studies, training sessions and workshops
(Thepaut et al., 2018). A large audience of the service is composed of intermediate users, loosely defined as
the community of operators in one of the intermediate steps between the primary producers of climate data
and the ultimate beneficiaries.

To address this audience, the strategy of C3S is to provide free and open access climate data and tools such
as historical observations (both satellite and ground-based), climate data records relevant for a number of
Essential Climate Variables (Bojinski et al., 2014), global and regional reanalyses, climate monitoring
bulletins, seasonal predictions, as well as both global (a selection of simulations from the Coupled Model
Intercomparison Project (CMIP (Taylor et al., 2012; Eyring et al., 2016)) and regional climate projections
from the Coordinated Regional Downscaling Experiment (Euro- and Med-CORDEX (Jacob et al., 2014;
Ruti et al., 2016)). A number of indices for various sectors can be calculated through cloud-based tools. For
instance, in order to address the specific needs of key sectoral users, climate impact indicators for common
variables such as “heating degree-days” can be calculated by the users and made available to others
(Buontempo et al., 2020). All this material is quality controlled following a standardised, transparent and
traceable framework.

C3S also facilitates the tailoring process, by providing a series of working open-source on-the-cloud
demonstrators which show how climate data can be transformed into actionable information to meet specific
user requirements. This tailoring process covers the chain between the definition of key indicators all the way to the user interface. The C3S products definition and production involve scientists that produced and assessed the data. A variety of potential users are involved in the definition of indicators and other products.

Through its quality assurance process and demonstrators, C3S provides a basic evaluation of all climate data it provides access, and it encourages the users to develop their own case-specific analysis within the C3S infrastructure. Trustworthiness and relevance of such an analysis are substantially strengthened through a distillation process, co-designed by the user and data provider, and drawing upon multiple lines of evidence and process-based evaluation of model fitness (Section 10.5).

Case study 2 – Interactive group activities. Science-application engagement is extremely challenging especially in critically important but complex contexts such as rapidly growing cities in developing nations (Culwick and Patel, 2017). The publicly funded Future Resilience for African CiTies And Lands (FRACTAL) project was conceived and designed in response to extensive and strong evidence and experience that useful and useable climate services require strong mutual relationships across the science-application interface that can be built using supportive processes and structures (Taylor et al., 2017).

Informed by this understanding, FRACTAL was grounded in a very reflexive and context guided approach with city decision making at its core (Taylor et al., 2017a). Representatives from selected southern African cities were included in the proposal design and, throughout the project, a core principle was to allow the city partners to lead and guide the process.

Two important elements were deployed in FRAC'TAL: “embedded researchers” and “learning labs”. Embedded Researchers were seconded into the municipality and served as the essential connection for the learning process within each city (Steynor et al., 2020). Learning Labs (Arrighi et al., 2016) were interactive structures in which participants from academia, local city government and councils, state-owned enterprises, communities and community development institutions, etc could interact. Embedded Researchers and Learning Labs were the backbone of ongoing learning processes within each city and resulted in more focused small-group dialogues, capacity development and training processes, and within-city research and engagement activities. Each Learning Lab focused initially on identifying “burning issues” without a requirement that they involve strong climate linkages. However, with the over-arching focus on resilience, discussions evolved in that direction and the burning issues identified often centered around water in peri-urban areas e.g., in Windhoek (Scott et al., 2018).

The learning labs also introduced and developed the concept of Climate Risk Narratives as a process and product (CRN; see Cross-Chapter Box 12.2, Figure 2 and Chapter 10 Box 10.2 on storylines) to generate and integrate climate and socio-economic information relevant to adaptation and resilience (Jack et al., 2020). The first CRNs were informed primarily by climate evidence, but also included some tentative socio-economic impact elements gleaned from literature and other studies. Their content was intentionally provocative and designed to promote debate and discussion, and subsequent iteration. Many participants noted that this was the first time that various important conversations across governance structures and disciplinary areas had occurred around what climate change may actually mean. This demonstrates the engagement value of CRNs as a key element in an iterative co-production process to ensure important details are included correctly, such as the local context, terms and names as well as providing reality checks on the impacts and societal responses (Jack et al., 2020).

This case study emphasises the positive contributions of the fit, tailoring and contextualization of climate information with respect to the specific decision-making needs of particular users (10.5 and WG2 17.4.4.2.2), the importance of participatory planning for risk management in urban areas (WG2 6.1.5 and 6.4.2) and the importance of networks and organizations which link researchers, policy-makers and end-users to promote adaptation in African cities (WG2 9.8.5.1). Upscaling this type of interactive activity to cater for the large number of user demands remains a challenge.
Cross-Chapter Box 12.2, Figure 2: Climate Risk Narrative infographic developed through the FRACTAL Windhoek Learning Lab process (adapted from Jack et al., 2020).

Case study 3 – Focused relationships. This broad category involves one-to-one engagement between a provider and a user with very specific needs. One such user is the Asian Development Bank (ADB) who has committed to making all its investments climate resilient by implementing a climate risk management framework (ADB, 2014, 2018; Lu, 2019). The climate risk management framework mandates all climate-sensitive investment projects undertake a climate risk and adaptation assessment, to identify material risks of a changing climate to the proposed project and potential adaptive measures to be incorporated into project design, implementation, maintenance and/or monitoring. Typically, loan project processing teams procure consulting services for a bespoke climate risk and adaptation assessment (CRA) for a specific project. The user-provider engagement is highly targeted and goal-oriented. An example of such a focused user-provider engagement is the CRA carried out as part of an investment project in Viet Nam, the Water Efficiency Improvement in Drought-Affected Provinces (WEIDAP) project.

In the wake of the El Niño-induced 2015-2016 severe drought causing major damage to agricultural land in the Central Highlands of Viet Nam, the WEIDAP project was initiated to improve water productivity of irrigated agriculture. Proposed project interventions include a package of both “soft” (e.g., policy, institutional and capacity building, on-farm water efficiency practices) and “hard” (modernized irrigation schemes) activities. To ensure that the project delivers expected benefits under a changing climate, consultants were recruited to carry out a detailed CRA, working as part of the overall project processing team. Through extensive consultations with the rest of the project team and review of literature including relevant climate projections, the CRA consultants chose to construct three broad climate scenarios for the 2050s (a time frame appropriate for the lifetime of the irrigation schemes being proposed under the project): a warm-and-wet, a hot-and-wet, and a hotter future. Outputs from a selection of CMIP5 models were analysed under these three scenarios, to derive changes in temperature, rainfall and potential evapotranspiration, which in turn were used as inputs to hydrological, crop and agro-economics models to assess the impacts of climate change on the overall project performance. Table 1 presents the summary of the key parameters under the three scenarios. Recommendations from the CRA included (largely minor) refinements and additional activities for drought planning, detailed engineering design of the relevant project components (such as access roads, river crossings and foundations), and support for poorer farmers who may not be able to afford access to water and climate-resilient technologies.

This case study illustrates that climate information distillation including a sustained iterative engagement between climate information users, producers and translators can improve the quality of the information and the decision-making (Section 10.5, WG2 17.4.4.2.2).

Cross-Chapter Box 12.2, Table 1: Summary of Annual Province-Level Changes in Temperature, Precipitation and Evapotranspiration under the Three Broad Scenarios in Southern Viet Nam (Scenario 1: warm-and-wet; Scenario 2: hot-and-wet; Scenario 3: hotter)  
(Source: Table 3 in (ADB, 2020))
12.7 Final Remarks

The assessment in this chapter is based on a rapidly growing body of new evidence from the peer-reviewed literature, direct calculations of climate projections from several new model ensembles, and results from other AR6 WGI chapters. Although a large amount of new information on CID changes and their uptake in climate services has become available since AR5, some challenges still remain. This section summarizes some of these main challenges, with a view to facilitating improved assessments in future. The section is organized following the order of chapter sections and consolidated according to key assessment components.

- The adoption of the climatic impact-driver (CID) framework could benefit more from stronger connections across physical climate and impact scientists, and between the science community and practitioners/stakeholders on the ground. Co-development of CID index definitions with impact scientists or stakeholders helps ensure their salience and utility {12.1, 12.2, 12.3, 12.6}.

- The ability to project all aspects of shifting CID profiles and their effects at fine, local scales is often reliant on dynamical downscaling and additional impact modelling steps, making a robust and full quantification of the uncertainties involved more challenging. Availability of multiple models and ease of connecting physical climate models at different scales can facilitate assessment {12.2, 12.3, 12.4, 12.5}.

- Regional and sub-regional differences in coverage and access of homogeneous historical records, in the deployment of regional model ensembles and the exploration of scenarios, and ultimately in peer-reviewed studies addressing the full range of past and current behavior, detection and attribution, and future projections challenge a uniformly robust assessment across all CIDs and regions of the world {12.4, 12.5}.

- Efforts to assess a consistent global, large scale view of CID changes across regions and sectors would benefit from additional coordinated studies adopting common CID indices, model protocols, time horizons and scenarios or global warming levels {12.3, 12.5}.

- Even though the body of peer-reviewed literature regarding climate services practices and products is growing, a large part is still documented only in grey literature arising from commercial consultancy, and thus not publicly and freely accessible {12.6}.
Frequently Asked Questions

FAQ 12.1: What is a climatic impact-driver (CID)?

A climatic impact-driver is a physical climate condition that directly affects society or ecosystems. Climatic impact-drivers may represent a long-term average condition (such as the average winter temperatures that affect indoor heating requirements), a common event (such as a frost that kills off warm-season plants), or an extreme event (such as a coastal flood that destroys homes). A single climatic impact-driver may lead to detrimental effects for one part of society while benefiting another, while others are not affected at all. A climatic impact-driver (or its change caused by climate change) is therefore not universally hazardous or beneficial, but we refer to it as a ‘hazard’ when experts determine it is detrimental to a specific system.

Climate change can alter many aspects of the climate system, but efforts to identify impacts and risks usually focus on a smaller set of changes known to affect, or potentially affect, things that society cares about. These climatic impact-drivers (CIDs) are formally defined in this Report as ‘physical climate system conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions’. Because people, infrastructure and ecosystems interact directly with their immediate environment, climate experts assess CIDs locally and regionally. CIDs may relate to temperature, the water cycle, wind and storms, snow and ice, oceanic and coastal processes or the chemistry and energy balance of the climate system. Future impacts and risk may also be directly affected by factors unrelated to the climate (such as socio-economic development, population growth, or a viral outbreak) that may also alter the vulnerability or exposure of systems.

CIDs capture important characteristics of the average climate and both common and extreme events that shape society and nature (see FAQ 12.2). Some CIDs focus on aspects of the average climate (such as the seasonal progression of temperature and precipitation, average winds and the chemistry of the ocean) that determine, for example, species distribution, farming systems, the location of tourist resorts, the availability of water resources and the expected heating and cooling needs for buildings in an average year. CIDs also include common episodic events that are particularly important to systems, such as thaw events that can trigger springtime plant development, cold spells that are important for fruit crop chill requirements, or frost events that eliminate summer vegetation as winter sets in. Finally, CIDs include many extreme events connected to impacts such as hailstorms that damage vehicles, coastal floods that destroy shoreline property, tornadoes that damage infrastructure, droughts that increase competition for water resources, and heatwaves that can strain the health of outdoor laborers.

Many aspects of our daily lives, businesses and natural systems depend on weather and climate, and there is great interest in anticipating the impacts of climate change on the things we care about. To meet these needs, scientists engage with companies and authorities to provide climate services – meaningful and possibly actionable climate information designed to assist decision-making. Climate science and services can focus on CIDs that substantially disrupt systems to support broader risk management approaches. A single CID change can have dramatically different implications for different sectors or even elements of the same sector, so engagement between climate scientists and stakeholders is important to contextualize the climate changes that will come. Climate services responding to planning and optimization of an activity can focus on more gradual changes in climate operating conditions.

FAQ 12.1, Figure 1 tracks example outcomes of seasonal snow cover changes that connect climate science to the need for mitigation, adaptation and regional risk management. The length of the season with snow on the ground is just one of many regional climate conditions that may change in the future, and it becomes a CID because there are many elements of society and ecosystems that rely on an expected seasonality of snow cover. Climate scientists and climate service providers examining human-driven climate change may identify different regions where the length of the season with snow cover could increase, decrease, or stay relatively unaffected. In each region, change in seasonal snow cover in turn may affect different systems in beneficial or detrimental ways (in the latter case, changing seasonal snow cover would be a ‘hazard’), although systems such as coastal aquaculture remain relatively unaffected. The changing profile of benefits...
and hazards connected to these changes in the seasonal snow cover CID in turn affects the profile of impacts, risks and benefits that stakeholders in the region manage in response to climate change.

[START FAQ12.1, FIGURE 1 HERE]

FAQ 12.1, Figure 1: A single climatic impact-driver can affect ecosystems and society in different ways. A variety of impacts from the same climatic impact-driver change, illustrated with the example of regional seasonal snow cover.

[END FAQ12.1, FIGURE 1 HERE]
FAQ 12.2: What are climatic thresholds and why are they important?

Climatic thresholds tell us about the tolerance of society and ecosystems so that we can better scrutinize the types of climate changes that are expected to impact things we care about. Many systems have natural or structural thresholds. If conditions exceed those thresholds, the result can be sudden changes or even collapses in health, productivity, utility or behavior. Adaptation and risk management efforts can change these thresholds, altering the profile of climate conditions that would be problematic and increasing overall system resilience.

Decision makers have long observed that certain weather and climate conditions can be problematic, or hazardous, for things they care about (i.e., things with socio-economic, cultural or intrinsic value). Many elements of society and ecosystems operate in a suitable climate zone selected naturally or by stakeholders considering the expected climate conditions. However, as climate change moves conditions beyond expected ranges, they may cross a climatic ‘threshold’ – a level beyond which there are either gradual changes in system behaviour or abrupt, non-linear and potentially irreversible impacts.

Climatic thresholds can be associated with either natural or structural tolerance levels. Natural thresholds, for instance, include heat and humidity conditions above which humans cannot regulate their internal temperatures through sweat, drought durations that heighten competition between species, and winter temperatures that are lethal for pests or disease-carrying vector species. Structural thresholds include engineered limits of drainage systems, extreme wind speeds that limit wind turbine operation, the height of coastal protection infrastructure, and the locations of irrigation infrastructure or tropical cyclone sheltering facilities.

Thresholds may be defined according to raw values (such as maximum temperature exceeding 35°C) or percentiles (such as the local 99th percentile daily rainfall total). They also often have strong seasonal dependence (see FAQ 12.3). For example, the amount of snowfall that a deciduous tree can withstand depends on whether the snowfall occurs before or after the tree sheds its leaves. Most systems respond to changes in complex ways, and those responses are not determined solely or precisely by specific thresholds of a single climate variable. Nonetheless, thresholds can be useful indicators of system behaviours, and an understanding of these thresholds can help inform risk management decisions.

FAQ 12.2 Figure 1 illustrates how threshold conditions can help us understand climate conditions that are suitable for normal system operation and the thresholds beyond which impacts occur. Crops tend to grow most optimally within a suitable range of daily temperatures that is influenced by the varieties being cultivated and the way the farm is managed. As daily temperatures rise above a ‘critical’ temperature threshold, plants begin to experience heat stress that reduces growth and may lower resulting yields. If temperatures reach a higher ‘limiting’ temperature threshold, crops may suffer leaf loss, pollen sterility, or tissue damage that can lead to crop failure. Farmers typically select a cropping system with some consideration to the probability of extreme temperature events that may occur within a typical season, and so identifying hot temperature thresholds helps farmers select their seed and field management strategies as part of their overall risk management. Climate experts may therefore aim to assist farm planning by providing information about the climate change-induced shifts to the expected frequency of daily heat extremes that exceed crop tolerance thresholds.

Adaptation and other changes in societies and environment can shift climatic thresholds by modifying vulnerability and exposure. For example, adaptation efforts may include breeding new crops with higher heat tolerance levels so that corresponding dangerous thresholds occur less frequently. Likewise, increasing the height of a flood embankment protecting a given community can increase the level of river flow that may be tolerated without flooding, reducing the frequency of damaging floods. Stakeholders therefore benefit from climate services that are based on a co-development process, with scientists identifying system-relevant thresholds and developing tailored climatic impact-driver indices that represent these thresholds (FAQ 12.1). These thresholds help focus the provision of action-relevant climate information for adaptation and risk management.
FAQ12.2, Figure 1: Crop response to maximum temperature thresholds. Crop growth rate responds to daily maximum temperature increases, leading to reduced growth and crop failure as temperatures exceed critical and limiting temperature thresholds, respectively. Note that changes in other environmental factors (such as carbon dioxide and water) may increase the tolerance of plants to increasing temperatures.
FAQ 12.3: How will climate change affect the regional characteristics of a climate hazard?

*Human-driven climate change can alter the regional characteristics of a climate hazard by changing the magnitude or intensity of a climate hazard, the frequency with which it occurs, the duration that hazardous conditions persist, the timing when a hazard occurs, or the spatial extent threatened by a hazard. By examining each of these aspects of a hazard’s profile change, climate services may provide climate risk information that allows decision makers to better tailor adaptation, mitigation and risk management strategies.*

A *climate hazard* is a climate condition with the potential to harm natural systems or society. Examples include heatwaves, droughts, heavy snowfall events and sea level rise. Climate scientists look for patterns in climatic impact-drivers to detect the signature of changing hazards that may influence stakeholder planning (FAQ 12.1). Climate service providers work with stakeholders and impacts experts to identify key system responses and tolerance thresholds (FAQ 12.2) and then examine historical observations and future climate projections to identify associated changes to the characteristics of a regional hazard’s profile. Climate change can alter at least five different characteristics of the hazard profile of a region (FAQ 12.3; Figure 1):

- **Magnitude or intensity** is the raw value of a climate hazard, such as an increase in the maximum yearly temperature or in the depth of flooding that results from a coastal storm with a 1% change of occurring each year.

- **Frequency** is the number of times that a climate hazard reaches or surpasses a threshold over a given period. For example, increases to the number of heavy snowfall events, tornadoes, or floods experienced in a year or in a decade.

- **Duration** is the length of time over which hazardous conditions persist beyond a threshold, such as an increase in the number of consecutive days where maximum air temperature exceeds 35°C, the number of consecutive months of drought conditions, or the number of days that a tropical cyclone affects a location.

- **Timing** captures the occurrence of a hazardous event in relation to the course of a day, season, year, or other period in which sectoral elements are evolving or co-dependent (such as the time of year when migrating animals expect to find a seasonal food supply). Examples include a shift toward an earlier day of the year when the last spring frost occurs or a delay in the typical arrival date for the first seasonal rains, the length of the winter period when the ground is typically covered by snow, or a reduction in the typical time needed for soil moisture to move from normal to drought conditions.

- **Spatial extent** is the region in which a hazardous condition is expected, such as the area currently threatened by tropical cyclones, geographical areas where the coldest day of the year restricts a particular pest or pathogen, terrain where permafrost is present, the area that would flood following a common storm, zones where climate conditions are conducive to outdoor labour, or the size of a marine heatwave.

Hazard profile changes are often intertwined or stem from related physical changes to the climate system. For example, changes in the frequency and magnitude of extreme events are often directly related to each other as a result of atmospheric dynamics and chemical processes. In many cases, one aspect of hazard change is more apparent than others, which may provide a first emergent signal indicating a larger set of changes to come (FAQ1.2).

Information about how a hazard has changed or will change helps stakeholders prioritize more robust adaptation, mitigation and risk management strategies. For example, allocation of limited disaster relief resources may be designed to recognize that tropical cyclones are projected to become more intense even as the frequency of those storms may not change. Planning may also factor in the fact that even heatwaves that are not record-breaking in their intensity can still be problematic for vulnerable populations when they persist over a long period. Likewise, firefighters recognize new logistical challenges in the lengthening of the fire weather season and an expansion of fire conditions into parts of the world where fires were not previously a great concern. Strong engagement between climate scientists and stakeholders therefore helps...
climate services tailor and communicate clear information about the types of changing climate hazards to be addressed in resilience efforts.

[START FAQ12.3, FIGURE 1 HERE]

FAQ 12.3, Figure 1: Types of changes to a region’s hazard profile. The first five panels illustrate how climate changes can alter a hazard’s intensity (or magnitude), frequency, duration, and timing (by seasonality and speed of onset) in relation to a hazard threshold (horizontal grey line). The difference between the historical climate (blue) and future climate (red) shows the changing aspects of climate change that stakeholders will have to manage. The bottom-right panel shows how a given climate hazard (such as a once-in-100-year river flood) may reach new geographical areas under a future climate change.

**Boxes:**

- **Cross-chapter boxes**
  - CC box 12.1: Reference to the assessment of Representative Key Risks and Reasons for Concern (ch. 4, 5, 6, 8, 9, 11, Atlas)
  - CC box 12.2: Climate information for climate services (ch. 10, 11, 12, Atlas)
Figure 12.3: Conceptual illustration of representative climatic impact-driver thresholds showing how 
graduating thresholds affect successive sectoral assets and lead to potentially more acute hazards as 
conditions become more extreme (exact values are not shown as these must be tailored to reflect 
diverse vulnerabilities of regional assets). Representative threshold definitions (T = instantaneous 
temperature; $\overline{T}$ = mean temperature): Cities and Infrastructure: $T_{\text{trans}}$ = temperature at which energy 
transmission lines efficiency reduced; $T_{\text{aircraft}}$ = temperature at which aircraft become weight-restricted for 
takeoff; $T_{\text{hotroads}}$ = temperature above which roads begin to warp; $T_{\text{stream}}$ = temperature at which streams 
are not capable of adequately cooling thermal plants; CDD$_{\text{min}}$ = Minimum temperature for calculating 
cooling degree days; HDD$_{\text{min}}$ = Maximum temperature for calculating heating degree days; $T_{\text{ice}}$ = 
temperature at which ice threatens transportation; $T_{\text{permafrost}}$ = mean seasonal temperature above which 
permafrost thaws at critical depths; $T_{\text{coldroads}}$ = temperature below which road asphalt performance suffers. 
Health: $T_{\text{deadly}}$ = temperatures above which prolonged exposure may be deadly (often combined with 
humidity for heat indices); $T_{\text{severe}}$ = temperatures above which prolonged exposure may cause elevated 
morbidity; $T_{\text{blooms}}$ = mean temperature for harmful algal or cyanobacteria blooms; $T_{\text{danger}}$ = level of 
dangerous cold temperatures (often combined with wind for chill indices); $T_{\text{overwinter}}$ = temperature below 
which disease vector species cannot survive winter. Ecosystems (CID indices for air and ocean 
temperature): $T_{\text{hotlim}}$ and $T_{\text{coldlim}}$ = limiting hot and cold temperatures for a given species range; $T_{\text{frost}}$ = 
frost threshold; $T_{\text{max}}$ and $T_{\text{min}}$ = maximum and minimum suitable annual mean temperatures for a given 
species; $T_{\text{crit}}$ = critical temperature above which a given species is stressed. Agriculture: $T_{\text{hotlim}}$ = 
temperature above which a crop or livestock species dies; $T_{\text{hotpest}}$ = maximum (or ‘lethal’) temperature 
above which an agricultural pest/disease/weed cannot survive; $T_{\text{opt}}$ = temperature at which productivity 
for a given crop is depressed; $T_{\text{opt}}$ = optimal mean temperature for a given plant’s productivity; GDD$_{\text{min}}$ = 
threshold temperature for growing degree days determining plant development; $T_{\text{chill}}$ = temperature below 
which chilling units are accumulated; $T_{\text{frost}}$ = temperature below which frost occurs; $T_{\text{frost}}$ = temperature
below which a hard frost threatens crops or livestock; $T_{\text{coldpest}} =$ minimum wintertime temperature below which a given agricultural pest cannot survive; $T_{\text{coldlim}} =$ minimum temperature below which a given crop cannot survive.
**Figure 12.4:** Median projected changes in selected climatic impact-driver indices based on CMIP6 models. (a-c) mean number of days per year with maximum temperature exceeding 35°C, (d-f) mean number of days per year with the NOAA Heat Index (HI) exceeding 41°C, (g-i) number of negative precipitation anomaly events per decade using the 6-month Standardised Precipitation Index, (j-l) mean soil moisture (%) and (m-o) mean wind speed (%). (p-r) shows change in extreme sea level (1:100 yr return period total water level from Vousdoukas et al. (2018)’s CMIP5 based dataset; meters). Left column is for SSP1-2.6, 2081-2100, middle column is for SSP5-8.5 2041-2060, and right column SSP5-8.5, 2081-2100, all expressed as changes relative to 1995-2014. Exception is extreme total water level which is for (p) RCP4.5 2100, (q) RCP8.5 2050 and (r) RCP8.5 2100, each relative to 1980-2014. Bias correction is applied to daily maximum temperature and HI data (see Technical Annex VI and Atlas.1.4.5). Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. See Technical Annex VI for details of indices. Figures SM 12.1-12.6 show regionally averaged values of these indices for the WGI reference AR6 regions for various model ensembles, scenarios, time horizons and global warming levels. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.5: Projected changes in selected climatic impact-driver indices for Africa. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m³ s⁻¹ km⁻²) from CORDEX models for 2041-2060 relative to 1995-2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 (meters; negative values indicate shoreline retreat) from the CMIP5 based data set presented by Vousdoukas et al., (2020). (c) Bar plots for Q100 (m³ s⁻¹ km⁻²) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colors, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5 based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al., (2020). Dots indicate regional mean change estimates and bars the 5th-95th percentile range of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.6: Projected changes in selected climatic impact-driver indices for Asia. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m$^3$ s$^{-1}$ km$^{-2}$) from CORDEX models for 2041-2060 relative to 1995-2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 (meters; negative values indicate shoreline retreat) from the CMIP5 based data set presented by Vousouskas et al., (2020). (c) Bar plots for Q100 (m$^3$ s$^{-1}$ km$^{-2}$) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colors, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change.
show CMIP5 based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al., (2020). Dots indicate regional mean change estimates and bars the 5th-95th percentiles ranges of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.7: Projected changes in selected climatic impact-driver indices for Australasia. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m$^3$ s$^{-1}$ km$^{-2}$) from CORDEX models for 2041-2060 relative to 1995-2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 (meters; negative values indicate shoreline retreat) from the CMIP5 based data set presented by Vousdoukas et al. (2020). (c) Bar plots for Q100 (m$^3$ s$^{-1}$ km$^{-2}$) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model.
ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5 based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al. (2020). Dots indicate regional mean change estimates and bars the 5th-95th percentiles ranges of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
**Figure 12.8:** Projected changes in selected climatic impact-driver indices for Central and South America. (a) Mean change in 1-in-100 year river discharge per unit catchment area ($Q_{100}$, $m^3 s^{-1} km^{-2}$) from CORDEX models for 2041-2060 relative to 1995-2014 for RCP8.5. (b) Shoreline position change along sandy coasts by the year 2100 relative to 2010 (meters; negative values indicate shoreline retreat) from the CMIP5 based data set presented by Vousdoukas et al. (2020). (c) Bar plots for $Q_{100}$ ($m^3 s^{-1} km^{-2}$) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) $Q_{100}$ absolute values in grey shades. The other columns (associated with the right y-axis) show the $Q_{100}$ changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) Bar plots for shoreline position change show CMIP5 based projections of shoreline position change along sandy coasts for 2050 and 2100 relative to 2010 for RCP8.5 (red) and RCP4.5 (blue) from Vousdoukas et al. (2020). Dots indicate regional mean change estimates and bars the 5th-95th percentiles ranges of associated uncertainty. Note that these shoreline position change projections assume that there are no additional sediment sinks/sources or any physical barriers to shoreline retreat. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.9: Projected changes in selected climatic impact-driver indices for Europe. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m$^3$ s$^{-1}$ km$^{-2}$), and (b) median change in the number of days with snow water equivalent (SWE) over 100 mm (from November to March), from EURO-CORDEX models for 2041-2060 relative to 1995-2014 and RCP8.5. Diagonal lines indicate where less than 80% of models agree on the sign of change. (c) Bar plots for Q100 (m$^3$ s$^{-1}$ km$^{-2}$) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) As for (c) but showing absolute values for number of days with SWE > 100mm, masked to grid cells with at least 14 such days in the recent past. See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.10: Projected changes in selected climatic impact-driver indices for North America. (a) Mean change in 1-in-100 year river discharge per unit catchment area (Q100, m$^3$.s$^{-1}$.km$^{-2}$), and (b) median change in the number of days with snow water equivalent (SWE) over 100 mm (from November to March), from CORDEX North America models for 2041-2060 relative to 1995-2014 and RCP8.5. Diagonal lines indicate where less than 80% of models agree on the sign of change. (c) Bar plots for Q100 (m$^3$.s$^{-1}$.km$^{-2}$) averaged over land areas for the WGI reference AR6 regions (defined in Chapter 1). The left column within each panel (associated with the left y-axis) shows the ‘recent past’ (1995-2014) Q100 absolute values in grey shades. The other columns (associated with the right y-axis) show the Q100 changes relative to the recent past values for two time periods (‘mid’ 2041-2060 and ‘long’ 2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown). The bars show the median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble. CMIP6 is shown by the darkest colours, CMIP5 by medium, and CORDEX by light. SSP5-8.5/RCP8.5 is shown in red and SSP1-2.6/RCP2.6 in blue. (d) As for (c) but showing absolute values for number of days with SWE > 100mm, masked to grid cells with at least 14 such days in the recent past. See Technical Annex VI for details of indices. A Caribbean Q100 bar plot is included here but assessed in the Small islands section (12.4.7). Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.11: Synthesis of the CID changes projected by 2050 (2041-2060) with high confidence, relative to reference period (1995-2014), together with the sign of change. Information is taken from the CID tables in Section 12.4. Some CIDs are grouped in order to streamline the information in order to fit in all information in the figure. Mean temperature, extreme heat, cold spells and frost are grouped under a single icon “heat”, as they are projected to change simultaneously, albeit heat and cold are changing in opposite directions. Coastal CIDs (relative sea level, coastal flooding and coastal erosion at sandy beaches) are also grouped. In the figure, the “coastal” icon indicates regions where at least two of the three individual coastal CIDs are projected to change with high confidence. Cases where only two of the three CIDs increase with high confidence are in Arctic North Europe, Russian Arctic and Arctic North West North America. A single icon is used for aridity, hydrological drought, and agricultural and ecological drought, and only the number of drought types that change is indicated. For the “Snow, ice” icon, information is taken from the evolution of the “Snow, Glacier and ice sheet” CID, and in most regions also have similar changes for “permafrost” and “lake, river and sea ice”. Exceptions are for NEN, RAR and Arctic NWN where snow is decreasing with medium confidence (thus not appearing in the figure), while permafrost and lake, river and sea ice is decreasing with high confidence. The location of the icon within the regions is arbitrary. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1). Icon sources: https://www.flaticon.com/authors/freepik
Figure 12.12: Illustration of different types of climate services. Products, for instance, can focus only on climate-related information or can be designed to integrate climate information with other decision-relevant context (vertical axis) and they can be very generic in terms of relevance to a wide range of sectors or stakeholders or customized to fit the needs of a specific sector or stakeholder (horizontal axis). Source: Adapted from (Visscher et al., 2020).
Cross-Chapter Box 12.2, Figure 1: Schematic of three broad categories of engagement between users and providers of climate services (adapted from Hewitt et al., 2017b).
Cross-Chapter Box 12.2, Figure 2: Climate Risk Narrative infographic developed through the FRACTAL Windhoek Learning Lab process (adapted from Jack et al., (2020)).
FAQ 12.1: **What is a climatic impact-driver (CID)?**

A climatic impact-driver (CID) is a climate condition that directly affects elements of society or ecosystems. Climatic impact-drivers and their changes can lead to positive, negative, or inconsequential outcomes (or a mixture).

**Regional climate change**

- **Possible changes**
  - Increase
  - No change
  - Decrease

**Impacts on societies and ecosystems**

- Examples for seasonal snow cover
  - Hazardous for crop planting
  - Beneficial for skiing resorts
  - Inconsequential for coastal aquaculture
  - Impacts on snow-camouflaged species
  - Beneficial for some predators

**FAQ 12.1, Figure 1:** A single climatic impact-driver can affect ecosystems and society in different ways. A variety of impacts from the same climatic impact-driver change, illustrated with the example of regional seasonal snow cover.
FAQ 12.2: What are climatic thresholds and why are they important? Many systems have thresholds that can lead to sudden changes, if climate conditions exceed them. Adaptation and risk management efforts can increase overall system resilience by identifying and changing tolerance thresholds.

**FAQ12.2, Figure 1:** Crop response to maximum temperature thresholds. Crop growth rate responds to daily maximum temperature increases, leading to reduced growth and crop failure as temperatures exceed critical and limiting temperature thresholds, respectively. Note that changes in other environmental factors (such as carbon dioxide and water) may increase the tolerance of plants to increasing temperatures.
FAQ 12.3: How will climate change affect climate hazards?

Climate change can alter the intensity and magnitude, frequency, duration, timing and spatial extent of a region’s climate hazards.

**FAQ 12.3, Figure 1: Types of changes to a region’s hazard profile.** The first five panels illustrate how climate changes can alter a hazard’s intensity (or magnitude), frequency, duration, and timing (by seasonality and speed of onset) in relation to a hazard threshold (horizontal grey line). The difference between the historical climate (blue) and future climate (red) shows the changing aspects of climate change that stakeholders will have to manage. The bottom-right panel shows how a given climate hazard (such as a once-in-100-year river flood) may reach new geographical areas under a future climate change.
Chapter 12: Climate change information for regional impact and for risk assessment - Supplementary Material

12.SM.1 Figures
Figure 12.SM.1: Regional projections for the number of days per year with maximum temperature exceeding 35°C for different scenarios, time horizons and global warming levels. The bar plots show projections from CMIP6 (darkest colours), CMIP5 (medium colours) and CORDEX (lightest colours) ensembles, for RCP8.5/SSP5-8.5 (red) and RCP2.6/SSP1-2.6 (blue), for the mid-term (2041-2060), long-term (2081-2100), and the recent past (grey, 1995-2014). Results for global warming levels (defined relative to the pre-industrial period 1850-1900) are shown in purple for 1.5°C, yellow for 2°C and brown for 4°C. The median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble and each time period are shown for the regional mean over land areas for the WGI reference AR6 regions (defined in Chapter 1). Bias adjustment is applied (see Atlas.1.4.5). The CORDEX ensemble is missing in regions that are not fully covered by the CORDEX domain (EEU, ESB, RAR, RFE and WSB). See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.SM.2: Regional projections for the number of days per year with the NOAA Heat Index exceeding 41°C for different scenarios, time horizons and global warming levels. 41°C corresponds to conditions that the US National Weather Service classifies into the category of “Danger” (Blazejczyk et al., 2012). The bar plots show projections from CMIP6 (darkest colours), CMIP5 (medium colours) and CORDEX (lightest colours) ensembles, for RCP8.5/SSP5-8.5 (red) and RCP2.6/SSP1-2.6 (blue), for the mid-term (2041-2060), long-term (2081-2100), and the recent past (grey, 1995-2014). Results for global warming levels (defined relative to the pre-industrial period 1850-1900) are shown in purple for 1.5°C, yellow for 2°C and brown for 4°C. The median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble and each time period are shown for the regional mean over land areas for the WGI reference AR6 regions (defined in Chapter 1). Bias adjustment is applied. The CORDEX ensemble is missing in regions that are not fully covered by the CORDEX domain (EEU, ESB, RAR, RFE and WSB). See Technical Annex VI for details of indices and bias adjustment. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Number of negative precipitation anomaly events per decade in AR6 regions

Total pages: 80
Figure 12.SM.3: Regional projections for the number of negative precipitation anomaly events per decade using the 6-month Standardised Precipitation Index for different scenarios, time horizons and global warming levels. The bar plots show projections from CMIP6 (darkest colours), CMIP5 (medium colours) and CORDEX (lightest colours) ensembles, for RCP8.5/SSP5-8.5 (red) and RCP2.6/SSP1-2.6 (blue), for the mid-term (2041-2060), long-term (2081-2100), and the recent past (grey, 1995-2014). Results for global warming levels (defined relative to the pre-industrial period 1850-1900) are shown in purple for 1.5°C, yellow for 2°C and brown for 4°C. The median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble and each time period are shown for the regional mean over land areas for the WGI reference AR6 regions (defined in Chapter 1). Units are events per decade. The CORDEX ensemble is missing in regions that are not fully covered by the CORDEX domain (EEU, ESB, RAR, RFE and WSB). See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.SM.4: Regional projections for changes in soil moisture for different scenarios, time horizons and global warming levels. The bar plots show projections of soil moisture as percentage changes relative to the recent-past (1994-2015) for the mid-term (2041-2060) and long-term (2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown), using CMIP6 (darkest colours), CMIP5 (medium colours) and CORDEX (lightest colours) ensembles. RCP8.5/SSP5-8.5 is shown in red and RCP2.6/SSP1-2.6 in blue. The median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble and each time period are shown for the regional mean over land areas for the WGI reference AR6 regions (defined in Chapter 1). The CORDEX ensemble is missing in regions that are not fully covered by the CORDEX domain (EEU, ESB, RAR, RFE and WSB) or because less than five simulations were available (NWN, NEN, WNA, CAN, ENA and NCA). See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Figure 12.SM.5: Regional projections for changes in mean wind speed for different scenarios, time horizons and global warming levels. The bar plots show projections of wind speed as percentage changes relative to the recent-past (1994-2015) for the mid-term (2041-2060) and long-term (2081-2100) and for three global warming levels (defined relative to the preindustrial period 1850-1900): 1.5°C (purple), 2°C (yellow) and 4°C (brown), using CMIP6 (darkest colours), CMIP5 (medium colours) and CORDEX (lightest colours) ensembles. RCP8.5/SSP5-8.5 is shown in red and RCP2.6/SSP1-2.6 in blue. The median (dots) and the 10th-90th percentile range of model ensemble values across each model ensemble and each time period are shown for the regional mean over land areas for the WGI reference AR6 regions (defined in Chapter 1). The CORDEX ensemble is missing in regions that are not fully covered by the CORDEX domain (EEU, ESB, RAR, RFE and WSB). See Technical Annex VI for details of indices. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).
Extreme Total Water Level in AR6 regions

Legend
- 95th percentile

Continents:
- Africa
- Europe
- Asia
- North-America
- Australasia
- Central and South-America
Figure 12.SM.6: Regional projections of extreme sea level (1-in-100 year return period extreme total water level (ETWL)). The bar plots show projections of regionally averaged ETWL from the CMIP5 based datasets presented in Vousdoukas et al. (2018) (filled circles, ‘V’ in legend), and the Kirezci et al., (2020) (open circles, ‘K’ in legend), for the WGI reference AR6 regions, for RCP8.5 (red) and RCP4.5 (blue). Dots represent the median estimate, and bars the 5th-95th percentiles representing the uncertainty associated with the projections for the mid-term (2050), long-term (2100) and the recent past (black, 1979/1980-2014). Units are meters. See Technical Annex VI for details about the index. Further details on data sources and processing are available in the chapter data table (Table 12.SM.1).

Executive summary

This Atlas chapter assesses changes in mean climate at regional scales, in particular observed trends and their attribution and projected future changes. The main focus is on changes in temperature and precipitation (including snow and derived variables in polar regions) over land regions, though other variables, including for oceanic regions, are also discussed. Projected changes are presented both as relative to levels of global warming and for future time periods under a range of emissions scenarios. In order to facilitate summarizing assessment findings, a new set of WGI reference regions is used within the chapter which were derived following broad consultation and peer review. These are used in other chapters for summarizing regional information. This includes the assessment of climatic impact-driver changes in Chapter 12, which incorporates the changes in mean climate assessed in the Atlas. Another important new development since AR5 is the AR6 WGI Interactive Atlas, which is described in this chapter and is used to generate results both for the Atlas and other regional chapters. It is also a resource allowing exploration of datasets underpinning assessment findings in other chapters of the report.

Observed trends and projections in regional climate

Most land areas have warmed faster than the global average (high confidence) and very likely by at least 0.1°C per decade since 1960. A surface temperature change signal has likely emerged over all land areas. Many areas very likely warmed faster since the 1980s, including areas of northern, eastern and south-western Africa, Australia, Central America, Amazonia and West Antarctica (0.2°C–0.3°C per decade), the Arabian Peninsula, Central and East Asia and Europe (0.3°C–0.5°C per decade) and Arctic and near-Arctic land regions (up to 1°C per decade, or more in a few areas). \{Figure Atlas.11, Interactive Atlas, Sections Atlas.3.1, Atlas.4.2, Atlas.5.1.2, Atlas.5.2.2, Atlas.5.3.2, Atlas.5.4.2, Atlas.5.5.2, Atlas.6.1.2, Atlas.6.2.2, Atlas.7.2, Atlas.8.2, Atlas.9.2, Atlas.10.2, Atlas.11.1.2, Atlas.11.2.2\}

Significant positive trends in precipitation have been observed in most of North Asia, parts of West Central Asia, South-eastern South America, Northern Europe, Eastern North America, Western Antarctica and the Arctic (medium confidence). Significant negative trends have been observed in the Horn of Africa and southwest Western Australia (high confidence), parts of the Russian Far East, some parts of the Mediterranean and of the Caribbean, Southeast and Northeast Brazil and southern Africa (medium confidence), with the last attributed to anthropogenic warming of the Indian Ocean. In the many other land areas there are no significant trends in annual precipitation over the period 1960–2015 though increases in average precipitation intensity have been observed in the Sahel and Southeast Asia (medium confidence). \{Figure Atlas.11, Interactive Atlas, Sections Atlas.3.1, Atlas.4.2, Atlas.5.1.2, Atlas.5.2.2, Atlas.5.3.2, Atlas.5.4.2, Atlas.5.5.2, Atlas.6.1.2, Atlas.6.2.2, Atlas.7.2, Atlas.8.2, Atlas.9.2, Atlas.10.2, Atlas.11.1.2, Atlas.11.2.2\}

The observed warming trends are projected to continue over the 21st century (high confidence) and over most land regions at a rate higher than the global average. At a global warming level of 4°C (i.e. relative to an 1850–1900 baseline) it is likely that most land areas will experience a further warming (from a 1995–2014 baseline) of at least 3°C and in some areas significantly more, including increases of 4°C–6°C in the Sahara/Sahel, Southwest, Central and Northern Asia; Northern South America and Amazonia, West Central and Eastern Europe; and Western, Central and Eastern North America, and up to 8°C or more in some Arctic regions. Across each of the continents, higher warming is likely to occur in northern Africa, the central interior of southern and Western Africa; in northern Asia; in Central Australia; in Amazonia; in northern Europe and northern North America (high confidence). Ranges of regional warming for global warming levels of 1.5°C, 2°C, 3°C and 4°C and for other time periods and emissions scenarios are available in the Interactive Atlas from Coupled Model Intercomparison Project Phases 5 and 6 (CMIP5, CMIP6) and Coordinated Regional Climate Downscaling Experiment (CORDEX) projections. \{Figure Atlas.12, Interactive Atlas, Sections Atlas.4.4, Atlas.5.1.4, Atlas.5.2.4, Atlas.5.3.4, Atlas.5.4.4, Atlas.5.5.4, Atlas.6.4, Atlas.7.4, Atlas.8.4, Atlas.9.4, Atlas.10.4, Atlas.11.4\}

For given global warming levels, model projections from CMIP6 show future regional warming and precipitation changes that are similar to those projected by CMIP5. However, the larger climate changes...
sensitivity in some CMIP6 models and differences in the model forcings lead to a wider range of and higher projected regional warming in CMIP6 compared to CMIP5 projections for given time periods and emissions scenarios. {Figure Atlas.13, Sections Atlas.4.4, Atlas.5.1.4, Atlas.5.2.4, Atlas.5.3.4, Atlas.5.4.4, Atlas.5.5.4, Atlas.6.1.4, Atlas.6.2.4, Atlas.7.4, Atlas.8.4, Atlas.9.4, Atlas.10.4, Atlas.11.1.4, Atlas.11.2.4}

Precipitation will change in most regions, either through changes in mean values or the characteristics of rainy seasons or daily precipitation statistics (high confidence). Regions where annual precipitation is likely to increase include the Ethiopian Highlands; East, South and North Asia; Southeast South America; northern Europe; northern and eastern North America and the polar regions. Regions where annual precipitation is likely to decrease include northern and southwest southern Africa and the Sahel, Indonesia, northern Arabian Peninsula, southwest Australia, Central America, southwest South America and southern Europe. Changes in monsoons are likely to result in increased precipitation in northern China and in South Asia in summer (high confidence). Precipitation intensity will increase in many areas, including in some where annual mean reductions are likely (e.g., Southern Africa) (high confidence). Ranges of regional mean precipitation change for global warming levels of 1.5°C, 2°C, 3°C and 4°C and for other time periods and emissions scenarios are available in Interactive Atlas from CMIP5, CORDEX and CMIP6 projections. {Figure Atlas.13, Interactive Atlas, Sections Atlas.4.4, Atlas.5.1.4, Atlas.5.2.4, Atlas.5.3.4, Atlas.5.4.4, Atlas.5.5.4, Atlas.6.1.4, Atlas.6.2.4, Atlas.7.4, Atlas.8.4, Atlas.9.4, Atlas.10.4, Atlas.11.1.4, Atlas.11.2.4}

Cryosphere, Polar Regions and Small Islands

Many aspects of the cryosphere either have seen significant changes in the recent past or will see them during the 21st century (high confidence). Snow cover duration has very likely reduced over Siberia and Eastern and Northern Europe. Also, it is virtually certain that snow cover will experience a decline in these regions and over most of North America during the 21st century, in terms of water equivalent, extent and annual duration. Over the Hindu Kush–Himalaya, glacier mass is likely to decrease considerably (nearly 50%) under the RCP4.5 and RCP8.5 scenarios. Snow cover has declined over Australia as has annual maximum snow mass over North America (medium confidence). Some high-latitude regions have experienced increases in winter snow (parts of northern Asia, medium confidence) or will do so in the future (very likely in parts of northern North America) due to the effect of increased snowfall prevailing over warming-induced increased snowmelt. {Sections 2.3.2.2, 3.4.2, Atlas.5.2.2, Atlas.5.3.4, Atlas.6.2, Atlas.8.2, Atlas.8.4, Atlas.9.2, Atlas.9.4}

It is very likely that the Arctic has warmed at more than twice the global rate over the past 50 years and that the Antarctic Peninsula experienced a strong warming trend starting in 1950s. It is likely that Arctic annual precipitation has increased, with the highest increases during the cold season. Antarctic precipitation and surface mass balance showed a significant positive trend over the 20th century, while strong interannual variability masks any existing trend over recent decades (medium confidence). Significant warming trends are observed in other West Antarctic regions and at selected stations in East Antarctica since the 1950s (medium confidence). Under all assessed emission scenarios, both Polar regions are very likely to have higher annual mean surface air temperatures and more precipitation, with temperature increases higher than the global mean, most prominently in the Arctic. {Sections Atlas.11.1.2, Atlas.11.1.4, Atlas.11.2.2, Atlas.11.2.4}

It is very likely that most Small Islands have warmed over the period of instrumental records. Precipitation has likely decreased since the mid-20th century in some parts of the Pacific poleward of 20° latitude in both hemispheres and in the Caribbean in June-July-August. It is very likely that sea levels will continue to rise in Small Island regions and that this will result in increased coastal flooding.

1 The term ‘recent decades’ refers to a period of approximately 30 to 40 years which ends within the period 2010–2020. This is used as many studies in the literature will analyse datasets over a range of climatologically significant periods (i.e., 30 years or more) with precise start and end dates and periods depending on data availability and the year of the study. An equivalent approximate description using specific years would be ‘since the 1980s’.

Do Not Cite, Quote or Distribute
Observed temperature trends are generally in the range of 0.15°C–0.2°C per decade. Rainfall trends in most other Pacific and Indian Ocean Small Islands are mixed and largely non-significant. There is limited evidence and low agreement on the cause of the Caribbean drying trend, though it is likely that both this and the Pacific drying trends will continue in coming decades with drying also projected in the part of the West Indian and Atlantic Oceans. Small Islands regions in the Western and equatorial Pacific and North Indian Ocean are likely to be wetter in the future. {Cross-Chapter Box Atlas.2, Sections Atlas.10.2, Atlas.10.4}

Model Evaluation, Technical Infrastructure and the Interactive Atlas

The regional performance of CMIP6 global climate models (GCMs) has improved overall compared to CMIP5 in simulating mean temperature and precipitation, though large errors still exist in some regions. In particular, improvements have been seen over Africa which has belatedly become a focus for GCM model development. Other specific improvement include over East Asia for temperature and the winter monsoon, over parts of South Asia for the summer monsoon, over Australia (including influences of modes of variability), in simulation of Antarctic temperatures and Arctic sea ice. Notable errors include large cold biases in mountain ranges in South Asia, a significant wet bias over Central Asia, in the East Asia summer monsoon and in Antarctic precipitation. An in-depth evaluation of CMIP6 models is lacking for several regions (North and Southeast Asia, parts of West Central Asia, Central and South America), though CMIP5 models have been evaluated for many of these. {Sections Atlas.4.3, Atlas.5.1.3, Atlas.5.2.3, Atlas.5.3.3, Atlas.5.4.3, Atlas.5.5.3, Atlas.6.1.3, Atlas.6.2.3, Atlas.7.3, Atlas.8.3, Atlas.9.3, Atlas.10.3, Atlas.11.1.3, Atlas.11.2.3}

Since AR5, the improvement in regional climate modelling and the growing availability of regional simulations through coordinated dynamical downscaling initiatives such as CORDEX, have advanced the understanding of regional climate variability, adding value to CMIP global models, particularly in complex topography zones, coastal areas and small islands, and in the representation of extremes (high confidence). In particular, regional climate models with polar-optimized physics are important for estimating the regional and local surface mass balance and are improved compared to reanalyses and GCMs when evaluated with observations (high confidence). There is still a lack of high-quality and high-resolution observational data to assess observational uncertainty in climate studies, and this compromises the ability to evaluate models (high confidence). {Sections Atlas.4.3, Atlas.5.1.3, Atlas.5.2.3, Atlas.5.3.3, Atlas.5.4.3, Atlas.5.5.3, Atlas.6.1.3, Atlas.6.2.3, Atlas.7.3, Atlas.8.3, Atlas.9.3, Atlas.10.3, Atlas.11.1.3, Atlas.11.2.3}

Significant improvements in technical infrastructure, open tools and methodologies for accessing and analysing observed and simulated climate data, and the progressive adoption of FAIR (findability, accessibility, interoperability, and reusability) data principles have very likely broadened the ability to interact with these data for a wide range of activities, including fundamental climate research, providing inputs into assessments of impacts, building resilience and developing adaptations. Tools to analyse and assess climate information have improved to allow development of information that goes beyond averages (e.g., on future climate thresholds and extremes) and that is relevant for regional climate risk assessments. {Sections Atlas.2.2, Atlas.2.3}

The Interactive Atlas is a new WGI product developed to take advantage of the interactivity offered by web applications by allowing flexible and expanded exploration of some key products underpinning the assessment (including extreme indices and climatic impact-drivers). This provides a transparent interface for access to authoritative IPCC results, facilitating their use in applications and climate services. The Interactive Atlas implements FAIR principles and builds on open tools and therefore is an important step towards making IPCC results more reproducible and reusable. {Section Atlas.2 and Interactive Atlas}
Atlas.1  Introduction

Atlas.1.1  Purpose

The Atlas is the final chapter of this Working Group I (WGI) Sixth Assessment Report (AR6) and comprises the Atlas Chapter and an online interactive tool, the Interactive Atlas. The Atlas assesses fundamental aspects of observed, attributed and projected changes in regional climate in coordination with other WGI chapters ( Chapters 2, 3, 4, 6, 8, 9, 10, 11, 12). In particular, it provides analyses and assessments of regional changes in mean climate (specifically surface temperature, precipitation and some cryospheric variables, such as snow cover and surface mass balance) and expands on and integrates results from other chapters across different spatial and temporal scales. The Atlas considers multiple lines of evidence including assessment of different global and regional observational datasets, attribution of observed trends and multiple model simulations from the Coupled Model Intercomparison Projects CMIP5 (Taylor et al., 2012a) and CMIP6 (Eyring et al., 2016; O’Neill et al., 2016), and the COordinated Regional Downscaling EXperiment (CORDEX) (Gutowski Jr. et al., 2016). The Atlas chapter also assesses model performance and summarizes cross-referenced findings from other chapters relevant for the different regions.

The Interactive Atlas allows for a flexible spatial and temporal analysis of the results presented in the Atlas and other Chapters, supporting and expanding on their assessments. In particular, the Interactive Atlas includes information from global observational datasets (and paleoclimate information) assessed in Chapter 2, and projections of relevant extreme indices (used in Chapter 11) and climatic impact-drivers (used in Chapter 12) allowing for a regional analysis of the results (Section Atlas.2.2). It provides information on climatic impact-drivers relevant to sectoral and regional chapters of the Working Group II (WGII) report, being informed by and complementing the work of Chapter 12 in creating a bridge to WGII. Similarly, a specific aim of the integration is synthesising information drawn from across multiple chapters that is relevant to the WGII report and the mitigation and sectoral chapters of the Working Group III (WGIII) report.

An overview of the main components of the Atlas chapter is provided in Figure Atlas.1. The Interactive Atlas is described in Section Atlas.2 and is available online at http://ipcc-atlas.ifca.es.

[START FIGURE ATLAS.1 HERE]

[END FIGURE ATLAS.1 HERE]

Atlas.1.2  Context and framing

Information on global and regional climate change in the form of maps, tables, graphs and infographics has always been a key output of IPCC reports. With the consensus that climate has changed and will continue to do so, policymakers are focusing more on understanding its implications, which often requires an increase in regional and temporal details of observed and future climate. The WGI contribution of the AR5 included a globally comprehensive coverage of land regions and some oceanic regions in the Atlas of Global and Regional Climate Projections (IPCC, 2013a), focusing on projected changes in temperature and precipitation. In the WGII contribution, Chapter 21, Regional Context (Hewitson et al., 2014) included continental scale maps of observed and future temperature and precipitation changes, subcontinental changes in high percentiles of daily temperature and precipitation, and a table of changes in extremes over subcontinental regions (updating an assessment in the Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation; SREX). However, there was only limited coordination between these two contributions despite the largely common data sources and their relevance across the two working groups and to wider communities of climate change-related policy and practice. This
resulted in inefficiencies and the potential for confusing or inconsistent information. The Atlas, with its links with other WGI/II/III chapters, has been designed to help address this.

Given the aims of the Atlas, there are several important factors to consider. There is a clear requirement for climate change information over a wide range of ‘regions’, and classes thereof, and temporal scales. There is also often the need for integrated information relevant for policy, practice and awareness raising. However, most other chapters in WGI are disciplinary, focusing on specific processes in the climate system or on its past or future behaviour, and have limited space to be spatially and temporally comprehensive. The Atlas provides an opportunity to facilitate this integration and exploration of information.

Developing this information often requires a broad range of data sources (various observations, global and regionally downscaled baselines and projections) to be analysed and combined and, where appropriate, reconciled. This is a topic which is assessed from a methodological perspective in Chapter 10 using a limited set of examples (see also Cross-Chapter Box 10.3). The Atlas then builds on this work with a more comprehensive treatment of the available results, largely (but not exclusively) based on CMIP5, CMIP6, and CORDEX, to provide wider coverage and to further demonstrate techniques and issues. These multiple lines of evidence are integrated in the Interactive Atlas, a new AR6 WGI product described in Section Atlas.2 allowing for flexible spatial and temporal analysis of this information with a predefined granularity (e.g., flexible seasons, regions, and baselines and future periods of analysis including time-slices and warming levels).

Generating information relevant to policy or practice requires understanding the context of the systems that they focus on. In addition to the hazards these systems face, their vulnerability and exposure, and the related socio-economic and other physical drivers, also need to be understood. To ensure this relevance, the Atlas is informed by the assessments in Chapter 12 and the regional and thematic chapters and cross-chapter papers of WGI. Therefore, it focuses on generating information on climatic impact-drivers and hazards applicable to assessing impacts on and risks to human and ecological systems whilst noting the potential relevance of these to related contexts such as the Sustainable Development Goals and the Sendai Framework for Disaster Risk Reduction.

Transparency and reproducibility are promoted in the Atlas chapter implementing FAIR principles for Findability, Accessibility, Interoperability, and Reusability of data (Wilkinson et al., 2016). More specifically, the Interactive Atlas provides full metadata of the displayed products (describing both the underlying datasets and the applied postprocessing) and most of the figures included in the Atlas chapter can be reproduced using the scripts and data provided in the WGI-Atlas repository (see Iturbide et al., 2021 and https://github.com/IPCC-WG1/Atlas).

**Atlas.1.3 Defining temporal and spatial scales and regions**

Over the past decades scientists have engaged in a wide array of investigations aimed at quantifying and understanding the state of the components of the land surface-ocean-atmosphere system, the complex nature of their interactions and impacts over different temporal and spatial scales. As a result, a great deal has been learned about the importance of an appropriate choice of these scales when estimating changes due to internal climate variability, trends, characterization of the spatiotemporal variability and quantifying the range of and establishing confidence in climate projections. It is therefore important to be able to explore a whole range of spatial and temporal scales and this section presents the basic definitions of those, and the domains of analysis, used by the Atlas accounting for potential synergies between WGI and WGII.

**Atlas.1.3.1 Baselines and temporal scales of analysis for projections across scenarios**

Chapter 1 has extensively explored this topic in Section 1.4.1 and Cross-Chapter Box 1.2. A summary of the main points relevant to the Atlas chapter and the Interactive Atlas are provided here.
There is no standard baseline in the literature although the World Meteorological Organization (WMO) recommends a 30-year baseline approach such as the climate normal period 1981–2010. However, it retains the 1961–1990 period as the historical baseline for the sake of supporting long-term climate change assessments (WMO, 2017). Using the WMO standards also provides sample sizes relevant to calculating changes in statistics other than the mean. The AR6 WGI has established the 1995–2014 period as recent past baseline period – for similar reasons to the 1986–2005 period used in AR5 WGI (IPCC, 2013b) – since 2014 (2005) is the final year of the historical simulations of the models (more details in Cross-Chapter Box 1.2).

The choice of a baseline can significantly influence the analysis results for future changes in mean climate (Hawkins and Sutton, 2016) (Cross-Chapter Box 1.2) as well as its variability and extremes. Thus, assessing the sensitivity of results to the baseline period is important. The Interactive Atlas (see Section Atlas.2) allows users to explore and investigate a wide range of different baseline periods when analysing changes for future time-slices or global warming levels:

- 1995–2014 period (AR6 20-year baseline),
- 1986–2005 period (AR5 20-year baseline),
- 1981–2010 period (WMO 30-year climate normal),
- 1850–1900 period (baseline used in the calculation of global warming levels).

This promotes cross-Working Group consistency and facilitates comparability with previous reports and across datasets. For instance, the AR5 and long-term WMO baselines facilitate the intercomparison of CMIP5, CORDEX and CMIP6 projections since all have historical simulations in these periods. Using more recent baselines introduces discontinuity for the CMIP5 and CORDEX models, since historical simulations end in 2005. A pragmatic approximation to deal with this issue is to use scenario data to fill the missing segment, for example for 2006 to 2014 use the first years of RCP8.5-driven transient projections in which the emissions are close to those observed. This approach is used in the Atlas chapter and Chapter 12.

When assessing changes over the recent past, many studies analyse datasets using a range of climatologically significant periods (i.e., 30 years or more) with precise start and end dates depending on data availability and the year of the study. To account for this, when generating assessments from this literature the term ‘recent decades’ is used to refer to a period of approximately 30 to 30 years which ends within the period 2010–2020. An equivalent approximate description using specific years would be ‘since the 1980s’.

Regarding the future reference periods, the Interactive Atlas presents projected global and regional climate changes at near-, mid- and long-term periods, respectively 2021–2040, 2041–2060 and 2081–2100, for a range of emissions scenarios (Section Atlas.1.3.3, Cross-Chapter Box 1.4).

### 1.3.2 Global warming levels

Noting the approach taken in the recent IPCC Special Report on Global Warming of 1.5°C (SR1.5) above 1850–1900 levels (IPCC, 2018b), the Atlas also presents global and regional climate change information at different Global Warming Levels (GWLS, see Cross-Chapter Box 11.1). In particular, to provide policy-relevant climate information and represent the range of outcomes from the emissions scenario and time periods considered, GWLS of 1.5°C, 2°C, 3°C and 4°C are considered. The information is computed from all available scenarios (e.g. only 1.5°C and 2°C GWL information can be computed from projections under the SSP1-2.6 scenario). The Interactive Atlas allows comparison of timings for global warming across the different scenarios and of spatial patterns of change, for example information at 2°C GWL is calculated from SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 projections (Section 4.2.4).

To calculate GWL information for the datasets used in the Atlas (CMIP6 and CMIP5; see Section Atlas.1.4), this chapter adopted the procedure used in Cross-Chapter Box 11.1. A model future climate simulation reaches the defined GWL of 1.5°C, 2°C, 3°C or 4°C when its global near-surface air temperature change averaged over successive 20-year periods first attains that level of warming relative to its simulation of the
1851-1990 climate. (1851–1900 defines the pre-industrial baseline period for calculating the required global
surface temperature baseline, Cross-Chapter Box 1.2). Note that this process is different from the one used in
the SR1.5 report which used 30-year future periods. If a projection stabilizes before reaching the required
threshold it is unable to simulate climate at that GWL and is thus discarded. For CORDEX simulations, the
periods of the driving GCM are used, as in Nikulin et al. (2018). Detailed reproducible information on the
GWLs used in the Atlas is provided in the Atlas repository (Iturbide et al., 2021).

Climate information at many temporal scales and over a wide range of temporal averaging periods is
required for the assessment of climate change and its implications. These range from annual to multi-decadal
averages required to characterise low-frequency variability and trends in climate to hourly or instantaneous
maximum or minimum values of impactful climate variables. In between, information on, for example,
seasonal rainfall is important and implies the need to include averaging periods whose relevance are
geographically dependent. As a result, the Atlas chapter presents results over a wide range of timescales,
daily to decadal, and averaging periods with the Interactive Atlas allowing a choice of user-defined
seasons and a range of predefined daily to multi-day climate indices.

Atlas.1.3.3 Spatial scales and reference regions

Many factors influence the spatial scales and regions over which climate information is required and can be
reliably generated. Despite all efforts in researching, analysing and understanding climate and climate
change, a key factor in determining spatial scales at which analysis can be undertaken is the availability and
reliability of data, both observational and from model simulations. In addition, information is required over a
wide range of spatial domains defined either from a climatological or geographical perspective (e.g., a region
affected by monsoon rainfall or a river basin) or from a socio-economic or political perspective (e.g., least-
developed countries or nation states). Chapter 1 provides an overview of these topics (Section 1.5.2). This
subsection discusses some relevant issues, summarizes recent advances in defining domains and spatial
scales used by AR6 analyses and how these can be explored with the Interactive Atlas.

Recent IPCC reports – AR5 Chapter 14 (Christensen et al., 2013) and SR1.5 Chapter 3 (Hoegh-Guldberg et
al., 2018) – have summarized information on projected future climate changes over subcontinental regions
defined in the SREX report (Seneviratne et al., 2012) and later extended in the AR5 from the 26 regions in
SREX to include the polar, Caribbean, two Indian Ocean, and three Pacific Ocean regions (hereafter known
as the AR5 WGI reference regions) (Figure Atlas.2a). In recent literature, new subregions have been used,
for example for North and South America, Africa and Central America, together with the new definition of
reference oceanic regions. Iturbide et al. (2020) describes an updated version of the reference regions which
is used in this report (hereafter known as AR6 WGI reference regions) and is shown in Figure Atlas.2b. The
goal of these subsequent revisions was to improve the climatic consistency of the regions so they represented
sub-continental areas of greater climatic coherency.

[START FIGURE ATLAS.2 HERE]

Figure Atlas.2: WGI reference regions used in the (a) AR5 and (b) AR6 reports (Iturbide et al., 2020). The latter
includes both land and ocean regions and it is used as the standard for the regional analysis of
atmospheric variables in the Atlas chapter and the Interactive Atlas. The definition of the regions and
companion notebooks and scripts are available at the Atlas repository (Iturbide et al., 2021).

[END FIGURE ATLAS.2 HERE]

The rationale followed for the definition of the reference regions was guided by two basic principles: 1)
climatic consistency and better representation of regional climate features and 2) representativeness of model
results (i.e., sufficient number of model grid boxes). The finer resolution of CMIP6 models (as compared, on
average, to CMIP5) yields better model representation of the reference regions allowing them to be revised
for better climatic consistency (e.g., dividing heterogeneous regions) while preserving the model representation. Figure Atlas.3 illustrates this issue displaying the number of grid boxes (over land for land regions) in the AR6 reference regions for two Interactive Atlas reference grids of horizontal resolutions of 1° and 2°, representative of the typical resolution of CMIP6 and CMIP5 models respectively. This figure shows that the new reference regions are well suited for the assessment of model results, with poorest model coverage for the New Zealand (NZ), Caribbean (CAR) and Madagascar (MAD) regions.

[START FIGURE ATLAS.3: HERE]

Figure Atlas.3: Number of land grid boxes (blue numbers) for the AR6 WGI reference regions for the reference grids representative of (a) CMIP6 and (b) CMIP5, at horizontal resolutions of 1° and 2° respectively. Colour shading indicate regions with fewer than 250 grid boxes indicating the number of grid boxes (darkest shading if fewer than 20 grid boxes). The polygons show the AR6 WGI reference regions of Figure Atlas.2.

[END FIGURE ATLAS.3 HERE]

AR6 WGI (land and open ocean) reference regions are used in the Interactive Atlas as the default regionalization for atmospheric variables. However, these regions are not optimum for the analysis of oceanic variables since, for instance, the five upwelling regions (Canary, California, Peru, Benguela and Somali) are mostly included in ‘land’ regions. Therefore, the alternative set of oceanic regions defined by their biological activity (Figure Atlas.4) is used in the Interactive Atlas for the regional analysis of oceanic variables (see Fay and McKinley, 2014; Gregor et al., 2019). Due to the many potential definitions of the regions relevant for WGI and WGII, some additional typological and socio-economic regions have also been included in the Interactive Atlas.

Atlas.1.3.4 Typological and socio-economic regions

In addition to contiguous spatial domains discussed in the previous section, some domains are defined by specific climatological, geographical, ecological or socio-economic properties where climate is an important determinant or influencer. In these cases the domains are subject to particular physical processes that are important for its climatology or that involve systems affected by the climate in a way that observations and climate model simulations can be used to understand. Many of these are the basis of the chapters and cross-chapter papers of the AR6 WGII report, namely river basins, biodiversity hotspots, tropical forests, cities, coastal settlements, deserts and semi-arid areas, the Mediterranean, mountains and polar regions. It is therefore important to generate climate information relevant to these typological domains and some examples of these used in the Interactive Atlas are shown in Figure Atlas.4.

[START FIGURE ATLAS.4 HERE]

Figure Atlas.4: Typological and socio-economic regions used in the Interactive Atlas. (a) Eleven ocean regions defined by their biological activity used for the regional analysis of oceanic variables; (b) ocean regions for small islands, including the Caribbean (CAR) and the North Indian Ocean (ARS and BOB); (c) land monsoon regions of North America, South America, Africa, Asia and Australasia; (d) major river basins; (e) mountain regions; (f) WGII continental regions. These regions can be used alternatively to the reference regions for the regional analysis of climatic variables in the Interactive Atlas. The definition of the regions and companion notebooks and scripts are available at the Atlas repository (Iturbide et al., 2021).

[END FIGURE ATLAS.4 HERE]
Atlas.1.4 Combining multiple sources of information for regions

This section introduces the observational data sources and reanalyses that are used in the assessment of regional climate change and for evaluating and bias-adjusting the results of models (more information on observational reference datasets is available in Annex I). It also introduces the different global and regional climate model outputs that are used for regional climate assessment considering both historical and future climate projections (Annex II). Many of these models are run as part of coordinated Model Intercomparison Projects (MIPs), including CMIP5, CMIP6 and CORDEX, described below. Combining information from these multiple data sources is a significant challenge (see Section 10.5 for an in-depth treatment of the problem) though if they can be used to generate robust information on regional climate change it can guide policy and support decisions responding to these changes. An important and necessary part of this process is to check for consistency amongst the data sources which is discussed in the final section.

Atlas.1.4.1 Observations

There are various sources of observational information available for global and regional analysis. Observational uncertainty is a key factor when assessing and attributing historical trends, so assessment should build on integrated analyses from different datasets (disparity, inadequacy and contradictions in existing datasets are assessed in Section 10.2). The Atlas chapter can supplement and complement Chapter 10 by providing the opportunity to visualise and expand on its assessment. This includes displaying maps of density of stations observations (including those that are used in the different datasets) and assessing observational uncertainty by using multiple datasets.

Two of the most commonly used variables in climate studies are gridded surface air temperature and precipitation. There are many datasets available (Annex I) and Chapter 2 provides an assessment of key global datasets, including blended land-air and sea-surface temperature datasets to assess Global Mean Surface Temperature (GMST). The Atlas analyses separately atmospheric and oceanic variables and for the former a number of common global datasets supporting the assessment done in other chapters is used, including those selected in Chapter 2, but considering land-only information for the blended products. In particular, for air temperature the Atlas uses CRUTEM5—the land component of the HadCRUT5 dataset—and CRU TS4.0 (version 4.04 used here) (Harris et al., 2020). For precipitation the Atlas includes CRU TS4, the Global Precipitation Climatology Centre (GPCC, v2018 used here) (Schneider et al., 2011), and Global Precipitation Climatology Project (GPCP, monthly version 2.3 used here) (Adler et al., 2018). Although the ultimate source of these datasets is surface station reported values (GPCP also includes satellite information), each has access to different numbers of stations and lengths of records and employs different ways of creating the gridded product and ensuring quality control. For oceanic variables, the most widely used sea surface temperature (SST) datasets are HadSST4 (Kennedy et al., 2019), which is the oceanic component of the HadCRUT5 dataset, ERSST (Huang et al., 2017a), and KaplanSST (Kaplan et al., 1998).

Figure Atlas.5 shows the spatial coverage of the total number of observation stations for different periods (1901–1910, 1971–1980, and 2001–2010) for two illustrative datasets: the CRU TS4.0 dataset for precipitation and the SST data in HadSST4. The former illustrates spatially the declining trend of station observation data used in the precipitation datasets for certain regions (South America, Africa) after the 1990s. This demonstrates the regional inhomogeneity and temporal change in station density, which is in part a consequence of many stations not reporting to the WMO networks and their data being held domestically or regionally. During early years a limited number of observations are available. This information is used in the Interactive Atlas to blank out regions not constrained with observations in those datasets providing station density information.
In addition to surface observations, satellites have been widely used to produce rainfall estimates. The advantage of satellite-based rainfall products is their global coverage including remote areas but there is significant uncertainty in these products over complex terrain (Rahmawati and Lubczynski, 2018; Satgé et al., 2019). Another recent development has been on gridded datasets for climate extremes based on surface stations, such as HadEX3 (Dunn et al., 2020).

There are some studies assessing observational datasets globally (Beck et al., 2017; Sun et al., 2018b) and regionally (Manzanas et al., 2014; Salio et al., 2015; Prakash, 2019), reporting large differences among them and stressing the importance of considering observational uncertainty in regional climate assessment studies. Uncertainty in observations is also a key limitation for the evaluation of climate models, particularly over regions with low station density (Kalogeromou et al., 2013; Kotlarski et al., 2019). More detailed information on these issues is provided in Section 10.2.

For regional studies, observational datasets with global coverage are complemented by a range of regional observational analyses and gridded products, such as E-OBS (Cornes et al., 2018) over Europe, Daymet (Thornton et al., 2016) over North America, or APHRODITE (Yatagai et al., 2012) over Asia. These are highlighted in various other chapters and the Atlas expands on their treatment, complementing discussions on discrepancies/conflicts in observations presented in Chapter 10 and expanding on and replicating their results for other regions. In particular, the Interactive Atlas includes the global and regional observational products described here to assess observational uncertainty over the different regions analysed.

**Atlas.1.4.2 Reanalysis**

There are currently many atmospheric reanalysis datasets with different spatial resolution and assimilation algorithms (see Annex I and Section 1.5.2). There are also substantial differences among these datasets due to the types of observations assimilated into the reanalyses, the assimilation techniques that are used, and the resolution of the outputs, amongst other reasons. For example, 20CR (Slivinski et al., 2019) only assimilates surface pressure and sea surface temperature to achieve the longest record but at relatively low resolution, while ERA-20C (Poli et al., 2016) only assimilates surface pressure and surface marine winds. At the other extreme, very sophisticated assimilation systems using multiple surface, upper air and Earth observation data sources are employed, for example ERA5 (Hersbach et al., 2020) and JRA-55 (Harada et al., 2016), which also have much higher resolutions. Most reanalysis datasets cover the entire globe, but there are also high-resolution regional reanalysis datasets which provide further regional detail (Kaiser-Weiss et al., 2019).

The Atlas and Interactive Atlas use information from ERA5 and from the bias-adjusted version WFDE5 (Cucchi et al., 2020) which is combined with ERA5 information over the ocean and used as the ISIMIP observational reference dataset W5E5 (Lange, 2019b). This reference is also used in the Atlas for model evaluation (Section Atlas.1.4.4) and for bias-adjusting model outputs (Section Atlas.1.4.5).

**Atlas.1.4.3 Global model data (CMIP5 and CMIP6)**

The Atlas chapter (and the Interactive Atlas) uses global model simulations from both CMIP5 and CMIP6, mainly historical and future projections performed under ScenarioMIP (O’Neill et al., 2016). This facilitates...
backwards comparability and thus the detection of new salient features and findings from recent science and
the latest CMIP6 ensemble. The selection of the models is based on availability of scenario data for the
variables assessed in the Atlas chapter and for those included in the Interactive Atlas (Section Atlas.2.2). In
particular, in order to harmonize the results obtained from the different scenarios as much as possible, only
models providing data for the historical scenario and at least two emission scenarios, RCP2.6, RCP4.5 and/or
RCP8.5 (for CMIP5) and SSP1-2.6, SSP2-4.5, SSP3-7.0 and/or SSP5-8.5 (for CMIP6), were chosen,
resulting in 29 and 35 models, respectively (see Cross-Chapter Box 1.4 for a description of the scenarios). In
the Atlas chapter (similarly to the regional Chapters 11 and 12) a single simulation is taken from each model
(see Section Atlas.12 for limitations of this choice). Since the RCP and SSP emission scenarios are not
directly comparable due to different regional forcing (Section 4.2.2), the Atlas includes Global Warming
Levels (GWLs) as an alternative dimension of analysis (see Cross-Chapter Box 11.1), which allows
intercomparison of results from different scenarios as an alternative to the standard analysis based on time-
slices for particular scenarios (Section Atlas.1.3.1). This dimension allows for enhanced comparability of
CMIP5 and CMIP6, since it constrains the regional patterns to the same global warming level for both
datasets.

Building on this information, the Interactive Atlas displays a number of (mean and extreme) indices and
climatic impact-drivers (CIDs) considering both atmospheric and oceanic variables (see Section Atlas.2.2).
Some of these indices have been selected in coordination with Chapters 11 and 12, in order to support and
extend the assessment performed in these chapters (see Annex VI for details on the indices). In order to
harmonize this information, the indices have been computed for each individual model on the original model
grids and the results have been interpolated to a common 2° (for CMIP5) and 1° (CMIP6) horizontal
resolution grids. In addition, for the sake of comparability with CMIP6 results (in particular when using
baselines going beyond 2005), the historical period of the CMIP5 and CORDEX datasets has been extended
to 2006–2014 using the first years of RCP8.5-driven transient projections (see Section Atlas.1.3.1). Tables
listing the CMIP5 and CMIP6 models used in the Atlas and in the Interactive Atlas for different scenarios
and variables are included as Supplementary Material (Tables Atlas.SM.1 and Atlas.SM.2, respectively);
moreover, full inventories including details on the specific ESGF versions are given in the Atlas GitHub
repository (Iturbide et al., 2021).

Chapter 3 and Flato et al. (2013) describe the evaluation of CMIP6 and CMIP5 models, respectively,
assessing surface variables and large-scale indicators. Section 10.3.3, assesses the general capability of
GCMs to produce climate output for regions.

Information from the existing CMIP5 and CMIP6 datasets is supplemented with downscaled regional
climate simulations from CORDEX. This facilitates an assessment of the effects from higher resolution
including whether this modifies the projected climate change signals compared to global models and adds
any value, especially in terms of high-resolution features and extremes.

**Atlas.1.4.4 Regional model data (CORDEX)**

Global model data, as generated by the CMIP ensembles, although available globally, have spatial
resolutions that are limited for reproducing certain processes and phenomena relevant for regional analysis
(around 2° and 1° for CMIP5 and CMIP6, respectively). The Coordinated Regional Climate Downscaling
Experiment (CORDEX) (Gutowski Jr. et al., 2016) facilitates worldwide application of Regional Climate
Models (RCMs, see Section 10.3.1.2), focusing on a number of regions (see Figure Atlas.6) with a typical
resolution of 0.44° (but also at 0.22° and 0.11° over some domains, such as Europe). However, only a few
simulations are available for some domains (Annex II, Tables AII.1 and AII.2), thus limiting the level of
analysis and assessment that can be performed using CORDEX data in some regions. Moreover, there are
regions where several domains overlap, thus providing additional lines of evidence. The use of multi-domain
grand ensembles to work globally with CORDEX data have recently been proposed (Legasa et al., 2020;
Spinoni et al., 2020). Ongoing efforts, such as the multi-domain CORDEX-CORE simulations are promoting
more homogeneous coverage and thus more systematic treatment of CORDEX domains (see Box Atlas.1).
A lot of progress has been made by the regional climate modelling community since AR5 (Table AII.2) to produce and make available evaluation (reanalysis-driven) simulations over the different CORDEX domains along with downscaled CMIP5 historical and future climate projection information under a range of emission scenarios, mainly RCP2.6, RCP4.5 and RCP8.5 (Tables AII.3 and AII.4). However, these ensembles cover only a fraction of the uncertainty range spanned by the full CMIP5 ensemble in the different domains (e.g., Ito et al., 2020b), Figure Atlas.16, Figure Atlas.17, Figure Atlas.21, Figure Atlas.22, Figure Atlas.24, Figure Atlas.26, Figure Atlas.28 and Figure Atlas.29). Therefore, comparison of CMIP5 and CORDEX results should be performed carefully, providing results not only for the full CMIP5 ensemble but also for the sub-ensemble formed by the driving models since results can diverge (Fernández et al., 2019; Iles et al., 2020).

The Atlas chapter and the Interactive Atlas use CORDEX information for the following eleven individual CORDEX domains (out of the fourteen domains shown in Figure Atlas.6): Northern, Central and South America, Europe, Africa, South, East and Southeast Asia, Australasia, Arctic and Antarctica; in addition, oceanic information has been used from the Mediterranean domain, which provides simulations from coupled atmosphere-ocean regional climate models. In order to harmonize the information across domains and to maximize the size of the resulting ensembles, all the available simulations for each individual CORDEX domain (including the standard 0.44° CORDEX and the 0.22° CORDEX-CORE) have been interpolated to a common regular 0.5°-resolution grid to provide a grand ensemble covering the historical and future emission RCP2.6, RCP4.5 and RCP8.5 scenarios, and also the reanalysis-driven simulations for evaluation purposes. In the case of the European domain, the dataset considered is the 0.11° simulations (CORDEX EUR-11, the same dataset as used in Chapter 12) which has been interpolated to a regular 0.25° resolution grid (the same used for the regional observations). In the case of the Mediterranean domain, oceanic information (sea surface temperature) is interpolated to a regular 0.11° grid. In all cases, the indices are computed on the original grids and the interpolation process is applied to the resulting indices. Moreover, for the sake of comparability with CMIP6 results (in particular when using baseline periods beyond 2005), the historical period of the CORDEX datasets has been extended to 2006–2014 using the first years of RCP8.5-driven transient projections in which the emissions are close to those observed (see Section Atlas.1.3.1); note that this procedure is also applied to CMIP5 simulations.

For the different CORDEX domains, the full ensembles of models (GCM-RCM matrix) used in the Atlas for the different scenarios and variables are described in the Supplementary Material (Tables Atlas.SM.3 to Atlas.SM.14) and in the Atlas repository (Ituridine et al., 2021), including full metadata relative to ESGF versions used and the periods with data available for the different simulations. In particular, the historical scenario information is only available from 1970 onwards for some models and therefore the common period 1970–2005 is used for historical CORDEX data in the Atlas. As a result, the WMO baseline period 1961–1990 is not available in the Interactive Atlas for CORDEX data.

Sections Atlas.4 to Atlas.11 assess research on CORDEX simulations over different regions, analysing past and present climate as well as future climate projections. They also focus on regional model evaluation in order to extend and complement the validation of global models done in Chapter 3, considering the specific regional climate and relevant large-scale and regional phenomena, drivers and feedbacks (Section 10.3.3). Besides the literature assessment, some simple evaluation diagnostics have been computed for the simulations used in the Atlas chapter to provide some basic information on model performance across regions. In particular biases for mean temperature and precipitation have been calculated for the eleven CORDEX domains analysed.
Figure Atlas.7 shows mean temperature and precipitation biases over the North American domain in RCM simulations driven by reanalysis and historical GCM simulations (see Section 10.3.2.5). Annual and seasonal (DJF and JJA) biases are computed for both the RCMs and driving GCMs. Biases in the reanalysis-driven RCMs result from intrinsic model errors, with the results displayed being spatially aggregated for each reference region. This same analysis is performed for the GCM-driven RCM simulations over the historical period 1986–2005. This allows comparison of the intrinsic bias of the RCMs with the biases resulting when driven by the different GCMs and patterns of behaviour in the RCMs, for example intrinsic warm and dry biases in ENA and WNA respectively or reduced RCM warm biases compared to the CCCma GCM in NEN and ENA. Similar results for the other CORDEX domains are included as Supplementary Material (Figures Atlas.SM.1 to Atlas.SM.10).

[START FIGURE ATLAS.7 HERE]

Figure Atlas.7: Evaluation of annual and seasonal air temperature and precipitation for the six North America subregions NWN, NEN, WNA, CNA, ENA and NCA (land only), for CORDEX-NAM RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas.1.4.2). Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.7 HERE]

[START BOX ATLAS.1 HERE]

BOX ATLAS.1: CORDEX-CORE

The main objective of CORDEX-CORE is to provide a global homogeneous foundation of high-resolution RCM projections to improve understanding of local phenomena and facilitate impact and adaptation research worldwide (Gutowski Jr. et al., 2016). The experimental framework is designed to produce homogeneous regional projections for most inhabited land regions using nine CORDEX domains at 0.22° resolution (Figure Atlas.6): North, Central and South America (NAM, CAM, SAM), Europe (EUR), Africa (AFR), East, South and Southeast Asia (EAS, WAS, SEA) and Australasia (AUS). Due to computational requirements, three GCMs were selected to drive the simulations, HADGEM2-ES, MPI-ESM, and NorESM covering, respectively the spread of high, medium and low equilibrium climate sensitivities from the CMIP5 ensemble at a global scale (with MIROC5, EC-Earth, GFDL-ES2M as secondary GCMs) focusing on two scenarios RCP2.6 and RCP8.5 (see Box Atlas.1, Figure 1). Two RCMs have contributed so far to this initiative (REMO and RegCM4) constituting an initial homogeneous downscaled ensemble to analyse mean climate change signals and hazards (Teichmann et al., 2020; Coppola et al., 2021), and there are ongoing efforts to extend the CORDEX-CORE ensemble with additional regional simulations (e.g., the COSMO-CLM community) to increase the ensemble size. CORDEX-CORE simulations are distributed as part of the information available for the different CORDEX domains at the Earth System Grid Federation (ESGF).

CORDEX-CORE spans the spread of the CMIP5 climate change signals for interquartile ranges of annual mean temperature and precipitation for most of the reference regions covered (Teichmann et al., 2020)(see Box Atlas.1, Figure 1). However, it is still a small ensemble and for other variables like extremes or climatic impact-drivers has only been partially investigated in Coppola et al. (2021) and needs further analysis.
Biases are often applied to climate model simulations to improve their applicability for assessing climate impacts and risk (for instance in the Inter-Sectoral Impact Model Intercomparison Project, ISIMIP (Rosenzweig et al., 2017). Bias-adjustment approaches (Section 10.3.1.3) are particularly beneficial when threshold-based indices are used, but they can introduce other biases, in particular when applied directly to coarse-resolution GCMs (Cross-Chapter Box 10.2). Bias-adjustment techniques should be chosen carefully for a particular application. In the Atlas, bias adjustment is not applied systematically (in particular it is not applied for the variables assessed in the Atlas chapter), and only the threshold-dependent extreme indices and climatic impact-drivers (CIDs) included in the Interactive Atlas are bias-adjusted (in particular frost days, and TX35, TX40 in coordination with Chapter 12). To facilitate integration with WGII, the Atlas uses the same bias-adjustment method as in ISIMIP3 (Lange, 2019a) and the same observational reference (W5E5, see Section Atlas.1.4.2), upscaled to the same resolution as the model to avoid downscaling artefacts (Cross-Chapter Box 10.2). The ISIMIP3 bias adjustment method is a trend-preserving approach that is recommended for general applications, as it reduces biases while preserving the original climate change signal (Casanueva et al., 2020). Following the recommendations given in Chapter 10, results in the Interactive Atlas are displayed for both the adjusted and the raw model output.

Spatial information on observed and projected future climate changes has always been a key output of IPCC reports. This information is typically represented in the form of maps of historical trends (from observational datasets) and of projected changes for future reference periods and scenarios relative to baseline periods (from multi-model ensembles). These maps usually include information on the robustness or uncertainty of the results such as the significance of trends or the consistency of the change across models. Visualization of this information combines two aspects that are intertwined: the core methodology (measures and thresholds) and its visual implementation. For observed trends, robustness can be simply ascertained by using an appropriate statistical significance test. However, for multi-model mean changes, the consistency across models for the sign of change (model agreement) and the magnitude of change relative to unforced climate variability (signal-to-noise ratio) provide two complementary measures allowing for simple or more complex representation.
comprehensive approaches to represent robustness and uncertainty. While they can be visually represented in various ways with more or less complexity (Retchless and Brewer, 2016), the most common implementation for maps in the climate science community remains the overlay of symbols and/or masking of the primary variable. This Cross-Chapter Box reviews the approaches followed in previous IPCC reports and describes the methods used across this WGI report, presenting the rationale and discussing its relative merits and limitations.

The objectives in AR6 for representing robustness and uncertainty in maps are 1) adopting a method that can be as coherent as possible across the different global/regional chapters while accommodating different needs, 2) being visually consistent across WGs, and 3) making the different layers of information on the maps as accessible as possible for the reader. As a result, a single approach is selected for observations and two alternative approaches (simple and advanced) are adopted for projected future changes. It is important to highlight that, as in previous reports, these approaches are implemented in maps at a grid-box level and, therefore, are not informative for larger spatial scales (e.g., over AR6 reference regions) where the aggregated signals are less affected by small-scale variability leading to an increase in robustness. This is particularly relevant for the AR6 regional assessments and approaches (e.g., for trend detection and attribution, Cross-Chapter Box 1.4, Section 11.2.4) which are performed for climatological regions and not at grid-box scale (Chapters 11, 12, Atlas). Both small and large scales are relevant (e.g., adaptation occurs at the smaller scales but also at the level of countries, which are typically larger than a few grid boxes). They are both addressed in the Interactive Atlas, which implements the above approaches for representing robustness in maps at the grid-box level, but also allows analysing region-wide signals (e.g., AR6 WG I reference regions, monsoon regions, etc.), helping to isolate background changes happening at larger scales (Section Atlas.2.2).

Approaches used in previous reports

Recent IPCC reports adopted different approaches for mapping uncertainty/robustness, including their calculation method and/or their visual implementation. In AR5 WGI '+' symbols were used to represent significant trends in observations at grid-box level. For future projections, different methods for mapping robustness were assessed (AR5 Box 12.1, Collins et al., 2013), while proposing as a reference an approach based on relating the multi-model mean climate change signal to internal variability, calculated as the standard deviation of non-overlapping 20-year means in the pre-industrial control runs. Regions where the multi-model mean change exceeded two standard deviations of the internal variability and where at least 90% of the models agreed on the sign of change were stippled (as an indication of a robust signal). Regions where the multi-model change was less than one standard deviation were hatched (small multi-model mean signal). However, this category did not distinguish areas with consistent small changes from areas of significant but opposing/divergent signals. In addition, the unstippled/unhatched areas were left undefined, since the categories were not mutually exclusive.

AR5 WGII (Hewitson et al., 2014) used hatching to represent non-significant trends in observations. For future projections, an elaborated approach with four mutually exclusive and exhaustive categories was proposed (to avoid some of the limitations of the AR5 WGI approach): very strong agreement (same as in WGI); strong agreement; divergent change; and little or no change. These depended on the percentage of models showing change greater than the baseline variability and/or agreeing on sign of change (using a 66% agreement threshold). Leaving the robust regions uncovered minimized any interference with the perception of underlying colours that encoded the primary information of the figure.

The two special reports IPCC SR1.5 (Hoegh-Guldberg et al., 2018) and SROCC (IPCC, 2019a, 2019c) adopted a simplified approach, using only model agreement (≥66% of models agree on sign of change) to characterize robustness. However, cross-hatching was used in SR1.5 to highlight robust areas where models agree, whereas the SROCC used hatching/shading to represent regions where models disagree. Similarly, stippling was used in SR1.5 to indicate regions with significant trends, whereas it was used in SROCC to represent regions where the trends were not significant.

Recent methodologies
Since AR5 there has been a growing interest for disentangling small consistent climate change signals from significant divergent opposite changes resulting in conflicting information (Tebaldi et al., 2011), and different statistical tests have been applied to assess the significance of signals working with the individual models forming the ensemble (Dosio and Fischer, 2018; Yang et al., 2018; Morim et al., 2019). Moreover, new approaches have been proposed to identify large changes of opposite sign that compensate in the mean (Zappa et al., 2021). Recent literature has also highlighted the respective risks of Type I vs Type II errors, which can be associated with the determination of robustness in analysed signals (Lloyd and Oreskes, 2018; Knutson et al., 2019). Type I errors are identifying signals when there are none, while Type II errors are concluding there is no signal when there is one. In the case of grid-box level analysis, the focus on small-scale features with inherently large signal-to-noise ratio may emphasize noise even though signals are present when aggregated at larger scale (Sections 11.2.4 and 11.2.5). Consequently, changes averaged over regions or a number of grid-boxes emerge from internal variability at a lower level of warming than at the grid-box level (e.g., Cross-Chapter Box Atlas.1, Figure 2). Hence, focus on grid-box significance enhances the risk of Type II errors for overlooking signals significant at the level of AR6 regions. The significance of signals is also affected by interdependence of single simulations considered in a given ensemble, for example when several come from the same modelling group and share parameterizations or model components (Knutti et al., 2013; Maher et al., 2021). The risk of Type II errors increases when a model ensemble includes several related simulations showing no signal.

The AR6 WGI approach

AR6 WGI adapts the approaches applied in previous IPCC reports into a comprehensive framework based on the two general principles followed by AR5 WGII: 1) not obscuring (with stippling or hatching) the areas where relevant/robust information needs to be highlighted (since stippling and hatching obstruct the visualisation of the colours, which can affect the perception/interpretation of the underlying data); 2) using mutually exclusive and exhaustive categories to avoid leaving areas undefined. The three adopted approaches (one for observations and two for model projections) are described in Cross-Chapter Box Atlas.1, Table 1. This framework integrates as much as possible the specificities of each WGI Chapter, proposing in some cases alternative thresholds.

**Approach A** is intended for observations and consists of two categories, one for areas with significant trends (colour, no overlay) and one for non-significant ones (coloured areas overlaid with ‘x’), typically using a two-sided test for a significance level of 0.1; Chapter 2 and Atlas trends have been calculated using OLS regression accounting for serial correlation (Santer et al., 2008).

**Approach B** is the simple alternative for model projections. It consists of two categories, one for model agreement (at least 80% of the models agree on the sign of change; colour, no overlay) and the other one for non-agreement (hatching). It is noted that model agreement is computed using ‘model democracy’ (i.e. without discarding/weighting models), since quantifying and accounting for model interdependence (shared building blocks) still remain challenging (Section 4.2.6). Different thresholds have been used in previous reports and in the literature. 80% has been widely used in CORDEX studies (Dosio and Fischer, 2018; Kjellström et al., 2018; Nikulin et al., 2018; Yang et al., 2018; Akperov et al., 2019; Rana et al., 2020) partially due to the small ensemble sizes available in some cases; this also helps to reduce the impact of model interdependence in the final results. Although 90% (used in AR5 WGI) provides high confidence on the forced change, it is deemed too stringent for precipitation-like variables and regional assessments and was therefore not included (see Cross-Chapter Box Atlas.1, Figure 1). The 66% threshold, which has been used in previous reports (e.g., SR1.5 and SROCC) and in the literature, is not used to avoid communicating weak confidence. Cross-Chapter Box Atlas.1, Figure 1 illustrates the application of this approach.

**Approach C** is a more advanced alternative for model projections, extending the AR5 WGI and simplifying the AR5 WGII approaches (fewer categories). It consists of three categories: ‘robust change’, ‘conflicting change’, and ‘no change or no robust change’ (see the details in Cross-Chapter Box Atlas.1, Table 1). The first two categories can be interpreted as areas where the climate change signal likely emerges from internal variability (i.e., it exceeds the variability threshold in ≥66% of the models). The variability threshold is defined as \( \gamma = \sqrt{Z} \cdot 1.645 \cdot \sigma_{20yr} \), where \( \sigma_{20yr} \) is the standard deviation of 20-year means, computed from...
non-overlapping periods in the pre-industrial control (after detrending with a quadratic fit as in AR5 WG1); in cases where this information is not available (e.g., for CORDEX or HighResMIP), the following approximation is used instead: \( y = \sqrt{2/20} \cdot 1.645 \cdot \sigma_{1\text{yr}}, \) where \( \sigma_{1\text{yr}} \) is the interannual standard deviation measured in a linearly detrended modern period (note that for white noise \( \sigma_{2\text{yr}} = \sigma_{1\text{yr}}/\sqrt{20} \)). The factor \( \sqrt{2} \) is used as in the AR5 WGI approach to account for the fact that the variability of a difference in means (the climate change signal) is of interest. This approach is an evolution of AR5 WGI method with three notable differences: (a) AR6 uses a lower threshold for internal variability (1.645 corresponding to a 90% confidence level, instead of 2 as used in AR5 WG1); (b) the threshold on agreement in sign is lowered from ≥90% to ≥80%, leading to more grid boxes classified as robust as opposed to conflicting signal; (c) the AR6 method compares signal to variability in each individual model and consequently introduces a 66% cut-off on significant changes implying that the climate change signal likely emerges from internal variability in the baseline period. This change is motivated by the criticisms of internal variability of the models, while it can differ largely across models.

Cross-Chapter Box Atlas.1, Figure 1 illustrates the application of this method considering the effect of the baseline period (1850–1900 versus 1995–2014) and shows that it provides similar results to related approaches proposed in the literature (Zappa et al., 2021).

The two alternative approaches discussed above allow visualisation of different levels of detail about on the projected change and are intended for different communication purposes. Approach B just informs on the consistency of the sign of change independent of its significance relative to internal variability, whereas approach C puts the projected changes into context of internal variability and allows highlighting of areas of conflicting signals. It is important to note that different approaches can be applied to the same variable between different chapters for different communication purposes. For example, in maps showing multi-model mean changes of precipitation, Chapter 4 adopts the approach C but Chapter 8 applies the approach B.

In terms of visual implementation, the approach follows recommendations resulting from conversations with IPCC national delegations: 1) having a consistent approach across WGs would aid consistency and reduce the risk of confusion; 2) defining ‘hatching’ as ‘diagonal lines’ in the caption would aid accessibility for non-expert audiences; 3) a clear and concise legend that explains what these patterns represent should be included directly in the figure; 4) information about model uncertainty should be overlaid such that it does not detract from the data underneath.

Since stippling is commonly used to represent statistical significance, hatching was chosen to ‘obscure’ the problematic categories in the above approaches; it also facilitates the visualisation of uncertainty in the Interactive Atlas when zooming in. To avoid confusion, methods or thresholds that were unrelated to the three approaches hereby presented were visualised with a different pattern (i.e., model improvement between low- and high-resolution simulations in Chapter 3; agreement between observation-based products in Chapter 5; correlation between two variables in Chapter 6).

### Simple approach (agreement)

For Chapter 6 (<5 model ensembles): more than \((n-1)/n\) models agree on the sign of change.

### B. Low model agreement

<80% agree on sign of change. For Chapter 6: fewer than \((n-1)/n\) models agree on the sign of change.

### C. Model projections. Advanced approach (significant change and agreement)

#### C.1. Robust signal (significant change and high agreement)

\(\geq 66\%\) of models show change greater than variability threshold \(\gamma\) and \(\geq 80\%\) of all models agree on sign of change.

#### C.2. No change or no robust signal

<66% of models show change greater than variability threshold.

#### C.3. Conflicting signals (significant change but low agreement)

\(\geq 66\%\) of models show change greater than variability threshold \(\gamma\) and <80% of all models agree on sign of change.

---

**Uncertainty at the grid-box and regional scales: interpreting hatched areas**

There is no one-size-fits-all method for representing robustness or uncertainty in future climate projections from a multi-model ensemble. One of the main challenges is the dependence of the significance on the spatial scale of interest: while a significant trend may not be detected at every location, a fraction of locations showing significant trends can be sufficient to indicate a significant change over a region, particularly for extremes (e.g., it is likely that annual maximum 1-day precipitation has intensified over the land regions globally even though there are only about 10% of weather stations showing significant trends; Figure 11.13). The approach adopted in WGI works at a grid-box level and, therefore, is not informative for assessing climate change signals over larger spatial scales. For instance, an assessment of the amount of warming required for a robust climate change signal to emerge can strongly depend on the considered spatial scale. A robust change in the precipitation extremes averaged over a region or a number of grid-boxes emerge at a lower level of warming than at the grid-box level because of larger variability at the smaller scale (Cross-Chapter Box Atlas.1, Figure 2).

---

**Cross-Chapter Box Atlas.1, Figure 2:** Climate change signals are more separable from noise at larger spatial scales. The figure is showing the global warming level associated with the
emergence of a significant increase in the probability due to anthropogenic forcing in the 1-in-20-year daily precipitation event using a 500-year sample from the CanESM2 large ensemble simulations. The left panel uses data analysed over a single grid box, with no spatial aggregation, while the right box uses data averaged over 25 grid boxes to represent moderate spatial aggregation. Aggregation over 25 grid boxes reduces natural variability, resulting in a smaller warming required for a clear separation between the signal and noise. Adapted from Kirchmeier-Young et al. (2019).

Atlas.2 The online ‘Interactive Atlas’

The WGI Interactive Atlas is a new AR6 product developed as part of the Atlas in consultation with other chapters to facilitate flexible synthesis information for regions, and to support the Technical Summary (TS) and the Summary for Policymakers (SPM), as well as the handshake with WGII. It includes multiple lines of evidence to support the assessment of observed and projected climate change by offering information for regions using both time-slices across scenarios and Global Warming Levels (GWLs). Coordination has been established with other chapters (particularly the regional chapters) adopting their methodological recommendations (Chapter 10) and using common datasets and agreed extreme indices and climatic impact-drivers (CIDs) to support and expand their assessment (Chapters 11 and 12).

The Interactive Atlas allows for flexible spatial and temporal analysis (Section Atlas.1.3) with a predefined granularity (predefined climatological and typological regions and user-defined seasons) through a wide range of maps, graphs and tables generated in an interactive manner building on a collection of global and regional observational datasets and climate projections (including CMIP5, CMIP6 and CORDEX; Section Atlas.1.4). In particular, the Interactive Atlas provides trends and changes for observations and projections in the form of interactive maps for predefined historical and future periods of analysis, the former including recent-past and paleoclimate (see Cross-Chapter Box 2.1) and the latter including future time-slices (near, medium and long term) across scenarios (RCPs and SSPs; see Cross-Chapter Box 1.4) and GWLs (1.5°C, 2°C, 3°C and 4°C; see Cross-Chapter Box 11.1). It also provides regional information (aggregated spatial values) for a number of predefined (reference and typological) regions in the form of time series, annual cycle plots, scatter plots (e.g., temperature versus precipitation), table summaries, and ensemble and seasonal stripe plots. This allows for a comprehensive analysis (and intercomparison, particularly using GWLs as a dimension of integration) of the different datasets at a global and regional scale.

The Interactive Atlas can be consulted online at http://ipcc-atlas.ifca.es. Figure Atlas.8 illustrates the main functionalities available: the controls at the top of the window allow the interactive selection of the dataset, variable, period (reference and baseline) and season which define a particular product of interest (e.g., annual temperature change from CMIP6 under SSP3-7.0 for the long-term 2081–2100 period relative to 1995–2104 in this illustrative case). Regionally aggregated information can be obtained interactively by clicking on one or several subregions on the map and by selecting one of the several options available for visuals (time series, annual-cycle plots, scatter and stripe plots) and tables.

[START FIGURE ATLAS.8 HERE]

Figure Atlas.8: Screenshots from the Interactive Atlas. (a) The main interface includes a global map and controls to define a particular choice of dataset, variable, period (reference and baseline) and season (in this example, annual temperature change from CMIP6 for SSP3-7.0 for the long-term 2081–2100 period relative to 1995–2104). (b–e) Various visuals and summary tables for the regionally averaged information for the selected reference regions.
A major goal during the development of the Interactive Atlas has been ensuring transparency and reproducibility of results, and promoting open science and Findability, Accessibility, Interoperability, and Reuse (FAIR) principles (Wilkinson et al., 2016) described in Atlas.2.3. As a result, full metadata are provided in the Interactive Atlas for each of the products, and the scripts used to generate the intermediated products (e.g., extreme indices and CIDs) and figures are available online in a public repository (Iturbide et al., 2021), which also includes simple notebooks illustrating key parts of the code suitable for reusability. These scripts are based on the climate4R open-source framework (Iturbide et al., 2019) and full metadata have been generated for all final products using the METACLIP framework (Bedía et al., 2019), which builds on standards and describes provenance of the datasets as well as the post-processing workflow.

**Atlas.2.1 Why an interactive online Atlas in AR6?**

The idea of an interactive online Atlas was first discussed in the IPCC Expert Meeting on Assessing Climate Information for the Regions (IPCC, 2018a). The meeting stressed the need for the AR6 regional Atlas to go beyond the AR5 experience in supporting and expanding the assessment of key variables/indices and datasets conducted in all chapters, ensuring traceability, and facilitating the ‘handshake’ between WGI and WGII. One of the main limitations of previous products, including the AR5 WGI Atlas (IPCC, 2013a), is their static nature with inherent limited options and flexibility to provide comprehensive regional climate information for different regions and applications. For instance, the use of standard seasons limits the assessment in many cases, such as regions affected by monsoons or seasonal rainband migrations or other phenomena-driven seasons. The limited number of variables which can be treated on a printed Atlas also prevents the inclusion of relevant extreme indices and CIDs. The development of an online Interactive Atlas for AR6 was proposed as a solution to overcome these obstacles, facilitating the flexible exploration of key variables/indices and datasets assessed in all chapters through a wide range of maps, graphs and tables generated in an interactive manner, and thus also providing support to the TS and SPM. One of the main concerns raised by this new online interactive product was the potential danger of having an unmanageable number of final products impossible to assess following the IPCC review process. This was addressed by designing the Interactive Atlas with limited and predefined functionality and granularity thus facilitating the review process and including use of open-source tools and code for traceability and reproducibility of results.

**Atlas.2.2 Description of the Interactive Atlas: functionalities and datasets**

The Interactive Atlas builds on the work done in the context of the Spanish National Adaptation Plan (PNACC – AdapteCCA: http://escenarios.adaptecca.es) to develop an interactive online application centralizing and providing key regional climate change information to assist the Spanish climate change impact and adaptation community. The functionalities included in the AR6 WGI Interactive Atlas are an evolution of those implemented in AdapteCCA and have been adapted and extended to cope with the particular requirements of the datasets and functionalities it includes. In particular, the Interactive Atlas allows analysis of global and regional information on past trends and future climate changes through a wide range of maps, graphs and tables generated in an interactive manner and building on six basic products (see Figure Atlas.8):

1. Global maps of variables averaged over time-slices across scenarios and GWLs, with robustness represented using the approaches described in Cross-Chapter Box Atlas.1.
2. Temporal series, displaying all individual ensemble members and the multi-model mean, with robustness represented as ranges across the ensemble (25th–75th and 10th–90th percentile ranges). The selected reference period of analysis is also displayed as context information, either a time-slice (near-, mid- or long-term) or a GWL (defined for a given model as the first 20-year period where its average surface temperature change first reaches the GWL relative to its 1850–1900 temperature).
3. Annual cycle plots representing individual models, the multi-model mean and ranges across the ensemble.
4. Stripe and seasonal stripe plots, providing visual information on changes across the ensemble (different models in rows with the multi-model mean on the top) and across seasons (months in rows, using the signal from the multi-model mean), respectively.
5. Two-variable scatter plots (e.g., temperature versus precipitation).
6. Tables with summary information.

The first of these products provides spatial information about the ensemble mean, while the latter five convey (spatially) aggregated information of the multi-model ensemble for particular region(s) selected by the user from a number of predefined alternatives (see Sections Atlas.1.3.3 and Atlas.1.3.4 for reference and typological regions, respectively).

The Interactive Atlas includes both atmospheric (daily mean, minimum and maximum temperatures, precipitation, snowfall and wind) and oceanic (sea surface temperature, pH, sea ice, and sea level rise) essential variables assessed in the Atlas chapter and Chapters 4, 8 and 9, as well as some derived extreme indices used in Chapter 11 and a selection of CIDs used in Chapter 12 (see Annex VI).

- Maximum of maximum temperatures (TXx) – see Chapter 11.
- Minimum of minimum temperatures (TNn) – see Chapter 11.
- Maximum 1-day precipitation (RX1day) – see Chapter 11.
- Maximum 5-day precipitation (RX5day) – see Chapter 11.
- Consecutive Dry Days (CDD) – see Chapter 11.
- Standardized Precipitation Index (SPI-6) – see Chapters 11 and 12.
- Frost days (FD), both raw and bias adjusted – see Chapters 11 and 12.
- Heating Degree Days (HD) – see Chapter 12.
- Cooling Degree Days (CD) – see Chapter 12.
- Days with maximum temperature above 35°C (TX35), both raw and bias adjusted – see Chapter 12.
- Days with maximum temperature above 40°C (TX40), both raw and bias adjusted – see Chapter 12.

The essential variables are computed for observations and reanalysis datasets as described in Sections Atlas.1.4.1 and Atlas.1.4.2 (note that the Atlas does not include observational datasets for extremes). Trend analyses are available for two alternative baseline periods (1961–2015 and 1980–2015, selected according to data availability). This expands the information available in Chapter 2 for global observational datasets, including new periods of analysis and new regional observational datasets which provide further insight into observational uncertainty.

Both essential variables and indices/CIDs are computed for CMIP5, CMIP6 and CORDEX model projections (Sections Atlas.1.4.3 and Atlas.1.4.4). The calculations are performed on the original model grids and results are interpolated to the reference regular grids at horizontal resolutions of 2° (CMIP5), 1° (CMIP6) and 0.5° (CORDEX) (Iturbi et al., 2021). Information is available for the historical, SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 scenarios for CMIP6, and historical, RCP2.6, RCP4.5 and RCP8.5 for CMIP5 and CORDEX, as documented in Annex II Tables 1-2 (for CMIP5/CMIP6) and Annex II Tables 3-14 (for the different CORDEX domains). All products (maps, graphs and tables) are available for different reference periods of analysis, either time-slices (2021–2040, 2041–2060 and 2081–2100 for near-, mid- and long-term future periods, respectively; see Section Atlas.1.3.1), or GWLs (1.5°C, 2°C, 3°C or 4°C; see Section Atlas.1.3.2), with changes relative to a number of alternative baselines (including 1850–1900 pre-industrial, and 1995–2014 recent past; see Section Atlas.1.3.1). Note that instead of blending the information from the different scenarios, the Interactive Atlas allows comparison of the GWL spatial patterns and timings across the different scenarios (see Cross Chapter Box 11.1).

Some of the above indices (in particular TX35 and TX40) are highly sensitive to model biases and the application of bias-adjustment techniques is recommended to alleviate this problem (see Cross-Chapter Box 10.2). Bias adjustment is performed as explained in Section Atlas.1.4.5.

The Interactive Atlas implements the approaches for representing robustness in maps at the grid-box level described in Cross-Chapter Box Atlas.1. These approaches are not necessarily informative for assessing...
trends and climate change signals over larger spatial scales where signals are less affected by small-scale variability leading to an increase in robustness. For regional analysis, the Interactive Atlas allows the analysis of aggregated region-wide signals and assessing their robustness at a regional scale thus complementing the previous approach for grid-box robustness representation. For example, Figure Atlas.9 shows large hatched areas for maximum 5-day precipitation in the South Asia region. When aggregated spatially, the region exhibits a robust wetting signal, with most ensemble members agreeing on the sign. This highlights that signals may not have emerged at the station- or grid-box scale but have clearly at aggregated scales, particularly for variables with high variability (e.g., extreme precipitation or cold extremes; see Cross-Chapter Box Atlas.1).

The advanced approach for representing robustness includes a new category for identifying conflicting signals, where models are projecting significant changes but of opposite signs. This is demonstrated in Figure Atlas.9 which shows a region of central Africa where models have significant changes in surface winds with some projecting increases and others decreases. This is clearly demonstrated in the time-series below the map which shows these wind-speed changes aggregated over the CAF reference region for each of the CMIP6 models and the opposing signals in many of these.

**[START FIGURE ATLAS.9 HERE]**

**Figure Atlas.9:** Analyzing robustness and uncertainty in climate change signals across spatial scales using the Interactive Atlas. The left panel shows projected annual relative changes for maximum 5-day precipitation from CMIP6 at 3°C of global warming level relative to the 1850–1900 baseline, through a map of the ensemble mean changes (panel top) and information on the regional aggregated signal over the South Asia reference region as time series (panel bottom). This shows non-robust changes (diagonal lines) at the grid-box level (due to the large local variability), but a robust aggregated signal over the region. The right panel shows projected surface wind speed changes from CMIP6 models for 2041–2060 relative to a 1995–2014 baseline under the SSP5-8.5 scenario, again with the ensemble mean changes in the map (panel top) and regionally aggregated time series over Central Africa for each model (panel bottom). This shows conflicting changes (crossed lines) at the grid-box level due to signals of opposite sign in the individual models displayed in the time series.

**[END FIGURE ATLAS.9 HERE]**

**Atlas.2.3 Accessibility, reproducibility and reusability (FAIR principles)**

The accessibility and reproducibility of scientific results have become a major concern in all scientific disciplines (Baker, 2016). During the design and development of the Interactive Atlas, special attention was paid to these issues in order to ensure the transparency of the products feeding into the Interactive Atlas (which are all publicly available). Accessibility is implemented in collaboration with the IPCC Data Distribution Centre (DDC), since all products underpinning the Interactive Atlas, including the intermediate products required for the indices and CIDs (monthly aggregated data), are curated and distributed by the IPCC-DDC and include full provenance information as part of their metadata. Atlas products are generated using the open source climate4R framework (Iturbide et al., 2019) for data processing (e.g. regridding, aggregation, index calculation, bias adjustment), evaluation and quality control (when applicable). Full metadata are generated for all final products using the METACLIP framework (Bedía et al., 2019), based on the Resource Description Framework (RDF) standard to describe the datasets and data-processing workflow.

In summary, a number of actions have been conducted in order to implement open access, reproducibility and reusability of results, including:

- Use of standards and open-source tools.
- Open access to raw data and derived Atlas products via the IPCC-DDC.
- Provision of full provenance metadata describing the product generation workflow.
- Access to code through an online repository (Iturbide et al., 2021), including the scripts needed for calculating the intermediate datasets and for reproducing some of the figures of the Atlas chapter.
• Provision of annotated (Jupyter) notebooks describing key elements of the code to provide guidance and facilitate reusability.

All final products visualized in the Interactive Atlas can be exported in a variety of formats, including PNG and PDF for bitmap and vector information, respectively. Moreover, in the case of the global maps, the final data underlying these products can be downloaded in GIS format (GeoTIFF), thus facilitating reusability of the information. Note that the images are final IPCC products (covered by the IPCC terms of use), whereas the underlying data are distributed by the IPCC-DDC under a more flexible license which facilitates reusability. Moreover, a comprehensive provenance metadata description has been generated, including all details needed for reproducibility, from the data sources to the different post-processes applied to obtain the final product. In these cases, there is also the possibility to download a PNG file augmented with attached metadata information (in JSON format). This metadata information (including the source code generating the product) can be accessed and interpreted automatically using specific JSON software/libraries. However, for the sake of simplicity, a human-readable version of the metadata is accessible directly from the Interactive Atlas describing the key information along the workflow.

Provenance is defined as a ‘record that describes the people, institutions, entities, and activities involved in producing, influencing, or delivering a piece of data or a thing’. This information can be used to form assessments about their quality, reliability or trustworthiness. In the context of the outcomes of the Interactive Atlas, having an effective way of dealing with data provenance is a necessary condition to ensure not only the reproducibility of results, but also to build trust on the information provided. However, the relative complexity of the data and the post-processing workflows involved may prevent a proper communication of data provenance with full details for reproducibility. Therefore, a special effort was made in order to build a comprehensive provenance metadata model for the Interactive Atlas products.

Provenance frameworks are typically based on RDF (Resource Description Framework), a family of World Wide Web Consortium (W3C) specifications originally designed as a metadata model (Candan et al., 2001). It is an abstract model that has become a general method for conceptual description of information for the Web, using a variety of syntax notations and serialization formats. METACLIP (Bedia et al., 2019) exploits RDF through specific vocabularies, written in the OWL ontology language, describing different aspects involved in climate product generation, from the data source to the post-processing workflow, extending international standard vocabularies such as PROV-O (Moreau et al., 2015). The METACLIP vocabularies are publicly available in the METACLIP repository (http://github.com/metaclip/vocabularies).

METACLIP emphasises the delivery of ‘final products’ (understood as any piece of information that is stored in a file, such as a plot or a map) with a full semantic description of its origin and meaning attached. METACLIP ensures ‘machine readability’ through reuse of well-defined, standard metadata vocabularies, providing semantic interoperability and the possibility of developing database engines supporting advanced provenance analytics. Therefore, this framework has been adopted to generate provenance information and attach it as metadata to the products generated by the Interactive Atlas. A specific vocabulary (`ipce_terms`) is created alongside the inclusion of new products in the Interactive Atlas and uses the controlled vocabularies existing from CMIP and CORDEX experiments. As an example, Figure Atlas.10 shows the semantic vocabularies needed to encode the information of the typical workflow for computing (from bias-adjusted data) any of the climate indices (extreme or CIDs) included in the Interactive Atlas.

[START FIGURE ATLAS.10 HERE]

Figure Atlas.10: Schematic representation of the Interactive Atlas workflow, from database description, subsetting and data transformation to final graphical product generation (maps and plots). Product-dependent workflow steps are depicted with dashed borders. METACLIP specifically considers the different intermediate steps consisting of various data transformations, bias adjustment, climate index calculation and graphical product generation, providing a semantic description of each stage and the different elements involved. The different controlled vocabularies describing each stage are indicated by the colours, with gradients indicating several vocabularies involved, usually meaning that specific individual instances are defined in `ipce_terms` extending generic classes of
‘datasource’. These two vocabularies, dealing with the primary data sources have specific annotation
properties linking their own features with the CMIP5, CMIP6 and CORDEX Data Reference Syntax,
taking as reference their respective controlled vocabularies. All products generated by the Interactive
Atlas provide a METACLIP provenance description, including a persistent link to a reproducible
source code under version control.

[END FIGURE ATL AS.10 HERE]

Atlas.2.4 Guidance for users

Atlas.2.4.1 Purpose of the Interactive Atlas

The primary purpose of the IPCC is to provide a policy relevant, non-prescriptive assessment of the state of
knowledge on climate change and its impacts. This purpose is different from the provision of information
targeted to implement climate policies, which is the focus of climate services and national climate change
assessment communities. IPCC assessments are based on quantitative observational and model-generated
data that are also used in many activities supporting the development of climate policies. However, the
functionality of the Interactive Atlas is primarily aimed at supporting the knowledge assessment.

Much of the assessment in this report is based on multiple lines of evidence (Cross Chapter Box 10.3). The
Interactive Atlas facilitates combining multiple observational and model-generated datasets and spatial and
temporal analyses that combine to support statements on the characteristics of the climate system. The use of
predefined spatial and temporal aggregations imposes constraints on the ability to make specific or tailored
assessments but does provide essential background and uncertainty information to generate broad findings
and provide confidence statements on these. Also, the inclusion of a selection of extremes and CIDs is a new
element in the Interactive Atlas and facilitates broader application including the handshake with WGII.

Below, some guidelines on the use, interpretation and limitations of the Interactive Atlas are given.

Atlas.2.4.2 Guidelines for the Interactive Atlas

Atlas.2.4.2.1 Quantitative support for assessments

Many assessment statements make use of evidence derived from observed changes, model projections, and
process-oriented attribution of changes to human interventions. The Interactive Atlas shows a small subset of
available observations that document climate change, namely surface air temperature and total precipitation
(and thus not including observations of other atmospheric and Earth system components used as part of the
evidence base for the report). Only datasets that have (near) global or large regional gridded spatial coverage
and go back multiple decades are used. For each variable multiple datasets are included, but some of these
have overlapping native ground-station observations and so are not independent (see Section Atlas.1.4.1). The
datasets show patterns of substantial spatial and temporal variability, and the empirical evidence of a
non-stationary climatology needs to be filtered from this information. Issues with quality, representativity,
and mutual consistency lead to constraints on their use for attribution of causes of trends (see Section
10.4.1.2 for examples). The practice of attributing trends and extreme events to human causes gives
confidence that these trends are expected to continue in the (near) future, provided the human drivers of
climate change remain unchanged. However, large internal variability at decadal time scales can be mis-
interpreted as an anthropogenic influence on the likelihood of extreme events, and in that case extrapolation
of trends cannot be expected to be a reliable predictor for the future (Schiermeier, 2018).

The Interactive Atlas gives access to a specific set of climate variables from a large number of climate model
simulations, particularly the (global) CMIP5, CMIP6 and (regional) CORDEX archives. The global model
outputs generally give a relatively coarse picture of climate change, which is an important line of evidence
for the detection and attribution of climate change, but is rarely directly applicable for local climate change
assessment or support of policy design (van den Hurk et al., 2018). To provide additional detail, downscaling
global projections with regional climate models (RCMs) or statistical downscaling can be undertaken but
also adds a source of uncertainty as it involves additional modelling (see Section 10.3).

The information displayed in the Interactive Atlas allows a number of sources of uncertainty to be quantified. ‘Observational uncertainty’ is represented by the use of multiple (albeit often not completely independent) observational datasets. ‘Uncertainty due to internal variability’ cannot be quantified directly since multiple realizations from historic and future projections are not accessible (the Interactive Atlas uses a single realization of each model). The use of a large collection of model systems allows for an elaborate quantification of ‘model uncertainty’. In addition, a comparison of CMIP5 and CMIP6 supports evidence of progress in model quality since the AR5, while the evaluation of the added value of RCMs reveals model uncertainty related to spatial resolution (see Section 10.3). Finally, the assessment of ‘scenario uncertainty’ is supported by the inclusion of multiple emission scenarios for both CMIP5, CORDEX and CMIP6.

The communication of uncertainty has a profound influence on the perception of information that is exchanged during the communication process. An assessment of uncertainty communication and the barriers to climate information construction is given in Section 10.5.4.

**Atlas 2.4.2.2 Insights from physical understanding**

The detailed technical findings in IPCC reports also serve as an important benchmark resource for the research community. The Interactive Atlas complements the IPCC assessment report as a repository of scientific information on global and regional climate and its representation in coordinated model ensemble experiments. Regional climate is governed by a mixture of drivers, such as circulation patterns, seasonal monsoons, annual cycles of snow and regional land-atmosphere feedbacks. Global warming may affect regional climate characteristics by altering the dynamics of their drivers. The Interactive Atlas allows the comparison of different levels of global warming on specific regional climate features but is not designed for advanced analysis of the relationship between drivers and regional climate characteristics. For this, tailored analysis protocols need to be applied, such as the aggregation of climate change information from ensembles of regional climate projections, and stratification according to drivers of regional climate such as patterns of atmospheric circulation (Lenderink et al., 2014). The analysis of complex regional climate characteristics resulting from compound drivers also require additional expert knowledge and data processing (Thompson et al., 2016). Section 12.6.2 assesses various categories of climate services, including tailored analysis of regional climate processes.

**Atlas 2.4.2.3 Construction of storylines**

Communicating the full extent of available information on future climate for a region, including a quantification of uncertainties, can act as a barrier to the uptake and use of such information (Lemos et al., 2012; Daron et al., 2018). To address the need to simplify and increase the relevance of information for specific contexts, recent studies have adopted narrative and storyline approaches (Hazeleger et al., 2015; Shepherd et al., 2018) (see Sections 1.4.4 and 10.5.3 for definitions and further discussion on these concepts). The use of region-specific climate storylines, including a role for local mechanisms, drivers and societal impacts generally requires detailed information that is typically not provided by the Interactive Atlas. However, background information and basic (scenario) assumptions can be derived from the Interactive Atlas which can be considered to provide an expert knowledge base from which to build targeted storylines and climate information.

**Atlas 2.4.2.4 Visual information**

The visual communication of climate information can take many forms. Besides the standard visual products typically used for communicating global and regional climate information to practitioners (e.g., maps, time series or scatter plots), the Interactive Atlas incorporates new visuals, for example ‘stripes’ (RMetS, 2019), facilitating the communication of key messages (e.g., warming and consistency across models) to a less technical audience. The various tabular and graphical representation alternatives included as options in the Interactive Atlas (Figure Atlas.8) facilitate exploring the information interactively from different perspectives and for different levels of detail, thus favouring the communication with the larger and diverse...
To support the use of visuals provided in the Interactive Atlas for application to different audiences, new insights since the AR5 have emerged from a range of scientific disciplines, including the cognitive and psychological sciences (Harold et al., 2016). Studies have used interviews and online surveys to assess interpretations of visuals used to communicate climate information and uncertainties (Daron et al., 2015; Lorenz et al., 2015; McMahon et al., 2015; Retchless and Brewer, 2016). They commonly find wide-ranging interpretations and varied understandings of climate information amongst respondents due to the choice of visuals. In addition, Taylor et al. (2015) found that preferences for a particular visualization approach do not always align with approaches that achieve greatest accuracy in interpretation. Choosing appropriate visuals for a particular purpose and audience can be informed by testing and evaluation with target groups.

### Atlas.2.4.2.5 Dedicated climate change assessment programs

Communication aimed at informing the general public about assessed scientific findings on climate change have a different purpose and format than if intended to inform a specific target audience to support adaptation or mitigation policies (Whetton et al., 2016). The growing societal engagement with climate change means IPCC reports are increasingly used directly by businesses, the financial sector, health practitioners, civil society, the media, and educators at all levels. The IPCC reports could effectively be considered a tiered set of products with information relevant to a range of audiences.

The Interactive Atlas does provide access to a collection of observational and modelling datasets, presented in a form that supports the distillation of information on observed and projected climate trends at the regional scale. Access to the repository of underlying datasets enables further processing for particular purposes. As noted above, it is not the intention nor the ambition of this IPCC assessment and the Interactive Atlas component to provide a climate service for supporting targeted policies. For this an increasing number of dedicated climate change assessment programs have been carried out, aiming at mapping climate change information relevant for adaptation and mitigation decision support.

For instance, the European Environment Agency (2018) provides an overview of European national climate change scenario programs. Most of these use CMIP5 (or earlier) global climate change ensembles driven by an agreed set of greenhouse-gas emission scenarios, followed by downscaling using RCMs and/or statistical methods, in order to generate regionally representative hydrometeorological indicators of climate change. In some cases, output of selected downscaled global and regional models is provided to users (Whetton et al., 2012; Daron et al., 2018). Uptake by users is strongly dependent on providing justification of the selection or for the downscaling procedure and if further steps are needed to tailor the information to local scales (Lemos et al., 2012). More comprehensive programs provide probabilistic climate information by careful analysis and interpretation of ensembles of model outputs (Lowe et al., 2018). The information is generally tailored to professional practitioners with expertise to interpret and process this probabilistic data. This top-down probabilistic information chain is not always able to highlight the essential climate change information for users, and alternative bottom-up approaches are encouraged (Frigg et al., 2013). Section 12.6.2 assesses climate services including the national climate assessments and user uptake.

### Atlas.3 Global synthesis

Most other chapters in WGI assess past or future behaviour of specific aspects of the global climate system and this section introduces some of the key results, specifically from Chapters 2, 4 and 9. This provides a global overview on observations and information from the CMIP5 and CMIP6 ensembles to underpin the regional assessments in the rest of the Atlas Chapter and the results displayed in the Interactive Atlas. Thus, its aim is not to generate an assessment of regional climate change directly but to provide the global context for this information derived later in the Atlas. Section Atlas.3.1 considers global atmospheric and land-surface information with global ocean information in Section Atlas.3.2.
Atlas.3.1 Global atmosphere and land surface

The principal atmospheric quantities of interest for understanding how climate change may impact human and ecological systems, as well as being key global indicators of change, are surface air temperature and precipitation. They are therefore a significant focus of the regional climate assessments in the following regional sections of the chapter (Atlas.4 to Atlas.11) and of the Interactive Atlas. Changes in these variables over land during the recent past (1960–2015) are shown in Figure Atlas.11 using results from two global datasets (assessed in Chapter 2) to illustrate both where there is robust information on observed trends and observational uncertainty.

For temperature, a clear signal of warming is seen over most land areas with an amplification at high latitudes, though all continents apart from Europe also have regions where trends are not significant. Significant changes in annual mean precipitation are seen over much more limited areas though with consistent increasing trends over some northern high-latitude regions and decreasing trends over smaller regions in tropical Africa, the Americas and Southwest Asia. The information conveyed in Figure Atlas.11 on both consensus in the signal of change and on observational uncertainty is used in this chapter as a line of evidence to assess historical observed trends.

As an alternative way of viewing and summarising information in the observational data, the panels (c) and (d) in Figure Atlas.11 show the time at which any significant temperature trends from the Berkeley Earth and CRUTEM5 datasets, averaged over the reference regions, emerged from interannual variability – with a signal to noise ratio greater than two (Hawkins et al., 2020). In the former a regionally averaged warming signal has emerged over all of the land reference regions, in the latter, emergence times are only calculated for those regions which have data available in more than 50% of the land area ( unlike Berkeley Earth, CRUTEM does not include spatial interpolation, see Section 2.3.1.1.3) and these are similar for all but one of the regions indicating that observational uncertainty does not change the main conclusion of widespread emergence of surface temperature signals over land regions.

Figure Atlas.11: Observed linear trends of signals in annual mean surface air temperature (a, b) and precipitation (c, f) in the Berkeley Earth, CRUTS and GPCC datasets (see Section Atlas.1 for dataset details). Trends are calculated for the common 1960–2015 period and are expressed as °C per decade for temperature and relative change (with respect to the climatological mean) per decade for precipitation. Crosses indicate regions where trends are not significant (at a 0.1 significance level) and the black lines mark out the reference regions defined in Section Atlas.1. Panels c and d display the period in which the signals of temperature change in data aggregated over the reference regions emerged from the noise of annual variability in the respective aggregated data. Emergence time is calculated for (c) Berkeley Earth (as used in (a)) and CRUTEM5. Regions in the CRUTEM5 map are shaded grey when data are available over less than 50% of the land area of the region. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

As described earlier, information on projected future changes is required both at different time periods in the future under a range of emissions scenarios but also for different global warming levels. Figure Atlas.12 shows the global surface air temperature change projection calculated from the CMIP6 ensemble mean of for the middle of the century under the SSP1-2.6 and SSP3-7.0 emissions scenarios compared to the end of the century warming under SSP3-7.0 and for a global warming level of 2°C. The patterns of changes are similar to the observed warming and there is a high level of consistency with CMIP5 in terms of both patterns and magnitude of change (Interactive Atlas). However, for the long-term future, warming in the CMIP6 ensemble is generally higher, reflecting the increase in the top end of the range of climate sensitivities amongst the CMIP6 GCMs (Figure Atlas.13).
Figure Atlas.12: Global temperature changes projected for the mid-century under SSP1-2.6 (left, top) and SSP3-7.0 (left, bottom) compared with a 2°C global warming level (right, top) and the end of the century under SSP3-7.0 (right, bottom) from the CMIP6 ensemble. Note that the future period warmings are calculated against a baseline period of 1995–2014 whereas the global mean warming level is defined with respect to the baseline period of 1851–1900 used to define global warming levels. The other three SSP-based maps would show greater warmings with respect to this earlier baseline. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Figure Atlas.12 demonstrates how temperature is projected to increase for all regions, and at a greater rate than the global average over many land regions and with significant amplification in the Arctic. It also shows the higher mid-century warming and significantly higher end of century warming under the high-emission SSP3-7.0 scenario compared to the low-emission SSP1-2.6 scenario. Conversely, comparing the projected 2°C Global Warming Level change with that projected additional warming compared to the recent past under the SSP1-2.6 scenario demonstrates the much smaller additional warming projected under this low-emission scenario. Finally, the maps display the CMIP6 ensemble mean projection but it is important to explore the full range of outcomes from the ensemble, for example when undertaking a comprehensive risk assessment in which temperature is an important hazard. This can be explored regionally in the Interactive Atlas (Section Atlas.2) by viewing the timeseries of changes for all of the models within the ensemble over the AR6 WGI reference regions (Figure Atlas.2:).

Changes in annual mean precipitation present a more complex picture with regions of decrease as well as increase and areas where there is model disagreement on the sign of the change, even when the signal is strong in the long-term future period as shown in Cross-Chapter Box Atlas.1, Figure 1. However, as with the temperature changes, there is a high level of consistency in the patterns and magnitude of the precipitation changes, with changes in some areas being larger in the long-term future period. Considering changes over land, Cross-Chapter Box Atlas.1, Figure 1 also shows that at lower warming levels there are many regions, especially in the southern hemisphere, where there is no robust signal of change from the models.

In addition to displaying results from global model ensembles as maps of projected changes and their robustness or as timeseries of the projected temporal evolution of the median and range of a climate statistic, it is often useful to generate area-averaged summaries of these statistics under different future emission scenarios or at specific global warming levels. This is demonstrated in Figure Atlas.13 and forms the basis of a common set of analyses which are presented for the reference regions in the regional assessments in the following Sections Atlases.4 to Atlas.11. It shows the range of projected changes compared to the 1850–1900 and the recent past 1995–2014 baseline periods for the CMIP5 and CMIP6 ensembles. The first four panels show: annual mean changes in temperature globally and over land only for various global warming levels and emission scenarios and time periods (left pair) and then again globally and for global land, changes in precipitation and temperature at the same global warming levels (right pair). The second four panels provide the same temperature and precipitation information globally and for global land only in the December–February and July–August seasons. These results demonstrate the consensus between the two ensembles for increased warming over land areas and increases in global precipitation at all warming levels and that global land precipitation increases more. They also show the increased precipitation response in DJF reflecting the large precipitation increases in the northern hemisphere higher latitudes in winter. Finally, they demonstrate the greater warming projected by the CMIP6 ensemble, as an average over the ensemble and the upper end of the range. See Chapter 4 for an in-depth assessment of these results.
Global warming leads to systematic changes in regional climate variability via various mechanisms such as thermodynamic responses via altered lapse rates (Kröner et al., 2017; Brogli et al., 2019) and land-atmosphere feedbacks (Boé and Terray, 2014). These can modify temporal and spatial variability of temperature and precipitation, including an altered seasonal and diurnal cycle and return frequency of extremes. Regional influences from and feedbacks with sea surface, clouds, radiation and other processes also modulate the regional response to enhanced warming, both locally and, via teleconnections, remotely.

Despite their potential to influence extremes in temperature, precipitation and other climatic impact-drivers and hazards, and thus risks to human and ecological systems, it is important to understand these links for developing adaptations in response to clear anthropogenic influences on individual hazards. This will also support the related fields of disaster risk reduction and global sustainable development efforts (Steptoe et al., 2018). They demonstrated that 15 regional hazards shared connections via the El Niño–Southern Oscillation, with the Indian Ocean Dipole, North Atlantic Oscillation and the Southern Annular Mode (see Annex IV) being secondary sources of significant regional interconnectivity (Figure Atlas.14). Understanding these connections and quantifying the concurrence of resulting hazards can support adaptation planning as well as multi-hazard resilience and disaster risk reduction goals.
quantified in Table Atlas.1: which lists the fraction of interannual variance in seasonal mean temperature and precipitation explained by variability in these modes. The table provides information on the influence of the teleconnections for selected seasons for the interannual to decadal modes and at an annual scale for the multi-decadal. The columns related to the interannual to decadal modes focus on the seasons where these connections are strongest but each mode of variability will often have influences in other seasons (for more details see Annex IV). The table shows that for many regions, seasonal temperature and precipitation is substantially modulated by these modes of variability, all regions feel some influence and variability in ocean basins often has influence in multiple remote regions.

[START TABLE ATLAS.1 HERE]

Table Atlas.1: Regional mapping of the teleconnections associated with the main modes of variability (Annex IV). Fraction of surface air temperature and precipitation variance explained at interannual timescale by each mode of variability (columns) for each AR6 region (rows) based on the coefficient of determination $R^2$. Units are in percent and non-significant values based on t-statistics at the 95% level confidence are indicated by a cross. HadCRUT (HAD), GISTEMP (GIS), Berkeley/Earth (BE), and CRU-TS (CRU) observed datasets are used to assess the strength of the teleconnection for surface air temperature and GPCC and CRU-TS are used for precipitation. The colour scale given on label bars shown at the bottom quantifies the values of the explained variance and also stands for the sign of the teleconnection for the positive phase of the mode. All data are linearly detrended prior the computation of the regression. Note that results are sensitive to the choice of the detrending function (linear, loess filter, 3-order polynomial function) but by few percent at most, which is well below the range of the observational uncertainty assessed here through the use of several observational products.

Atlas-39  
Total pages: 196
As with the atmosphere, there are several key ocean-related quantities which are relevant for understanding how climate change may impact human and ecological systems and/or key global indicators of change. These include ocean surface temperature and heat content, sea surface height, sea ice cover and thickness, and certain chemical properties such as ocean acidity and oxygen concentration. For example, there is growing awareness of the threat presented by ocean acidification to ecosystem services and its socio-economic consequences are becoming increasingly apparent and quantifiable (Hurd et al., 2018) and SR1.5 (IPCC, 2018c) noted a significant impact of low levels of global warming on the state of the global oceanic ecosystems and food security. For instance, 70–90% of coral reefs are projected to decline at a warming level of 1.5°C, with larger losses at 2°C.

Thus, because of their importance to coastal populations and infrastructure and ocean ecosystems, the Interactive Atlas focuses on change in sea-surface temperature, sea level and pH. Figure Atlas.15: shows projected changes sea-surface temperature and sea level at the end of the century under SSP1-2.6 and SSP5-8.5 emissions, demonstrating the much larger changes seen with the higher-emission scenario. The projected changes in sea level show the significantly greater increases, of up to 1 m locally, under a high-emissions future. Regional details of these projected changes under a range of emission scenarios and time periods can be explored in the Interactive Atlas. An in-depth assessment of these changes is presented in Section 5.3 and Chapter 9.

Figure Atlas.15: Projected changes in sea surface temperature (top), sea level rise (bottom) for 2081–2100 under the SSP1-2.6 (left) and SSP5-8.5 (right) emission scenarios compared to a 1995–2014 baseline period from the CMIP6 ensemble. For sea surface temperature, diagonal lines indicate regions where 80% of the models do not agree on the sign of the projected changes. Further details on data
sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.15 HERE]

Atlas.4 Africa

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes are in Chapter 11 (Table 11.4–11.6) and climatic impact-drivers in Chapter 12 (Table 12.1-12.12).

Atlas.4.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.4.1.1 Key features of the regional climate

Africa has many varied climates which can be categorized as dry regime in the Saharan region, tropical humid regime in West and East Africa except for parts of the Greater Horn of Africa (alpine) and the Sahel (semi-arid), and a dry/wet season regime in the northern and southern African region including the Namibian desert; each climate region has its local variations resulting in very high spatial and temporal variations (Peel et al., 2007). Based on the varied climates, nine subregions are defined for Africa (see Figure Atlas.16): the Mediterranean region (MED) including North Africa, Sahara including parts of the Sahel (SAH), West Africa (WAF), Central Africa (CAF), North Eastern Africa (NEAF), South Eastern Africa (SEAF), West Southern Africa (WSAF), East Southern Africa (ESAF) and Madagascar (MDG).

The climatic features that characterize the intra-seasonal and inter-annual variability of Africa are mainly the Madden-Julian Oscillation (MJO) which is confined to the deep tropics during boreal winter, Pacific Decadal Variability (PDV), and the shift of the Atlantic Inter Tropical Convergence Zone in response to changes in the meridional SST gradient. A positive phase of the PDV weakens African monsoons (Meehl and Hu, 2006)(Figure AIV.8d) and MJO phase 4 suppresses convection over the equatorial Africa (Figure AIV.10a) (see Annex IV). Other features influence specific subregions. For instance, El Niño events increase precipitation in eastern Africa and decreases precipitation in southern Africa. Over southern Africa there is a strong link between ENSO and droughts (Meque and Abiodun, 2015). The positive phase of the IOD increases rainfall in eastern tropical Africa in boreal autumn to early winter (Figure AIV.5d), while the negative phase induces the reduction in rainfall. West African monsoon is influenced by Atlantic Zonal Mode (AZM) with decreased rainfall over the Sahel and increased rainfall over Guinea (Losada et al., 2010). Positive Atlantic Multidecadal Variability (AMV) influences positive anomalies all year round over a broad Mediterranean region, including North Africa.

Atlas.4.1.2 Findings from previous IPCC assessments

The most recent IPCC reports, AR5 and SR1.5 (Christensen et al., 2013; Hoegh-Guldberg et al., 2018), state that over most parts of Africa, minimum temperatures have warmed more rapidly than maximum temperatures during the last 50 to 100 years (medium confidence). In the same period minimum and maximum temperatures have increased by more than 0.5°C relative to 1850-1900 (high confidence). While the quality of ground observational temperature measurements tends to be high compared to that of measurements for other climate variables, Africa remains an under-represented region as reported in SR1.5 (Hoegh-Guldberg et al., 2018; IPCC, 2018c). Based on the Coupled Model Intercomparison Project Phase 5 (CMIP5) ensemble and reported in IPCC AR5 and SR1.5, surface air temperatures in Africa are projected to rise faster than the global average increase and likely to increase by more than 2°C and up to 6°C by the end of the century relative to the late 20th century if global warming reaches 2°C (Bindoff et al., 2013; Niang et al., 2014; Hoegh-Guldberg et al., 2018). The higher temperature magnitudes are projected during boreal summer. Southern Africa is likely to exceed the global mean land surface temperature increase in all seasons.
by the end of the century. Temperature projections for East Africa indicate considerable warming under RCP8.5 where average warming across all models is approximately 4°C by the end of the century. According to SROCC, eastern Africa like other regions with smaller glaciers is projected to lose more than 80% of its glaciers by 2100 under RCP8.5 (medium confidence) (Hock et al., 2019b).

West Africa has also experienced an overall reduction of rainfall over the 20th century, with a recovery towards the last 20 years of the century (Christensen et al., 2013). Over the last three decades rainfall has decreased over East Africa especially between March and May/June. Projected rainfall changes over Africa in the mid and late 21st century is uncertain. In regions of high or complex topography such as the Ethiopian Highlands, downscaled projections indicate likely increases in rainfall and extreme rainfall by the end of the 21st century. However, Northern Africa and the south-western parts of South Africa are likely to have a reduction in precipitation.

The consequence of increased temperature and evapotranspiration, and decreased precipitation amount, in interaction with climate variability and human activities, have contributed to desertification in dryland areas in Sub-Saharan Africa (medium confidence) as reported in SRCC (Mirzabaev et al., 2019).

### Atlas.4.2 Assessment and synthesis of observations, trends and attribution

Figure Atlas.11: shows observed trends in annual mean surface temperature and indicates it has been rising rapidly over Africa over 1960–2015 and with significant increases in all regions of 0.1°C–0.2°C per decade and higher over some northern, eastern and south-western regions (high confidence) (see also Interactive Atlas). This is confirmed by an independent analysis performed for a longer period (1961–2018) over areas where long-term homogeneous temperature time-series are available (Engelbrecht et al., 2015). More specifically over the Horn of East Africa, the long-term mean annual temperature change between 1930 and 2014 showed two distinct but contrary trends: significant decreases between 1930 and 1969 and increases from 1970 to 2014 (Ghebrezegabher et al., 2016). North Africa has an overall warming in observed seasonal temperature (Barkhordarian et al., 2012; Lelieveld et al., 2016) with positive trends in annual minimum and maximum temperatures (Vizy and Cook, 2012). Temperatures over West Africa have increased over the last 50 years (Mouhamed et al., 2013; Niang et al., 2014) with a spatially variable warming reaching 0.5°C per decade from 1983 to 2010 (Sylla et al., 2016). West Africa has also experienced a decrease in the number of cool nights as well as more frequent warm days and warm spells (Mouhamed et al., 2013; Ringard et al., 2016). Similarly, East Africa has experienced a significant increase in temperature since the beginning of the early 1980s (Anyah and Qiu, 2012) with an increase in seasonal mean temperature. Over South Africa, positive trends were found in the annual mean, maximum and minimum temperatures for 1960–2003 in all seasons, except for the central interior (Kruger and Shongwe, 2004; Zhou et al., 2010; Collins, 2011; Kruger and Sekele, 2013; MacKellar et al., 2014), where minimum temperatures have decreased significantly (MacKellar et al., 2014). Inland southern Africa, minimum temperatures have increased more rapidly than maximum temperatures (New et al., 2006).

Most areas lack enough observational data to draw conclusions about trends in annual precipitation over the past century. In addition, many regions of Africa have discrepancies between different observed precipitation datasets (Sylla et al., 2013; Panitz et al., 2014). A statistically significant (95% confidence level) decrease in rainfall and the number of rainy days is reported in autumn over the east, central and north-eastern parts of South Africa in spring and summer during 1960–2010 (MacKellar et al., 2014; Kruger and Nxumalo, 2017). Central Africa has experienced a significant decrease in total precipitation which is likely associated with a significant decrease of the length of the maximum number of consecutive wet days (Aguilar et al., 2009). Furthermore, rainfall decreased significantly in the Horn of Africa (Tierney et al., 2015) with the largest reductions during the long rains season March to May (Lyon and Dewitt, 2012; Viste et al., 2013; Rowell et al., 2015). Over mountainous areas significant increases are found in the number of rain days around the southern Drakensberg in spring and summer during the period 1960–2010 (MacKellar et al., 2014). Similarly, southern West Africa is observed to have had more intense rainfall from 1950 to 2014 during the second rainy season of September to November (Nkrumah et al., 2019). The Sahel region also had more intense rainfall throughout the rainy season (Panthou et al., 2014, 2018b, 2018a; Sanogo et al., 2015; Gaetani
et al., 2017; Taylor et al., 2017; Biasutti, 2019) during the period 1980–2010. Southern African rainfall shows a significant downturn of $-0.013$ mm day$^{-1}$ year$^{-1}$ in recent decades and $-0.003$ mm day$^{-1}$ year$^{-1}$ for longer periods during 1900–2010 (Jury, 2013) (low confidence).

Temperature increases over Africa in the 20th century can be attributed to the strong evidence of a continent-wide anthropogenic signal in the warming (Hoerling et al., 2006; Min and Hense, 2007; Stott et al., 2010, 2011; Niang et al., 2014) (Figure 3.8). More specifically over West Africa, the clear emergence of temperature change (Figure Atlas.11:) is due to the relatively small natural climate variability in the region which generates narrow climate bounds that can be easily surpassed by relatively small climate changes (Niang et al., 2014). Warming over North Africa is largely due to anthropogenic climate forcing (Knippertz et al., 2003; Barkhordarian et al., 2012; Diffenbaugh et al., 2017).

The drying observed over the Sahel in the 1960s to 1970s has been attributed to warming of the South Atlantic SST and southern African drying as a response to Indian Ocean warming (Hoerling et al., 2006; Dai, 2011). Enhanced rainfall intensity since the mid-1980s over the Sahel (Maidment et al., 2015; Sanogo et al., 2015) is associated with increased greenhouse gases suggesting an anthropogenic influence (Biasutti, 2019) (medium confidence). In the last decade, the changes in the timing of onset and cessation of rainfall over Africa have been linked to changes in the progression of the tropical rainband and the Saharan Heat Low (Dunning et al., 2018; Wainwright et al., 2019). Moreover, later onset and earlier cessation of Eastern Africa rainfall is associated with a delayed and then faster movement of the tropical rainband northwards during the boreal spring and northward shift of the Saharan Heat Low (Wainwright et al., 2019) driven by anthropogenic carbon emissions and changing aerosol forcings (medium confidence). Over East Africa, the drying trend is associated with an anthropogenic-forced relatively rapid warming of Indian Ocean SSTs (Williams and Funk, 2011; Hoell et al., 2017); a shift to warmer SSTs over the western tropical Pacific and cooler SSTs over the central and eastern tropical Pacific (Lyon and Dewitt, 2012); multidecadal variability of SSTs in the tropical Pacific, with cooling in the east and warming in the west (Lyon, 2014); and the strengthening of the 200-mb easterlies (Liebmann et al., 2017). However, decadal natural variability from SST variations over the Pacific Ocean has also been associated with the drying trend of the East Africa (Wang et al., 2014; Hoell et al., 2017) with an anthropogenic-forced rapid warming of Indian Ocean SSTs (medium confidence).

**Atlas.4.3 Assessment of model performance**

Model development has advanced in the world, but Africa still lags as a focus and in its contribution (James et al., 2018). None of the current generation of general circulation models (GCMs) was developed in Africa (Watterson et al., 2014), and the relevant processes in the continent have not been the priority for model development but treated in a one-size-fit-all approach (James et al., 2018) except for a few studies that focused on convective-permitting climate projections (Stratton et al., 2018; Kendon et al., 2019). However, there are growing efforts to boost African climate science by running and evaluating climate models over Africa (Endris et al., 2013; Kalognomou et al., 2013; Gbobaniyi et al., 2014; Engelbrecht et al., 2015; Klutse et al., 2016; Gibba et al., 2019).

The CMIP project previously did not result in improved performance for Africa (Flato et al., 2013; Rowell, 2013; Whittleston et al., 2017) and culling ensembles based on existing metrics for Africa fails to reduce the range of uncertainty in precipitation projections (Roehrig et al., 2013; Yang et al., 2015; Rowell et al., 2016) but biases over Africa are lower in CMIP6 compared to CMIP5 (Almazroui et al., 2020b). Nonetheless, the CMIP5 ensemble has been evaluated over Africa to advance its application for climate research (Biasutti, 2013; Rowell, 2013; Dike et al., 2015; McSweeney and Jones, 2016; Onyutha et al., 2016; Wainwright et al., 2019) as has, more recently, the CMIP6 ensemble (Almazroui et al., 2020b).

Coordinated Regional Downscaling Experiment (CORDEX) regional climate models have been widely evaluated over Africa. They capture the occurrence of the West African Monsoon jump and the timing and amplitude of mean annual cycle of precipitation and temperature over the homogeneous subregions of West Africa (Gbobaniyi et al., 2014), simulate eastern Africa rainfall adequately (Endris et al., 2013) and over

*Do Not Cite, Quote or Distribute*
Southern Africa capture the observed climatological spatial patterns of extreme precipitation (Pinto et al., 2016). They simulate also the phasing and amplitude of monthly rainfall evolution and the spatial progression of the wet season onset well over Southern Africa (Shongwe et al., 2015). However, discrepancies and biases in present-day rainfall are reported over Uganda from the RCM-simulated rainfall compared to three gridded observational datasets (Kisembe et al., 2018). Specifically, they reported that the CORDEX models underestimate annual rainfall of Uganda and struggle to reproduce the variability of the long and short rainy seasons.

**Atlas.4.4 Assessment and synthesis of projections**

Research over Africa has improved since AR5 and though SR1.5 (de Coninck et al., 2018) has synthesised new information for the continent, there is still not enough literature on specific areas for assessment. CMIP5 and CMIP6 projections (Figure Atlas.16:) are for continued warming, with median projected regional warming for 2080–2100 compared to 1995–2014 of between 1°C and 2°C under SSP1-2.6/RCP2.6 emissions and exceeding 4°C in and some regions 5°C under SSP5-8.5/RCP8.5 emissions. The central interior of Southern and Northern Africa are likely to warm faster than equatorial and tropical regions (Interactive Atlas). Projections from CMIP5 show that East Africa is likely to warm by 1.7°C–2.8°C and 2.2°C–5.4°C under the RCP4.5 and RCP8.5 scenarios respectively in the period 2071–2100 relative to 1961–1990 (Ongoma et al., 2018). Over southern Africa, areas in the south-western region of the subcontinent, covering South Africa and parts of Namibia and Botswana, are projected to experience the largest increase in temperature, which are expected to be greater than the global mean warming (Maure et al., 2018). A large ensemble of CORDEX Africa simulations have been used to project the impact of 1.5°C and 2°C global warming levels (GWLS) (Klutze et al., 2018; Lennard et al., 2018; Maure et al., 2018; Mba et al., 2018; Nikulin et al., 2018; Osima et al., 2018). While a few studies addressed the whole African continent (Lennard et al., 2018; Nikulin et al., 2018), some focused on specific regions of Africa (Diedhiou et al., 2018; Klutze et al., 2018; Kumi and Abiodun, 2018; Maure et al., 2018; Mba et al., 2018). CORDEX simulations project robust warming over Africa in excess of the global mean (Lennard et al., 2018; Nikulin et al., 2018) and over West Africa the magnitude of regional warming reaches the 2080–2100 global warming level one to two decades earlier (Mora et al., 2013; Ntang et al., 2014; Sylla et al., 2016; Klutse et al., 2018). Temperature increases projected under RCP8.5 over Sudan and northern Ethiopia implying that the Greater Horn of Africa would warm faster than the global mean relative to 1971–2000 (Osima et al., 2018). Over North Africa, summer mean temperatures from CORDEX, CMIP5 (RCP8.5) and CMIP6 (SSP5-8.5) are projected to increase beyond 6.0°C by the end of the century with respect to the period 1970–2000 (Schilling et al., 2012; Ozturk et al., 2018; Almahrouz et al., 2020b), see also the Interactive Atlas. Note that results for the CORDEX-AFR over the Mediterranean (MED) are consistent with those reported from the CORDEX-EUR dataset (Figure Atlas.24; Section Atlas.1.3), in agreement with Legasa et al. (2020).

[START FIGURE ATLAS.16 HERE]

Figure Atlas.16: Regional mean change in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Africa (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlaying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February-March (DJFM; middle panel) and June-July-August-September (JJAS; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and
Projected rainfall changes over Africa in the mid and late 21st century are uncertain in many regions, highly variable spatially and with differing levels of model agreements (Figure Atlas.16) though with robust projections of decreases in MED and WSAF and increases in NEAF and SEAF by 2080–2100 under high emission (Interactive Atlas). Some uncertainties are reported over parts of Africa from CORDEX projections (Dosio and Panitz, 2016; Endris et al., 2016; Klutse et al., 2018). For example, large uncertainties are associated with projections at 1.5°C and 2°C of global warming over Central Africa (Mba et al., 2018) and over the Sahel (Ghobaniyi et al., 2014; Sylla et al., 2016). Over southern Africa, enhanced warming is projected to result in a reduction in mean rainfall across the region (Maître et al., 2018) and in particular over the Limpopo Basin and smaller areas of the Zambezi Basin in Zambia, and also parts of Western Cape, South Africa, under a global warming of 2°C. The projections of reduced precipitation in summer rainfall regions of southern Africa are associated with delayed wet season onsets in spring (Dunning et al., 2018) due to a northward shift and delayed breakdown of the Congo Air Boundary (Howard and Washington, 2020). However, projected rainfall intensity over southern Africa is likely to increase and be magnified under RCP8.5 compared with RCP4.5 for the period 2069–2098 relative to the reference period (1976–2005) (Pinto et al., 2018). For West Africa, rainfall projection is uncertain because of the contrasting signals from models (Dosio et al., 2019). Nonetheless, West Africa river basin-scale irrigation potential would decline under 2°C of global warming even for areas where water availability increases (Sylla et al., 2018). The western and eastern Sahel are projected as hotspots for delayed rainfall onset dates of about four days and six days causing reduced length of rainy season in the 1.5°C to 2°C warmer climates under RCP4.5 and RCP8.5 scenarios (Kumi and Abiodun, 2018). Projected delay in rainfall cessation dates and a longer length of rainy season over the western part of the Guinea coast is likely under the same scenarios (Sellami et al., 2016; Kumi and Abiodun, 2018; Figure Atlas.16). There is a tendency towards an increase in annual mean precipitation over central Sahel and eastern Africa (Figure Atlas.16, Nikulin et al., 2018) especially over the Ethiopian highlands with up to 0.5 mm day−1 (Oshima et al., 2018).

**Atlas.4.5 Summary**

The rate of surface temperature increase has generally been more rapid in Africa than the global average and by at least 0.1°C to 0.2°C during 1960–2015 (high confidence). Minimum temperatures have increased more rapidly than maximum temperatures over inland southern Africa (medium confidence). Since 1970, mean temperature over East Africa has shown an increasing trend but showed a decreasing trend in the previous 40 years (medium confidence).

The Horn of Africa has experienced significantly decreased rainfall during the long rain season from March to May (high confidence) and drying trends in this and other parts of Africa are attributable to oceanic influences (high confidence), resulting from both internal variability and anthropogenic causes. Drying over the Sahel in the last century was attributed to an increase in the South Atlantic SST and more recently over southern African as a response to anthropogenic-forced Indian Ocean warming. Drying over East Africa is associated with decadal natural variability in SSTs over the Pacific Ocean. The enhanced rainfall intensity over the Sahel in the last two decades is associated with increased greenhouse gases indicating an anthropogenic influence (medium confidence).

Relative to the late 20th century, annual mean temperature over Africa is projected to rise faster than the global average (very high confidence) with the increase likely to exceed 4°C by the end of the century under RCP8.5 emissions. The central interior of Southern and Northern Africa are likely to warm faster than equatorial and tropical regions (high confidence).
There are contrasting signals in the projections of rainfall over some parts of Africa until the end of the 21st century (high confidence) though changes in any given region are generally projected with medium confidence. In regions of high or complex topography such as the Ethiopian Highlands, downscaled projections indicate increases in rainfall by the end of the 21st century. However, Northern Africa and the south-western parts of South Africa are likely to have a reduction in precipitation under higher warming levels (high confidence). Over West Africa, rainfall is projected to decrease in the Western Sahel subregion (medium confidence) and increase in the central Sahel subregion (low confidence) and along the Guinea Coast subregion (medium confidence). Rainfall amounts are projected to reduce over the western part of East Africa, but to increase in the eastern part of the region (medium confidence). Southern Africa is projected to have a reduction in annual mean rainfall but increases in rainfall intensity by 2100 (medium confidence).

Atlas.5 Asia

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes are in Chapter 11 (Table 11.7–11.9) and climatic impact-drivers in Chapter 12 (Table 12.4). It covers most Asian territories of the region (Figure Atlas.17) with the exception of the Russian Arctic, RAR, which is assessed as part of the Arctic in section 11.2. These include West and East Siberia (WSB, ESB) and the Russian Far East (RFE) in the north; West and East Central Asia (WCA, ECA), the Tibetan Plateau (TIB) and East Asia (EAS); and the Arabian Peninsula (ARP), South and Southeast Asia (SAS, SEA) in the south. Figure Atlas.17: supports the assessment of regional mean changes in annual mean surface air temperature and precipitation over Asia. Due to the high climatological and geographical heterogeneity of Asia, the assessment is performed over five sub-continental areas: East Asia (EAS+ECA), North Asia (WSB+ESB+RFE), South Asia (SAS+TIB), Southeast Asia (SEA) and Southwest Asia (ARP+WCA).

[START FIGURE ATLAS.17 HERE]

Figure Atlas.17: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Asia (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlaying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively, for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.17 HERE]
**Atlas.5.1 East Asia**

**Atlas.5.1.1 Key features of the regional climate and findings from previous IPCC assessments**

**Atlas.5.1.1.1 Key features of the regional climate**

The climatic regions defined for East Asia include central and eastern China, Japan and Korea Peninsula (regions ECA and EAS in Figure Atlas.17). East Asia is significantly influenced by monsoon systems (see Section 8.3.2.4.2). The seasonal advance or retreat of the East Asian summer monsoon (EASM) rain band is crucial to local climate. The East Asian winter monsoon (EAWM) has significant influence on the weather and climate over East Asia and plays an important role in regulating winter temperatures including strong cold events and snowstorms (Wang and Chen, 2014; Wang and Lu, 2016). The East Asian monsoons exhibit considerable variability on a wide range of time scales, including notable interannual variabilities that includes an effect of the El Niño Southern Oscillation (ENSO) (Wang et al., 2000) and the Indian Ocean Dipole (IOD) (Takaya et al., 2020), and significant inter-decadal variabilities in the 20th century resulted from the effect of Pacific Decadal Variability (PDV) (Zhou et al., 2009), see also Annex IV and Table Atlas.1.: The thermal conditions of both the Tibetan Plateau and related ocean regions play key roles in modulating the intensity of the monsoon circulation. The East Asian monsoons are mainly driven by land-sea thermal contrast and, thus, are deeply affected by global climate change (Ding et al., 2014; Gong et al., 2018).

**Atlas.5.1.1.2 Findings from previous IPCC assessments**

The findings of the IPCC AR5 (Christensen et al., 2013) stated that the EASM and EAWM circulations have experienced an inter-decadal scale weakening since the 1970s, leading to a warmer climate in winter and enhanced mean precipitation along the Yangtze River Valley (30°N) but deficient mean precipitation in North China in summer. Since the middle of the 20th century, it is likely that there has been an increasing trend in winter temperatures across much of Asia (Christensen et al., 2013). The numbers of cold days and nights have decreased and the numbers of warm days and nights have increased over Asia (Hartmann et al., 2013). It is likely that there are decreasing numbers of snowfall events where increased winter temperatures have been observed (Hartmann et al., 2013). The SRCCL reports a land-use change induced cooling as large as –1.5°C in eastern China between 1871 and 2007 (Hartmann et al., 2013). The summer rainfall amount over East Asia shows no clear trend during the 20th century.

The IPCC AR5 (Christensen et al., 2013) reports a significant increase in mean temperatures in southeastern China, associated with a decrease in the number of frost days under the SRES A2 scenario. The CMIP5 model projections indicate an increase of temperature in both boreal winter and summer over East Asia for RCP4.5. Based on CMIP5 model projections, there is medium confidence in an intensified EASM and increased summer precipitation over East Asia. More than 85% of CMIP5 models show an increase in mean precipitation of the EASM, while more than 95% of models project an increase in heavy precipitation events (Christensen et al., 2013). SROCC states that future projections of annual precipitation indicate increases of the order of 5% to 20% over the 21st century in many mountain regions, including the Himalaya and East Asia (Hock et al., 2019b). SR1.5 reports that statistically significant changes in heavy precipitation between 1.5°C and 2°C of global warming are found in East Asia (Hoegh-Guldberg et al., 2018).

**Atlas.5.1.2 Assessment and synthesis of observations, trends and attribution**

Summer (June-August) mean temperature in Eastern China has increased by 0.82°C since reliable observations were established in the 1950s (Sun et al., 2014). Based on historical meteorological observations, the best estimate of the linear trend of annual mean surface air temperature (SAT) for China with 95% uncertainty ranges is 0.38 ± 0.05°C per decade for 1979–2015 (Li et al., 2017). From 1960 to 2010, the increasing trend of temperature was about 0.34°C per decade in the arid region of northwest China, higher than the average over China (Li et al., 2012a; Xu et al., 2015). Over South Korea, warming is 1.4–2.6 times larger than global trends. The increase is 1.90°C during 1912–2014 and 0.99°C during 1973–2014 (Park et al., 2017) with a 25–45% urbanization contribution. The annual temperature increased in large cities

Do Not Cite, Quote or Distribute
Precipitation trends over East Asia show considerable regional differences (medium confidence). Mean precipitation has shown negligible sensitivity to the warming trend with consequently limited overall trends in China though summer rainfall daily frequency and intensity show respectively decreasing and increasing trends from 1961 to 2014 (Zhou and Wang, 2017). The summer precipitation trends over eastern China display a dipole pattern, characterized by positive anomalies in the central-eastern China along the Yangtze River Valley and negative anomalies in the north China since the 1950s (Section 8.3.2.4.2). This pattern has changed with the enhanced rainfall in the Huaihe River Valley and decreased in the regions south of the middle and lower reaches of the Yangtze River Valley since the 2000s (Liu et al., 2012; Zhao et al., 2015). The climate in northwest China changed from ‘warm-dry’ to ‘warm-wet’ condition in the mid-1980s (Peng and Zhou, 2017; Wang et al., 2020), with an increase rate of annual precipitation of about 3.7% per decade from 1961 to 2015 (Wu et al., 2019a) and 11.2 mm per decade between 1960 and 2011 in northern Xinjiang (Xu et al., 2015). Mean rainfall and the number of rainy days during the Meiyu-Baiu-Change period from June to September have increased during 1973–2015 in Korea (Lee et al., 2017). The precipitation trend has caused a large increase in summer precipitation at a rate of 40.6 ± 4.3 mm per decade, resulting in an increase of annual precipitation of 27.7 ± 5.5 mm per decade in South Korea from 1960 to 2012 (Kim et al., 2016b). Precipitation amounts exhibited a slight decrease at both the annual and seasonal scales in Japan for the period 1901–2012 (Duan et al., 2015).

Agriculture intensification through oasis expansion in Xinjiang region has increased summer precipitation in the Tianshan mountains (Zhang et al., 2009, 2019b; Deng et al., 2015; Guo and Li, 2015; Yao et al., 2016; Xu et al., 2018; Cai et al., 2019) (high confidence from medium evidence with high agreement). However, there is very low confidence of the effect of oasis expansion on the temperature warming trend (Han and Yang, 2013; Li et al., 2015; Yuan et al., 2017).

In the context of climate warming, intense snowfalls have hit China frequently in recent winters and have caused severe damages to the sustainability of the society (Sun et al., 2019). Observations generally show a decrease in the frequency and an increase in the mean intensity of snowfalls in north-western, north-eastern and south-eastern China and the eastern Tibetan Plateau since the 1960s (Zhou et al., 2018), but the results may depend on the objective criteria for identifying wintertime snowfall (Luo et al., 2020a).

**Atlas 5.1.3. Assessment of model performance**

Current climate models perform poorly in simulating the mean precipitation in East Asia, including the phase of the northward progression of the seasonal rain band (Zhang et al., 2018b). Although there has been an improvement in the simulation of mean states, interannual variability, and past climate changes in the progression from CMIP3 to CMIP5, some previously documented biases (such as the ridge position of the western North Pacific Subtropical High and the associated rainfall bias) are still evident in CMIP5 models (Sperber et al., 2013; Zhou et al., 2017). Most models capture the main characteristics of the winter mean circulation over East Asia reasonably well, but they still suffer from difficulty in predicting the interannual
variability of the EAWM (Shin and Moon, 2018). Models have improved from CMIP5 to CMIP6 for climatological temperature and EAWM (Jiang et al., 2020a). Some CMIP6 models also show improvements in simulating the annual mean and interannual variation of precipitation (Sellar et al., 2019; Tatebe et al., 2019; Wu et al., 2019b). The performance of models is sensitive to cumulus convection schemes and horizontal resolution (Haarsma et al., 2016; Wu et al., 2017; Kusunoki, 2018b). High-resolution atmospheric general circulation models (AGCM) successfully reproduce the intensity and the spatial pattern of the EASM rainfall (Li et al., 2015; Yao et al., 2017; Ito et al., 2020a) and improve the simulation of the diurnal cycle of precipitation rates and the probability density distributions of daily precipitation over Korea, Japan and northern China (Lin et al., 2019), but increasing horizontal resolution (at the typical scales used in GCMs) is not always a panacea for solving model biases (Roberts et al., 2018).

Recent studies using CORDEX-EA models with resolution about 12–25 km showed that the RCMs produce relatively more detailed regional features of the temperature distribution compared with the driving GCMs (Tang et al., 2016). Over China, RCMs provide more spatial details and in general reduce the biases of their driving GCMs, in particular in DJF (December–January–February) and over areas with complex topography (Wu and Gao, 2020). However, RCMs also show biases in simulating East Asian precipitation and its variability (Park et al., 2016; Zhou et al., 2016; Zou and Zhou, 2016), and do not always show added value compared to the driving GCMs (Li et al., 2018a). For example, by comparing inter-GCM and inter-RCM differences around the Japan archipelago, it was found that RCM generate relatively large differences in precipitation (Suzuki-Parker et al., 2018). The RCM multi-model ensemble produces superior simulation compared to that of a single model (Jin et al., 2016; Guo et al., 2018a). A comparative study of RCMs at different spatial resolutions showed with coarse-resolution they present some limitations and high-resolution RCMs offer added value for several evaluation metrics (Park et al., 2020).

**Assessment and synthesis of projections**

The development of climate models provides a solid basis for projection of future monsoon changes under different global warming scenarios. Coupled model simulations indicate that East Asia will likely experience higher warming than the global mean conditions across all global warming levels (Figure Atlas.17:) and with the projected warmer greater in ECA than EAS. Also, in the CMIP6 ensemble, the multi-model mean and 90th percentile warming for a given period and emissions scenario are consistently greater than in the CMIP5 ensemble. Larger warming magnitudes are projected to occur in the southern, north-western, and north-eastern regions of China, parts of Mongolia, the Korean Peninsula, and Japan than in other regions (Li et al., 2018b). Projections indicated that the winter SAT increases over the East Asian continent, and the precipitation increases over the northern East Asian continent in winter reaching 1.5°C and 2.0°C global warming under the RCP4.5 and RCP8.5 scenarios (Miao et al., 2020).

Projected annual precipitation changes in the CMIP5 and CMIP6 ensembles are positive for all warming levels in ECA and for the higher warming levels in EAS. Changes in precipitation per degree Celsius global warming are larger in DJF than in JJA in ECA but show smaller seasonal difference in EAS (Figure Atlas.17). The EASM precipitation is projected to increase but with a complex spatial structure (Kitoh, 2017; Moon and Ha, 2017). Simulations from CMIP5 models show that compared with the current summer climate, both SAT and precipitation increase significantly over the East Asian continent during the 1.5°C warming period (Chen et al., 2019a), and the main mode of EASM precipitation changing from tripolar to dipolar (Wang et al., 2018). The increase in precipitable water in the wet EASM region is only slightly greater than global average but the increase in precipitation is much greater (Li et al., 2019b). The monsoon circulation in the lower troposphere is projected to strengthen due to the enhanced thermal forcing by the Tibetan Plateau (He et al., 2019; He and Zhou, 2020), which causes the increased summer precipitation over the East Asian continent. Precipitation over eastern China increases for almost all months under global warming in projections from GCMs with different horizontal resolutions (Kusunoki, 2018a). Also, under RCP scenarios, in the 21st century, mean precipitation is projected to increase (Kim et al., 2020) especially in the late afternoons (Oh and Suh, 2018) over the Korean Peninsula due to global warming and associated changes in EASM. Increase in JJA mean precipitation is projected in northern East Asia consistently among the CMIP models, while northward migration of early summer East Asian rain band such as the Meiyu-Baiu-
Changma is delayed along with that of the mid-latitude westerly jet in the future (Horinouchi et al., 2019). However, the geographical distribution of precipitation change tends to depend more on the cumulus convection scheme (Ose, 2017) and horizontal resolution of models rather than on SST distributions. Under the RCP4.5 and the RCP8.5 scenarios, the interannual variability in EASM rainfall is projected by the multi-model ensemble mean to increase in the 21st century (Ren et al., 2017). Further studies showed a projected increase in heavy rainfall together with increases in rainfall intensity (Endo et al., 2017). Multi-model intercomparison indicates significant uncertainties in future projections of climate change in East Asia, although precipitation increases consistently across models (Zhou et al., 2017). Simulations under RCP4.5 scenario project that the number of snow days will be reduced by the end of the 21st century relative to 1986–2005, primarily owing to the decline of light snowfall events. The total amount is projected to increase in north-western China but decrease in the other subregions (Zhou et al., 2018).

The increasing temperature trends under RCP scenarios were consistently reproduced in projections using CORDEX-EA models (Kim et al., 2016b) as reported in AR5 using GCMs. However, changes in annual and seasonal mean precipitation exhibit significant inter-RCM differences with larger magnitudes and variability than in the GCMs (Ham et al., 2016; Ozturk et al., 2017; Sun et al., 2018a; Zhang et al., 2018a). RCM simulations project that the Meiyu-Baiu-Changma heavy rainfall will significantly increase in northern Japan at the end of the 21st century under the RCP8.5 scenario (Osakada and Nakakita, 2018), but projected precipitation amount and number of precipitation days in summer around and over Japan differ as a result of RCM uncertainty (Suzuki-Parker et al., 2018). Annual total snowfall is projected to decrease in most parts of Japan except for Japan's northern island under RCP2.6 (Kawase et al., 2021).

Statistically downscaling of 37 CMIP5 GCMs for Xinjiang, China projected pronounced temperature increase of 0.27°C to 0.51°C per decade from 2021 to 2060 while precipitation change was projected to be between −1.7% to 6.8% per decade and varying seasonally and spatially (Luo et al., 2018). A decrease of precipitation was projected in the western region of Xinjiang during summer. More extreme rainfall events were projected to occur during summer and autumn.

**Atlas.5.1.5 Summary**

In East Asia annual mean temperature has been increasing since the 1950s (high confidence). The linear trend of annual mean surface air temperature likely exceeded 0.1°C per decade over most of East Asia from 1960 to 2015. Trends of annual precipitation show considerable regional differences with areas of both increases and decreases (medium confidence) and with increases over northwest China and South Korea (high confidence). Agricultural intensification through oasis expansion in Xinjiang region has increased summer precipitation in the Tianshan mountains (high confidence).

GCMs still show poor performance in simulating the mean rainfall and its variability over East Asia, especially over regions characterized by complex topography. The CMIP6 models have improved from CMIP5 for climatological temperature and winter monsoon but show little improvements for the summer monsoon. The RCMs produce relatively more detailed regional features, but do not always produce superior simulations compared with the driving GCMs.

The annual mean surface temperature over East Asia will very likely increase under all emissions scenarios and global warming levels. Larger warming magnitudes will likely occur in the northern part of EAS and in ECA. Precipitation is likely to increase over land in most of EAS at the end of the 21st century under higher emissions scenario (SSP3-7.0, RCP8.5, SSP5-8.5) and global warming levels and in ECA under all emissions scenarios and global warming levels. Summer precipitation increase is likely to occur in East Asia, corresponding to the strengthened summer monsoon circulation.
Atlas.5.2 North Asia

Atlas.5.2.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.5.2.1.1 Key features of the regional climate

North Asia extends from the Ural Mountains in the west to the Pacific Ocean in the east and from the
Russian Arctic in the north to Southwest Asia and East Asia in the south. Its most recognizable features are
boreal forests and permafrost. In AR6 North Asia is divided into three reference regions (Figure Atlas.17):
West Siberia (WSB) with a continental climate, warm summers and cold winters, many waterlogged areas
and several natural zones due to a large extent from south to north and heterogeneity in regional climates;
East Siberia (ESB) which is mainly highland with extensive permafrost and a more severe continental
climate characterised by harsh, long winters and short, hot summers, and by less precipitation and snow
cover than in neighbouring regions; and the Russian Far East (RFE) with a monsoon-influenced climate, cold
winters and wet summers in the south and cold winters and cool summers almost without precipitation in the
north. WSB and ESB are mainly influenced by NAO and NAM (Annex IV.2.1) and AO with associated
atmospheric blocking by the Siberian High that exhibits a pronounced decadal-to-multidecadal variability
(see also Table Atlas.1). RFE is under the influence of the ENSO (Annex IV.2.3) and the PDV (Annex
IV.2.6) that mostly affect rainfall variability.

Atlas.5.2.1.2 Findings from previous IPCC assessments

In the previous IPCC assessment cycles, the three subregions comprising North Asia in this section along
with Eastern Europe and the Asian Arctic were considered as either Northern Eurasia or Russia in AR4 and
AR5. WGI AR5 stated that for North and Central Asia CMIP5 models had difficulty in representing
climatological means of both temperature and precipitation, which is partly related to the scarceness of
observational data in northern parts of the region and to issues related to the estimation of biases with coarse
resolution models (Christensen et al., 2013). In CMIP3 projections under different RCP scenarios, North
Asia temperatures increase more in winter (DJF) than summer (JJA) (Seneviratne et al., 2012). With most
models projecting increased precipitation significantly above the 20-year natural variability, it was
concluded that precipitation in northern Asia will very likely increase (Christensen et al., 2013).

SRCCL identified aridisation of the climate in southern Eastern Siberia between 1976 and 2016 as causing
an extension of the steppes polewards whilst climate change also extended the vegetation season, increasing
forest productivity in most of boreal Siberia, but increasing risk of wildfire and tree mortality (Mirzabaev et
al., 2019). SROCC noted the warming climate has caused permafrost thaw and loss of ground ice, and thus
land subsidence and collapse, disturbing ecosystems and human infrastructure. Permafrost stability,
hydrology and vegetation were also impacted by recent extensive fires burning into the organic soil layer
(Meredith et al., 2019). SR1.5 noted that future, higher levels of warming lead to greater impacts in key
systems such as the Siberian ecosystems, identified as one of the threatened systems (‘Reason for Concern 1
– RFC1’) (Hoegh-Guldberg et al., 2018) with impacts at 2°C expected to be greater than those at 1.5°C
(medium confidence).

Atlas.5.2.2 Assessment and synthesis of observations, trends and attribution

 Increases in surface air temperature (SAT) have been observed since the mid-1970s over the whole of North
Asia (Frolov et al., 2014), and particularly over the north-eastern part (Gruza et al., 2015) (see also Figure
Atlas.18). Trends of annual SAT in the northern part of the region during the last decades were very likely
twice as strong as the global average (Figure Atlas.11) (Frolov et al., 2014; Mokhov, 2015; Sherstyukov,
2016) with trends in RFE of 0.8°C–1.2°C per decade for the 1976–2014 period and more intense warming
strengthening from south to north observed in spring in ESB (Frolov et al., 2014; Ippolitov et al., 2014;
Kokorev and Sherstiukov, 2015).

Recent strong warming in polar regions (Section Atlas.11.2) was accompanied by cooling in winter in mid-
latitude regions particularly in the southern part of WSB and ESB (Cohen et al., 2014; Ippolitov et al., 2014;
These temperature decreases were strongly correlated with significant warming over the Barents-Kara Sea (greater than 2.5°C per decade during 2003–2017) and sea-ice loss suggesting a causal link (Outten and Esau, 2012; Semenov et al., 2012; Overland et al., 2016; Semenov, 2016; Wegmann et al., 2018; Meleshko et al., 2019; Susskind et al., 2019) though recent studies (Blackport et al., 2019; Clark and Lee, 2019) have shown that both phenomena result from mid-latitude circulation variability (see also Cross-Chapter Box 10.1). In addition, significant warming in the last decade has halved the cooling trend in southern WSB from −0.6°C per decade during 1976–2012 to −0.3°C per decade during 1976–2018 (Frolov et al., 2014; Roshydromet, 2019) (high confidence).

Annual precipitation totals very likely increased over North Asia in the last half century along with more heavy and less light precipitation, more freezing rain and less freezing drizzle (Wen et al., 2014; Groisman et al., 2016; Ye et al., 2017; Chernokulsky et al., 2019) (see Figure Atlas.11 and Interactive Atlas). The highest increase was observed over regions of Siberia and RFE with estimated trends of 10–25 mm per decade for the 1976–2014 period (Kokorev and Sherstiukov, 2015) or 5% per decade for the 1976–2018 period (Roshydromet, 2019). Increases over southern RFE are the largest (over 50 mm per decade) and mostly due to positive changes in convective precipitation intensity in the region in summer season (JJA) during 1966–2016 (medium confidence) (Chernokulsky et al., 2019). A decreasing trend was observed in central WSB, northern ESB, the Baikal and Transbaikal regions, the Amur River region, and Primorje territories of RFE (the Kamchatka and Chukchi Peninsulas) with up to −20 mm per decade for the 1976–2014 period (Kokorev and Sherstiukov, 2015) or 15–20% per decade for the 1976–2018 period (Roshydromet, 2019). Overall, solid precipitation predominantly decreased in North Asia and very likely caused both less Snow Cover Extent (SCE) and Snow Water Equivalent (SWE), attributable to the anthropogenic influence with high confidence (Sections 2.3.2.2, 3.4.2).

Snow characteristics depend on both temperature and precipitation, and observed trends over North Asia show large spatial heterogeneity and interannual variability (Figure Atlas.13) leading to medium confidence. The highest trend in maximum snow depth has increased over Siberia, the Okhotsk sea coast and in southern RFE since 1960s (Callaghan et al., 2011; Loginov et al., 2014), with trends during 1976–2016 of 1.8 cm (in WBS), 1.1 cm (in ESB), and 4.6 cm (in RFE) per decade (Bulygina et al., 2017). Snow cover duration increased in Yakutia, Sakhalin Island and some other coastal areas of the Pacific Ocean in RFE during 1980–2009 (Callaghan et al., 2011) and decreased in WSB and ESB (Bulygina et al., 2017; Roshydromet, 2019). However, Gorbatenko et al. (2019) reported that in southeastern WSB maximal snow depth has increased by 5–20 cm and duration of steady snow cover by between 4 and 10 days during 1989–2016 (Figure Atlas.18).

[START FIGURE ATLAS.18 HERE]

Figure Atlas.18: Linear trends for the 1980–2015 period based on station data from the World Data Centre of the Russian Institute for Hydrometeorological Information (RIHMI-WDC) (Bulygina et al., 2014). (a) Snow season duration from 1 July to 31 December (days per decade); (b) snow season duration from 1 January to 30 June (days per decade); (c) maximum annual height of snow cover (mm per decade). Trends have been calculated using ordinary least squares regression and the crosses indicate nonsignificant trend values (at the 0.1 level) following the method of Santer et al. (2008) to account for serial correlation. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.18 HERE]

Atlas.5.2.3 Assessment of model performance

Temperature trends and means derived from reanalysis datasets (JRA-25, MERRA) correctly represented temperature variability shown in observational data over the Asian territory of Russia for the 1976–2010 period (Loginov et al., 2014). Assessment of CRU TS 3.22, CRUTEMP4, ERA-Interim and NCEP2 datasets against station data over North Asia for annual and seasonal air temperature has shown that the ERA-Interim...
GCMs capture the main synoptic processes affecting North Asia and the CMIP5 ensemble simulates the temporal evolution of the magnitude and position of the Siberian High (SH) over the period 1872–2005 (Fei and Yong-Qi, 2015). CMIP5 models simulate a weakened intensity of the winter SH and a strengthened interannual variability compared to observations (Fei and Yong-Qi, 2015). The characteristics of blocking events over the region (number, duration, intensity and frequency) were reasonably well reproduced by GCMs (Mokhov et al., 2014) and most overestimate the annual mean temperature over northern Eurasia (Interactive Atlas). Biases in simulated annual surface air temperature simulation primarily come from winter (DJF) season and are relatively smaller in other seasons (Miao et al., 2014; Peng et al., 2019). Most GCMs capture the main decadal SAT trend (Miao et al., 2014) though CMIP5 GCMs fail to capture the decreasing temperature trend over East Siberia (Fei and Yong-Qi, 2015). Possible causes of GCMs inability to represent the recent slowdown of warming is discussed more in Cross-Chapter Box 3.1. For CMIP5, models with higher resolution do not always perform better than those with lower resolutions (medium confidence) (Miao et al., 2014).

Sixteen CMIP5 model simulations of SAT variability over Eurasia were evaluated against CRU observations for permafrost subregions (Peng et al., 2019), showing a warm bias in northwest Eurasia capturing the climate warming over the 20th century and its acceleration during the late 20th century. CMIP5 GCMs generally underestimate daily temperature range compared with observations over north-eastern Russia (Sillmann et al., 2013; Lindvall and Svensson, 2015). Currently there is no literature on the CMIP6 ensemble over the region though a few single-model studies are available (Voldoire et al., 2019; Wu et al., 2019b).

There is very limited use of RCMs for North Asia. CORDEX-CAS covers North Asia except parts of RFE and ARCTIC-CORDEX the northern regions (Figure Atlas.6). For CORDEX-CAS three RCMs (REMO, ALARO-0 and CLMcom) have been used and have warm biases for maximum temperatures, cold biases for minimum temperatures and a wet bias in the north during the winter (Top et al., 2021). Rain gauges, however, are known to have problems in terms of measuring properly solid precipitation (e.g., drifting snow) which can greatly affect the accuracy of precipitation observations over North Asia (Harris et al., 2014).

Atlas.5.2.4 Assessment and synthesis of projections

CMIP5 and CMIP6 projections are consistent in the direction and ranges of surface temperature change which are higher than the global average and with ensemble mean warming of around 6°C for the 4°C GWL. Projected precipitation changes are also consistent with significant increases in winter, of up to 40% in the ensemble mean for the highest warming levels, and lower increases in summer except for WSB where changes are small and suggest drying at the 4°C GWL (Figure Atlas.17; Interactive Atlas).

The CMIP5 ensemble projects a warming of the annual mean SAT over northern Eurasia in the 21st century, likely in the range of 0.8°C–1.0°C (RCP2.6), 2.3°C–3.1°C (RCP4.5) and up to 7.2°C (RCP8.5) (Miao et al., 2014; Peng et al., 2019). Mid-latitude permafrost subregions in Eurasia are projected to warm more than the global mean and non-permafrost territories, with ensemble area-averaged changes of 1.7°C (RCP2.6), 3.2°C (RCP4.5) or 6.4°C (RCP8.5) in 2081–2100 relative to 1986–2005 (Peng et al., 2019).

Over the Central Asia CORDEX domain, RegCM4.3.5 simulations driven by two different CMIP5 GCMs (HadGEM2-ES and MPI-ESM-MR) project SAT warming for 2071–2100 relative to 1971–2000 of about 3°C–4°C during the summer for RCP4.5 to over 7°C for all seasons for RCP8.5. Projected warming is most evident on the large continental Siberian Plateau with boreal and sub-boreal climates and biomes (i.e., taiga forests and tundra) during the winter season (Ozturk et al., 2017). The Voeikov Main Geophysical Observatory (MGO) RCM, driven by five CMIP5 GCMs for the RCP8.5 scenario, projects a faster increase
in annual minimum temperature as compared with maximum temperature over the whole territory of Russia (Kattsov et al., 2017), and the smallest change in growing season lengths (i.e., periods with daily temperatures over 5°C, 10°C and 15°C) in the area of northern taiga in WSB and ESB comparable with other territories of Russia during the 21st century (Torzhkov et al., 2019).

For precipitation, MGO RCM projections for the Arctic-CORDEX domain under the RCP8.5 scenario are for increases in annual totals for northern North Asia, a decrease in summer over ESB for 2006–2100 relative to 1951–2005 and significant increases in the upper limit of intense precipitation over most of the region in winter (Kattsov et al., 2017; Khlebnikova et al., 2018). Other RCM projections show that in most seasons and for all future periods, precipitation in Siberia is not projected to change with respect to the 1971–2000 period, except under the RCP8.5 scenario for the winter and autumn (Öztürk et al., 2017). This very limited and controversial evidence leads to low confidence in RCM precipitation projections for North Asia and since the projections of GCMs and ESMs are more physically consistent, assessment of future precipitation changes is based on CMIP5/CMIP6 presented in Figure Atlas.17: and the Interactive Atlas.

Atlas.5.2.5 Summary

Annual surface air temperature and precipitation have very likely increased and maximum snow depth has likely increased over most of North Asia since the mid-1970s. The highest warming has been found in spring in ESB and RFE, strengthening from south to north with linear trends of 0.8°C–1.2°C per decade over the 1976–2014 period (high confidence). A temperature decrease was identified just in winter in the southern part of WSB and ESB as a result of natural variability, but halved from −0.6°C per decade in 1976–2012 to −0.3°C per decade for the longer 1976–2018 period due to recent warmer winters (high confidence). Over North Asia annual precipitation increases with estimated trends of 5–15 mm per decade in the 1976–2014 period have been recorded with an exception over the Kamchatka and the Chukchi Peninsulas where decreases up to −20 mm per decade in the same period have been found (medium confidence). Snow cover duration has very likely decreased over Siberia and increases in maximum snow depths of 1.8 cm, 1.1 cm, and 4.6 cm per decade have been observed for WSB, ESB, and RFE respectively from 1976 to 2016 (limited evidence).

Most of the CMIP5 and some CMIP6 GCMs overestimate the annual mean air temperature and precipitation over North Asia region (medium confidence). GCMs generally represent the observed decadal temperature trend (medium confidence) and biases primarily come from the winter (DJF) season (high confidence). Results of a very limited number of RCMs applied over the whole region show that they have warmer biases for maximum and colder biases for minimum temperatures (medium agreement, limited evidence). Sparsity of observational data particularly in the northern part of ESB and the whole of the RFE results in low confidence in the assessments of model performance in North Asia.

Surface air temperature and precipitation in North Asia are projected to increase further (high confidence) with warming higher than the global average and around 6°C at the 4°C GWL. Temperature change in 2080–2099 relative to 1981–2000 is likely in the range of 3°C in summer to 4.9°C in winter under the RCP4.5 scenario, and 5.6°C in summer to 9.7°C in winter under the RCP8.5 scenario. Precipitation is projected to increase with ensemble mean changes of 9% in summer under both RCP4.5 and RCP8.5 and of 22% and 56% in winter respectively.

Atlas.5.3 South Asia

Atlas.5.3.1 Key features of the regional climate and findings from IPCC previous assessments

Atlas.5.3.1.1 Key features of the regional climate

The countries in this region are mostly semi-arid to arid and therefore depend heavily on the summer monsoon (June–September, JJAS) which is when most of the precipitation falls over the South Asia region (SAS) (Figure Atlas.17):. The topographic mechanical effect of the Tibetan Plateau (TIB) promotes moisture
convergence downstream which triggers the early summer monsoon onset particularly over the Bay of Bengal and South China. In winter, Westerly Disturbances (WD) bring moisture from the Atlantic Ocean. The WD interaction with Himalayas causes precipitation over northern and western parts of South Asia that is crucial to maintain the glacier mass balance. The observed teleconnection patterns over SAS for temperature shows cooling effects during NAM and warming effect when in positive phase with ENSO, IOB, AMM and AMV (Annex IV). IOD also influences South Asian precipitation (Annex IV).

**Atlas.5.3.1.2 Findings from previous IPCC assessments**

Recent IPCC reports assessed that it is very likely that the mean annual temperature over South Asia has increased during the past century (Figure 2.21 in Hartmann et al., 2013, Figure 24-2 in Hijioka et al., 2014), and the frequency of cold (warm) days and nights have decreased (increased) across most of Asia since about 1950 (Figure 2.32 in Hartmann et al., 2013). AR5 assessed that there is high confidence that the large-scale patterns of surface temperature are generally well simulated by the CMIP5 models through with problems in some regions, particularly at higher elevations over the Himalayas (Flato et al., 2013). CMIP5 models projected for the 21st century a significant increase in temperature over South Asia (high confidence from robust evidence) and in projections of increased summer monsoon precipitation (medium confidence) (Collins et al., 2013). AR5 assessed there is high confidence that high-resolution regional downscaling, which generate results complementary to those from global climate models, adds value to the simulation of spatial variations in climate in regions with highly variable topography (e.g., distinct orography, coastlines), and for mesoscale phenomena and extremes (Flato et al., 2013).

Inconsistent evidence was found on the declining trends in mean precipitation and increasing droughts from 1950 onwards considering 1960–1990 as the baseline period. Similarly, SREX (Table 3-3 in Seneviratne et al., 2012) reported low confidence (due to lack of literature) in trends in climate indices related to extreme precipitation events. The Indian summer monsoon circulation was found to have weakened, but this was compensated by increased local atmospheric moisture content leading to more rainfall (medium confidence). It is likely that the occurrence of snowfall events is decreasing in South Asia along with other regions due to an increase in winter temperatures (Hock et al., 2019b). Based on satellite- and surface-based remote sensing it is very likely that aerosol optical depth has increased over southern Asia since 2000.

**Atlas.5.3.2 Assessment and synthesis of observations, trends and attribution**

Recent studies show that annual mean land temperatures over India warmed at a rate of around 0.6°C per century during 1901–2018, which was primarily contributed by a significant increase in annual maximum temperature of 1.0°C per century, while the annual minimum temperature showed a lesser increasing trend of 0.18°C per century during this period, with significant rise only in the recent few decades (1981–2010) at a rate of 0.17°C per decade (Srivastava et al., 2017, 2019). The annual average of daily maximum and minimum temperatures has increased over almost all Pakistan with a faster increasing trend in the south (high confidence). Minimum temperatures have increased faster (0.17°C–0.37°C per decade) than maximum temperatures (0.17°C–0.29°C per decade) with the diurnal temperature range reduced (−0.15°C to −0.08°C per decade) in some regions (Khan et al., 2019).

There has been a noticeable declining trend in rainfall with monsoon deficits occurring with higher frequency in different regions in South Asia (see also Section 8.3.2.4 on the South Asian monsoon). Concurrently, the frequency of heavy precipitation events has increased over India, while the frequency of moderate rain events has decreased since 1950 (high confidence) (Goswami et al., 2006; Dash et al., 2009; Christensen et al., 2013; Krishnan et al., 2016; Kulkarni et al., 2017; Roxy et al., 2017). There is a considerable spread in the seasonal and annual mean precipitation climatology and interannual variability among the different observed precipitation datasets over India (Collins et al., 2013; Prakash et al., 2014; Kim et al., 2018; Ramarao et al., 2018). Yet, the regions of agreement among datasets lend high confidence that there has been a decrease in mean rainfall over most parts of the eastern and central north regions of India (Singh et al., 2014; Roxy et al., 2015; Juneng et al., 2016; Krishnan et al., 2016; Guhathakurta and Revadekar, 2017; Jin and Wang, 2017; Latif et al., 2017). A global modelling study with high resolution
over South Asia (Sabin et al., 2013) indicated that a juxtaposition of regional land-use changes,
anthropogenic-aerosol forcing and the rapid warming signal of the equatorial Indian Ocean was crucial to
simulate the observed Indian summer monsoon weakening in recent decades (medium confidence).

A dipole-like structure in summer monsoon rainfall trends is observed over the northern Indo-Pakistan area
with significant increases over Pakistan and decreases over central north India resulting from strengthening
(weakening) of vertically integrated meridional moisture transport over the Arabian Sea (Bay of Bengal)
(low confidence) (Latif et al., 2017). Positive annual precipitation trends are observed in global and regional
datasets (Figure Atlas.11: and Interactive Atlas) during 1960–2015 and over arid provinces of Pakistan (for
Rabi and Kharif cropping seasons) during 1951–2015 of 2.8–34.8 mm per decade (Khan et al., 2020) imply
high confidence for increased precipitation in Pakistan. Observations located in the monsoon-dominated strip
in Pakistan indicate that the mean monsoon onset became earlier during 1971–2010 (Ali et al., 2020).

Snow and glaciers are the main water resources of all countries in South Asia. Glacier melting is mainly
controlled by natural phenomena but anthropogenic emissions of black carbon (BC) are now making a
significant contributing to total glacial melting in the Hindu Kush Himalaya (HKH) region (Menon, 2002;
Ramanathan et al., 2007; Ramanathan and Carmichael, 2008). BC concentration is seven to ten times higher
in mid-altitudes (1000–4000 metres above sea level) than at high altitudes (>4000 metres above sea level).
The concentration of BC sampled from the surface of snow/ice samples as well as ice core records shows
decreasing ice albedo and an acceleration in glacier melting (Wester et al., 2019) (see also Cross Chapter
Box 10.4). Karakoram and western HKH snow cover is increasing, a phenomena known as the ‘Karakoram
anomaly’, and partially attributed to an increase in strength of westerly disturbances (Wester et al., 2019).

Significant glacier retreat has been observed since 1960 in TIB with lower rates in the interior of the region
(Yao et al., 2007). A large interdecadal variation in snow cover is also observed from 1960 to 2010.
Observations and model simulations showed that the increasing temperature of frozen grounds is leading to
thawing and reduced depth of permafrost, with further significant reductions projected under future global
warming scenarios (Yang et al., 2019) (medium confidence).

Atlas.5.3.3 Assessment of model performance

Whilst simulations of Indian summer monsoon rainfall (ISMR) have improved in CMIP5 compared to
CMIP3 in terms of northward propagation, time for peak monsoon and withdrawal (Sperber et al., 2013)
they fail to simulate the trends in monsoon rainfall and the post-1950 weakening of monsoon circulation
(Saha et al., 2014). This is partially attributed to the failure of coarse resolution CMIP5 models to simulate
fine-resolution processes such as orographic effects or land surface feedback, and problems in cloud
parameterization result in an overestimation of convective precipitation fraction (Singh et al., 2017a). In
CMIP6, a significant improvement is found in capturing the monsoon spatiotemporal patterns over India,
particularly in the Western Ghats and north-eastern Himalayan foothills (Gusain et al., 2020). Over Pakistan
the CMIP6 models simulate surface temperature better in JJA than DJF (Karim et al., 2020). The CMIP6
ensemble underestimates annual mean temperature over all of South Asian with mixed results for
precipitation (Almazroui et al., 2020c). The CMIP6 GCMs have a large cold bias in both mean annual
maximum and minimum temperatures in the complex Karakorum and Himalayan mountain ranges but
exhibit warm biases in mean annual minimum temperature in most of the rest of South Asia.

Regional climate model (RCM) downscaling of CMIP5 models as part of CORDEX South Asia uses higher
resolution (50 km) and improved surface fields such as topography and coastlines to resolve better the
complexities of the monsoon and other hydrological processes (Giorgi et al., 2009). The added value of their
simulations, relative to the driving GCMs, presents a complex picture. CORDEX RCMs better represent
spatial patterns of temperature (Sanjay et al., 2017), the spatial features of precipitation distribution
associated with the Indian summer monsoon (Choudhary and Dimri, 2018) and the simulation of monsoon
active- and break-phase composite precipitation (Karmacharya et al., 2016). The RCMs follow the driving
GCMs in underestimating seasonal mean surface air temperature and overestimating spatial variability in
precipitation. They amplify CMIP5 cold biases over almost the entire region, including over the HKH
region, Afghanistan and southwest Pakistan during winter (Iqbal et al., 2017) and substantial cold biases of
6°C–10°C are found over the Himalayan watersheds of the Indus Basin (Nengker et al., 2018; Hasson et al.,
2019). Neither RCMs nor their driving CMIP5 GCMs reproduce well the region’s precipitation climatology
(Mishra, 2015). In addition, important characteristics of ISMR such as northward and eastward propagation,
onset, seasonal rainfall patterns, intra-seasonal oscillations and patterns of extremes did not show consistent
improvement (Singh et al., 2017b). Also, these RCM simulations have not demonstrated added value in
capturing the observed changes in ISMR characteristics over recent decades though RegCM4 simulations at
25 km showed high accuracy in capturing monsoon precipitation characteristics and atmospheric dynamics
in historical simulations (Ashfaq et al., 2020).

Evaluation of four global reanalysis products (ERA5 and ERA-Interim, JRA-55 and MERRA-2, Section
Atlas.1.4.2) for snow depth and snow cover over the TIB was performed against 33 in situ station
observations, Interactive Multisensor Snow and Ice Mapping System (IMS) snow cover and a satellite
microwave snow depth dataset (Orsolini et al., 2019). Most of the reanalyses showed a systematic
overestimation. Only ERA-Interim assimilated IMS snow cover at high altitudes, whereas ERA5 did not and
the excessive snowfall, snow depth and snow cover in ERA5 was attributed to this difference. The analysis
of annual maximum consecutive snow-covered days for the period 1980–2018 over TIB using JRA-55 and
Passive Microwave satellite observations showed decreasing trend in all time periods and in recent snow
seasons for MERRA-2 (Bian et al., 2020). The uncertainty assessment of model physics in snow modelling
over TIB using ground-based observations and high-resolution snow-cover satellite products from the
Moderate Resolution Imaging Spectroradiometer (MODIS) and Feng Yun-3B (FY3B) suggests that errors
can be overcome by optimizing parameterizations of the snow cover fraction rather than optimizing physics-
scheme options (Jiang et al., 2020b).

Atlas.5.3.4 Assessment and synthesis of projections
CMIP5 and CMIP6 surface temperature projections are consistent across the range of global warming levels
with increases greater than the global average, more so over TIB (Figure Atlas.17b). CMIP6 models show
higher sensitivity to greenhouse gas emissions, projecting higher warming for a given emission scenario. The
north-western parts of South Asia, mainly covering Karakorum and Himalayan mountain ranges, are
projected to warm more (over 6°C under SSP5-8.5, with higher warming in winters than in summer, see
Interactive Atlas) and this will accelerate glacier melting in the region. The warming pattern of maximum
and minimum temperatures are projected to intensify in higher latitudes compared with mid-latitudes of
South Asia in CMIP5 simulations for all RCP scenarios (Ullah et al., 2020).

Seasonal precipitation projections show increased winter precipitation over the western Himalayas and
decreased precipitation over the eastern Himalayas. On the other hand, summer precipitation projections
show a robust increase over most of South Asia, with the largest over the arid region of southern Pakistan
and adjacent areas of India, under SSP5-8.5 (Almazroui et al., 2020c). Daily bias-adjusted projections from
13 CMIP6 GCMs using all emission scenarios project a warmer (3°C–5°C) and wetter (13–30%) climate in
South Asia in the 21st century (Mishra et al., 2020).

With continued global warming and anticipated reductions in anthropogenic aerosol emissions in the future,
CMIP5 models project an increase in the mean and variability of summer monsoon precipitation over India
by the end of the 21st century, together with substantial increases in daily precipitation extremes (medium
confidence) (Gnanaseelan et al., 2020), see also Section 8.4.2.4 on changes in the South Asian monsoon. The
CMIP5 GCMs consistently project an increase in the moisture transport over the Arabian Sea and Bay of
Bengal towards the end of 21st century, an increase in moisture convergence and consequent increases in
monsoon rainfall over the Indo-Pakistan region which are higher under RCP8.5 than RCP4.5 (Srivastava and
Delsole, 2014; Mei et al., 2015; Latif, 2017). Out of 20 CMIP5 GCMs, four showed an increase in
magnitude and lengthening of all-India summer monsoon under RCP8.5. The intensity of both strong and
weak monsoons is projected to increase during the period 2051–2099 (Srivastava and Delsole, 2014).

Summer precipitation changes in South Asia are consistent between CMIP3 and CMIP5 projections, but the
model spread is large for winter precipitation changes. Changes in summer monsoon rainfall will dominate:
annual changes over South Asia (Woo et al., 2019). CMIP3 GCMs project a gradual increase in annual precipitation over monsoon-dominated areas of Pakistan throughout the 21st Century and increases in humid and semi-arid climate areas (Saeed and Athar, 2018).

Warming of 2.5°C to 5°C is projected over northern Pakistan and India (Syed et al., 2014). CORDEX-South Asia projections over northeast India under RCP4.5 for the period 2011–2060, show increasing trends for both seasonal maximum and minimum temperature over northeast India (Interactive Atlas). The future projections of South Asian monsoon from the CORDEX-CORE exhibit a spatially robust delay in the monsoon onset, an increase in seasonality, and a reduction in the rainy season length over parts of South Asia at higher levels of radiative forcing (Ashfaq et al., 2020).

With the TIB continuing to warm, snow cover and snow water equivalent are projected to decrease but with regional differences due to synoptic influences (Wester et al., 2019) and Cross-Chapter Box 10.4. There is limited evidence on whether the ‘Karakoram Anomaly’ will persist in coming decades, but its long-term persistence is unlikely with continued projected warming (high confidence) (Section 9.5.1.1). It is projected that peak river flow at higher altitudes will commence earlier, due to warming influences on snow cover area and snow/glacier melt rates and with more precipitation falling as rain rather than snow, and the magnitude and seasonality of flow will change over South Asia (Charles et al., 2016).

Atlas.5.3.5 Summary

Mean, minimum and maximum daily temperatures in South Asia are increasing and winters are getting warmer faster than summers (high confidence). The South Asian monsoon has shown contrasting behaviour over India and Pakistan. There is high confidence that there has been a decrease in mean rainfall over most parts of the eastern and central north regions of India and an increase in precipitation in Pakistan.

Global model performance over the region has improved from CMIP3 to CMIP5 to CMIP6 in the multi-model ensemble mean simulation of the amplitude and phase of the seasonal cycles of temperature and precipitation. However, there was no appreciable improvement in regions with steep orography, and there has remained substantial inter-model spread in seasonal and annual mean temperatures over South Asia with generally cold biases which are largest in the complex Karakorum and Himalayan mountain ranges. CMIP6 GCMs also show a dry bias (15–20%) in mean annual precipitation in the majority of South Asia region with a wet bias in Nepal, Pakistan and northern India.

It is likely that surface temperatures over South Asia (SAS and TIB) will increase greater than the global average, more so over TIB, and with projected increases of 4.6°C (3.4°C– 6.0°C) during 2081–2100 compared with 1995–2014 under SSP5-8.5 and 1.3°C (0.7°C– 2.0°C) under SSP1-2.6 (Interactive Atlas). Summer monsoon precipitation in South Asia is likely to increase by the end of the 21st century while winter monsoons are projected to be drier. Over the same time periods CMIP6 models project an increase in annual precipitation in the range 14–36% under SSP5-8.5 and 0.4–16% under SSP1-2.6 (medium confidence).

With continued warming, TIB snow cover and snow water equivalent are likely to decrease and with more precipitation falling as rain rather than snow in SAS. It is projected that the peak river flow at higher altitudes will commence earlier due to the effect of warming on snow cover and snow/glacier melt rates, causing changes in magnitude and seasonality of flow.

Atlas.5.4 Southeast Asia

Atlas.5.4.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.5.4.1.1 Key features of the regional climate

The Southeast Asia region is composed of countries that are part of Indochina (or mainland Southeast Asia)

Do Not Cite, Quote or Distribute
and countries that are very archipelagic in nature and have strong land-ocean-atmosphere interactions, including those that are part of the Maritime Continent and the Philippines. Its climate is mainly tropical (i.e., hot and humid with abundant rainfall). Rainfall seasonal variability in the region is mainly affected by the synoptic-scale monsoon systems, the north-south migration of the ITCZ and tropical cyclones (mainly for the Philippines and Indochina) while intraseasonal variability can be influenced by the MJO (Annex IV). Temperature and especially rainfall are also interannually affected by ENSO and Indian Ocean Basin and Dipole (IOB/IOD) modes (Annex IV, Table Atlas.1).

Atlas.5.4.1.2 Findings from previous IPCC assessments

WGI AR5 showed that the mean annual temperature of Southeast Asia has been increasing at a rate of 0.14°C to 0.20°C per decade since the 1960s, along with an increasing number of warm days and nights, and a decreasing number of cold days and nights (Christensen et al., 2013). AR5 also reported the lack of sufficient observational records to allow for a full understanding of past precipitation trends in most of the Asian region, including Southeast Asia, and that precipitation trends that were available differed considerably across the region and between seasons (Christensen et al., 2013).

On projected changes, findings from AR5 showed that warming is very likely to continue with substantial subregional variations over Southeast Asia (Christensen et al., 2013). The median increase in temperature over land projected by the CMIP5 ensemble mean ranges from 0.8°C in RCP2.6 to 3.2°C in RCP8.5 by the end of the 21st century. Moderate future increases in precipitation are very likely, with projected ensemble mean increases of 1% in RCP2.6 to 8% in RCP8.5 by 2100. In the SR1.5, there is a projected increase in flooding and runoff over Southeast Asia for a 1.5°C to 2°C global warming, and these will increase even more for a greater than 2°C level of warming (Hoegh-Guldberg et al., 2018).

Atlas.5.4.2 Assessment and synthesis of observations, trends and attribution

Within the last decade, there has been an increasing number of studies on climatic trends over Southeast Asia, carried out on a regional basis (Thirumalai et al., 2017; Cheong et al., 2018) or focused on specific countries (Cinco et al., 2014; Villafuerte et al., 2014; Mayowa et al., 2015; Villafuerte and Matsumoto, 2015; Guo et al., 2017a; Sa’adi et al., 2017; Supari et al., 2017; Tan et al., 2021). They document virtually certain significant increases in mean as well as extreme temperature. The minimum temperature extremes very likely warmed faster compared to the maximum temperature. Temperatures, including extremes, are strongly influenced by ENSO in the region (Cinco et al., 2014; Thirumalai et al., 2017; Cheong et al., 2018). Over much of the regions, extreme high temperature occurred mostly in April and almost all April extreme temperatures occur in El Niño years (Thirumalai et al., 2017). In most of Southeast Asia (except for the north-eastern areas), there was likely an increase in the number of warm nights with El Niño episodes within the period 1972–2010 (Cheong et al., 2018).

Changes in mean precipitation are less spatially coherent over Southeast Asia. Over Thailand, the average number of rain days has decreased by 1.3 to 5.9 days per decade while average daily rainfall intensity has increased by 0.24–0.73 mm day\(^{-1}\) per decade (Limsakul and Singhurck, 2016). Precipitation is also affected by ENSO events (Tangang et al., 2017; Supari et al., 2018). Over Southeast Asia, there has been a significant increase in the amount of precipitation and its extremes with La Niña episodes in the past decades, especially during the winter monsoon period (high confidence) (Villafuerte and Matsumoto, 2015; Limsakul and Singhurck, 2016; Cheong et al., 2018).

Figure Atlas.11 shows trends in mean temperature and precipitation during 1960–2015 for two global datasets, indicating a significant overall warming over Southeast Asia (high confidence), with higher rates of warming in Malaysia, Indonesia, and the southern areas of mainland Southeast Asia (low confidence). Annual mean precipitation trends (see also Interactive Atlas which includes the regional dataset Aphrodite, see section Atlas.1.4.1) over the region are mostly not significant except for increases over parts of Malaysia, Vietnam and southern Philippines (medium confidence).
It is important to note that the availability, quality, and temporal and spatial density of observation data may lead to uncertainties and varying results in Southeast Asia (Juneng et al., 2016). Some efforts have been made to produce better observationally-based gridded datasets for the region (e.g., Nguyen-Xuan et al., 2016; van den Besselaar et al., 2017; Yatagai et al., 2020).

Atlas 5.4.3 Assessment of model performance

Performance in simulating rainfall over Southeast Asia varies among CMIP5 GCMs (high confidence). Only some are capable of reasonably simulating the rainfall seasonal cycle and spatial pattern (Siew et al., 2013; Raghavan et al., 2018). Over mainland Southeast Asia, the performance of CMIP5 GCMs in simulating rainfall during wet season was superior to that for annual and dry season precipitation (Li et al., 2019a).

RCMs have been intensively used over the region in recent years in a series of single or multi-model experiments and there is medium confidence that they reproduce reasonably well seasonal climate patterns of temperature, precipitation and large-scale circulation over the different subregions of Southeast Asia with added values compared to their host GCMs (Van Khiem et al., 2014; Kwan et al., 2014; Ngo-Duc et al., 2014, 2017; Juneng et al., 2016; Katsfey et al., 2016; Loh et al., 2016; Raghavan et al., 2016; Cruz et al., 2017; Ratna et al., 2017; Trinh-Tuan et al., 2018; Nguyen-Thuy et al., 2021). RCM ensemble means tend to outperform the individual models in representing the climatological mean state (Ngo-Duc et al., 2014; Trinh-Tuan et al., 2018; Nguyen-Thi et al., 2020). There is relatively high consistency among the simulations of historical climate over mainland Southeast Asia compared to those over the Maritime Continent for both seasonal and inter-annual variability (Ngo-Duc et al., 2017). The consistency in rainfall simulations was lower than for temperature simulations.

Some RCMs showed a systematic cold bias (Manomaiphiboon et al., 2013; Kwan et al., 2014; Ngo-Duc et al., 2014; Loh et al., 2016; Cruz and Sasaki, 2017; Cruz et al., 2017) that was mainly due to model physics (Manomaiphiboon et al., 2013; Kwan et al., 2014) and/or the biases in the SST forcing (Ngo-Duc et al., 2014). A few simulations revealed a warm bias over some areas such as in the Maritime Continent (Cruz et al., 2017) or Vietnam (Van Khiem et al., 2014). The biases for rainfall in GCMs and RCMs over Southeast Asia were found to be less systematic with wet or dry biases depending on the subregions (Manomaiphiboon et al., 2013; Kwan et al., 2014; Van Khiem et al., 2014; Juneng et al., 2016; Nguyen-Thi et al., 2020; Supari et al., 2020; Tangang et al., 2020) although wet biases were more pronounced in RCMs (Kwan et al., 2014; Van Khiem et al., 2014; Kirono et al., 2015; Juneng et al., 2016; Supari et al., 2020; Tangang et al., 2020). Some RCMs overestimated rainfall interannual variability (Juneng et al., 2016) while some others underestimated it (Kirono et al., 2015). Simulated rainfall amount is sensitive to the choice of convective scheme (Juneng et al., 2016; Ngo-Duc et al., 2017) and the choice of land-surface scheme (Chung et al., 2018). Rainfall biases in current climate simulations can be greatly reduced if a bias correction method such as quantile mapping is applied (Trinh-Tuan et al., 2018). The pattern of tropical cyclone numbers in the region were reasonable represented by RCM outputs (Van Khiem et al., 2014; Kieu-Thi et al., 2016; Herrmann et al., 2020).

Atlas 5.4.4 Assessment and synthesis of projections

Mean temperature in Southeast Asia is projected to continue to rise through the 21st century (virtually certain, very high confidence). Projections by multi-model regional climate simulations of CORDEX-SEA showed a temperature increment over land under RCP8.5 to range from 3°C to 5°C by the end of 21st century relative to pre-1986–2005 period (Tangang et al., 2018). For the same periods, the average mean temperature increase over land projected by CMIP5 (CMIP6) varies from 0.9 ± 0.3°C (1.2 ± 0.4°C) under RCP2.6 (SSP1-2.6) to 3.5 ± 0.7°C (3.8 ± 0.9°C) under RCP8.5 (SSP5-8.5) (Interactive Atlas). For all Global Warming Levels (GWLs) the land region is projected to warm by a slightly smaller amount than the global average, with 10th–90th percentile ranges for CMIP5 (CMIP6) of 1.2°C to 1.6°C (1.2°C to 1.5°C) for the 1.5°C GWL and of 3.3°C to 4.0°C (3.3°C to 3.9°C) for the 4°C GWL relative to the 1850–1900 baseline (calculated from RCP8.5 (SSP5-8.5) projections). Changes for other warming levels, periods, and emissions
pathways are shown in Figure Atlas.17 and can be explored in the Interactive Atlas.

Projections of future rainfall changes are highly variable among sub-regions of Southeast Asia and among the models (high confidence). The CMIP5 and CMIP6 ensembles showed an increase in annual mean precipitation over most land areas by the mid and late 21st century, although only with a strong model agreement for higher warming levels (Interactive Atlas, Figure Atlas.17), while CORDEX produces a general decrease in projected precipitation (Figure Atlas.17). Based on CORDEX Southeast Asia multi-model simulations, significant and robust increases of mean rainfall over Indochina and the Philippines were projected while there is a drying tendency over the Maritime Continent during DJF for the early, mid and end of the 21st century periods under both RCP4.5 and RCP8.5 (Tangang et al., 2020) (Figure Atlas.19). At the end of the 21st century during DJF and under RCP8.5, an increase of 20% in mean rainfall is projected over Myanmar, northern central Thailand and northern Laos, and of 5–10% over the eastern Philippines and northern Vietnam. During JJA, significant drier conditions are projected over almost the entire Southeast Asia except over Myanmar and northern Borneo. Over the Indonesian region, especially Java, Sumatra and Kalimantan, as much as a 20–30% decrease in mean rainfall is projected during JJA by the end of the 21st century. The projected drier condition over Indonesia from CORDEX is consistent with that of (Kusunoki, 2017; Giorgi et al., 2019; Kang et al., 2019; Supari et al., 2020) and is associated with enhanced subsidence over the region (Kang et al., 2019; Tangang et al., 2020).

[START FIGURE ATLAS.19 HERE]

Figure Atlas.19: The RCM projected changes in mean precipitation between the early (2011–2040), mid (2041–2070) and late (2071–2099) 21st century and the historical period 1976–2005. Data are obtained from the CORDEX-SEA downscaling simulations. Diagonal lines indicate areas with low model agreement (less than 80%). Adapted from Tangang et al. (2020).

[END FIGURE ATLAS.19 HERE]

Atlas.5.4.5 Summary

It is virtually certain that annual mean temperature has been increasing in Southeast Asia in the past decades while changes in annual mean precipitation are less spatially coherent though with some increasing trends over parts of Malaysia, Vietnam and southern Philippines (medium confidence).

Although various biases still exist, there is high confidence that the models can reproduce seasonal climate patterns well over the different subregions of Southeast Asia. There is medium confidence that the RCMs show added value compared to their host GCMs over the region.

Projections show continued warming over Southeast Asia, but likely by a slightly smaller amount than the global average. Projected changes in rainfall over Southeast Asia vary, depending on model, subregion and season (high confidence) with consistent projections of increases in annual mean rainfall from CMIP5 and CMIP6 over most land areas (medium confidence) and decreases in summer rainfall from CORDEX projections over much of Indonesia (medium confidence).

Atlas.5.5 Southwest Asia

Atlas.5.5.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas 5.5.1.1 Key features of the regional climate

Southwest Asia includes the Arabian Peninsula (ARP) and West Central Asia (WCA) reference regions (Figure Atlas.17). ARP has a semi-arid or arid desert climate with very low annual mean precipitation and very high temperature. Its temperature is influenced by SST variations over the tropical ocean (e.g., ENSO)
Rainfall is influenced by the IOD and ENSO with more rainfall during El Niño (Kang et al., 2015; Kumar et al., 2015; Abid et al., 2018; Kamil et al., 2019) and less during La Niña (Atif et al., 2020). The wet season in ARP is mainly from November to April and the dry season is from June to August. Rainfall is confined mostly to the south-western part of the Peninsula and contribution of extreme events to the total rainfall varies within 20–70% from region to region and season to season (Almazroui, 2020b; Almazroui and Saeed, 2020). WCA is separated from Eastern Europe by the Caucasus Mountains, is adjacent to ARP, with South Asia (SAS) to the south and West Siberia (WSB) to the north, and lies between the Mediterranean (MED), Tibetan Plateau (TIB) and East Central Asia (ECA) regions. WCA is heterogeneous in terrain with the Zagros Mountains and Iranian Plateau in the west and southwest, the Caspian Sea and lowland with deserts in the north and northeast. The regional climate of WCA is influenced by the NAO and ENSO and it is typically semi-arid or arid with a strong gradient in both precipitation and temperature from the mountains to the plains and from north to south.

**Atlas 5.5.1.2 Findings from previous IPCC assessments**

The IPCC AR5 established it is **very likely** that temperatures will continue to increase over WCA in all seasons whilst projections of decreased annual mean precipitation had **medium confidence** due to **medium agreement** resulting from model-dependent subregional and seasonal changes (Christensen et al., 2013). AR5 also concluded that for a better understanding of the climate of the region, results of high-resolution regional climate models also need to be assessed and CMIP5 models generally had difficulties simulating the mean temperature and precipitation climatology for Southwest Asia. This is partly related to the poor spatial resolution of the models not resolving the complex mountainous terrain and the influence of different drivers of the European, Asian and African climates. However, observational data scarcity and issues related to the comparison of observations with coarse-resolution models added to the uncertainty and remained poorly analysed in peer-reviewed literature on climate model performance (Christensen et al., 2013).

SR1.5 stated that even for 1.5°C and 2°C of global warming, Southwest Asia is among the regions with the strongest projected increase in hot extremes with more urban populations exposed to severe droughts in West Asia, while an increase of heavy precipitation events is projected in mountainous regions of Central Asia (Hoegh-Guldberg et al., 2018; IPCC, 2018c). Higher temperatures with less precipitation will **likely** result in higher risks of desertification, wildfire and dust storms exacerbated by land-use and land-cover changes in the region with consequent effects on human health. Further drying of the Aral Sea in Central Asia will **likely** have negative effects on the regional microclimate adding to the growing wind erosion in adjacent deltaic areas and deserts that is already resulting in a reduction of the vegetation productivity including croplands. There is also a projected increase of precipitation intensity in the Arabian Peninsula which is **likely** to lead to higher soil erosion particularly in winter and spring due to floods (Mirzabaev et al., 2019). WCA includes high mountains with enhanced warming above 500 m where, regardless of the emissions scenario, decreases in snow cover are projected due to increased winter snowmelt and more precipitation falling as rain (**high confidence**). A very strong interannual and decadal variability, as well as scarce in situ records for mountain snow cover, have prevented a quantification of recent trends in High Mountain Asia (Hock et al., 2019b).

**Atlas 5.5.2 Assessment and synthesis of observations, trends and attribution**

Since the AR5, there has been an increasing number of studies on past climate change in Southwest Asia though meteorological stations are sparsely scattered in the region. They are mainly located in the plains below 2 km of altitude, very scarce in mountainous areas and have declined in number in WCA since the end of the Soviet Union in 1991. This increases the uncertainty in both temperature and precipitation trends particularly for elevated areas (Christensen et al., 2013; Huang et al., 2014) (**high confidence**). So researchers use other sources of climate data in the region, particularly freely available gridded data (see Annex I).

Globally drylands showed an enhanced warming over the past century of 1.2°C to 1.3°C, significantly higher than the warming over humid lands (0.8°C to 1.0°C) (Huang et al., 2017b). A strong increase in annual surface air temperature of 0.27°C to 0.47°C per decade has been found over WCA between 1960 and 2013.
Observed warming over northern ARP is higher than over the south, where minimum temperatures are increasing faster than maximum temperatures (Almazroui, 2020a). The rate of mean temperature increase is estimated at 0.10°C per decade over 1901–2010 (Attada et al., 2019), while it has reached 0.63°C (likely in the range of 0.24°C to 0.81°C) per decade for the more recent period of 1978–2019 (Almazroui, 2020a). An overall increasing trend of annual precipitation (0.66 mm per decade) was found over Central Asia based on GPCC V7 data for the period 1901–2013 (Hu et al., 2017), but annual trends were found not significant over the shorter period 1960–2013 (see also Figure Atlas.11 and Interactive Atlas). Winter precipitation saw a significant increase of 1.1 mm per decade (Song and Bai, 2016). These estimates have low to medium confidence since the satellite precipitation products have large systematic and random errors in mountainous regions. Moreover CMORPH and TRMM products fail to capture the precipitation events in the ice/snow-covered regions in winter and show a substantial false-alarm percentage in summer, but the gauge-corrected GSMAP performs better than other products (Song and Bai, 2016; Guo et al., 2017b; Hu et al., 2017; Chen et al., 2019b). Over the elevated part of eastern WCA precipitation increases in the range of 1.3–4.8 mm per decade during 1960–2013 were observed (very high confidence) (Han and Yang, 2013; Li et al., 2013; Hu et al., 2014, 2017; Huang et al., 2017; Deng and Chen, 2017; Zhang et al., 2019a, 2017; Guo et al., 2019a, 2017; Yu et al., 2019; Haag et al., 2019; Hu et al., 2017; Huang et al., 2017; Deng and Chen, 2017; Zhang et al., 2019a, 2017; Guo et al., 2019a, 2017; Yu et al., 2019; Haag et al., 2019; Yu et al., 2019). Reductions in spring precipitation and increases in winter have been reported for Uzbekistan over the period 1979–2013 based on station data but these are not significant (Khaydarov and Gerlitz, 2019). There is very low confidence of impact of the Aral Sea shrinking on precipitation (Chen et al., 2011; Jin et al., 2017).

A decreasing trend of precipitation is reported for ARP with the mean value of −6.3 mm per decade (range of −30 mm to 16 mm) for the period 1978–2019 (low confidence) with large interannual variability over Saudi Arabia, which covers 80% of the region (AlSarmi and Washington, 2011; Almazroui et al., 2012; Donat et al., 2014). The same decreasing trend in precipitation totals and an increasing trend in the number of consecutive dry days are found for most of the Iranian plateau (medium confidence) (Rahimi and Fatemi, 2019; Fathian et al., 2020; Sharafi and Mir Karim, 2020). January-to-March mean snow cover and depth over mountainous areas decreased between 2000 and 2019 (low to medium confidence due to limited evidence) (Safarianzengir et al., 2020).

Atlas.5.5.3 Assessment of model performance

There is limited evidence about the performance of GCMs and RCMs in representing the current climate of Southwest Asia due to very few studies evaluating models over this region, but literature is now emerging particularly on CMIP5/CMIP6 and CORDEX simulations.

Over ARP, surface temperature biases for 18 of 30 CMIP5 models are within one standard deviation of the observed variability (Almazroui et al., 2017). A warm bias in summer and a cold bias for others months along with an underestimation of wet season precipitation and an overestimation in the dry season have been reported in 26 CMIP5 models (Lelieveld et al., 2016). 30 CMIP6 GCMs have limited skill in simulating weather extremes and regional precipitation.
RCM simulations using the CORDEX-MENA domain reproduce the main features of the mean surface climatology over ARP with moderate biases (high confidence). RegCM4 driven by five GCMs (HadGEM2, GFDL, CNRM, CanESM2, and ECHAM6) showed an ensemble mean cold bias of about −0.7°C and dry bias of −13% over ARP (Almazroui, 2016) with a cold (warm) bias over western (south-eastern) areas (Syed et al., 2019). Temperature biases in 30-year historical simulations with WRF using three different radiation parameterizations were within ±2°C and mostly caused by surface long-wave radiation errors which affected night-time minimum temperatures over 70% of the domain (Zittis and Hadjinicolaou, 2017). Mean absolute errors in COSMO-CLM driven by ERA-Interim were about 1.2°C for temperature, 15 mm per month for precipitation and 9% for total cloud cover, and with new parameterizations of albedo and aerosols optimized for the region the RCM simulated the main climate features of this very complex area (Bucchignani et al., 2016). RegCM.4.4 also simulated the main features of the observed climatology (especially for dry regions) with temperature biases within ±3.0°C. Annual precipitation was overestimated with winter and spring underestimated (Ozturk et al., 2018).

Four RCMs (REMO, RegCM4.3.5, ALARO-0, and COSMO-CLM5.0) driven by ERA-Interim, NCEP2 reanalyses and two different GCMs reproduced reasonably well the spatio-temporal patterns for temperature and precipitation though underestimated diurnal temperature range and had cold biases over mountainous and high plateau regions in all seasons. There is low confidence in this result because of low station density and a lack of high-elevation stations and with biases dependent on the choice of the observational dataset. However, the performance of both GCMs and RCMs is better than reanalyses when compared to available observations (Mannig et al., 2013; Ozturk et al., 2017; Russo et al., 2019; Top et al., 2021).

Atlas 5.5.4 Assessment and synthesis of projections

Temperature and precipitation projections from CMIP5/CMIP6 and CORDEX for different global warming levels, SSP and RCP scenarios, time periods and baselines are shown in Figure Atlas.17 and further details can be explored in the Interactive Atlas.

In WCA, projections for different GWLs are consistent not only in annual and seasonal warming but in ranges of the projections. Under RCP8.5, annual mean temperature will likely exceed 2°C by mid-century (compared with 1995–2014) and reach up to 4.8°C–6°C by the end of the century (Yang et al., 2017) with faster warming projected by the CMIP6 ensemble under SSP5-8.5. In individual county-level studies on GCM future climate projections temperatures increased by up to 7°C by the end of the century, depending on season and emission scenario (Allaberdiev, 2010; MENRPG, 2015; Vermishev, 2015; Gevorgyan et al., 2016; Osborn et al., 2015; Aalto et al., 2017; IDOE, 2017; Salman et al., 2017). Statistical downscaling of 18 CMIP5 GCMs projected an annual temperature increase of 0.37°C per decade (under RCP4.5) with the maximum in northern WCA and warming most conspicuous in summer (Luo et al., 2019). RCM downscaling of GCMs over Central Asia projected a larger increase of temperature under RCP8.5 for the 2071–2100 period, ranging from 5°C to 8°C (Ozturk et al., 2017).

In ARP, the projected change in ensemble mean annual temperature from 30 CMIP6 models is from 1.6°C (SSP1-2.6) to 5.3°C (SSPS-8.5) by 2070–2099 compared to 1981–2010 (Almazroui et al., 2020a). The projected warming is the highest in the north, reaching 5.9°C and lowest in the south (4.7°C). COSMO-CLM projections over the CORDEX-MENA domain show for ARP and WCA a strong warming with marked seasonality for the end of the 21st century, ranging from 2.5°C in winter under RCP4.5 to 8°C in summer under RCP8.5 and with large increases found over high-altitude areas in winter and spring (Bucchignani et al., 2018; Ozturk et al., 2018). The CMIP5 multi-model mean warming in boreal summer in 2070–2099, compared with 1951–1980, is projected to be about 2.5°C and 6.5°C at the 2°C and 4°C global warming levels respectively (Huang et al., 2014).
Future projections of precipitation in Southwest Asia have large uncertainties and thus low confidence. There are few significant changes, little consensus on the sign and with a tendency for reduction in CMIP5 being reversed in CMIP6 across all warming levels (Ozturk et al., 2018). Statistical downscaling of 18 CMIP5 GCMs under RCP4.5 projected an increase in precipitation of 4.6 mm per decade in Southwest Asia during 2021–2060 relative to 1965–2004 (Luo et al., 2019). CMIP5 simulations project a general decrease in precipitation over lowlands in Turkey, Iran, Afghanistan and Pakistan (Ozturk et al., 2017) and increase over high-mountain regions (Aalto et al., 2017; Salman et al., 2018). At a 4°C global warming level, the multi-model mean annual precipitation for Turkmenistan and parts of Tajikistan and Uzbekistan is projected to decrease by 20%, with somewhat stronger relative decreases in summer (Reyer et al., 2017). Over northern WCA, the CMIP5 ensemble mean projects increases of over 3 mm per decade under RCP2.6 and over 6 mm per decade under RCP4.5 and RCP8.5 over the 21st century (Huang et al., 2014). Mean annual precipitation is projected to rise by 5.2% at the end of the 21st century (2070–2099) under RCP8.5, compared to 1976–2005, while mean annual snowfall is projected to decrease by 26.5% in Central Asia (Yang et al., 2017).

However, regardless of the sign of the precipitation change in the high-mountain regions of Central Asia, the influence of the warming on the snowpack will very likely cause important changes in the timing and amount of the spring melt (Diffenbaugh et al., 2013).

In ARP, the projected change in ensemble mean annual precipitation from 30 CMIP6 models ranges from 3.8% (−2.6% to 28.8%) to 31.8% (12.0% to 106.5%) under SSP1-2.6 and SSP5-8.5 emissions for the period 2080–2100 compared with 1995–2014 (Almazroui et al., 2020a). Northwest ARP precipitation is projected to decrease between −6% to −27% per decade and in the south precipitation to increase by up to 8.6% per decade. CMIP6 projections are in line with those from CMIP5 and CMIP5, however they are less variable in the central area in CMIP6. The uncertainty associated with precipitation over ARP is large because of very low annual amounts and high variability.

**Atlas 5.5.5 Summary**

Increase in annual surface air temperature over Southwest Asia are very likely in the range of 0.24°C to 0.81°C per decade over the last 50–60 years. Annual precipitation change over ARP since 1970 is estimated at −6.3 mm per decade (and in the range of −30 to 16 mm per decade) and over WCA is generally not significant except over the elevated part of eastern WCA where increases between 1.3 mm and 4.8 mm per decade during 1960–2013 have been observed (very high confidence). In mountainous areas, the scarcity and decline of the number of observation sites since the end of the former Soviet Union from 1991 increase the uncertainty of the long-term temperature and precipitation estimates (high confidence).

Mean temperature biases in RCMs are within ±3°C in Southwest Asia, and annual precipitation biases are positive in almost all parts of the region except over the ARP where they are negative in the wet season (November to April) and over WCA in winter and spring (from December to May) (medium confidence). Since regional model evaluation literature has only recently emerged there is medium evidence about the performance of RCMs in Southwest Asia though with medium to high agreement on mean temperature and precipitation biases. RCMs simulate colder temperatures than observed over mountainous and high plateau regions (limited evidence, high agreement).

Further warming over Southwest Asia is projected in the 21st century to be greater than the global average, with rates varying from 0.25°C to 0.8°C per decade depending on the season and scenario and maximum rates found in the northern part of the region in summer (high confidence). The influence of the warming on the snowpack will very likely cause changes in the timing and amount of the spring melt. CMIP6 projected changes in annual precipitation totals are in the range of −3% to 29% (SSP1-2.6) and 12% to 107% (SSP5-8.5) in ARP (medium confidence). Strong spatio-temporal differences with overall precipitation decreases projected in the central and northern parts of WCA in summer (JJA) with increases in winter (DJF) (medium confidence).
Atlas.6 Australasia

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes are in Chapter 11 (Table 11.10–12) and climatic impact-drivers in Chapter 12 (Table 12.5).

Atlas.6.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.6.1.1 Key features of the regional climate

Australasia is divided into five regions for the Atlas (Figure Atlas.21), as follows: New Zealand (NZ), with a varied climate with diverse landscapes, mainly maritime temperate with four distinct seasons; Northern Australia (NAU) which is mainly tropical with monsoonal summer-dominated rainfall (monsoon season December to March, see Annex V), but with a hot, semi-arid climate in the south of the region; Central Australia (CAU) with a predominantly hot, dry desert climate; Eastern Australia (EAU) with a temperate oceanic climate at the coast to semi-arid inland; and Southern Australia (SAU) which ranges from Mediterranean and semi-arid in the west to mainly cool temperate maritime climate in the southeast. Various remote drivers have notable teleconnections to regions within Australasia, including an effect of the El Niño Southern Oscillation and the Indian Ocean Dipole (Table Atlas.1, Annex IV). Much of southern NZ and SAU are affected by systems within the westerly mid-latitude circulation, in turn affected by the Southern Annular Mode. The monsoon and the Madden-Julian Oscillation affect rainfall variability in northern Australia.

Atlas.6.1.2 Findings from previous IPCC assessments

The AR5 WGI and WGII reports (IPCC, 2013c; Stocker et al., 2013; Reisinger et al., 2014) give very high confidence that air and sea temperatures in the region have warmed, cool extremes have become rarer in Australia and New Zealand since 1950, while hot extremes have become more frequent and intense (e.g., it is very likely that the number of warm days and nights have increased). The AR5 reported it is virtually certain that mean air and sea temperatures will continue to increase, with very high confidence that the greatest increase will be experienced by inland Australia and the smallest increase by coastal areas and New Zealand. The AR5 reported a range of different precipitation trends within the region. For example, while annual rainfall has been significantly increasing in north-western Australia since the 1950s (very high confidence), it has been decreasing in the northeast of the South Island of New Zealand over 1950–2004 (very high confidence) and over southwest of Western Australia. In line with these trends, WGI reported it is likely that drought has decreased in north-western Australia. Future projections for precipitation extremes indicate an increase in most of Australia and New Zealand, in terms of rare daily rainfall extremes (i.e., current 20-year return period events) and of short duration (sub-daily) extremes (medium confidence). Likewise, however, there is a projected increase the frequency of drought in southern Australia (medium confidence) and in many parts of New Zealand (medium confidence). Owing to hotter and drier conditions there is high confidence that the occurrence of fire weather will increase in most of southern Australia, and medium confidence that the fire danger index will increase in many parts of New Zealand.

AR5 reported mean sea levels have also increased in Australia and New Zealand at average rates of relative sea-level rise of 1.4 ± 0.6 mm yr⁻¹ from 1900 to 2011, and 1.7 ± 0.1 mm yr⁻¹ from 1900 to 2009, respectively (very high confidence). The assessment found that the volume of ice in New Zealand has declined by 36–61% from the mid-late 1800s to the late 1900s (high confidence), while late-season significant snow depth has also declined in three out of four Snowy Mountain sites in Australia between 1957 and 2002 (high confidence). As mean sea-level rise is projected to continue for at least several more centuries, there is very high confidence that this will lead to large increases in the frequency of extreme sea-level events in Australia and New Zealand. On the other hand, the volume of winter snow and the number of days with low-elevation snow cover in New Zealand are projected to decrease in the future (very high confidence), while both snow
depth and area are projected to decline in Australia (very high confidence).

SROCC (Hock et al., 2019b) reports on the observed and projected decline in snow cover in Australasia, as well as the retreat of New Zealand glaciers following an advance in 1983–2008 due to enhanced snowfall. It also reports on the vulnerability of some Australian communities and ecosystems to sea level rise, increases in the intensity and duration of marine heatwaves driven by human influence (high confidence), the decrease in frequency of tropical cyclones landfall on eastern Australia since the late 1800s (low confidence in an anthropogenic signal), and presented a case study on the multiple hazards, compound risk and cascading impacts from climate extremes in Tasmania in 2015/2016 (including an attributable human influence on some events). SRCL (Mirzabaev et al., 2019) found widespread vegetation ‘greening’ has occurred in parts of Australia, and an increase in the desertification and drought risk in future in southern Australia.

**Atlas.6.2 Assessment and synthesis of observations, trends and attribution**

Reliable station observations are available from around 1900 in Australasia, but in some regions the coverage was and remains poor. Australia and New Zealand have continued to warm, and many rainfall trends have continued since the AR5. Changes and trends in temperature and precipitation from 1961 to 2015 from three different global data sets are displayed in Figure Atlas.11 and the Interactive Atlas and show significant (at 0.1 significance level) warming trends over the southern and eastern Australia. Most of the observed changes in precipitation over the region are not significant over this period. Although observed datasets (e.g. GPCC and GPCP) generally agree on a significant drying trend in the southern regions of New Zealand during the shorter 1980 to 2015 period, this is in fact the reverse of the longer-term trends in 1961 to 2015 (Interactive Atlas).

For a longer-term perspective based on high-quality regional datasets, Figure Atlas.20 shows Australasia has warmed over the last century (very high confidence). Australian mean temperature has increased by 1.44 ± 0.24°C during the period 1910–2019 using the updated observed temperature dataset ACORN-SATv2.1, with 2019 Australia’s hottest year on record and nine out of ten warmest years on record occurring since 2005 (Trewin et al., 2020). Much of the warming has occurred since 1960, there is clear anthropogenic attribution of this change and emergence of the signal from the 1850-1900 climate (BOM and CSIRO, 2020; Hawkins et al., 2020). Warming has been more rapid than the national average in central and eastern Australia, with a warming minimum and non-significant trends since the 1960s in the northwest (CSIRO and BOM, 2015; BOM and CSIRO, 2020). The National Institute of Water and Atmospheric Research temperature record, NIWA NZ, shows a warming of 1.13 ± 0.27°C during the period 1909–2019, although several stations show non-significant trends since 1960 (Figure Atlas.20), including a warming minimum in the southeast at least partly due to a persistent shift in atmospheric circulation (Sturman and Quénol, 2013; MFE and Stats NZ, 2017, 2020).

**START FIGURE ATLAS.20 HERE**

**Figure Atlas.20:** Observed trends in mean annual temperature (a–b) and summer (DJF) and inter (JJA) precipitation (c–d) for Australia and New Zealand from high-quality regional datasets. Time series show anomalies from 1961–1990 average and 10-year running mean; maps show annual linear trends for 1960–2019; rainfall trends are shown in % per decade, crosses show areas and stations with a lack of significant trend and regions of seasonally dry conditions (<0.25 mm day⁻¹) are masked and outlined in red. Datasets are Australian Climate Observation Reference Network – Surface Air Temperature version 2.1 (ACORN-SATv2.1) for Australian temperature, the Australian Gridded Climate Data (AGCD) for Australian rainfall (Evans et al., 2020a), and the 30-station high-quality network for New Zealand temperature and rainfall. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

**END FIGURE ATLAS.20 HERE**

Do Not Cite, Quote or Distribute
Since 1960, precipitation has increased in much of mainland Australia in austral summer and decreased in many regions of southern and eastern Australia in austral winter (Figure Atlas.20). A detectable anthropogenic signal of increases in precipitation in Australia has been reported particularly for north central Australia and for a few regions along the south-central coast for the period 1901–2010 (Knutson and Zeng, 2018). Seasonally, there is a significant decline in winter rainfall in southwest Western Australia (Figure Atlas.20), with an attributable human influence with high confidence (robust evidence and medium agreement) (Delworth and Zeng, 2014, and others) (see Section 10.4). Rainfall trends in the southeast are not significant since 1960 but have shown a notable reduction since the 1990s, and there is limited evidence for the attribution of this change to human influence (e.g., Rauniyar and Power, 2020). In New Zealand between 1960 and 2019 in both summer and winter, rainfall increased in some stations in the South Island and decreased at many stations in the North Island, however most station trends are not statistically significant (Figure Atlas.20) (MFE and Stats NZ, 2020). In JJA, Milford Sound (increasing) and Whangaparaoa (decreasing) trends are significant.

In Australia, there has been a decrease in snow depth and area since the late 1950s, especially in spring (BOM and CSIRO, 2018). Based on a reconstructed snow cover record, the recent rapid decrease in the past five decades has been shown to be larger by more than an order of magnitude than the maximum loss for any 5-decade period over the past 2000 years (McGowan et al., 2018). In New Zealand, from 1977 to 2018, glacier ice volume decreased from 26.6 km$^3$ to 17.9 km$^3$ (a loss of 33%) (Salinger et al., 2019).

**Atlas.6.3 Assessment of climate model performance**

Most studies assessed in WGII AR5 were based on Coupled Model Inter-comparison Project Phase 3 (CMIP3) models and Special Report on Emission Scenarios (SRES) scenarios and CMIP5 models whenever available. WGI AR5 reported that model biases in annual temperature and rainfall are similar to or lower than other continental regions outside the tropics, with temperature biases generally <1°C in the multi-model mean and <2°C in most models over Australia compared to reanalysis, and with a wet bias over the Australian inland region but a dry bias near coasts and mountain regions of both Australia and New Zealand.

Early results from CMIP6 suggest incremental improvements compared to CMIP5 in the simulation of the mean annual climatology of temperature and precipitation of the Indo-Pacific region surrounding Australasia, the teleconnection between ENSO and IOD and Australian rainfall and other relevant climate features (Grose et al., 2020). These assessments suggest that confidence in projections is similar to AR5 or incrementally improved. The CORDEX Australasia simulations are found to have cold biases in daily maximum temperature and an overestimation of precipitation but overall showed added value in the simulation of the current climate (Di Virgilio et al., 2019; Evans et al., 2020b).

**Atlas.6.4 Assessment and synthesis of projections**

Similar to the global average (Chapter 4), mean temperature in Australasia is projected to continue to rise through the 21st century at a magnitude proportional to the cumulative greenhouse-gas emissions (virtually certain, very high confidence, robust evidence), CMIP5 and CMIP6 results are shown in Figure Atlas.21. A higher end to the range of temperature projections is found in CMIP6 compared to CMIP5 (Grose et al., 2020), produced by a group of models with high climate sensitivity (Forster et al., 2019), and this creates a higher multi-model-mean change. For example, projections for Australasia including ocean between 1995–2014 and 2081–2100 are 1.4°C (1.1°C to 1.8°C 10th–90th percentile range) in CMIP5 under RCP4.5, but 1.8°C (1.3°C to 2.5°C) in CMIP6 under SSP2-4.5.

Using warming levels, the results can be directly compared accounting for the different distribution of climate sensitivities in the two ensembles. In this framework, Australasia (land only) is projected to warm by a similar amount to the global average: 1.4°C to 1.8°C for the 1.5°C warming level, through to 3.9°C to 4.8°C for the 4°C warming level from the 1850–1900 baseline in CMIP6 using SSP5-8.5 (results using other SSPs and from CMIP5 are similar). Projected warming is greater over land than ocean, greater in Australia
than in New Zealand, and greater over inland Australia than coastal regions. Due to historical warming, projected temperature change from the AR6 baseline of 1995–2014 is lower: 0.3°C to 1.0°C for the 1.5°C warming level, through to 2.9°C to 4.0°C for the 4°C warming level. Changes for other warming levels, subregions and emissions pathways are shown in Figure Atlas.21 and can be explored in the Interactive Atlas. Regional modelling suggests projected temperature increase is higher in mountainous areas than surrounding low-elevation areas in New Zealand and Australia (Olson et al., 2016; MfE, 2018).

[START FIGURE ATLAS.21 HERE]

Figure Atlas.21: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Australasia (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.21 HERE]

In line with recent trends, a significant reduction in annual mean rainfall in southwest Australia is projected, with the greatest reduction in winter and spring (very likely, high confidence). There is more than 80% model agreement for projected mean annual rainfall decrease in southwest Western Australia for both mid (2041–2060) and far (2081–2100) future, and for all warming levels (Interactive Atlas). Rainfall decreases, mainly in winter and spring, are also projected for other regions within southern Australia with only medium confidence (medium evidence and medium agreement). Almost all models project continued drying in SAU in winter (JJA) and also in spring (SON), but a few models show little change. CMIP5 and CMIP6 results are similar or with a slightly narrower range in the latter (Figure Atlas.21). CORDEX produces a similar range of change in winter rainfall change for SAU as a whole. Circulation change is the dominant driver of these projected reductions; explaining the range of model results for southern Australia (CSIRO and BOM, 2015; Mindlin et al., 2020). Studies of winter rainfall change and circulation in southern Australia suggest the wettest changes in winter rainfall change may possibly be rejected (Grose et al., 2017, 2019a).

The model mean projection of northern Australian wet season precipitation (a period including DJF) is for little change under all SSPs and warming levels, with low confidence in the direction of change as the projections include both large and significant decrease and increases (Figure Atlas.21, Interactive Atlas). Evidence from warming patterns suggests a constraint on the dry end of projections (Brown et al., 2016), and the CMIP6 ensemble suggests that the projection follows the zonally-averaged rainfall response in the southern hemisphere rather than changes in the western Pacific (Narsey et al., 2020). There is also evidence for a projected increase in rainfall variability in northern Australia in scales from days to decades (Brown et al., 2017). Liu et al. (2018) find that under 1.5°C warming, central and northeast Australia is projected to become wetter, however this projection has low confidence. There are similar projections from CMIP5 and CMIP6 (Figure Atlas.21).
Projections for EAU vary by season, with moderate model agreement on a decrease in rainfall in winter and spring, but with lower agreement in CMIP6 compared to CMIP5, and low model agreement on the direction of change in summer (Figure Atlas.21). CAU shows a similar range of change as EAU, with low model agreement on the direction of change in DJF, moderate agreement on direction of change in JJA, but significant changes are projected by some models. Other seasonal and regional rainfall changes in Australia are reviewed in Dey et al. (2019).

For the NZ reference region, precipitation is projected to increase in winter and annual rainfall, with some differences in magnitude between CMIP5, CMIP6 and CORDEX (Figure Atlas.21). This projection of rainfall increase is a function of changes in the southern extent of the region, and notable regional differences are expected. Regional modelling suggests precipitation increases in the west and south of New Zealand and decreases in the north and east (MfE, 2018), with medium confidence, and with notable differences by season. Liu et al. (2018) project that the North Island will be drier, while the South Island will be wetter under both 1.5°C and 2°C warming levels. The projected increase in precipitation in the far future (2081–2100) for the southern regions of NZ has high agreement (Interactive Atlas). Other seasonal and regional rainfall changes in Australia can be explored in the Interactive Atlas.

The CORDEX Australasia simulations produce some regional detail in projected precipitation change associated with important features such as orography. Areas where there is coincident ‘added value’ in the simulation of the current climate and ‘potential added value’ as new information in the projected climate change signal (collectively termed ‘realised added value’) in Australia include the Australian Alps, Tasmania and parts of northern Australia (Di Virgilio et al., 2020). There have been several studies of regional climate change for New Zealand and states within Australia at fine resolution (5–12 km) that have produced important insights. One is enhanced drying in cool seasons on the windward slopes of the southern Australian Alps (decreases of 20–30% compared to 10–15% in the driving models), and conversely a chance of enhanced rainfall increase on the peaks of mountains in summer (Grose et al., 2019b), with the summer finding in line with those for the European Alps (Giorgi et al., 2016). Under future warming, the snowpack in Australia is projected to decrease by approximately 15% and 60% by 2030 and 2070 respectively under the SRES A2 scenario (Di Luca et al., 2018), while in New Zealand the number of annual snow days is projected to decrease by 30 days or more by 2090 under RCP8.5 (MfE, 2018). New Zealand is also projected to lose up to 88 ± 5% of its glacier volume by the end of the 21st century (Chinn et al., 2012; Hock et al., 2019a).

**Atlas.6.5 Summary**

There is very high confidence that the climate of Australia warmed by around 1.4°C and New Zealand by around 1.1°C since reliable records began in 1910 and 1909 respectively, with human influence the dominant driver. Warming is virtually certain to continue, with a magnitude roughly equal to the global average temperature. A significant decrease in April to October rainfall in southwest Western Australia is observed from 1910 to 2019, is attributable to human influence with high confidence and is very likely to continue in future noting consistent projections in CMIP5 and CMIP6. Other observed and projected rainfall trends are less significant or less certain. Model representation of the climatology of Australasian temperature and rainfall has improved since AR5, through an incremental improvement between CMIP5 and CMIP6 and the development of coordinated regional modelling through CORDEX-Australasia. Snow cover is likely to decrease throughout the region at high altitudes in both Australia and New Zealand (high confidence).

**Atlas.7 Central and South America**

The assessment in this section focuses on changes in average surface temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes are in Chapter 11 (Table 11.13–15) and climatic impact-drivers in Chapter 12 (Table 12.6).
considers climate change over the regions shown in Figure Atlas.22, extending to all territories from Mexico to South America, including the Caribbean islands. This figure supports the assessment of regional mean changes over the region which, due to the high climatological and geographical heterogeneity, has been split into two subregions: Central America and the Caribbean, and South America.

[START FIGURE ATLAS.22 HERE]

Figure Atlas.22: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Central America, the Caribbean and South America (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.22 HERE]

Atlas.7 Central America and the Caribbean

Atlas.7.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.7.1.1 Key features of the regional climate

The Central America and Caribbean region is assessed considering three reference regions South Central America (SCA), including the isthmus and the Yucatan peninsula; North Central America (NCA), including Mexico (centre and north) and the Caribbean (CAR), including the Greater Antilles, the Lesser Antilles, the Bahamas and other small islands (see Figure Atlas.22); NCA is also covered in Section Atlas.9 North America.

Precipitation in most of SCA is characterized by two maxima in June and September, an extended dry season from November to May, and a shorter relatively dry season between July and August known as the midsummer drought (MSD) (Magaña et al., 1999; Perdigón-Morales et al., 2018) (see Chapter 10). To some extent, precipitation seasonality is explained by the migration of the Intertropical Convergence Zone (ITCZ) (Taylor and Alfaro, 2005). The climate of NCA is temperate to the north of the Tropic of Cancer, with marked difference between winter and summer, modulated by the North American monsoon (NAMerM, Section 8.3.2.4.4): CAR has two main seasons, characterized by differences in temperature and precipitation. The wet or rainy season, with higher values of temperature and accumulated precipitation, occurs during the boreal summer and part of spring and autumn (Gouirand et al., 2020). The MSD is also present in the Greater Antilles and the Bahamas (Taylor and Alfaro, 2005), influenced by the oscillations of the North Atlantic Subtropical High (NASH), interacting with the Pacific and Atlantic branches of the ITCZ and modulated by the Atlantic Warm Pool and the Caribbean Low-Level Jet (CLLJ), while the Atlantic ITCZ is responsible for the unimodal rainfall cycle of the central and southern Lesser Antilles (Martinez et al., 2019). The CLLJ is a persistent climatological feature of the low-level circulation in the Central Caribbean, with a characteristic semi-annual cycle with maxima in the summer (main) and winter (secondary) (Amador, 1998; Magaña et al., 2019).
1999; Whyte et al., 2008). Temporal variability is influenced by several large-scale atmospheric modes (see Annex IV and Table Atlas.1). A significant positive correlation between precipitation rates in CAR and the Atlantic Multidecadal Variability was found (Enfield et al., 2001). A similar result was found in southern Mexico (north of SCA) in the MSD region (Méndez and Magaña, 2010; Cavazos et al., 2020) (see case-study discussion in Section 10.4.2.3). On the other hand, ENSO favours wet conditions in NCA, but its effect is modulated by Pacific Decadal Variability (Maldonado et al., 2016).

One of the most prominent features of the regional climate is the incidence of tropical cyclones (TCs), which represent an important hazard for almost all the countries of the region between June and November. A detailed assessment is given in Chapter 11.

Atlas.7.1.1.2 Findings from previous IPCC assessments

According to the AR5 (Christensen et al., 2013), significant positive trends of temperature have been observed in Central America (high confidence), while significant precipitation trends are regionally dependent, especially during the summer. In addition, changes in climate variability and in extreme events have severely affected the region (medium confidence). A decrease in mean precipitation is projected in SCA and NCA. El Niño and La Niña teleconnections are projected to move eastwards in the future (medium confidence), while changes in their effects on other regions, including Central America and the Caribbean is uncertain (medium confidence). There is medium confidence in projections showing an increase in seasonal mean precipitation on the equatorial flank of the ITCZ affecting parts of Central America and the Caribbean.

In relation to the 1986–2005 baseline period, temperatures are very likely to increase by the end of the century, even for the RCP2.6 scenario, with changes of more than 5°C in some regions for the RCP8.5 scenario. Precipitation change is projected to vary between +10% and –25% (medium confidence) (Christensen et al., 2013). SR1.5 (Hoegh-Guldberg et al., 2018) states there is a high agreement and robust evidence that at the 1.5°C global warming level the Caribbean region will experience a 0.5°C to 1.5°C warming compared to the 1971–2000 baseline period, with greatest warming over larger land masses.

Atlas.7.1.2 Assessment and synthesis of observations, trends and attribution

Significant warming trends between 0.2°C and 0.3°C per decade have been observed in the three reference regions of Central America in the last 30 years (Planos Gutiérrez et al., 2012; Jones et al., 2016c; Hidalgo et al., 2017), with the largest increases in the North America monsoon region (high confidence) (Cavazos et al., 2020) (see also Figure Atlas.11 and the Interactive Atlas). There is high confidence of increasing temperature over parts of NCA, reaching 0.5°C per decade in Mexico and southern Baja California. with a lower rate (0.2°C per decade) in the Yucatan Peninsula and the Guatemala Pacific coastal region (Cueto et al., 2010; García Cueto et al., 2013; Martínez-Austria et al., 2016; Martínez-Austria and Bandala, 2017; Navarro-Estupiñan et al., 2018; Cavazos et al., 2020) and CAR (McLean et al., 2015) over the last 30 to 40 years. Cooling trends have been detected in limited areas of Honduras and northern Panama (Hidalgo et al., 2017).

Changes in mean precipitation rates are less consistent and long-term trends are generally weak. Different databases show significant differences depending mainly on the type and resolution of data (Centella-Artola et al., 2020). Small positive trends were observed in the total annual precipitation (Stephenson et al., 2014). In SCA and CAR, trends in annual precipitation are generally non-significant, with the exception of small significant positive trends for subregions or limited periods (Planos Gutiérrez et al., 2012; Hidalgo et al., 2017) and the 1970–1999 trends in precipitation in SCA are generally non-significant (Jones et al., 2016a; Hidalgo et al., 2017). Positive trends in the duration of the MSD have been found in this region over the past four decades (Anderson et al., 2019) (low confidence). For CAR see also Section Atlas.10 Small Islands.

Atlas.7.1.3 Assessment of model performance

The ability of climate models to simulate the climate in this region has improved in many key aspects

Do Not Cite, Quote or Distribute
Regional climate models (RCMs) forced with reanalyses and atmosphere-only global climate models provide simulations with a reasonably good performance over the core North American monsoon, mostly in NCA (high confidence) (Bukovsky et al., 2013; Cerezo-Mota et al., 2015). RCMs also reproduce the seasonal spatial patterns of temperature and the bimodal rainfall characteristics of the NCA, SCA and CAR (high confidence) (Karmalkar et al., 2013; Centella-Artola et al., 2015; Martínez-Castro et al., 2018b; Cavazos et al., 2020; Vichot-Llano et al., 2020) though in some subregions specific models overestimate and shift the month of the maxima. RCM simulations in the region do not necessarily improve with the size of the domain, as important features of the regional circulation and key rainfall climate features, such as the CLLJ and MSD, are well represented for a variety of domains of different sizes (Centella-Artola et al., 2015; Cabos et al., 2018; Martínez-Castro et al., 2018b; Cavazos et al., 2020; Vichot-Llano et al., 2020) (high confidence).

Atlas.7.1.4 Assessment and synthesis of projections

Figure Atlas.22 and the Interactive Atlas synthesize regional mean changes in annual mean surface air temperature and precipitation for the Central America reference regions for CMIP6, CMIP5 and CORDEX for different warming levels and time periods. At the 1.5°C GWL, it is very likely that average annual temperature in Central America over land surpasses 1.3°C (CAR), 1.7°C (NCA) and 1.6°C (SCA). For the 3°C GWL, the corresponding projected ensemble mean regional warming values are 2.7°C (CAR), 3.5°C (NCA) and 3.1°C (SCA). CAR average annual warming is below the level of global warming, while the two continental reference regions are close to the global warming level with CMIP6 and CMIP5 showing very consistent results (Figure Atlas.22). However, when focusing in time slices instead of warming levels, the CMIP6 projections show systematically higher median values than CMIP5. CORDEX results are also consistent with the previous findings, though the subset of driving models spans a smaller range of uncertainty, particularly over CAR. Results have also been reported for this region based on CMIP5, CMIP6 and downscaled simulations over the CORDEX CAM domain or similar smaller domains (Taylor et al., 2013a; Nakaegawa et al., 2014; Imbach et al., 2018; Vichot-Llano et al., 2019; Almazroui et al., 2021). Statistical downscaling methods have been also applied to CMIP5 projections to obtain bias-adjusted regional projections (Colorado-Ruiz et al., 2018; Taylor et al., 2018; Vichot-Llano et al., 2019).

Global and regional models consistently project warming in the whole region for the end of the century, under RCP4.5 and RCP8.5 for CMIP5 projections with greater warming for continental compared to insular territories, likely reaching values between 2°C and 4°C (high confidence) (Campbell et al., 2011; Karmalkar et al., 2011; Cavazos and Arriaga-Ramírez, 2012; Cantet et al., 2014; Chou et al., 2014; Coppola et al., 2014; Hidalgo et al., 2017; Colorado-Ruiz et al., 2018; Imbach et al., 2018). The greatest warming of 5.8°C for the end of the century was projected for northern Mexico under RCP8.5 (Colorado-Ruiz et al., 2018), using an ensemble of CMIP5 GCMs (see also the Interactive Atlas).

Regarding precipitation, it is likely that the annual average precipitation changes for the 1.5°C GWL will be in the ranges of –11% to 0% in CAR, from –12% to 0% in SCA, and from –10% to +3% in NCA (Interactive Atlas). For the 3°C GWL, the corresponding annual average precipitation changes will be from –17% to –2% in CAR, from –16% to +2% in NCA, and from –23% to 0% in SCA. A clear drying tendency is observed for the 3°C GWL relative to the 1.5°C GWL. Maloney et al. (2014) examined 21st-century climate projections of North American climate in CMIP5 models under RCP8.5, including Central America and the Caribbean. Summertime drying was projected in CAR and SCA for most of the models, with good agreement. The strongest drying is projected to occur during July and August which are the months when the MSD occurs in many subregions (Figure Atlas.22 and the Interactive Atlas). Intensification of the MSD in SCA was also projected by using the Rossby Centre Regional Climate Model (RCA4) (Corrales-Suastegui et al., 2020), but with future decrease in area and frequency (see Cross-Chapter Box Atlas.2). They also found a projected intensification of CLLJ and drying for the future time slice of 2071–2095, relative to their baseline of 1981–
2005. Decreased precipitation was also projected for SCA (Imbach et al., 2018) with the 8-km resolution Eta RCM during the rainy season, including an intensification of the MSD, although no significant change was projected for the CLLJ.

Colorado-Ruiz et al. (2018) assessed an ensemble of 14 GCMs from CMIP5 for a 1971–2000 baseline period, projecting precipitation decreases of between 5% and 10% by the end of the century for the RCP4.5 and RCP8.5 scenarios respectively. The greatest decrease in precipitation is projected during summer reaching 13%, especially in southern Mexico, Central America and the Caribbean. Dynamically downscaled simulations (Bukovsky et al., 2015) also projected a decrease of precipitation for the middle of the century (2041–2069) relative to 1971–1999 for the north of Mexico, though despite good agreement amongst the models, these results must be considered of low confidence, because of their poor simulation of important monsoon physical processes. Vichot-Llano et al. (2021) used a multiparameter ensemble of RegCM4, driven by the CMIP5 global model HagGEM2-ES projections to conclude that, relative to the 1975–2004 baseline, in the near (2020–2049) and more prominently in the far (2070–2099) future, drier conditions will prevail at over the eastern Caribbean. The projected future warming trend was statistically significant at the 95% confidence level over CAR and SCA. Almazroui et al. (2021) used an ensemble of 31 CMIP6 models to estimate climate change signals of temperature and precipitation in six reference regions in North, Central America and the Caribbean, finding a decrease in precipitation (10–30%) over Central America and the Caribbean under three scenarios with regional and seasonal variations.

There is high agreement and high confidence in the projected decrease of precipitation by the end of the century for most of the region particularly for annual and summer precipitation, but there is low confidence on the magnitude of this decrease which varies between 5% and 50% for different projections and different subregions (see extended information in the Interactive Atlas).

The status of climate extreme trends and projections for the region has been assessed in Chapter 11 and the main findings are synthesized here. There is high confidence in the projections of significant heatwave events at the end of the century in SCA (Angeles-Malaspina et al., 2018) and an increase in warm days and warm nights over this region and CAR (Stennett-Brown et al., 2017). For CAR islands, using dynamically downscaled CMIP3 models, Karmalkar et al. (2013) projected increase in drought severity at the end of the century, mainly due to precipitation decrease during the early wet season. In SCA projections suggest an increase in the MSD (Imbach et al., 2018) and increase in consecutive dry days (Chou et al., 2014), consistent with the projections of Stennett-Brown et al. (2017).

**Atlas.7.1.5 Summary**

Significant warming trends between 0.2°C and 0.3°C per decade have been observed in the three reference regions of Central America in the last 30 years, with the largest increases in the North America monsoon region (high confidence). Changes in mean precipitation rates are less consistent and long-term trends are generally weak. Small positive trends were observed in the total annual precipitation in part of the region.

Warming in the continental part of the region is projected to increase in the range of the mean global values for GWL of 1.5°C and 3°C, but in the Caribbean regional warming will be lower. Precipitation is projected to decrease with increasing GWLs especially for CAR and SCA.

Projected change in mean annual precipitation shows a large spatial variability across Central America and the Caribbean. Under moderate future emissions overall negative but non-significant precipitation trends are projected for the 21st century (low confidence). Under higher emissions scenarios and at higher GWLs, average precipitation is likely to decrease in most of the region, particularly in the north-western and central Caribbean and part of continental Central America, especially in SCA.
**Atlas.7.2 South America**

**Atlas.7.2.1 Key features of the regional climate and findings from previous IPCC assessments**

**Atlas.7.2.1.1 Key features of the regional climate**

Regional synthesis of observed and modelled climate in South America is challenging due to the latitudinal extent of the continent, the Andes mountains, and local to regional climatic features, which are influenced by multiple drivers. The main large-scale drivers include many modes of natural variability (Annex IV.2): the interdecadal modes, Atlantic Multidecadal Variability (AMV) and Pacific Decadal Variability (PDV); the interannual-to-annual modes, El Niño-Southern Oscillation (ENSO), the Indian Ocean Dipole (IOD), the Southern Annular Mode (SAM) and the North Atlantic Oscillation (NAO); seasonal variability driven by the meridional migration of the Intertropical Convergence Zone and the timing and intensity of the South American Monsoon System (SAM); and the Madden-Julian Oscillation sub-seasonal mode of natural variability (MJO) and the behaviour at finer scales of the tropical easterly waves.

The regional assessment in this section emphasizes the seven new South American reference regions (Figure 7.22) (Iturbide et al., 2020) that have a largely consistent climate and response to climate change and can be used for analysis and impact studies (Solman et al., 2008; Neukom et al., 2010; Barros et al., 2015; Nobre et al., 2016). At the subregional scale, several phenomena drive climate variability. Brazil's northeast (North-Eastern South America; NES) is the most densely populated dryland globally and recurrently affected by climatic extremes. The climate variability, particularly the precipitation, is marked by strong interannual variability related to ENSO, the ITCZ, and the North Tropical Atlantic Ocean SSTs (Marengo et al., 2018a). The densely populated, highly productive subregion of South-Eastern South America (SES) has cooling during the last decades of the 20th century, except for a cooling off the Chilean coast in about 1°C during the same period. WGI AR5 (Flato et al., 2013) noted that climate simulations from CMIP3 and CMIP5 models were able to represent well the main climatological features, such as seasonal mean and annual cycle (high confidence), although some biases remained over the Andes, Amazon basin and for the South America Monsoon. On the other hand, climate models from CMIP5 showed better results when compared to CMIP3.
The SR1.5 (Hoegh-Guldberg et al., 2018) assessed that a further increase of 0.5°C or 1°C is likely to have detectable effects on mean temperature and precipitation in South America, particularly in tropical regions (NWS, NAS, SAM and NES), as well as in SES given that changes in mean temperatures and precipitation have already been attributed in the last decades for global warming of less than 1°C.

**Atlas.7.2.2 Assessment and synthesis of observations, trends and attribution**

Studies on climatic trends in South America indicate that mean temperature and extremely warm maximum and minimum temperatures have shown an increasing trend (high confidence), particularly for a large region in northern South America and the south-western Andes (NSA, SAM, NES, SWS and the north of SES) (Skanski et al., 2013; de Barros Soares et al., 2017). Also, the trend of the difference between the annual mean of the daily maximum temperature and the annual mean of the daily minimum temperature was positive – up to 1°C per decade – over the extra-tropics with the maximum temperature generally increasing faster than the minimum temperature, while a negative trend – up to −0.5°C per decade – was observed over the tropics.

Regionally, analyses of temperatures point to an increased warming trend (high confidence) over Amazonia over the last 40 years, which reached approximately 0.6°C–0.7°C (Figure Atlas 11 and the Interactive Atlas) and with stronger warming during the dry season and over the southeast. The analyses also showed that 2016 was the warmest year since at least 1950 (Marengo et al., 2018b). Andean temperatures showed significant warming trends, especially at inland and higher-elevation sites, while trends are non-significant or negative at coastal sites (Vuille et al., 2015; Burger et al., 2018; Vicente-Serrano et al., 2018; Pabón-Caicedo et al., 2020) (high confidence). Over central Chile, positive trends are largely restricted to austral spring, summer and autumn seasons for mean, maximum and minimum temperatures (Burger et al., 2018; Vicente-Serrano et al., 2018). Over Peru trends of maximum air temperature were mainly amplified during the austral summer, but trends of cold season minimum air temperature showed an opposite pattern, with the strongest warming being recorded in the austral winter (Vicente-Serrano et al., 2018).

In general, the spatial patterns of observed trends in temperature are more consistent than for precipitation across the whole South America (Interactive Atlas) (de Barros Soares et al., 2017) (medium confidence). In southeast Brazil there is a region of highly significant decrease of rainfall in both wet and dry seasons recorded in the period 1979–2011 (Rao et al., 2016) (Interactive Atlas). The most consistent evidence of positive rainfall trend occurs in the southern part of the La Plata Basin (southern Brazil, Uruguay, and north-eastern Argentina) (de Barros Soares et al., 2017) (high confidence). By contrast, there is high confidence that annual rainfall has decreased over northeast Brazil during the last decades (Carvalho et al., 2020).

Contrary to temperature changes, trends in annual precipitation exhibit different signs across sectors in the Andes. For instance, annual precipitation trends in north tropical (north of 8°S) and south tropical (8°S–27°S) Andes do not show a homogeneous pattern. Over the subtropical Andes, central Chile shows a robust signal of declining precipitation since 1970 (Pabón-Caicedo et al., 2020) (high confidence).

Observational studies show that the dry-season length over southern Amazonia has increased significantly since 1979 (Fu et al., 2013; Alves, 2016) (high confidence). In the Peruvian Amazon-Andes basin, there is no trend in mean rainfall during the period 1965–2007 (Lavado Casimiro et al., 2012) though statistically significant decreases in total annual rainfall in the central and southern Peruvian Andes from 1966 to 2010 were found (Heidinger et al., 2018). Despite that, recent analyses of Amazon hydrological and precipitation data suggest an intensification of the hydrological cycle over the past few decades (Gloor et al., 2015). In general, these changes are attributed mainly to decadal climate fluctuations (high confidence), ENSO, the Atlantic SST north-south gradient, feedbacks between fire and land-use change mainly across southern south-eastern Amazon and changes in the frequency of organized deep convection (Fernandes et al., 2016a; Sánchez et al., 2015; Tan et al., 2015).

Since AR5, there has been limited attribution literature in the South America. Recent publications based on observational and modelling evidence assessed that anthropogenic forcing in CMIP5 models explains with the overall warming (high confidence) over the entire South American continent, including the increase in the frequency of extreme temperature events (Hannart et al., 2015) such as the Argentinian heatwave of...
December 2013 (Chapter 11). It has a detectable influence in explaining positive and negative precipitation trends observed in regions such as SES and the Southern Andes (Vera and Díaz, 2015; de Barros Soares et al., 2017; Boisier et al., 2018; de Abreu et al., 2019). Despite that, there is limited evidence that human-induced greenhouse gas emissions had an influence on the 2014/2015 water shortage in Southeast Brazil (Otto et al., 2015). Extreme event attribution on sub-continental scales is assessed in Chapter 11 and continental-scale attribution in Chapter 3.

In summary, analyses of historical temperature time series point strongly to an increased warming trend (high confidence) across many South American regions, except for a cooling off the Chilean coast. Annual rainfall has increased over south-eastern South America and decreased in most tropical land regions, particularly in central Chile (high confidence). The number and strength of extreme events, such as extreme temperatures, droughts and floods, have already increased (medium confidence) (see Table 11.7).

It is noted that the major barrier to the study of climate change in many regions of South America is still the absence or insufficiency of long time series of observational data (Carvalho, 2020; Condom et al., 2020). Most national datasets were created in the 1970s and 1980s, preventing a more comprehensive long-term trend analysis. To fulfil the users’ demand for climatological and meteorological data products covering the whole region, several interpolation techniques have been used with reanalysis and gridded gauge-analysis products to add the necessary spatial detail to the climate analyses over land and for climate variability and trend studies but these are subject to uncertainties (Skansi et al., 2013; Rozante et al., 2020).

**Atlas.7.2.3 Assessment of model performance**

Since AR5 the number of publications on climate model performance and their projections in South America has increased, particularly for regional climate modelling studies (Giorgi et al., 2009; Boulanger et al., 2016; Ambrizzi et al., 2019) and the understanding of their strengths and weaknesses (high confidence).

Most global and regional climate models can simulate reasonably well the current climatological features of South America, such as seasonal mean and annual cycles. However, significant biases persist mainly at regional scales (high confidence) (Torres and Marengo, 2013; Blázquez and Nuñez, 2013b; Gulizia et al., 2013; Joetzjer et al., 2013; Jones and Carvalho, 2013; Gulizia and Camilloni, 2015; Zazulie et al., 2017a; Abadi et al., 2018; Barros and Doyle, 2018; Solmán and Blázquez, 2019; Teichmann et al., 2020; Fan et al., 2020; Rivera and Arnould, 2020). During the dry season, precipitation is underestimated in most models over Amazonia (medium evidence and high agreement) (Torres and Marengo, 2013; Yin et al., 2013; Solman and Blázquez, 2019). Over regions with complex orography, such as the tropical Andes of NWS, CMIP5 models tend to underestimate precipitation which is associated with the misrepresentation of the Pacific ITCZ and the local low-level jets (Sierra et al., 2015, 2018), whereas over the subtropical central Andes in AWS, the models are found to overestimate both mean temperature and precipitation values (limited evidence and high agreement) (Zazulie et al., 2017b; Rivera and Arnould, 2020; Díaz et al., 2021). Most models show a dry bias over SES (Díaz and Vera, 2017; Barros and Doyle, 2018; Solman and Blázquez, 2019; Díaz et al., 2021) associated with an underestimation of the northern flow that brings water vapour into the region (medium confidence) (Gulizia et al., 2013; Zazulie et al., 2017a; Barros and Doyle, 2018). The biases in seasonal precipitation, annual precipitation and climate extremes over several regions of South America were reduced, including the Amazon, central South America, Bolivia, eastern Argentina and Uruguay, in the CMIP5 models when compared to those of CMIP3 (medium confidence) (Joetzjer et al., 2013; Gulizia and Camilloni, 2015; Díaz and Vera, 2017). The evidence is still insufficient to determine whether CMIP6 biases are reduced when compared with CMIP5 simulations regarding precipitation and its variability in South America. The temperature and precipitation patterns of anomalies associated with ENSO in the tropical South America (NWS, NSA and NES) are better captured by GCMs in tropical South America (NWS, NSA and NES) than in extra-tropical South America (SES), particularly during austral summer and autumn (limited evidence and high agreement) (Tedeschi and Collins, 2016; Perry et al., 2020).

Based on regional simulations, studies showed that some RCMs improve the quality of the simulated climate when compared with the driving GCM (medium evidence and high agreement) (Llopard et al., 2014; Sánchez...
Regional climate model (RCM) simulations over South America can reproduce the main features of temperature and precipitation in terms of both spatial distributions (Solman et al., 2013; Falco et al., 2019) and seasonal cycles over the different climate regimes, including the main SAmerM features (high confidence) (Jacob et al., 2012; Solman, 2013; Llopart et al., 2014; Reboita et al., 2014a; de Jesus et al., 2016; Lyra et al., 2018; Bozkurt et al., 2019; Ashfaq et al., 2020). However, RCMs showed systematic biases such as precipitation overestimations and temperature underestimations along the Andes throughout the year (high confidence) although these biases may be artificially amplified by the lack of a dense observational station network (Jacob et al., 2012; Solman et al., 2013; Bozkurt et al., 2019; Falco et al., 2019). RCMs tended to show dry biases over the Amazon and the northern part of the continent (SAM, NSA) during DJF and during the maximum precipitation associated with the intertropical convergence zone (ITCZ) over NSA during JJA (medium evidence and high agreement) (Solman et al., 2013; Falco et al., 2019). Temperature overestimation and precipitation underestimation over La Plata Basin (in SES) are also RCM common biases with the warm bias amplified for austral summer and the dry bias amplified for the rainy season (high confidence) (Solman et al., 2013; Reboita et al., 2014a; Solman, 2016; Falco et al., 2019). Despite their relevance RCM simulations at very high resolution (less than 10 km) are still few in South America (high confidence) and are mainly designed for specific regions or purposes (Lyra et al., 2018; Bozkurt et al., 2019; Bettolli et al., 2021).

The evaluation of statistical downscaling models (ESD) in representing regional climate features in South America has increased since the AR5, however there are still few ESD studies over the different subregions. Precipitation simulations based on ESD models are able to reproduce mean precipitation over tropical and subtropical South American regions, especially over maximum precipitation areas in western Colombia, south-eastern Peru, central Bolivia, Chile and the La Plata basin (medium confidence) (Souvignet et al., 2010; Mendes et al., 2014; Palomino-Lemus et al., 2015, 2017, 2018; Troin et al., 2016; Soares dos Santos et al., 2016; Borges et al., 2017; Bettolli and Penalba, 2018; Araya-Osses et al., 2020; Bettolli et al., 2021). Temperature simulations are fewer but show added value to GCM simulations (medium evidence and high agreement) (Souvignet et al., 2010; Borges et al., 2017; Bettolli and Penalba, 2018; Araya-Osses et al., 2020).

Overall, climate modelling has made some progress in the past decade but there is no model that performs well in simulating all aspects of the present climate over South America (high confidence). The performance of the models varies according to the region, time scale, and variables analysed (Abadi et al., 2018). There is also a fairly narrow spread in the representation of temperature and precipitation over South America by the CMIP5 GCMs and also the RCMs; with biases that can be associated with the parametrizations and schemes of surface, boundary layer, microphysics and radiation used by the models. Finally, observational reference datasets, such as reanalysis products, used in the calibration and validation of climate models also can be quite uncertain and may explain part of the apparent biases present in climate models (high confidence).

Atlas.7.2.4 Assessment and synthesis of projections

It is very likely that annual mean temperature will increase over South America, with a wide range of projected changes of 1.0°C to 6.0°C by the end of the 21st century (from RCP2.6/SSP1-2.6 to RCP8.5/SSP5-8.5 emissions, Figure Atlas.22). Overall, GCMs project higher temperature change than RCMs in austral summer and winter over all subregions and in winter mainly over the central part of the continent (Coppola et al., 2014; Llopart et al., 2020; Teichmann et al., 2020) (see also the Interactive Atlas). The largest warmings over the South American continent are projected for the Amazon basin (SAM and NSA) and the central Andes range (southern SAM, northern SWS and south-eastern NWS), Figure Atlas.22, especially during the dry and dry-to-wet transition seasons (austral winter and spring) (Blázquez and Nuñez, 2013a; Coppola et al., 2014; Pabón-Caicedo et al., 2020; Teichmann et al., 2020) (high confidence).

Using warming levels (Figure Atlas.22), the temperature is projected to increase at or above the level of global warming in all regions apart from SSA with additional warming (compared to a 1995–2014 baseline) of over 4°C for the 4°C warming level in NSA and SAM. Changes for other warming levels, subregions and
emissions pathways are shown in Figure Atlas.22 and can be explored with the Interactive Atlas.

In general, models show a wide regional range in the direction and the magnitude of mean precipitation change in many South American regions, with large significant increases and decreases (Figure Atlas.22, Interactive Atlas). In the medium and long term, under the high-emission scenario, the CMIP5 multi-model ensemble projected an increase in precipitation (generally greater than 10%) in SES and NWS and a decrease (less 10%) in NSA across seasons (high confidence, robust evidence) (Solman, 2013; Chou et al., 2014; Coppola et al., 2014; Llopart et al., 2014, 2020, Reboita et al., 2014b, 2020; Sánchez et al., 2015; Menéndez et al., 2016; Ruscica et al., 2016; Bozkurt et al., 2018a; Zaninelli et al., 2019). Also, in parts of SWS, annual precipitation is projected to decrease (up 30%) by the late 21st century (Souvignet et al., 2010; Palomino-Lemus et al., 2017, 2018; Bozkurt et al., 2018a). Under high RCPs, the CMIP5 ensemble projects that all Brazilian regions will experience more rainfall variability in the future, so drier dry periods and wetter wet periods on daily, weekly, monthly and seasonal timescales, despite the future changes in mean rainfall being currently uncertain (medium confidence) (Alves et al., 2020). Regarding the SAmerM, it is very likely that the monsoon will experience changes in its life cycle by the end of the 21st century for both RCP4.5 and RCP8.5 emissions and, in particular, delayed onset. However there is low agreement on the projected changes in terms of extreme and total precipitation of the monsoon season in South America (Llopart et al., 2014; Ashfaq et al., 2020). Changes in the SAmerM are assessed in Section 8.3.2.4.5.

Projected changes in seasonal precipitation and their uncertainties generally agree with the annual changes, particularly for the decreases in SWS (Figure Atlas.22). DJF precipitation changes in NSA and SAM are largely uncertain, with weak agreements in the projections, particularly for CMIP5 and CMIP6 ensembles, which project almost no change and decreasing precipitation for NSA and a narrow range from slight increases to no change respectively for SAM.

**Atlas.7.2.5 Summary**

In summary, it is virtually certain that the climate of South America has warmed. Studies on climate trends in South America indicate that mean temperature, maximum and minimum temperatures have increased over the last 40 years. Long-term observed precipitation trends show an increase over south-eastern South America and decreases in most tropical land regions (high confidence).

Evaluation of global and regional climate model simulations have increased over South America in the past decade and shown improved performance. However, the results reveal that no model performs well in simulating all aspects of the present climate (very likely). On the other hand, there is still a lack of high-quality and high-resolution observational data that may explain part of the important biases present in climate models (high confidence).

Climate model projections show a general increase in annual mean surface temperature over the coming century for all emission scenarios (RCPs and SSPs) (high confidence) consistent with the observed warming and with all regions except SSA warming faster than the global average. Unlike temperature, annual precipitation has patterns of decrease in North-eastern South America (NES) and South-western South America (SWS) and increase in southern South America (SES) and North-western South America (NWS) (high confidence), with small changes projected under a low-emission scenario. However, there is low confidence in the magnitude because of the large spread among models, both GCMs and RCMs.

**Atlas.8 Europe**

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and snow), including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment of changes in extremes are in Chapter 11 (Table 11.16–11.18) and climatic impact-drivers in Chapter 12 (Table 12.7).
Atlas.8.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.8.1.1 Key features of the regional climate

Westerly winds and the accompanying Atlantic storm track with cyclones and anticyclones travelling from the Atlantic towards inland Europe are the main climatic features that characterize daily to inter-annual variability in the European region. The Siberian High in winter determines cold weather in East Europe and can affect other regions with cold outbreaks. Intra-seasonal and inter-annual variations are driven by modes of climate variability such as the North Atlantic Oscillation (see Table Atlas.1 and Annex IV.2). Global warming can lead to systematic changes in regional climate variability via thermodynamic responses such as altered lapse rates (Kröner et al., 2017; Brogli et al., 2019) and land-atmosphere feedbacks (Zampieri and Lionello, 2011; Boé and Terray, 2014). Regional feedbacks involving the land-sea contrast, sea surface, land surface, clouds, aerosols, radiation and other processes modulate the regional response to enhanced warming.

Four climatic regions are defined for Europe (see Figure Atlas.24). The Mediterranean region (MED) in the south is characterized by mild winters and hot and dry summers (Mediterranean climate; see Section 10.6.4.2). It covers both Europe and Africa, and MED assessments in this section generally imply the entire MED domain unless stated otherwise. The Western and Central Europe region (WCE) has distinct summer and winter seasons with increasing continentality of climate eastwards. The northern region (NEU), close to the Atlantic Ocean, is characterized by high humidity and relatively mild winters, and strong exposure to the Atlantic storm track. Eastern Europe (EEU) covers the western part of Russia and neighbouring territories and has continental characteristics. Many regional datasets and model projections assessed here do not sufficiently cover the EEU region.

Atlas.8.1.2 Findings from previous IPCC assessments

AR5 WG II (Kovats et al., 2014) reports with high confidence that observed climate trends show regionally varying changes in temperature and rainfall in Europe. The average temperature in Europe has continued to increase, with seasonally different rates of warming being greatest in high latitudes in Northern Europe. Annual precipitation has increased in Northern Europe and decreased in parts of Southern Europe. SROCC (Hock et al., 2019b) reports with high confidence that a reduction in snow cover at low elevation and glacier extent is observed in recent decades, with consequent changes in annual and seasonal runoff patterns. According to the SROCC report (IPCC, 2019b) there is high agreement that observed vegetation greening and forestation in the last 30 years cools summertime surface temperature and warms winter temperature due to decreased snow cover and increased snow shading in forested areas. It is very likely that aerosol column amounts have declined over Europe since the mid-1980s.

AR5 (Collins et al., 2013) reports that the ability of models to simulate the climate in Europe has improved in many important aspects. Particularly relevant for this region are increased model resolution and a better representation of the land-surface processes in many of the models that participated in CMIP5. The spread in climate model projections is still substantial, partly due to pronounced internal variability in this region (particularly NAO and AMO). In the winter half year, NEU and WCE are likely to have increased mean precipitation associated with increased atmospheric moisture and moisture convergence and intensification in extratropical cyclone activity. No change or a moderate reduction is projected for MED. In the summer half year, it is likely that NEU and WCE mean precipitation will have only small changes with a notable reduction in MED. According to SR1.5 (Hojgh-Guldberg et al., 2018), these precipitation changes are more pronounced at 2°C than at 1.5°C of global warming. For a 2°C global warming, an increase in runoff is projected for north-eastern Europe while decreases are projected in the Mediterranean region, where runoff differences between 1.5°C and 2°C global warming will be most prominent (medium confidence). According to SROCC (Hock et al., 2019b) the RCP8.5 projections lead to a loss of more than 80% of the ice mass from small glaciers by the end of century in Central Europe (high confidence). Snow cover and glaciers are projected to decrease all along the 21st century.
Atlas.8.2 Assessment and synthesis of observations, trends and attribution

To support climatological analyses and model evaluation, national meteorological and hydrological services are increasingly making available high spatial and temporal resolution gridded and in situ homogenized and quality-checked datasets (Déqué and Somot, 2008; Vidal et al., 2010; Rauthe et al., 2013; Noël et al., 2015; Spinoni et al., 2015b; Ruti et al., 2016; Fantini et al., 2018; Lussana et al., 2018; Herrera et al., 2019; Skrynyk et al., 2020). The inclusion of additional station data and data rescue activities lead to a better representation of extreme precipitation statistics than the global- or continental-scale datasets (see Section Atlas.1.4.1). Recent gridded products merging radar and station data allow higher spatial and temporal resolutions to be reached (Haiden et al., 2011; Tabary et al., 2011; Berg et al., 2016; Fumière et al., 2020). A number of regional reanalysis products has become available for the European region (Bollmeyer et al., 2015; Bach et al., 2016; Dahlgren et al., 2016; Landelius et al., 2016). A European ensemble of regional reanalyses from 1961 to 2019 is shown to add accuracy and reliability in comparison to global reanalysis products, but also introduces additional uncertainties, especially for threshold-based climate indices (Kaiser-Weiss et al., 2019). However, gridded European datasets are unreliable over data-sparse regions. Also, many datasets employ different approaches to interpolation and gridding, which adds to their uncertainty and complicates comparative evaluations (Berthou et al., 2018; Fantini et al., 2018; Kotlarski et al., 2019). For some subregions and performance metrics differences between datasets have been shown to be of the same magnitude as errors in regional climate models (Prein et al., 2016; Prein and Gobiet, 2017; Fantini et al., 2018), but observational uncertainty is substantially reduced when datasets of similar nature and representativeness are used (Kotlarski et al., 2019).

In addition to the global display of observed temperature and precipitation trends in Figure Atlas.11, annual mean temperature and precipitation trends between 1980 and 2015 calculated from the gridded ensemble E-OBS dataset (Cornes et al., 2018) are shown in Figure Atlas.23, together with time series of temperature and precipitation anomalies relative to the 1980–2015 mean value from E-OBS, CRU, EWEMBI and Berkeley for temperature, and E-OBS, CRU, GPCC and GPCP for precipitation (see also Figure 2.11 for global mean values, and Section Atlas.1.4.1 for description of global datasets).

In NEU continued warming has been observed, particularly during spring. An annual mean temperature increase of 0.4°C per decade was reported between 1970 and 2008 (Rutgersson et al., 2015). In WCE temperature increases since the mid 20th century have been documented for Poland (Degirmendžić et al., 2004) and Ukraine (Boychenko et al., 2016; Balabukh and Malitskaya, 2017). Land-only observations indicate a rapid increase in summer (JJA) mean surface air temperature since the mid-1990s (Dong et al., 2017). In Eastern Europe no significant trend in winter mean air temperatures was found between 1881 and 2016 in Belarus (Logonov et al., 2018). In parts of the European area of the MED spring and summer temperatures are reported to increase faster than in the other seasons (Brunetti et al., 2006; Homar et al., 2009; Lionello et al., 2012; Philandras et al., 2015; Gonzalez-Hidalgo et al., 2016; Vicente-Serrano et al., 2017) (see also the Mediterranean case study in Section 10.6.4 and Figure 10.18). Figure Atlas.23 shows that since 1980 in each European region all datasets show a consistent warming of annual mean temperature of 0.04°C yr⁻¹ to 0.05°C yr⁻¹. Trends in European land temperature cannot be explained without accounting for anthropogenic warming offset by anthropogenic aerosol emissions (see Section 8.3.1.1 and Figure 3.8). It is virtually certain that annual mean temperature continues to increase in each European subdomain.

Multidecadal trends in mean precipitation are generally small and non-significant. Apart from difficulties related to observational coverage (Prein and Gobiet, 2017), gauge undercatch (e.g., Murphy et al., 2019) and data inhomogeneity (e.g., Camuffo et al., 2013), strong interannual and multidecadal variability is dominant over at least the last two centuries. However, significant precipitation trends have been recorded for recent periods, for example in south-western Europe between 1960 and 2000 (Peña-Angulo et al., 2020) and between 1961 and 2015 in NEU (Interactive Atlas). Also, some studies suggest that in the MED precipitation has declined and more frequent and severe meteorological droughts have occurred between 1960 and 2000 (Spinoni et al., 2015a; Gudmundsson and Seneviratne, 2016), and in some regions cannot be explained without anthropogenic forcing (Knutson and Zeng, 2018) (see also Section 10.4.1.2). Other studies suggest that this trend can be seen as an expression of multidecadal internal variability driven mainly by the North Atlantic Oscillation (Table Atlas.1) (Kelley et al., 2012; Zittis, 2018). Global dimming and brightening also
are reported to affect precipitation trends in the Mediterranean region (see Section 8.3.1.6 and Figure 8.7).

The large-scale spatial patterns of the E-OBS annual mean precipitation trend between 1980 and 2015 shown in Figure Atlas.23 is broadly consistent with trends derived from CRU, GPCP and GPCC (Figure Atlas.11) but with more explicit spatial detail. Trends calculated for regional averages are sensitive to the selection of the time window: for 1980–2015 annual mean precipitation averaged over the regions shows a positive trend (not significant at $p = 0.05$), while for CRU and GPCP the trend calculated over 1901–2015 is positive for NEU, EEU and WCE, and non-significant for MED. Precipitation trends in the MED are significant only in selected areas (Lionello et al., 2012; MedECC, 2020). Also the NEU trends show large spatial variability and are subject to decadal variability related to NAO (Heikkilä and Sorteberg, 2012), but are generally positive over the 20th century (Figure Atlas.23). There is medium confidence that annual mean precipitation in NEU, WCE and EEU has increased since the early 20th century. In the European Mediterranean observed land precipitation trends show pronounced variability within the region, with magnitude and sign of trend in the past century depending on time period and exact study region (medium confidence).

Trends in snowfall and snow melt are related to seasonal changes in both temperature and precipitation. In EEU melt onset dates have advanced by 1–2 weeks in the 1979–2012 period (Mioduszewski et al., 2015). Over Eurasia, trends in spring and early summer snow cover extent increased over the 1971–2014 period (Hernández-Henríquez et al., 2015). Between 1966 and 2012, averaged over entire Eurasia, monthly mean snow depth decreased in autumn and increased in winter and spring (Zhong et al., 2018), while the snow cover extent was reported to have decreased during the past 40 years (Bulygina et al., 2011). In NEU late winter and early spring snow depth and snow cover decreases since the early 1960s are reported over Finland (Luomaranta et al., 2019) and Norway (Rizzi et al., 2018) with a dependence on altitude (Skaugen et al., 2012), while winter snow depth increased in northern Sweden (Kohler et al., 2006). It is very likely that since the early 1980s in snow-dominant areas in NEU and EEU the length of the snowfall season is reduced with regional warming, and the melt onset dates have advanced.

[START FIGURE ATLAS.23 HERE]

Figure Atlas.23: (a) Mean 1980–2015 trend of annual mean surface air temperature (°C per decade) from E-OBS (Cornes et al., 2018). Data for non-European countries in the MED area are masked out. (b) Time series of mean annual temperature anomaly relative to the 1980–2015 period (shown with grey shading) aggregated for the land area in each of the four European subregions, from E-OBS, CRU, Berkeley and ERA5 (see Section Atlas.4.1 for description of global datasets). Mean trends for 1901–2015, 1961–2015 and 1980–2015 are shown for each data set in corresponding colours in the same units as panel (a) (see legend in upper panel). (c) As panel (a) for annual mean precipitation (mm day$^{-1}$ per decade); (d) as panel (b) for annual mean precipitation, and data sets E-OBS, CRU, GPCP and GPCC. Note that E-OBS data are not shown in panels b and d for region EEU. For the MED region data are aggregated over the European countries alone. Trends have been calculated using ordinary least squares regression and the crosses indicate non-significant trend values (at the 0.1 level) following the method of Santer et al. (2008) to account for serial correlation. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.23 HERE]

The increasing trend in surface shortwave radiation, documented in AR5 (Hartmann et al., 2013) to have occurred since the 1980s and referred to as a brightening effect, is substantiated over Europe and the Mediterranean region (Nabat et al., 2014; Sanchez-Lorenzo et al., 2015; Cherif et al., 2020). This increasing trend has been attributed to the decrease in anthropogenic sulphate aerosols over the 1980–2012 period (Nabat et al., 2014). In model sensitivity experiments, the aerosol trend has been quantified to explain 81 ± 16% of the European surface shortwave trend and 23 ± 5% of the European surface temperature warming. It is likely that trends in anthropogenic aerosols in Europe have generated positive trends in shortwave radiation and surface temperature since the 1980s (see also Sections 6.3.3.1, 8.3.1.6 and 10.6.4).
Assessments of observed European trends in meteorological extremes and CIDs are reported elsewhere in this report. Section 11.3.5 documents and attributes an increase in the frequency and extent of heatwaves and daily maximum temperatures, and Section 11.6.2 discusses the uncertainty concerning the detection of trends in meteorological droughts, and the role of increasing atmospheric evaporative demand on hydrological and ecological/agricultural droughts. Section 8.3.1.8 reports on increasing aridity trends in the Mediterranean related to soil moisture declines and increases in atmospheric water vapor demand. Section 11.4.2 reports on the increased likelihood and intensity of daily precipitation extremes, while Sections 11.5.2 and 12.4.5.2 discuss implications for peak streamflow. Section 12.4.5.5 discusses the increased likelihood of wildfires, while Section 12.4.5.3 discusses the substantial decadal variability in mean wind speed and the trends in wind storms and gusts. The acceleration of sea level rise in the Atlantic and European seas has been discussed in Section 12.4.5.5.

**Atlas.8.3 Assessment of model performance**

A global evaluation of annual mean temperature and precipitation from the CMIP6 ensemble is presented in Sections 3.3.1 and 3.3.2 respectively. In general, annual mean temperature is slightly underestimated at high latitudes and overestimated in the MED area. Temporal evolution of decadal temperature oscillations in Europe simulated by the CMIP6 historical simulations is well reproduced (Fan et al., 2020). Fernandez-Granja et al. (2021) report an overall improvement of CMIP6 compared to CMIP5 to reproduce atmospheric weather patterns over Europe.

Regional climate models (RCMs; Section 10.3.1.2) have been extensively evaluated for a range of climate features over Europe (Casaua et al., 2016; Vaittina Aar et al., 2016; Ivanov et al., 2017; Krakovska et al., 2017; Terzaghi et al., 2017; Cavicchia et al., 2018; Drobinski et al., 2018; Fantini et al., 2018; Harzallah et al., 2018; Panthou et al., 2018b). Standard assessments of RCMs driven by reanalyses, typically run at 12–25 km spatial resolution, confirm that the Euro-CORDEX and Med-CORDEX ensembles are capable of reproducing the salient features of European climate (Kotlarski et al., 2014; Krakovska, 2018) and represent European circulation features realistically (Cardoso et al., 2016; Drobinski et al., 2018; Flaounas et al., 2018; Sanchez-Gomez and Somot, 2018). Seasonal and regionally averaged temperature biases generally do not exceed 1.5°C, while precipitation biases can be up to ±40% (Kotlarski et al., 2014). Extensive evaluation of a large collection of RCM-GCM combinations show a general wet, cold and windy bias compared to observations and reanalyses, but none of the models is systematically performing best or worst (Vautard et al., 2020). Higher-resolution simulations do show improved performance in reproducing the spatial patterns and seasonal cycle of not only extreme precipitation but also mean precipitation over all European regions (Mayer et al., 2015; Fantini et al., 2018; Soares and Cardoso, 2018; Ciarlo et al., 2020)(see also Sections 10.3.3.4 and 10.3.3.5 for an extensive evaluation of the added value of increased simulation resolution).

In line with findings reported in Section 10.3.3.8, several studies argue that both GCMs and RCMs underestimate the observed trend in European summer temperature (Dosio, 2016; Boë et al., 2020b), indicating that essential processes are missing or that the natural variability is not correctly sampled (Dell’Aquila et al., 2018). Nabat et al. (2014) argued that including realistic aerosol variations enables climate models to correctly reproduce the summer warming trend (as is required for attributing continental annual temperature trends; Section 8.3.1.1). However, other studies showed models to be sensitive also to local effects, such as land-surface processes, convection, microphysics, and snow albedo (Vautard et al., 2013; Davin et al., 2016). In Euro-CORDEX the warm and dry summer bias over southern and south-eastern Europe is reduced compared to the previous ENSEMBLES simulations (Kotragkou et al., 2015; Giot et al., 2016; Prein and Gobiet, 2017; Dell’Aquila et al., 2018). Natural variability has strongly affected the historical warming and large ensembles are necessary for a correct estimation of the forced signal versus natural variability (Aalbers et al., 2018; Lehner et al., 2020).

Specific assessments of Convection Permitting RCMs (CPRCMs, running at a resolution of typically 1 to 3 km and designed for extreme precipitation characteristics) is undertaken in Section 10.3.3.4.1. A unique CPRCM ensemble has been applied over the great Alpine domain and improves representation of mean and extreme precipitation compared to coarser resolution models (Ban et al., 2021; Pichelli et al., 2021).

Do Not Cite, Quote or Distribute
The role of aerosol forcing is increasingly analysed as new and more realistic aerosol datasets become available (Nabat et al., 2013; Pavlidis et al., 2020), and as RCMs begin to include interactive aerosols (Nabat et al., 2012, 2015, 2020; Drugé et al., 2019). Explicitly accounting for aerosol effects in RCMs leads to improved representation of the surface shortwave radiation at various scales: long-term means (Gutiérrez et al., 2018), day-to-day variability (Nabat et al., 2015), and long-term trends (Nabat et al., 2014).

New, or updated, higher-resolution, coupled atmosphere-ocean-ice model systems have been found to improve simulations of observed climate features over the Baltic area compared to atmosphere-only model versions, including correlation between precipitation and SST, between surface heat-flux components and SST, and weather events like convective snow bands over the Baltic Sea (e.g., Tian et al., 2013; Van Pham et al., 2014; Gröger et al., 2015; Wang et al., 2015a; Pham et al., 2017). Coupled atmosphere-land-river-ocean Regional Climate System Models (RCSMs) from Med-CORDEX have similar skill as the ENSEMBLES and the Euro-CORDEX ensembles to represent decadal variability of Mediterranean climate and its extremes (Cavicchio et al., 2018; Dell’Aquila et al., 2018; Gaertner et al., 2018). Panthou et al. (2018b) showed that over land, differences between atmosphere-only and coupled RCMs are confined to coastal areas that are directly influenced by SST anomalies. In contrast, Van Pham et al. (2014) showed significant differences in seasonal mean temperature across a widespread continental domain.

Statistical downscaling methods are assessed in Section 10.3.3.7, including the intercomparison and evaluation activities performed in the framework of VALUE and Euro-CORDEX over Europe.

**Atlas.8.4 Assessment and synthesis of projections**

Simulations from CMIP5 and CMIP6 indicate pronounced geographical patterns and scenario dependence of the projections of mean temperature and precipitation. Global warming projected under SSP5-8.5 emissions in CMIP6 exceeds the warming projected by RCP8.5 emissions in CMIP5 (Forster et al., 2019) (see also Section 4.3). In selected regions in Europe CMIP6 also projects a systematically higher mean temperature than CMIP5 (Seneviratne and Hauser, 2020). The annual mean projections from CMIP5, CMIP6 and 0.11° resolution EURO-CORDEX contained in the Interactive Atlas are shown for the four European regions in Figure Atlas.24. For each region and season a warming offset between the preindustrial (1850–1900) and the recent past (1995–2014) baselines is also shown. The results confirm higher CMIP6 long-term annual mean warming rates for WCE, EEU and MED and a larger inter-model spread for each region. For given global warming levels, regional annual mean temperature change in CMIP5 and CMIP6 are largely consistent and higher than the global average, most prominently in EEU. For high warming levels the CMIP5 subset of 8 GCMs used to drive the EURO-CORDEX simulations show a lower annual mean temperature change than the full CMIP5 ensemble in each of the European subregions. This illustrates the large inter-model spread and implications for subsampling a relatively small subset from the full ensemble. Regional warming is strongest in continental EEU away from the Atlantic and in MED during summer (Lionello and Scarascia, 2018). The assessment of EURO-CORDEX projections for levels of global warming of 1.5°C and 2.0°C indicate enhanced local warming even at relatively low global warming levels, particularly towards the north in winter (Schaller et al., 2016; Dosio and Fischer, 2018; Kjellström et al., 2018; Teichmann et al., 2018).

Some signatures of climate change projected by GCMs are modified by RCMs and CPRCMs. Projections of temperature, precipitation and wind in RCMs may deviate from GCM signals dependent on the dominant atmospheric circulation (Kjellström et al., 2018). In many areas RCMs produce lower warming rates and higher precipitation (less drying) in summer (Fernández et al., 2019; Boé et al., 2020a). Also for mean surface shortwave radiation systematic differences between GCM and RCM outputs are found (Bartók et al., 2017; Gutiérrez et al., 2020). Although RCMs generally have a smaller bias for the present climate (Sørland et al., 2018) and better cloud representation (Bartók et al., 2017), the representation of aerosol forcing (Boé et al., 2020a; Gutiérrez et al., 2020), air-sea coupling (Boé et al., 2020a) or vegetation response to elevated atmospheric CO₂ (Schwingshackl et al., 2019) give rise to systematic biases in RCM projections. The comparison between EURO-CORDEX and the CMIP5 subset shown in Figure Atlas.24 illustrates that the RCMs primarily modify the climate change warming signal from the driving GCMs for MED and WCE in summer (Boé et al., 2020a).
Changes in precipitation clearly show a seasonal signature and a meridional gradient over Europe. Mean precipitation increases by 4% to 5% per °C of global warming in NEU, EEU and WCE in DJF, and decreases in summer in WCE and MED (Jacob et al., 2018) (see Figure Atlas.24). CMIP5 projections of precipitation change in MED are strongest in DJF in the south, while changes in JJA are dominant in the northern (European) part of MED, Lionello and Scarascia (2018). The European north-south gradient in precipitation response is confirmed by the EURO-CORDEX experiment (Coppola et al., 2020), but Figure Atlas.24 shows that the JJA precipitation reduction in WCE projected by CMIP5 and CMIP6 at higher warming levels has low confidence in the CORDEX simulations. Precipitation in JJA in EEU is reduced in CMIP6, while little change is shown in CMIP5. Quantitative estimations of climate change features from regional climate projections in Eastern Europe (Partasenok et al., 2015; Kattsov et al., 2017) have low confidence due to the use of relatively small ensembles of GCMs and/or RCMs, and limited evaluation of model performance in the region.

Over specific geographic features such as high mountains, RCMs further modify the climate change signal of precipitation simulated by the low-resolution GCMs (Giorgi et al., 2016; Torma and Giorgi, 2020). This is especially true for summer precipitation over the Alps where opposite signs of changes in mean and extreme precipitation are generated by the CMIP5 GCM ensemble and the 12-km Med-CORDEX and EURO-CORDEX RCM ensembles (Giorgi et al., 2016) (see also Section 10.6.4.7).

[START FIGURE ATLAS.24 HERE]

Figure Atlas.24: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Europe (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively, for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.24 HERE]

Regional warming is virtually certain to extend the observed downward trends in snow accumulation, snow water equivalent and length of the snow cover season in NEU and low altitudes in mountainous areas in the Alps and Pyrenees (very high confidence). This is supported by regional and global multi-model and/or single-model ensemble projections including CMIP5, PRUDENCE, ENSEMBLES and EURO-CORDEX (Jylhä et al., 2008; Steger et al., 2013; Mankin and Diffenbaugh, 2015; Schmucki et al., 2015; Marty et al., 2017; Frei et al., 2018) and attributed to changes in the snowfall fraction of precipitation and to increased snow melt. In mountain areas a strong dependence of projected snow trends on altitude is shown, with most pronounced effects below 1500 m (López-Moreno et al., 2009). Terzaghi et al. (2017) showed a large positive bias in the amplitude of the annual snow cycle of EURO-CORDEX 0.11° simulations driven by GCM projections, while reanalysis-driven RCMs showed good agreement with in-situ observations.

Regional ocean warming in projections with RCMs for the Baltic and North Sea (Gröger et al., 2015) and
for the Mediterranean (Darmaraki et al., 2019) is associated with increased intensity and frequency of marine
heatwaves in the Mediterranean (see Section 12.4.5.5), strong freshening in the Baltic, and, for some
simulations, changes in the circulation in response to non-uniform changes in air-sea interaction (Dieterich et
al., 2019). Med-CORDEX RCSM and CMIP5 GCM results agree well on the Mediterranean SST warming
rate (Mariotti et al., 2015; Darmaraki et al., 2019); see also the Interactive Atlas.

Assessments of projected changes in meteorological extremes and CIDs are reported elsewhere in this report.
Extreme precipitation and temperature often exhibit a different response to global warming than mean
to values. Increased intensity and frequency of extreme temperatures and heatwaves is assessed in Sections
11.3.5 and 12.4.5.1. Changes in the hydrological cycle include enhanced soil moisture decline in southern
Europe, drying in summer and autumn in central Europe, and spring drought due to early snow melt in
northern Europe (Sections 8.4.1, 11.6.5 and 12.4.5.2). Changes in mean and extreme wind are very uncertain
(Section 12.4.5.3), while sea level rise will increase the frequency of occurrence of extreme sea level at most
European coasts (Section 12.4.5.5).

Atlas.8.5 Summary

An assessment of recent literature largely confirms the findings of previous IPCC reports but with additional
detail and (in some cases) higher confidence due to improvements in observations, reanalyses and methods.
Observational data sets with global coverage are complemented by the E-OBS gridded ensemble temperature
and precipitation dataset, a range of regional observational analyses, and regional reanalysis products. New
RCM experiments, including CPRCMs and regional coupled climate system models, mostly coordinated
under the umbrella of CORDEX, have generated many new projections and process studies.

The representation of mean European climate features by GCMs and RCMs is improved compared to
previous IPCC assessments (medium confidence), in spite of persisting biases in annual mean and seasonal
temperature and precipitation characteristics. The added value of regional downscaling of GCMs by RCM
projections for summer mean temperature, precipitation and shortwave radiation is constrained by the
representation of processes that lead to a systematic difference between RCM and driving GCM, such as
aerosol forcing (medium confidence).

It is virtually certain that annual mean temperature continues to increase in each European region. There is
medium confidence that annual mean precipitation in NEU, WCE and EEU has increased since the early 20th
century. In the European Mediterranean trends in annual mean precipitation contain substantial spatial and
temporal variability (medium confidence). It is very likely that since the early 1980s in snow-dominant areas
in NEU and EEU the length of the snowfall season is reduced with regional warming, and the melt onset
dates have advanced. It is likely that decreasing trends in anthropogenic aerosols in Europe have generated
positive trends in shortwave radiation and surface temperature since the 1980s.

At increasing levels of global warming, there is very high confidence that temperature will increase in all
European areas at a rate exceeding global mean temperature increases, while increased mean precipitation
amounts at high latitudes in DJF and reduced JJA precipitation in southern Europe will occur with medium
confidence for global warming levels of 2°C or less, and with high confidence for higher warming levels. At
high latitudes and low-altitude mountain areas in Europe strong declines in snow accumulation are virtually
certain to occur with further increasing regional temperatures (very high confidence).

Atlas.9 North America

The assessment in this section focuses on changes in average temperature and precipitation (rainfall and
snow) for North America, including the most recent years of observations, updates to observed datasets, the
consideration of recent studies using CMIP5 and those using CMIP6 and CORDEX simulations. Assessment
of changes in extremes are in Chapter 11 (Table 11.19–21) and climatic impact-drivers in Chapter 12 (Table
12.8).
**Atlas.9.1 Key features of the regional climate and findings from previous IPCC assessments**

**Atlas.9.1.1 Key features of the regional climate**

The recent-past climate of North America is characterized by high spatial heterogeneity and by variability at diverse temporal scales. Considering the traditional Köppen-Geiger classification, North America covers all main climate types (see reference region descriptions below). Important geographical features influence local climates over various distances, like the Rocky Mountains through cyclogenesis (Grise et al., 2013) and the Great Lakes through lake-effect snowfall (Wright et al., 2013). The cryosphere is an important component of the climate system in North America, with fundamental roles for sea ice cover, snow cover and permafrost. The ocean surrounding the continent also influence its climate, with water temperatures strongly influencing hurricane activity which impacts the coasts of eastern Mexico and south-eastern USA (Walsh et al., 2010). Temporal variability is influenced by several large-scale atmospheric modes (Annex IV, Table Atlas.1) with the North Atlantic Oscillation (NAO) affecting north-eastern USA and eastern Canada precipitation (Whan and Zwiers, 2017), and El Niño–Southern Oscillation (ENSO) affecting temperature and precipitation in California, although in a complex and not yet fully understood manner (Yoon et al., 2015; Yeh et al., 2018).

The reference regions defined for summarising North America climate change (Figure Atlas 26) include:

- North-Western North America (NWN), characterized by a subarctic climate with cool summers and rainfall all year round;
- North-Eastern North America (NEN), which also has a subarctic climate with sections of tundra climate in the far north (these two northern regions are also discussed in Section Atlas.11.2, Polar Arctic; Western North America (WNA), which has a complex but mainly cold semi-arid climate; the Central North America (CNA) with a mainly by continental climate in the northern part of the region and humid subtropical in the southern portion; Eastern North America (ENA) with a humid continental climate in the northern half and a humid subtropical climate to the south; Northern Central America (northern Mexico) (NCA), has a temperate climate to the north of the Tropic of Cancer, with marked differences between winter and summer, modulated by the North American monsoon (Peel et al., 2007). NCA, also covered in Section 7.1 Central America, has a temperate climate to the north of the Tropic of Cancer, with marked differences between winter and summer, modulated by the North American monsoon (Peel et al., 2007).

**Atlas.9.1.2 Findings from previous IPCC assessments**

The IPCC AR5 (Bindoff et al., 2013; Hartmann et al., 2013) found that the climate of North America has changed due to anthropogenic causes (high confidence), in particular with primarily increasing annual precipitation and annual temperature (very high confidence). Assessment of CMIP5 ensemble projections concluded that mean annual temperature over North America and annual precipitation north of 45°N will very likely continue to increase in the future. Also, CMIP5 projects increases in winter precipitation over Canada and Alaska and decreases in winter precipitation over the southwestern USA and much of Mexico.

The CMIP5 multi-model ensemble generally reproduces the observed spatial patterns but somewhat underestimates the extent and intensity of the North American Monsoon, and also underestimates wetting over Central North America over the period of 1950–2012 during winter season according to AR5 (Flato et al., 2013). In the long-term (2081–2100), the largest changes of precipitation over North America are projected to occur in the mid and high latitudes and during winter (Kirtman et al., 2013).

SR1.5 (Hoegh-Guldberg et al., 2018) reported a stronger warming compared to the global mean over Central and eastern North America, and a weakening of storm activity over North America under 1.5°C of global warming. SROCC (Hock et al., 2019b) reported that snow depth or mass is projected to decline by 25% mainly at lower elevations over the high mountains in Western North America. SRCCCL (Mirzabaev et al., 2019) observed vegetation greening in central North America with high confidence.
### Atlas.9.2 Assessment and synthesis of observations, trends, and attribution

The observed trends in annual mean surface temperature (see Figure Atlas.11 and the Interactive Atlas) across near-Arctic latitudes are exceptionally pronounced (>0.5°C per decade), significant and consistent across datasets except for far northeast Canada where trends are not significant in the CRU dataset. Significant positive trends are seen across the rest of North America during 1960–2015 (Figure Atlas.11) though over the shorter 1980–2015 period the regional dataset Daymet (Thornton et al., 2016) records non-significant changes over southern Alaska, western and south-central Canada, and north-central USA (Interactive Atlas). An analysis of annual mean surface temperature in the Berkeley Earth dataset aggregated over the reference regions (Figure Atlas.11) demonstrates that a temperature change signal has emerged over all regions of North America. There is a detectable anthropogenic influence (medium confidence) on the observed upward annual temperature trends in western and northern North America (Vose et al., 2017; Wang et al., 2017b; Smith et al., 2018).

Compared to temperature, trends in annual precipitation over 1960–2015 are generally non-significant though there are consistent positive trends over parts of ENA and CNA (Figure Atlas.11) and Daymet (Interactive Atlas) (high confidence). The global and regional datasets in Figure Atlas.11 and Interactive Atlas also indicate significant decreases in precipitation in parts of south western US and north western Mexico (see also Figure 2.15) though these are not all spatially coherent so there is only medium confidence in a drying trend over this region.

Several factors account for the differences in temperature and precipitation trend significance. Observed trends in precipitation are relatively modest compared to the very large natural interannual variability of precipitation. Furthermore, the precipitation observing network is spatially inadequate (see Section 10.2.2.3) and temporally inconsistent (see Section 10.2.2.2) over some regions of North America, particularly over Arctic and mountainous areas. So detection of multidecadal trends is difficult, especially for regions with summertime convective precipitation maxima that may be spatially patchy (Easterling et al., 2017). See Section 2.3 for further discussion of precipitation trends.

There is evidence of a recent decline in the overall North American annual maximum snow mass, with a trend for non-alpine regions above 40°N during 1980–2018 estimated from the bias-corrected GlobSnow 3.0 data (Pulliainen et al., 2020) (medium confidence). This is despite technical challenges with in situ measurements and remote sensing retrievals of snow variables (Larue et al., 2017; Smith et al., 2017; Wang et al., 2017a; Zeng et al., 2018), spatial heterogeneity and interpolation assumptions that affect gridded reference products, notably over alpine and forested areas (Mudryk et al., 2015; Dozier et al., 2016; Cant et al., 2019) and breaks in instruments and procedures (Kunkel et al., 2007; Mortimer et al., 2020). Changes in snow cover have evolved in a complex way, with both positive and negative trends and differing from one metric to another (Knowles, 2015; Brown et al., 2019). Evidence of large-area snow cover decline includes decreases in annual maximum snow depth and in snow water equivalent (Vincent et al., 2015; Kunkel et al., 2016; Mote et al., 2018), as well as a shortening of the snow season duration (Knowles, 2015; Vincent et al., 2015). However, reported snow decline trends are statistically significant only for a fraction of the concerned areas or locations (see Figure Atlas.25) (low confidence). See also Sections 2.3.2.2 and 9.5.3.1.

Rupp et al. (2013) applied a standard fingerprinting approach to CMIP5 models and determined that the decline in Northern Hemisphere spring snow cover extent could only be explained by simulations that included natural and anthropogenic forcing. In an attribution study focusing on direct physical causes, it was found that increased spring snowmelt in northern Canada was driven by warming-induced high latitudes changes such as atmospheric moisture, cloud cover, and energy advection (Mioduszewski et al., 2014).

In an analysis of drivers of the record low snow water equivalent (SWE) values of spring 2015 in the western US, it was found that the relative importance of greenhouse gases varies spatially (Mote et al., 2016). See also Section 3.4.2 for further discussion of anthropogenic influences on snow extent.
CMIP6 models have been evaluated in the literature, although these studies have not included the full set of CMIP6 simulations. Fan et al. (2020) established on a continental basis for North America that temperature pattern correlations were quite accurate. Thorarindsottir et al. (2020) compared maximum and minimum temperatures over Europe and North America with several observational datasets and found that the CMIP6 ensemble agreed better with ERA5 data than did CMIP5. Srivastava et al. (2020) evaluated historical CMIP6 simulations for precipitation, comparing them with several observational datasets over the continental US. Most models show a wet bias over the eastern half of continental USA and the northeast region while dry biases persist in the central part of the country (Akinsanola et al. (2020a) and Almazroui et al. (2021)). The spatial structure of biases is similar in CMIP5 and CMIP6, but with lower magnitudes in CMIP6. Agel and Barlow (2020) examined 16 CMIP6 models over the north-eastern US for precipitation and did not find a distinct improvement over CMIP5, although they did find the higher resolution models tended to perform better. On the basis of the evidence so far, there is medium confidence that CMIP6 models are improved compared to CMIP5 in terms of biases in mean temperature and precipitation over North America.

North America has been extensively used as a testbed for regional climate model (RCM) experiments, such as the North American Regional Climate Change Assessment Program (NARCCAP) (Mearns et al., 2009), the MultiRCM Ensemble Downscaling (MRED) (Yoon et al., 2012), and NA-CORDEX (Bukovsky and Mearns, 2020). Therefore, much performance evaluation has been conducted with a focus on specific climate features in North America. For the North American monsoon region, multi-model performance evaluation (Bukovsky et al., 2013; Tripathi and Dominguez, 2013; Cerezo-Mota et al., 2015) or a single member performance (Lucas-Picher et al., 2013; Martynov et al., 2013; Šeparović et al., 2013) demonstrated the added value of RCMs, particularly more recent CORDEX simulations, through improved simulation of summertime precipitation and the climatological wintertime storm tracks across the western United States. NA-CORDEX simulations were more successful at reproducing weather types compared to a single model-based large perturbed-physics ensemble (Prein et al., 2019). The application of a complex evaluation tool to the full suite of NA-CORDEX simulations found that the higher resolution simulations (25 km vs 50 km) of precipitation were improved, particularly for daily intensity (Gibson et al., 2019).

However, deficiencies have also been reported. For example, storm occurrence over the East Coast of North America was found (Poan et al., 2018), and amplitude in the simulated annual cycle was generally excessive in NA-CORDEX simulations. RCMs tend to produce more (less) precipitation over mountains (the coastal plains) (Cerezo-Mota et al., 2015) and winter precipitation in the western US had large positive biases in all RegCM simulations, regardless of the driving GCM (Mahoney et al., 2021).

Recently, convective-permitting RCMs have been used to simulate North American climate features and generated better simulations of precipitation. For example, summer precipitation over the south-western USA was improved due to better representation of organized mesoscale convective systems at the sub-daily scale (Castro et al., 2012; Liu et al., 2017; Prein et al., 2017b; Pal et al., 2019), the diurnal cycle of convection (Nesbitt et al., 2008), and in terms of means (and extremes) for the north-eastern United States (Komurcu et al., 2018).

Recent studies have examined RCMs simulation of SWE, a quantity of primary importance notably for hydrological modelling though its ground measurements are restricted by relatively high time and monetary costs (Smith et al., 2017; Odry et al., 2020) which limit model assessment. Also, studies often emphasize that
a false impression of model skill for SWE can be obtained by compensating temperature and precipitation biases. Assessment frameworks have dealt with these issues by considering observational uncertainty (Mccrary et al., 2017) and by decomposing SWE biases into their contributing processes (Rhoades et al., 2018; Xu et al., 2019). SWE biases exceed observational uncertainty in several 50-km reanalysis-driven NARCCAP simulations over several regions, for all cold months (Mccrary et al., 2017). Analyses of NA-CORDEX simulations show that refining spatial resolution from 50 to 12 km improves certain (but not all) aspects of SWE, stemming from improved mean precipitation and topography-related temperature (Xu et al., 2019). Similarly an assessment of RCM simulations of freezing rain over Eastern Canada found a mix of improved and deteriorated aspects from higher resolution (St-Pierre et al., 2019).

**Atlas.9.4 Assessment and synthesis of projections**

[START FIGURE ATLAS.26 HERE]

Figure Atlas.26: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in North America (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlaying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.26 HERE]

CMIP5 and CMIP6 surface temperature and precipitation projections over the region are similar, with all regions warming more than the global average, most prominently those in the north most (Figure Atlas.26). CMIP6 projects, for scenarios and time-periods, higher temperature changes (see also Chapter 4) with this contrast more accentuated in the long-term future and at higher global warming levels. The higher warming in the north (also see the Interactive Atlas) is clear when comparing NEN, with increases from 2.5°C to over 11°C on an annual basis for SSP5-8.5 (near-term to long-term compared to a 1995–2014 baseline), to NCA, where changes range from 1.5°C to 6°C across the same periods. Maps showing changes in temperature and precipitation, and their robustness, are available in the Interactive Atlas. The number of model results (i.e., ensemble size used to generate these figures) differs, and this sample size difference may affect the results, but the patterns and magnitudes of change are generally consistent and thus it is very likely that temperatures will increase throughout the 21st century in all land areas, with stronger warming in the far north.

CMIP5 results have been analysed extensively (e.g., Maloney et al., 2014) and used in major climate change assessments. The most recent US National Climate Assessment analysis of CMIP5 focusing on RCP4.5 and RCP8.5 for two future time periods stated that the USA would continue to warm regardless of scenario but is likely to be higher with higher emissions scenarios (e.g., RCP8.5). Projected changes in precipitation are somewhat complex, but increased precipitation dominates in winter and spring, whereas in summer changes are more variable and uncertain. Canada’s Changing Climate Report (Bush and Lemmen, 2019) presents changes in temperature and precipitation, as well as other variables, such as snow, for future periods in...
Canada using results from CMIP5. It indicates that annual and winter precipitation is projected to increase everywhere in Canada over the 21st century with larger percentage increases in the north. Temperature is also projected to increase, regardless of scenario, and with larger changes occurring in the north.

To provide the basis for generating additional information compared to that derived from CMIP5 the NA-CORDEX experiments were designed to involve a GCM-RCM matrix which included multiple GCMs that sampled the full range of climate sensitivity, multiple RCMs, at two different spatial resolutions (25 and 50 km) and a range of emissions scenarios (in most cases RCP4.5 and RCP8.5) (Mearns et al., 2017). Karmalkar (2018) noted that the NA-CORDEX model covers subregional ranges of temperature change from the CMIP5 GCMs better than NARCCAP did for the CMIP3 models. This structural design shift provides greater confidence in the NA-CORDEX results in terms of sampling the uncertainty across the CMIP5 models (Figure Atlas.27) (Bukovsky and Mearns, 2020). The pattern of warming is as seen in CMIP5 and CMIP6 which also builds confidence that the RCMs generate high-resolution results consistent with CMIP5 on large scales whilst providing added value over regions such as the complex topography of the Rocky Mountains in the US West, which are not well resolved in the GCMs. There is high confidence that downscaling a subset of CMIP models that spans the range of climate sensitivities in the full ensemble is critical for producing a representative range of dynamically downscaled projections.

[START FIGURE ATLAS.27 HERE]

Figure Atlas.27: Changes (2070–2099 relative to 1970–1999) in the annual mean surface air temperature by three GCMs (GFDL ESM2M, MPI ESM-LR, HadGEM2-ES) and two RCMs (WRF and RegCM4) nested in the GCMs, for the RCP8.5 scenario (after Bukovsky and Mearns, 2020).

[END FIGURE ATLAS.27 HERE]

There are striking contrasts in the seasonal results for precipitation for the subregions (Figure Atlas.26). The northern regions and ENA all show steady increases with the global warming levels (very high confidence). For example, the projected increases in NEN region range from 7% in the near term to 40% at the end of the 21st century for the SSP5-8.5 scenario. In contrast, projected changes for NCA are for significant decreases both on an annual basis (Interactive Atlas) and in winter and which become greater as warming increases (Akinsanola et al., 2020b; Almazroui et al., 2021). The other two regions (WNA and CNA) exhibit mainly increases in winter. In summer, distributions are in general less uniform except for NWN and NEN which display steady increases with global warming levels (but smaller than in winter). WNA and CNA mainly show decreases (based on the median values) but with some models projecting increases. Projections from the NA-CORDEX ensemble are consistent with those from the GCMs whilst providing greater detail of precipitation changes over the mountains and along the coasts (Bukovsky and Mearns, 2020)(Interactive Atlas). Similar results are found in other analyses of RCM projections (Wang and Kotamarthi, 2015; Ashfaq et al., 2016; Teichmann et al., 2020). Also, further analysis of the NA-CORDEX projections showed substantial changes in weather types related to increased monsoonal flow frequency and drying of the northern Great Plains in summer (Prein et al., 2019).

In summary, NEN, NWN and most of ENA will very likely experience increased annual mean precipitation, with greater increases at higher levels of warming (very high confidence). In NCA decreases predominate on an annual basis and particularly in winter (high confidence). Projected changes in summer are highly uncertain throughout other regions apart from the far northern parts of NEN and NWN which will likely experience increases (high confidence).

As discussed in Section 10.3.3.4 an important advance in regional modelling over the past decade or so is the use of convection-permitting regional models (CPMs) (Prein et al., 2015, 2017b). There have been a number of experiments using CPMs over North America (e.g., Rasmussen et al., 2014; Prein et al., 2015, 2019; Liu et al., 2017; Komurcu et al., 2018). A CPM study over North America that investigated changes in Mesoscale Convective Systems projected that by the end of the century, assuming an RCP8.5 scenario, their
frequency more than tripled and associated precipitation increased by 80% (Prein et al., 2017a). A multiple nesting of WRF over north-eastern US downscaling to 3 km a CESM GCM climate projection assuming an RCP8.5 scenario, found a different pattern of precipitation change of mixed increases and decreases compared to the GCM projection of increases every month (Komurcu et al., 2018). These investigations demonstrate the potential of very high-resolution simulations to add important dimensions to our understanding of regional climate change, though not necessarily to reduce uncertainty (high confidence).

It is virtually certain that snow cover will experience a general decline across North America during the 21st century, in terms of extent, annual duration and SWE, based on CMIP5 (Maloney et al., 2014), CMIP6 (Mudryk et al., 2020), NA-CORDEX (Mahoney et al., 2021) and NARCCAP (e.g., McCravy and Mearns, 2019) simulations. For some regions the decline could be discernible over the next few decades, for example in western USA (Fyfe et al., 2017). It is, however, likely that some high-latitude regions will rather experience an increase in certain winter snow cover properties (Mudryk et al., 2018; McCravy and Mearns, 2019), due to snowfall increase (Krausting et al., 2013a) prevailing over the warming effect. Discussion of changes in snow in the future is also covered in Section 9.5.3, but for larger regions.

The fraction of precipitation falling as snow is projected to decrease practically everywhere over North America, including over western USA and south-western Canada (Mahoney et al., 2021), and in the Great Lakes basin where lake-effect precipitation is important (Suriano and Leathers, 2016). In this basin, the frequency of heavy lake-effect snowstorms is expected to decrease during the 21st century, except for a possible temporary increase around Lake Superior by mid-century, if local air temperatures remain low enough (Notaro et al., 2015). CMIP5 simulations of the periods 1981–2000 and 2081–2100 over central and eastern USA suggest a northward shift in the transition zone between rain-dominated and snow-dominated areas, by about 2° latitude under the RCP4.5 scenario and 4° latitude under the RCP8.5 scenario (Ning and Bradley, 2015). Rain-on-snow event properties over North America should also evolve during the 21st century, with non-trivial dependencies on the positioning relative to the freezing line (Jeong and Sushama, 2018) and on elevation (Musselman et al., 2018).

**Atlas.9.5 Summary**

Across North America it is very likely that positive surface temperature trends are persistent. Across near-Arctic latitudes of North America increases are exceptionally pronounced, greater than 0.5°C per decade (high confidence). In parts of eastern and central North America it is likely that annual precipitation has increased over the period of 1960 to 2015 but with no clear trends in other regions except for parts of south-western US and north-western Mexico where there is medium confidence in drying.

Model representation of the climatology of mean temperature and precipitation has likely improved compared to the AR5 over North America. This is aided by continuous model development, and the existence of new coordinated modelling initiatives such as NA-CORDEX. There is high confidence that downscaling a subset of CMIP models that spans the range of climate sensitivities in the full ensemble is critical for producing a representative range of dynamically downscaled projections.

It is virtually certain that annual and seasonal surface temperatures over all of North America will continue to increase at a rate greater than the global average, with greater increases in the far north. It is very likely, based on global and regional model future projections, that on an annual time scale precipitation will increase over most of North America north of about 45°N and in eastern North America, and it is likely that it will decrease in the southwest US and northern Mexico, particularly in winter. Elsewhere the direction of change of precipitation is uncertain. It is virtually certain that snow cover will experience a decline over most regions of North America during the 21st century, in terms of water equivalent, extent and annual duration. It is however very likely that some high-latitude regions will rather experience an increase in winter snow water equivalent, due to the snowfall increase prevailing over the warming effect.
**Atlas.10**  Small islands

**Atlas.10.1 Key features of the regional climate and findings from previous IPCC assessments**

**Atlas.10.1.1 Key features of the regional climate**

Many small islands lie in tropical regions and their climate varies depending on a range of factors with location, extent and topography having major influences. In general, their climate is determined by that of the broader region in which they lie as they have little influence on the regional climate although steep topography can induce higher rainfall totals locally. Temperature variability tends to be low due to the influence of the surrounding ocean, most marked in the tropics where oceanic temperature ranges are small. However, seasonal rainfall variability can often be significant, both through the annual cycle and also interannually through the influence of many modes of variability (for more details see Cross-Chapter Box Atlas.2., Annex IV and Section Atlas.7.1 for the Caribbean). Many small islands are exposed to tropical cyclones and the associated hazards of high winds, storm surges and extreme rainfall, and many low-lying islands are exposed to regular flooding from natural high tide and wave activity. In the Pacific, phases of the El Niño Southern Oscillation result in periods of warmer or cooler than average temperatures following the upper ocean warming of El Niño events or cooling of La Niña events, and respectively weaker and stronger trade winds. El Niño conditions also lead to drought in Melanesian islands and increased typhoons and storm surges in French Polynesia with La Niña conditions causing drought in Kiribati. Other islands experience increased rainfall during these periods.

**Atlas.10.1.2 Findings from previous IPCC assessments**

The AR5 noted observed temperature increases of 0.1°C–0.2°C per decade in Pacific Islands and that warming was very likely to continue across all Small Island regions (Christensen et al., 2013; IPCC, 2013a). It also reported decreased rainfall over the Caribbean, increases over the Seychelles, streamflow reductions over the Hawaiian Islands and projections of reduced rainfall over the Caribbean and drier rainy season for many of the southwest Pacific Islands (Christensen et al., 2013; IPCC, 2013a; Nurse et al., 2014). The remaining findings are derived from the SROCC (IPCC, 2019a). Ocean warming rates have likely increased in recent decades with marine heatwaves increasing and very likely to have become longer-lasting, more intense and extensive as a result of anthropogenic warming. Open ocean oxygen levels have very likely decreased and oxygen minimum zones have likely increased in extent. There is very high confidence that global mean sea level rise has accelerated in recent decades which, combined with increases in tropical cyclone winds and rainfall and increases in extreme waves, has exacerbated extreme sea level events and coastal hazards (high confidence). It is virtually certain that during the 21st century, the ocean will transition to unprecedented conditions with further warming and acidification virtually certain, increased upper ocean stratification very likely and continued oxygen decline (medium confidence). There is very high confidence that marine heatwaves and medium confidence that extreme El Niño and La Niña events will become more frequent. It is very likely that these changes will be smaller under scenarios with low greenhouse-gas emissions. Global mean sea level will continue to rise and there is high confidence that the consequent increases in extreme levels will result in local sea levels in most locations that historically occurred once per century occurring at least annually by the end of the century under all RCP scenarios (high confidence). In particular, many small islands are projected to experience historical centennial events at least annually by 2050 under RCP2.6 and higher emissions. The proportion of Category 4 and 5 tropical cyclones, and associated precipitation rates and storm surges, along with average tropical cyclone intensity are projected to increase with a 2°C global temperature rise, thereby exacerbating coastal hazards.

**Atlas.10.2 Assessment and synthesis of observations, trends and attribution**

Significant positive trends in temperature ranging from 0.15°C per decade (over the period 1953–2010) to 0.18°C per decade (over the period 1961–2011) are noted in the tropical Western Pacific, where the significant increasing trends in the warm and cool extremes are also spatially homogeneous (Jones et al.,...
2013; Whan et al., 2014; Wang et al., 2016). Similarly, much of the Caribbean region showed statistically significant warming (at the 95% level) over the 1901–2010 period (Jones et al., 2016b). Observation records in the Caribbean region indicate a significant warming trend of 0.19°C per decade and 0.28°C per decade in daily maximum and minimum temperatures, respectively, with statistically significant increases (at the 5% level) in the number of warm days and warm nights during 1961–2010 (Taylor et al., 2012b; Stephenson et al., 2014; Beharry et al., 2015).

A weather station-based annual precipitation trend analysis over 1901–2010 in the Caribbean region indicated some locations with detectable decreasing trends (Knutson and Zeng, 2018), which were attributable in part to anthropogenic forcing. These include southern Cuba, the northern Bahamas, and the Windward Islands although significant trends were not found over the shorter periods of 1951–2010 and 1981–2010. In Caribbean Islands, a Palmer Drought Severity Index dataset from 1950 to 2016 showed a clear drying trend in the region (Herrera and Ault, 2017). The 2013–2016 period showed the most severe drought during the period and was strongly related to anthropogenic warming, which would have increased the severity of the event by 17% and its spatial extent by 7% (Herrera et al., 2018). However, a seasonal analysis of observations grouped into large subregions of the Caribbean revealed no significant long-term trends in rainfall over 1901–2012 but significant inter-decadal variability (Jones et al., 2016b). Declines in summer rainfall (−4.4% per decade) and maximum five-day rainfall (−32.6 mm per decade) over 1960–2005 were reported for Jamaica (CSGM, 2012) and an insignificant decrease in summer precipitation was observed for Cuba for 1960 to 1995 (Naranjo-Díaz and Centella, 1998). Three of four stations examined for Puerto Rico exhibited declining JJA rainfall over 1955–2009 with the trend statistically significant at the 95% level for Canóvana (Méndez-Lázaro et al., 2014). In the Caribbean, positive regional trends in precipitation of 2% and trends in extremes during 1961 to 2010 were found to be not statistically significant (at the 5% level) (Stephenson et al., 2014; Beharry et al., 2015). Positive trends in JJA rainfall over Cuba and Jamaica are seen in the CRU, whereas they are negative over Cuba for GPCP; over eastern Hispaniola they are positive in CRU and negative in CHIRPS (Cavazos et al., 2020).

In Hawai‘i, between 1920 and 2012, over 90% of the islands showed reduced rainfall and streamflow, an increase in the frequency of days with zero flow (Strauch et al., 2015; Frazier and Giambelluca, 2017) and robust positive trends in the drought frequency and severity (McGree et al., 2016). Over the western Pacific, interannual and decadal variabilities also drive long-term trends in rainfall. Recent analysis of station data showed spatial variations in the mostly decreasing but non-significant trends in annual and extreme rainfall over the Western Pacific from 1961–2011 (low confidence) (McGree et al., 2014). Over the southern subtropical Pacific decreases in annual, JJA, SON and extreme rainfall and increasing drought frequency in western region has been observed since 1951 (Jovanovic et al., 2012; McGree et al., 2016, 2019).

Over the Western Indian Ocean significant warming trends have been reported for Mauritius (1.2°C during 1951–2016 (MESDDBM, 2016)), La Réunion (0.18°C per decade over 1968–2019 (Météo-France, 2020)) and Maldives (MEE, 2016). Both Mauritius and La Réunion have experienced rainfall decreases of 8% during 1951–2016 and 1.2% per decade during 1961–2019 with generally weak, non-significant rainfall trends during 1967–2012.

Assessing observed climate change for Small Islands is often constrained by low station density (Ryu and Hayhoe, 2014; Jones et al., 2016c), digitization requirements or data sharing limitations (Jones et al., 2016c). Station data typically have longer temporal coverage relative to satellite products but are limited in spatial coverage (Cavazos et al., 2020). For Small Island nations, spatial gaps between observations can be very large due to isolation of the islands (Wright et al., 2016). Additionally over past decades, the number of station observations has declined substantially in Mauritius (Dhurmea et al., 2019), Hawai‘i (Bassiouni and Oki, 2013; Frazier and Giambelluca, 2017) and most Pacific Island countries since the 1980s (Jones et al., 2013; McGree et al., 2014, 2016). In Fiji, meteorological stations were located on or by the coast and sparse in the interior (Kumar et al., 2013). Notable topography and land use may result in changes in climatic conditions over small distances (Foley, 2018), making the observational density particularly relevant.

Moreover, many stations have little metadata available, including those in Vanuatu, the Solomon Islands and Papua New Guinea (Whan et al., 2014). Compared to earlier decades, little metadata are currently being gathered due to low priority and limited digitization efforts.
documented in the western Pacific islands (McGree et al., 2014), which will challenge the homogenization of long-term observational records. Challenges in the Caribbean include maintaining continuous daily time series with metadata, converting climatological data into digital formats and making them freely available (Stephenson et al., 2014; Beharry et al., 2015; Jones et al., 2016c). This is also an issue in the Pacific as many data are kept in national (local) databases, with only a fraction having been incorporated into global datasets (Wihan et al., 2014).

Because of the small number of stations used for interpolation and the complex mountainous topography, gridded product for these small islands should be interpreted with caution (Frazier and Giambelluca, 2017). For the Antilles, the error in estimating CRU2.0 monthly precipitation can stand locally between 20% and 40%. Over the Caribbean, (Cavazos et al., 2020) found a discrepancy across gridded observational datasets (CRU, CHIRPS, and GPCP) in detecting orographic precipitation especially during boreal summer making their use in climate model evaluation challenging (Herrera and Ault, 2017). Furthermore, some reanalysis products such as the 0.7° x 0.7° ERA-Interim reanalysis are not adequate as many of the smaller Caribbean islands are not represented as land (Jones et al., 2016c).

**Atlas.10.3 Assessment of model performance**

An assessment of model performance for the Caribbean region is contained in Section Atlas.7.1 on Central America. In summary, the ability of climate models to simulate the climate over the region has improved in many key respects with the application of increased model resolution and a better representation of the land-surface processes of particular importance in these advances (high confidence). Regional climate models (RCMs) simulate realistically seasonal surface temperature and precipitation patterns including the bimodal rainfall in the precipitation annual cycle although with some timing biases in some regions (high confidence). The important regional circulation and precipitation features, the Caribbean Low-Level Jet and the mid-summer drought, are well represented over a variety of RCM domains covering the region (high confidence).

Over the tropical Pacific, surface temperature biases in CMIP6 models remain similar to those in CMIP5, although are reduced in the higher resolution models in the HiResMIP ensemble. CMIP6 models generally represents trends in sea surface temperatures better than CMIP5 (see Section 9.2.1 for more details). For precipitation, the persistent tropical Pacific bias of the double ITCZ (erronious bands of excessive rainfall both sides of the equatorial Pacific) is still present in CMIP6 models although is slightly improved compared to those in CMIP3 and CMIP5 models (Section 3.3.2.2). Application of downscaling techniques (RCMs and stretched-grid GCMs) using resolutions finer than 10 km over the Pacific can capture topographic influences on wind and rainfall to generate realistic simulations of island climates – for example over Fiji and New Caledonia, (Chattopadhyay and Katzfey, 2015; Dutheil et al., 2019). In both cases applying bias adjustment to the sea surface temperatures used as a lower boundary condition for the downscaling models was important to generate realistic simulations.

**Atlas.10.4 Assessment and synthesis of projections**

Projected median temperature increases for Small Islands from the CMIP5 ensemble range from 1°C (RCP4.5) to 1.5°C (RCP8.5) in the period 2046–2065, and from 1.3°C (RCP4.5) to 2.8°C (RCP8.5) by 2081–2100 relative to 1986–2005 (Harter et al., 2015). Spatial variations in the warming trend are projected to increase by the end of the 21st century, with relatively higher increases in the Arctic and sub-Arctic islands, and in the equatorial regions compared with islands in the Southern Ocean (Harter et al., 2015). In the western Pacific, temperatures are projected to increase by 2.0°C to 4.5°C by the end of the 21st century relative to 1961–1990 (Wang et al., 2016). The warming over land in the Lesser Antilles is estimated to be about 1.6°C (3.0°C) by 2071–2100 for the RCP4.5 (RCP8.5) scenario, relative to 1971–2000 (Cantet et al., 2014). Projections from the CMIP6 ensemble support these findings (Figure Atlas.28) and across global warming levels from 1.5°C to 4°C CMIP5 and CMIP6 consistently project lower levels of warming for Small Islands than the global average (see also the Interactive Atlas).
Figure Atlas.28: Regional mean changes in annual mean surface air temperature, precipitation and sea level rise relative to the 1995–2014 baseline for the reference regions in Small Islands (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlaying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). Bar plots in the right panel show the median (dots) and 5th–95th percentile range (bars) sea level rise from the CMIP6 ensemble (see Chapter 9 for details) for the same time periods and scenarios. The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

The CMIP5 ensemble median projected a precipitation decreases of up to ~16% over the Caribbean, parts of the Atlantic and Indian Oceans and southern sub-tropical and eastern Pacific Ocean, and increases of up to 10% over parts of the western Pacific and Southern Ocean, and up to 55% in the equatorial Pacific islands under RCP6.0 in the period 2081–2100 relative to 1986–2005 (Harter et al., 2015). A projected decrease in annual precipitation is also noted over the Lesser Antilles under the RCP4.5 and RCP8.5 scenarios (Cantet et al., 2014). Seasonal rainfall is projected to decrease in most areas in Hawai‘i, except for the climatically wet windward side of the mountains, which would increase the wet and dry gradient over the area (Timm et al., 2015). The average precipitation changes in Hawai‘i are estimated to be about ~11% to ~28% under RCP4.5 during the wet season, and about ~4% to ~28% under RCP4.5 during the dry season in the period 2041–2071 relative to 1975–2005, with larger changes under RCP8.5 (Timm et al., 2015). There are still uncertainties in the projected changes, which have been attributed to factors including insufficient model skill in representing topography in the small islands, and high variability in climate drivers. However, the broad-scale pattern of projected wetter conditions in the western and equatorial Pacific, North Indian and Southern Oceans and of drier conditions over the Caribbean, parts of the Atlantic, West Indian and the southern sub-tropical and eastern Pacific Oceans are further strengthened in the CMIP6 ensemble (Figure Atlas.28) which are thus likely regional responses as the climate continues to warm.

The negative trend in future summer rainfall in the Caribbean and Central America is projected to be strongest during the mid-summer (June–August) based on studies using GCMs (Rauscher et al., 2008; Karmalkar et al., 2013; Karmacharya et al., 2017; Taylor et al., 2018). The future summer drying over the Caribbean is associated with a projected future strengthening of the Caribbean Low-Level Jet (Taylor et al., 2013b), Rauscher et al. (2008) hypothesized that the simulated 21st century drying over Central America represents an early onset and intensification of the mid-summer drought. The westward expansion and intensification of the NASH associated with the mid-summer drought occurs earlier under A1B, with stronger low-level easterlies. Rauscher et al. (2008) further suggested that the eastern Pacific ITCZ is also located further southward and that there are some indications that these changes could be forced by ENSO-like warming of the tropical eastern Pacific and increased land-ocean heating contrasts over the North American continent. Other studies also suggest a future intensification of the NASH due to changes in land-sea temperature contrast resulting from increased greenhouse-gas concentrations (Li et al., 2012b).
**Atlas.10.5 Summary**

It is very likely that all Small Island regions have warmed with significant trends recorded from at least the 1960s in all territories or nations. Trends include 0.15°C–0.18°C per decade in the tropical Western Pacific (1953 to 2011), significant warming over the Caribbean (1901–2010) with trends of 0.19°C (0.28°C) per decade in daily maximum (minimum temperatures) (1961–2010) and in La Réunion of 0.18°C per decade (1968–2019). There are fewer significant trends in precipitation in these regions though several locations in the Caribbean have detectable decreasing trends (high confidence), in part attributable to anthropogenic forcing (limited evidence). Also, it is likely that drying has occurred since the mid-20th century in some parts of the Western Indian Ocean, and in the Pacific poleward of 20° latitude in both the northern and southern hemispheres.

It is very likely that Small Island regions will continue to warm in the coming decades at a level slightly lower than the global mean. Small Island regions in the Western and equatorial Pacific, North Indian and Southern Ocean are likely to be wetter in the future and those in the Caribbean, parts of the Atlantic and West Indian Oceans and the southern sub-tropical and eastern Pacific Ocean drier.

[START CROSS-CHAPTER BOX ATLAS.2 HERE]

**Cross-Chapter Box Atlas.2: Climate information relevant to water resources in Small Islands**

**Coordinators:** Tannecia Stephenson (Jamaica), Faye Abigail Cruz (Philippines)

**Contributors:** Donovan Campbell (Jamaica), Subimal Ghosh (India), Rafiq Hamdi (Belgium), Mark Hemer (Australia), Richard G. Jones (UK), James Kossin (USA), Simon McGree (Australia/Fiji), Blair Trewin (Australia), Sergio M. Vicente-Serrano (Spain)

Constructing regional climate information for Small Islands involves synthesis from multiple sources. This cross-chapter box presents information relevant to water resources, drawing on several chapters in AR6 and Section Atlas.10. It introduces the context and current evidence base followed by an assessment of trends and projections in rainfall, temperature and sea levels across Small Islands and highlight key findings.

**Regional context**

Small Islands are predominantly located in the Pacific, Atlantic and Indian Oceans, and in the Caribbean (Nurse et al., 2014; Shultz et al., 2019). They are characterized by their small physical size, being surrounded by large ocean expanses, vulnerability to natural disasters and extreme events and relative isolation (Nurse et al., 2014) (Section 12.4.7, Section Atlas.10, Glossary). These and nearby larger islands (e.g., Madagascar, Cuba) are often water-scarce with low water volumes due to increasing demand (from population growth and tourism), aging and poorly designed infrastructure (Burns, 2002) and decreasing supply (from pollution, changes in precipitation patterns, drought, saltwater intrusion, regional sea level rise, inadequate water governance (Belmar et al., 2016; Mycoo, 2018) and competing and conflicting uses (Cashman, 2014; Gheuens et al., 2019) (Section 8.1.1.1). In the Caribbean, groundwater is the main freshwater source and depends strongly on rainfall variability (Post et al., 2018) while rain, ground or surface water are the primary sources for the Pacific islands depending on island type (volcanic or atoll), size and quality of groundwater reserves (Burns, 2002). Groundwater pumping and increasing sea levels also affect water availability by increasing the salinity of the aquifer (e.g., Bailey et al., 2015, 2016) thus reinforcing negative drought effects from reduced rainfall and increased evaporative demand from higher temperatures. For example, in 54% of the Marshall Islands, groundwater is highly vulnerable to droughts (Barkey and Bailey, 2017).

**The climate of Small Islands and findings from previous IPCC assessments**

Intraseasonal to interannual rainfall in the Caribbean and in the Indian and Pacific Ocean is influenced by the trade winds, the passage of tropical cyclones (TCs), Madden-Julian Oscillation (MJO), easterly waves, migrations of the Inter-Tropical Convergence Zone (ITCZ) and the North Atlantic Subtropical High (NASH)
for the Caribbean, the South Pacific Convergence Zone (SPCZ) and western North Pacific summer monsoon for the Pacific and the South Asian monsoons for the Indian Ocean. The relevant dominant modes of climate variability (Annex IV, Section 8.3.2.9) are El Niño-Southern Oscillation (ENSO) and the Indian Ocean Dipole (IOD) which have been associated with extreme events in the islands (Stephenson et al., 2014; Kruk et al., 2015; Frazier et al., 2018). The modes of climate variability are modulated by Pacific Decadal Variability (PDV), Interdecadal Pacific Oscillation (IPO) and Atlantic Multidecadal Variability (AMV). These modes show no sustained trend since the late 19th century (high confidence) (Section 2.4).

The AR5 WGI reports observed temperature increases of 0.1°C–0.2°C per decade in Pacific Islands with these trends very likely to continue under high emissions, and projects a drier rainy season for many islands in the southwest Pacific (Christensen et al., 2013). AR5 WGI reports rainfall reductions over the Caribbean, increases over the Seychelles, streamflow reductions over the Hawaiian Islands and salt-water intrusion into groundwater reserves in Pacific Islands resulting from storm surges and high tides (Nurse et al., 2014). SROCC (IPCC, 2019a) finds very high confidence that global mean sea level rise has accelerated in recent decades which has exacerbated extreme sea level events and flooding (high confidence). It will continue to rise with consequent increases in extreme levels so that the historical one-in-a-century extreme local sea level will become an annual event by the end of the century under all RCP scenarios (high confidence). In particular, many Small Islands are projected to experience historical centennial events at least annually by 2050 under RCP2.6, RCP4.5 and RCP8.5 emissions. The proportion of Category 4 and 5 TCs and associated precipitation rates along with their average intensity are projected to increase with a 2°C global temperature rise which will further increase the magnitude of resultant storm surges and flooding. The SROCC cross-chapter box on Low-lying Islands and Coasts (Magnan et al., 2019) focused on sea level rise and oceanic changes and their impacts, therefore the assessment presented here on climate changes relevant to water resources, including precipitation and temperature, is complementary.

Observations and attribution of changes

Cross-Chapter Box Atlas.2: presents an overview of observed subregional trends relevant to water resources in some Small Islands and island regions largely from 1951. Some general observed climate trends include higher magnitude and frequency of temperatures including warm extremes (medium to high confidence; Table 11.7, Sections 12.4.7.1, Atlas.10.2), declines in high intensity rainfall events (low to medium confidence; Table 11.7), regional sea level rise with strong storm surge and waves resulting in increased coastal flood intensity (high confidence, Section 12.4.7.4, Section Atlas.10.2), and increased intensity and intensification rates of tropical cyclones at global scale (medium confidence, Sections 11.7.1.2, 12.4.7.3) and ocean acidification (virtually certain, Chapters 2, 6 and 9, Section Atlas.3.2).

No significant long-term trends are observed for annual Caribbean rainfall over the 20th century (low confidence; Section Atlas.10.2). Over the western Pacific, generally decreasing but non-significant trends are noted in annual total rainfall from 1961 to 2011 (low confidence; Section Atlas.10.2; Table 11.5). June-July-August (JJA) rainfall over the Caribbean shows some drying tendencies that may be linked to the combined effect of warm ENSO events and a positive NAO phase (Giannini et al., 2000; Méndez-Lázaro et al., 2014; Fernandes et al., 2015b), or to warm ENSO events and a positive PDV (Maldonado et al., 2016). The work of Herrera et al. (2018) however suggests that anthropogenic influences may also be possible though proposed mechanisms to date have not decoupled the influence of anthropogenic trends versus natural decadal variability (Vecchi et al., 2006; Vecchi and Soden, 2007; DiNezio et al., 2009).

Southern hemisphere subtropical Pacific June–November drying has been associated with intensification of the subtropical ridge and associated declines in baroclinicity (Whan et al., 2014). Austral summer drying in the southwest French Polynesia subregion has been linked with increased greenhouse-gas and ozone changes (Fyfe et al., 2012). The southern hemisphere jet stream has likely shifted polewards (Section 2.3.1.4.3) which is attributed largely to a trend in the Southern Annular Mode (Section 3.7.2).

These assessments are constrained by limited availability of observational datasets and of scientific studies. Assessment of observed climate change for Small Islands is often constrained by low station density (Ryu and Hayhoe, 2014; Jones et al., 2016c), short periods of record, digitization requirements or data sharing.
limitations (Jones et al., 2016c), availability of metadata (McGree et al., 2014; Stephenson et al., 2014; Jones et al., 2016b), challenges in some gridded product representations of variability, for example for complex topography (Frazier and Giambelluca, 2017), and challenges characterizing the impact of vertical land motion on sea level rise (Wöppelmann and Marcos, 2016) (see also Section Atlas.10.2).

Information on future climate changes

Small Islands will very likely continue to warm this century, though at a rate less than the global average (Figure Atlas.28), with consequent increased frequency of warm extremes for the Caribbean and Western Pacific islands, and heatwave events for the Caribbean (high confidence) (Table 11.7). Annual and JJA rainfall declines are likely for some Indian and southern Pacific regions with drying over southern French

**Figure Atlas.28**
Rainfall is very likely to decline over the Caribbean, in the annual mean and especially in JJA, with a stronger and more coherent signal in CMIP6 compared to CMIP5 (Figure Atlas.28, Interactive Atlas) and reductions of 20–30% by the end of the century under high future emissions (SSP5-8.5). This JJA drying has been linked to a future strengthening of the Caribbean Low Level Jet (CLLJ) (Taylor et al., 2013b), a westward expansion and intensification of the NASH, stronger low-level easterlies over the region, a southwardly placed eastern Pacific ITCZ (Rauscher et al., 2008), and changing dynamics due to increased greenhouse-gas concentrations (Li et al., 2012b) (very high confidence). Projections from 15 GCM and two RCM experiments for 2080–2089 relative to 1970–1989 were for a generally drier Caribbean and a robust summer drying (Karmalkar et al., 2013). More recent downscaling studies (e.g., Taylor et al., 2018; Vichot-Llano et al., 2021) also project a drier Caribbean and longer dry spells (Van Meerbeek, 2020).

Sea level rise is very likely to continue in all Small Island regions (Figure Atlas.28, see also Sections 9.6.3.3 and 12.4.7.4) and its the effects will be compounded by TC surge events. In general, the most intense TCs are likely to intensify and produce more flood rains with warming, however detailed effects of climate change on TCs will vary by region (Knutson et al., 2019)(Section 11.7.1). Bailey et al. (2016) projected a 20% decline in groundwater availability by 2050 in Coral Atoll islands of the Federal States of Micronesia and stressed that under higher sea level rise the decrease could be higher than 50% due to marine water intrusion into aquifers, as well as drought events.

Summary of information distilled from multiple lines of evidence

It is very likely that most Small Islands have warmed over the period of instrumental records. The clearest precipitation trend is a likely decrease in JJA rainfall over the Caribbean since 1950. There is limited evidence and low agreement for the cause of the observed drying trend, whether it is mainly caused by decadal-scale internal variability or anthropogenic forcing, but it is likely that it will continue over coming decades. It is likely that drying has occurred since the mid-20th century in some parts of the Pacific poleward of 20° latitude in both the northern and southern hemispheres and that these will continue over coming decades. Rainfall trends in most other Pacific and Indian Ocean Small Islands are mixed and largely non-significant. It is very likely that sea levels will continue to rise in all Small Island regions and this will result in increased coastal flooding with the potential to increase salt-water intrusion into aquifers in Small Islands.

Whilst this assessment demonstrates that the climate of Small Islands has and will continue to change in diverse ways, constructing climate information for Small Islands is challenging. This is due to observational issues, incomplete understanding of some modes of variability and their representation by climate models and the lack of availability of large ensembles of regional climate model simulations and limited studies to decouple internal variability and anthropogenic influences.

[END CROSS-CHAPTER BOX ATLAS.2 HERE]

Atlas.11 Polar regions

The assessment in this section focuses on changes in average temperature, precipitation (rainfall and snow) and surface mass balance over the polar regions, Antarctica and the Arctic, including the most recent years of observations, updates to observed datasets, the consideration of recent studies using CMIP5 simulations and those using CMIP6 and CORDEX simulations. Findings are presented for West Antarctica (WAN), East Antarctica (EAN) and three Arctic regions, Arctic Ocean (ARO), Greenland/Iceland (GIC) and Russian Arctic (RAR) (Figure Atlas.29) with some reference also to North-Eastern North America (NEN), North-Western North America (NWN) and Northern Europe (NEU), which are covered more extensively in Sections Atlas.9 and Atlas.8 respectively. Subregional changes are discussed when relevant, for example the Antarctic Peninsula (AP) as a subregion of WAN. The Southern Ocean (SOO) region is assessed in Chapter 9 with changes in climatic impact-drivers assessed in Chapter 12 (12.4.9, Table 12.11) and some extremes in
Chapter 11 (Table 11.7–9 for RAR). Chapter 9 provides an overall assessment of the ice sheet processes and changes, as part of the cryosphere, ocean and sea level change assessment.

[START FIGURE ATLAS.29 HERE]

Figure Atlas.29: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Arctic and Antarctica (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM/15).

[END FIGURE ATLAS.29 HERE]

Atlas.11 Antarctica

Atlas.11.1 Key features of the regional climate and findings from previous IPCC assessments

Atlas.11.1.1 Key features of the regional climate

The Antarctic region, covered by an ice sheet and surrounded by the Southern Ocean, is characterized by polar climate. It is the coldest, windiest and driest continent on Earth and plays a pivotal role in regulating the global climate and hydrological cycle. Antarctica has a mean temperature of −35°C (Lenaerts et al., 2016) and receives 171 mm yr⁻¹ water equivalent of snowfall (north of 82°S, estimate based on satellite measurements during 2006–2011) (Palerme et al., 2014). Precipitation in Antarctica occurs mostly in the form of snowfall and diamond dust, with sporadic coastal rainfall during the summer over the Antarctic Peninsula and sub-Antarctic islands. Drizzle events sometimes occur during warm air intrusions (Nicolas et al., 2017) at relatively low temperatures (Silber et al., 2019). Precipitation constitutes the largest component of the surface mass balance (SMB), which also includes sublimation (from the surface or drifting snow), meltwater runoff and redistribution by wind (Lenaerts et al., 2019). SMB can be considered as a proxy of precipitation if averaged over an annual cycle (Gorodetskaya et al., 2015; Bracegirdle et al., 2019). Precipitation and SMB exhibit spatial and temporal variability controlled by atmospheric large-scale low-pressure systems and moisture advection from lower latitudes. SMB is an important component of the total ice-sheet mass balance (Section 9.4.2.1). The Antarctic contribution to sea level results from the imbalance between net snow accumulation and ice discharge into the ocean (Box 9.1). Ice shelves buttress the ice sheet and are influenced by oceanic and atmospheric drivers (Box 9.1).

Antarctic climate variability is influenced by the Southern Annular Mode (SAM) and regionally by other modes, including ENSO, Pacific-South American Pattern, Pacific Decadal Variability, Indian Ocean Dipole and Zonal Wave 3 (Annex IV). Climate change in Antarctica and the Southern Ocean is influenced by interactions between the ice sheet, ocean, sea ice, and atmosphere (Meredith et al., 2019) (Sections 9.2.3.2, 9.3.2 and 9.4.2). In addition to Chapter 9, Antarctica is discussed across the report: global climate links (Chapters 2 and 10), attribution (Chapter 3), global water cycle (Chapter 8), extremes (Chapter 11), and...
climatic impact-drivers (Chapter 12).

**Atlas.11.1.1.2 Findings from previous IPCC assessments**

AR5 (Vaughan et al., 2013) reported warming over Antarctica since 1950s, mostly over AP and WAN, attributed to the positive trend in the SAM. These trends in the Antarctic temperature were given low confidence due to substantial multi-annual to multi-decadal variability, as well as uncertainties in magnitude and spatial trend structure. AR5 reported low confidence that anthropogenic forcing has contributed to the temperature change in Antarctica. AR5 highlighted a large interannual variability in snow accumulation with no significant trend since 1979 around Antarctica, and high confidence in the overall mass loss from Antarctica, accelerated since 1990s.

In this and the following paragraphs findings are from SROCC (Meredith et al., 2019) unless otherwise stated. Warming trends were reported over parts of WAN with record surface warmth over WAN during the 1990s compared to the past 200 years, and AP surface melting intensifying since the mid-20th century. No significant temperature trends were reported over EAN and there was low confidence in both WAN and EAN trend estimates due to sparse in situ records and large interannual to interdecadal variability. In the AP, concomitant increase in temperature and foehn winds due to positive SAM caused increased surface melting over the Larsen ice shelves (medium confidence). Strong warming between the mid-1950s and the late 1990s led to the collapse of the Larsen B ice shelf in 2002, which had been intact for the 11,000 years (medium confidence).

Snowfall increased over the Antarctic ice sheet over AP and WAN, offsetting some of the 20th century sea level rise (medium confidence). Longer records suggest either a decrease in snowfall over the Antarctic ice sheet over the last 1000 years or a statistically negligible change over the last 800 years (low confidence).

Recent warming in the AP and consequent ice shelf collapse are likely linked to anthropogenic ozone and greenhouse-gas forcing via the SAM and anthropogenically-driven Atlantic sea surface. Also, there is high confidence in the influence of tropical sea surface temperature on the Antarctic temperature and Southern Hemisphere mid-latitude circulation, as well as the SAM. There is medium agreement but limited evidence of an anthropogenic forcing effect on Antarctic ice-sheet mass balance (low confidence) and partitioning between natural and human drivers of atmospheric and ocean circulation changes remains very uncertain.

In AR5 Church et al. (2013) gave medium confidence in model projections of a future Antarctic SMB increase, implying a negative contribution to global mean sea level rise, consistent with a projection of significant Antarctic warming. Church et al. (2013) also gave high confidence to the relationship between future temperature and precipitation increases in Antarctica on physical grounds and from ice core evidence. In Meredith et al. (2019), the total mass balance projections derived from ice sheet models were reported without separating the SMB though projections were reported of increased precipitation and continued strengthening of the westerly winds in the Southern Ocean.

**Atlas.11.1.2 Assessment and synthesis of observations, trends and attribution**

Figure Atlas.30 (Antarctic map inset) shows near surface air temperature trends for 1957-2016 and 1979-2016 at the stations where observations are available for at least 50 years and the detected trends have statistical significance of at least 90% according to the most recent (after SROCC) studies (Jones et al., 2019; Turner et al., 2020). It is very likely that the western and northern AP has been warming significantly since 1950s (0.49 ± 0.28°C per decade during 1957–2016 and 0.46 ± 0.15°C during 1951–2018 at Faraday–Vernadsky station; 0.29 ± 0.16°C per decade during 1957–2016 at Esperanza station), with no significant trends reported in the eastern AP during the same period (Gonzalez and Fortuny, 2018; Jones et al., 2019; Turner et al., 2020). Short-term cooling trends, strongest during austral summer, have been reported at AP stations during 1999–2016 but the absence of warming and cooling at some stations during 1999–2016 is consistent with natural variability and there is no evidence of a shift in the overall warming trend observed since 1950s (Turner et al., 2016, 2020; Gonzalez and Fortuny, 2018; Jones et al., 2019; Bozkurt et al., 2020).
Significant warming at the Byrd station (0.29 ± 0.19°C per decade during 1957–2016) confirms and extends earlier trend estimates (0.42 ± 0.24°C per decade during 1958–2010) and is representative of the entire WAN warming (0.22 ± 0.12°C per decade from 1958 to 2012 averaged over WAN excluding AP, medium confidence due to lack of observations) (Bromwich et al., 2013, 2014; Jones et al., 2019). WAN and AP show statistically significant warming in the HadCRUTv5 observational dataset (Figure 2.11b). There is a high confidence in the long-term warming trend at the AP and WAN also at the century scale based on reconstructions (Zagorodnov et al., 2012; Stenni et al., 2017; Lyu et al., 2020) confirming the trends estimated by earlier studies assessed in the SROCC (Meredith et al., 2019). The century-scale warming trend in the AP is very likely an emerging signal compared to natural variability, while the WAN warming trend falls in the high end of century-scale trends over the last 2000 years (Stenni et al., 2017) (medium confidence).

In EAN, during 1957-2016, three stations showed significant warming (Scott base 0.22 ± 0.15, Novolazarevskaya 0.13 ± 0.09 and Vostok 0.15 ± 0.13°C per decade), while other stations with long-term observations indicated no statistically significant trends (Figure Atlas.30). During 1979-2016, three coastal stations showed cooling, while at South Pole a warming trend was detected, increasing to 0.61±0.54 °C per decade during 1989-2018 (Jones et al., 2019; Clem et al., 2020; Turner et al., 2020) (Figure Atlas.30). The century-scale warming in Queen Maud Land Coast based on the ice-core reconstructions is within the range of centennial internal variability (Stenni et al., 2017).

While a trend towards a positive phase of the SAM since the 1970s likely explains a significant part of the warming at the northern AP, it had a cooling effect on the continental WAN and EAN (particularly strong in DJF, Table.Atlas.1). Warming in western AP and over WAN during 1957–2016 (Figure.Atlas.30) and through to 2020 (Figure 2.11) is likely due to significant contribution of other factors, such as tropical Pacific forcing through PDV, ENSO, Amundsen Sea Low position/strength and also anthropogenic climate change (Jones et al., 2019; Scott et al., 2019; Wille et al., 2019; Donat-Magnin et al., 2020; Turner et al., 2020).

Since SROCC, new studies confirmed the influence of foehn wind and cloud radiative forcing on Larsen C surface melt (Elvidge et al., 2020; Gilbert et al., 2020; Turton et al., 2020). In the WAN, summer surface-melt occurrence over ice shelves may have increased since the late 2000s (Scott et al., 2019). It is likely that increased meltwater ponding and resulting hydrofracturing have been important mechanisms of the rapid disintegration of the Larsen B ice shelf (Banwell et al., 2013; MacAyeal and Sergienko, 2013; Robel and Banwell, 2019). Ice shelf disintegration and relevant processes are discussed in Sections 9.4.2.1 and 9.4.2.3.

Direct observations of snowfall in Antarctica using traditional gauges are highly uncertain and records from precipitation radars (Gorodetskaya et al., 2015; Grazzioli et al., 2017; Sarchilli et al., 2020) are not long enough to assess trends. Estimates of precipitation and SMB are largely model-based due to the paucity of in-situ observations in Antarctica (Lenaerts et al., 2019; Hanna et al., 2020). Antarctic SMB is dominated by precipitation and removal by sublimation with very small amounts of melt mostly important only on the ice shelves. Climate models and satellite records (IMBIE team et al., 2018; Rignot et al., 2019; Mottram et al., 2021) suggest that strong interannual variability of Antarctic-wide SMB over the satellite period currently masks any existing trend (Figure Atlas.30) in spite of a possible ozone depletion-related precipitation increase over the 1991–2005 period (Lenaerts et al., 2018). No significant Antarctic-wide SMB trend continent-wide SMB trend is inferred since 1979 (IMBIE team et al., 2018; Medley and Thomas, 2019).

While ice core reconstructions show a significant increase in the western AP SMB since 1950s (Thomas et al., 2017; Medley and Thomas, 2019; Wang et al., 2019), this trend is not reproduced by regional climate models or reanalyses used to drive them (Figure Atlas.30) (van Wessem et al., 2016; Wang et al., 2019).

According to the ice core reconstructions, SMB over WAN (including AP) has likely increased during the 20th century with trends of 5.4 ± 2.9 Gt yr⁻¹ per decade (1900–2010) (Wang et al., 2019) mitigating global mean sea level rise by, respectively, 0.28 ± 0.17 mm per decade (WAN excluding AP, during 1901–2000) and 0.62 ± 0.17 mm per decade (AP, during 1979–2000) (Medley and Thomas, 2019). Significant spatial heterogeneity in SMB trends has been observed over AP and WAN:

- western AP has likely experienced a significant increase in SMB beginning around 1930 and accelerating during 1970–2010, which is outside of the natural variability range of the past 300 years (Thomas et al., 2017; Medley and Thomas, 2019; Wang et al., 2019);
• eastern AP has no significant SMB trends during the same period (low confidence, observations limited to one ice core and large interannual variability) (Thomas et al., 2017; Engel et al., 2018);

• overall WAN SMB (excluding AP) was stable during 1980–2009 but exhibited high regional variability (Medley et al., 2013): significant increases (5–15 mm per decade during 1957–2000) to the east of the West Antarctic ice sheet divide and significant decrease (−1 to −5 mm per decade during 1901–1956, and −5 to −15 mm per decade during 1957–2000) to the west (Medley and Thomas, 2019; Wang et al., 2019).

The SMB of EAN increased during the 20th century which mitigated global mean sea level rise by $0.77 \pm 0.40$ mm per decade during 1901–2000 (Medley and Thomas, 2019) (medium confidence). EAN SMB has been increasing at a much lower rate since 1979 as shown by observations, while regional climate models show strong interannual variability masking any trend (Medley and Thomas, 2019; Rignot et al., 2019) (Figure Atlas.30) (low confidence due to limited observations). EAN SMB changes during the 20th century and recent decades showed large spatial heterogeneity:

• With significant increases likely in Queen Maud Land (QML): 5.2 ± 3.7% per decade during 1920–2011 measured in ice core near the Kohnen station (Medley et al., 2018), an increase on the plateau (Altin et al., 2015), and stable conditions during 1993–2010 along the annual stake line from Syowa (coast) to Dome F (plateau) (Wang et al., 2015b); increases during 1911–2010 (Thomas et al., 2017) with anomalously high SMB observed in 2009 and 2011 (Boening et al., 2012; Lenaerts et al., 2013; Gorodetskaya et al., 2014);

• increases in Wilkes Land and Queen Mary Land during 1957–2000 (Thomas et al., 2017; Medley and Thomas, 2019) (low confidence due to limited observations and strong spatial variability);

• a likely stable SMB in the interior of the East Antarctic plateau during the 1901–2000 period and the last decades (Thomas et al., 2017; Medley and Thomas, 2019);

• stable in Adelie Land (annual stake line during 1971–2008) (Agosta et al., 2012) (low confidence due to limited evidence).

Regional trends of the last 50 years (1961–2010) and 100 years (1911–2010) are within centennial variability of the past 1000 years, except for coastal QML (unusual 100 year decrease in accumulation) and for coastal Victoria Land (unusual 100 year decrease in accumulation) (Thomas et al., 2017). Nevertheless, the current EAN SMB is not unusual compared to the past 800 years (Frezzotti et al., 2013).

The geographic pattern of accumulation changes since the 1950s bears a strong imprint of a trend towards a more positive phase of the SAM (e.g., Medley and Thomas, 2019), which could be linked to ozone depletion (Lenaerts et al., 2018) or large-scale atmospheric warming (Frieler et al., 2015; Medley and Thomas, 2019). More evidence has emerged showing the importance of the Pacific-South American Pattern, ENSO and Pacific Ocean convection, and large-scale blocking causing warm-air intrusions and both extreme precipitation and melt events, responsible for large interannual SMB variability (high confidence) (Gorodetskaya et al., 2014; Bodart and Bingham, 2019; Scott et al., 2019; Turner et al., 2019; Wille et al., 2019; Adusumilli et al., 2021). This strengthens evidence for an important connection between Antarctic climate and tropical sea surface temperature stated by SROCC (Meredith et al., 2019). Section 3.4.3 and SROCC (Meredith et al., 2019) provide a discussion of attribution of Antarctic ice sheet changes.

### Atlas.11.1.3 Assessment of model performance

This section provides evaluation of atmospheric global and regional climate models, including reanalyses. Evaluation of the ice sheet models and relevant processes, including selection of the atmospheric models used to drive ice sheet models, is given in Section 9.4.2.2.

One of the major systematic biases in CMIP5 and earlier GCMs was an equatorward bias in the latitude of the Southern Hemisphere mid-latitude westerly jet, which is significantly reduced in the CMIP6 ensemble (Bracegirdle et al., 2020a). GCM Southern Ocean sea-ice biases are also of importance as they influence 21st century temperature projections in Antarctica and simulation of present day temperatures are highly sensitive to these biases (Agosta et al., 2015; Bracegirdle et al., 2015). A positive bias in near-surface temperature...
over the Antarctic plateau is seen in CMIP5 models (Lenaerts et al., 2016).

CMIP6 GCMs showed an improved representation of the Antarctic near-surface temperature compared to CMIP5 but little improvement (maintaining positive bias) in Antarctic precipitation estimates (Palmerme et al., 2017; Roussel et al., 2020). An analysis of the 1850–2000 SMB mean, trends and interannual and spatial variability suggests slightly worse agreement with ice-core-based reanalyses in CMIP6 than CMIP5 (Gorte et al., 2020). Comparison of CMIP6 models with CloudSat satellite products and an ice-core-based SMB reconstruction showed almost all the models overestimate current Antarctic precipitation, some by more than 100% (Palmerme et al., 2017; Gorte et al., 2020). GCM simulations of surface snow-melt processes are of variable quality, with extremely simple representations, or non-existent (Agosta et al., 2015; Trusel et al., 2015). Though most meltwater refreezes in the snowpack in current climate simulations this may be an issue in the future climate simulations under global warming as run-off is projected to increase (Kittel et al., 2021).

Since CMIP5, representation of snow (Lenaerts et al., 2016) and stable surface boundary layers (Vignon et al., 2018) has improved in some atmospheric GCMs. In one example, the CMIP6 model CESM2 simulation of cloud and precipitation showed substantial improvements (Schneider et al., 2020) though surface melting is still considerably overestimated compared to RCMs and satellite products (Trusel et al., 2015; Lenaerts et al., 2016).

Assimilation of observations in reanalysis products yields realistic temperature patterns and seasonal variations, with the recent ERA5 reanalysis showing improved performance compared to others for mean and extreme temperature, wind and humidity, though a warm bias in the near-surface air temperatures remains (Retamales-Muñoz et al., 2019; Tetzner et al., 2019; Dong et al., 2020; Gorodetskaya et al., 2020).

The ability of the reanalyses to simulate precipitation and SMB is more variable: they generally overestimate the latter (Gossart et al., 2019; Roussel et al., 2020), but are well suited to provide atmospheric and sea surface boundary conditions to drive RCMs.

Recent higher-resolution simulations covering the entire Antarctic ice sheet with a grid spacing of 12 to 50 km include five Polar-CORDEX RCMs – RACMO2 (van Wessem et al., 2018), MAR (Agosta et al., 2019; Kittel et al., 2021), COSMO-CLM2 (Souverijns et al., 2019), HIRHAM5 (Lucas-Picher et al., 2012), and MetUM (Walters et al., 2017; Mottram et al., 2021) – and one stretched-grid GCM – ARPEGE (Beaumet et al., 2019). RCM simulations forced by ERA-Interim agree well with automatic weather station temperatures, with high correlation (R² > 0.9) and low bias (<1.5°C) except for high resolution HIRHAM5 (−2.1°C) and MetUM (−3.4°C), which are not internally nudged models (Mottram et al., 2021). RCMs generally underestimate the observed SMB but with biases lower than 20%, except for COSMO-CLM2 at lower elevations (<1200 m) and HIRHAM5 and MetUM at higher elevations (>2200 m) (Mottram et al., 2021).

These RCM simulations lead to estimates of the grounded Antarctic ice sheet SMB ranging from 2133 Gt yr⁻¹ to 2328 Gt yr⁻¹ when considering the four simulations compatible with the IMBIE2 Antarctic total mass budget (IMBIE team et al., 2018; Mottram et al., 2021). However, the simulated spatial pattern of SMB differs widely between models suggesting the importance of missing or under-represented processes in the models, such as drifting-snow transport and sublimation (Agosta et al., 2019), cloud-precipitation microphysical processes (van Wessem et al., 2018) and snowpack modelling (Mottram et al., 2021).

Comparisons of integrated SMB estimates between models are also complicated by different resolutions and continental ice masks, with models showing large differences in the absolute SMB (Mottram et al., 2021) but better agreement for SMB annual rates (Figure Atlas.30)

Finer resolution RCM studies demonstrate improved representation of precipitation and temperature gradients (van Wessem et al., 2018; Bozkurt et al., 2020; Donat-Magnin et al., 2020; Elvidge et al., 2020), and strength of katabatic winds (Bintanja et al., 2014; Souverijns et al., 2019) in coastal and mountainous regions. Adequate representation of some processes is still lacking, including drifting snow, sublimation of falling snow or the spectral dependency of snow albedo (Lenaerts et al., 2019). Non-hydrostatic regional models, for example Polar-WRF, MetUM or HARMONIE-AROME at spatial resolutions up to 2 km further improve regional RCM simulations, but are still often unable to resolve relevant feedbacks and foehn processes (Grosvenor et al., 2014; Elvidge et al., 2015, 2020; Elvidge and Renfrew, 2016; King et al., 2017; Turton et al., 2017; Bozkurt et al., 2018b; Hines et al., 2019; Vignon et al., 2019; Gilbert et al., 2020).
Existing uncertainties in the Antarctic climate representation by both GCMs and RCMs cause significant spread in the future Antarctic climate and SMB projections (Gorte et al., 2020; Kittel et al., 2021). Run-time bias adjustment in atmospheric GCMs (Krinner et al., 2019, 2020) (see also Cross-Chapter Box 10.2) has been proposed to provide low-bias present and consistently-corrected future RCM forcing (reducing the need for coupled model selection), which could be used directly for Antarctic climate projections (Krinner et al., 2019).

[START FIGURE ATLAS.30 HERE]

Figure Atlas.30: (Upper panels) Time series of annual surface mass balance (SMB) rates (in Gt a⁻¹) for Greenland ice sheet and its regions (shown in the inset map) for the periods 1972–2018 (Mouginot et al., 2019) and 1980–2012 (Fettweis et al., 2020) using 13 different models. (Lower panels) Time series of annual SMB rates (in Gt a⁻¹) for the grounded Antarctic ice sheet (excluding ice shelves) and its regions (shown in the inset map) for the periods 1979–2019 (Rignot et al., 2019) and 1980–2016 (Mottram et al., 2021) using five Polar-CORDEX regional climate models. The Antarctic inset map also shows the location of the stations discussed in section Atlas.11.1.2 where observations are available for at least 50 years. Colors indicate near surface air temperature trends for 1957–2016 (circles) and 1979–2016 (diamonds) statistically significant at 90% (Jones et al., 2019; Turner et al., 2020). Stations with an asterisk (*) are where significance estimates disagree between the two publications. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

[END FIGURE ATLAS.30 HERE]

Atlas.11.1.4 Assessment and synthesis of projections

This section provides an assessment of projections in temperature, precipitation and SMB. See Section 9.4.2 for projected changes in the ice sheet total mass balance and relevant processes and see Section 4.3.1 (Table 4.2) and Section 4.5.1 for Antarctic temperature projections relative to other regions.

The Antarctic region is very likely to experience a significant increase in annual mean temperature and precipitation by the end of this century under all emission scenarios used in CMIP5 and CMIP6 (Bracegirdle et al., 2015, 2020b; Frieler et al., 2015; Lenaerts et al., 2016; Previdi and Polvani, 2016; Palerme et al., 2017) (Figure Atlas.29). Ensemble means (and 10th–90th percentile ranges) of end-of-century (2081–2100) projected Antarctic surface air temperature change from 35 CMIP6 models and relative to 1995–2014 are 1.2°C (0.5°C–2.0°C) for the SSP1-2.6 emissions scenarios, 2.3°C (1.3°C–3.4°C) for SSP2-4.5, 3.5°C (2.0°C–5.0°C) for SSP3-7.0 and 4.4°C (2.8°C–6.4°C) for SSP5-8.5 (Interactive Atlas). Both temperature and precipitation projections are characterised by a relatively large multi-model range (Figure Atlas.29, Interactive Atlas). A strong regional variability is present with the projected changes over coastal Antarctica not scaling linearly with global forcing. While continental mean temperatures are linearly related to global mean temperatures in CMIP6 models, the relative increase in coastal temperatures are higher for low-emissions scenarios due to stronger relative Southern Ocean warming and relatively stronger effects of ozone recovery (Bracegirdle et al., 2020b). A higher multi-model average increase in temperature is projected by CMIP6 models compared to CMIP5, with a 1.3°C higher mean Antarctic near-surface temperature at the end of 21st century (Kittel et al., 2021). While similar median temperature changes are projected for WAN and EAN, the former shows larger spread and higher projected temperature range in both CMIP5 and CMIP6 models and for all scenarios (Figure Atlas.29). CORDEX-Antarctica simulations show a mean and range in the future temperature changes similar to the subset of CMIP5 models used to drive them for the RCP8.5 scenario and 1.5°C, 2°C and 3°C global warming levels (GWL) (Figure Atlas.29).

There is high confidence that projected future surface-air temperature increase over Antarctica will be accompanied by precipitation increase (Figure Atlas.29). CMIP6 models show a similar or larger but more constrained increase in precipitation (more models agreeing with larger precipitation increase) for the same GWLs compared to CMIP5. For example, over WAN during JJA for 3°C GWL, CMIP6 and CMIP5 models project a median 15% increase in precipitation with a 10th–90th percentile range of 7–25% in CMIP6
models and of 3–24% in CMIP5. Average precipitation changes relative to 1995–2014 over WAN and EAN are largely similar, and show projected increases for SSP2-4.5 (SSP5-8.5) of around 5% (5%) for 2021–2040, 7% (10%) for 2041–2060, and 12% (25%) for 2081–2100 with smaller increases projected for SSP1-2.6 emissions, reaching around 5% in 2081–2100. Regionally, the largest relative precipitation increase is projected (under all scenarios) for the eastern part of WAN, the western AP, large parts of EAN plateau and over coastal EAN within 0°E–90°E longitudinal sector (Interactive Atlas). The largest increase in absolute precipitation amount is projected along the coastal regions, with the largest increase over coastal WAN and the western AP, and is projected to be largely driven by the increase in maximum 5-day precipitation (Interactive Atlas), which is in line with the dominant contribution of extreme snowfall events to the total annual precipitation in the present Antarctic climate (Boening et al., 2012; Gorodetskaya et al., 2014; Turner et al., 2020). Under all emission scenarios, the coastal precipitation increase corresponds to the snowfall increase, except for the northern and central part of the western AP, where snowfall is projected to decrease and rainfall to increase (similarly to the tendency towards increased precipitation, decreased snowfall and increase in rainfall over the Southern Ocean) (Interactive Atlas).

From 2000 to 2100, the grounded Antarctic SMB is projected to mitigate sea level rise for RCP4.5 (RCP8.5) by the following sea level equivalents (SLE), 0.03 ± 0.02 m (0.08 ± 0.04 m SLE) from 30 CMIP5 models and for SSP2-4.5 (SSP5-8.5) by 0.03 ± 0.03 m SLE (0.07 ± 0.04 m SLE) from 24 CMIP6 models (Gorte et al., 2020). Subsets or downscaling of CMIP AOGCMs lead to 21st century cumulative projections in the range of 0.05 ± 0.03 m SLE for CMIP5 RCP8.5 and 0.08 ± 0.04 m SLE for CMIP6 SSP5-8.5 (Gorte et al., 2020; Nowicki et al., 2020; Seroussi et al., 2020; Kittel et al., 2021). Use of model subsets reduces spread leading to either lower or higher climate sensitivity in the Antarctic depending on the selection method. For example, models selected by Gorte et al. (2020) based on SMB ice-core reconstruction from Medley and Thomas (2019) tend to underestimate strong winter sea ice area (Agosta et al., 2015; Roach et al., 2020) and show reduced 21st century increase in Antarctic SMB compared to the full ensembles (Agosta et al., 2015; Bracegirdle et al., 2015). A different subset of models is used for ISMIP6 (Section 9.4.2.3) which gives a lower increase in Antarctic SMB than the full ensemble for CMIP5 but a larger increase for CMIP6.

Polar-CORDEX RCMs show higher variability in precipitation projections compared to CMIP5 models with a similar spatial pattern of the areas with precipitation increase over continental Antarctica but with higher local magnitude and also showing a larger increase over the Weddell Sea ice shelves (Interactive Atlas). CMIP5 and CMIP6 models, bias-adjusted based on regional climate model simulations, showed that the projected warming is expected to result in increased surface melting over the Antarctic ice shelves, with meltwater runoff under RCP8.5 and SSP5-8.5 becoming larger than precipitation over ice shelves over the period 2045–2050, surpassing intensities that were linked with the collapse of Larsen A and B ice shelves (Trusel et al., 2015; Kittel et al., 2021). Given the existing uncertainty in the present precipitation and SMB simulations and the significant range in the projected precipitation increase under various emissions scenarios in CMIP5, CMIP6 and CORDEX models, there is medium confidence that the future Antarctic SMB will have a negative contribution to sea level during the 21st century under all emissions scenarios (see Section 9.4.2.3 for assessment of the drivers of future Antarctic ice sheet change and Section 9.4.2.6 for longer time scales).

Atlas.11.1.5 Summary

Observations show a very likely widespread, strong warming trend starting in 1950s in the Antarctic Peninsula. Significant warming trends are observed in other West Antarctic regions and at selected stations in East Antarctica (medium confidence). Antarctic precipitation and SMB showed a significant positive trend over the 20th century according to the ice cores, while large interannual variability masks any existing trend over the satellite period since the end of 1970s (medium confidence).

An assessment of model performance for the present day shows that high-resolution regional climate models with polar-optimised physics are important for estimating SMB and generating climate information, and show improved realizations compared to reanalyses and GCMs when evaluated against observations. At the same time, CMIP6 GCMs showed an improved representation of the Antarctic near-surface temperature...
compared to CMIP5, though still struggle with the representation of precipitation. There is therefore medium confidence in the capacity of climate models to simulate Antarctic climate and SMB changes.

Under all assessed emission scenarios, both West and East Antarctica are very likely to have higher annual mean surface air temperatures and more precipitation, which will have a dominant influence on determining future changes in the SMB (high confidence). However, due to the challenges of model evaluation over the region and the possibility of increased meltwater runoff described above, there is only medium confidence that the future contribution of the Antarctic SMB to sea level this century will be negative under all greenhouse-gas emission scenarios.

**Atlas.11.2 Arctic**

**Atlas.11.2.1 Key features of the regional climate and findings from previous IPCC assessments**

**Atlas.11.2.1.1 Key features of the regional climate**

The Arctic region comprises the Arctic Ocean (ARO), Russian Arctic (RAR), Greenland and Iceland (GIC) and other surrounding land areas in Europe (NEW) and North America (NEN, NWN) (Figure Atlas 29). The region is one of the coldest and driest regions on Earth and plays a key role influencing global and regional climates and the hydrological cycle. A number of physical processes contribute to amplified Arctic temperature variations as compared to the global temperature, in particular thermodynamic changes that include the increase in surface absorption of solar radiation due to surface albedo feedbacks related with sea-ice, ice, and snow-cover retreat as well as poleward energy transports, water-vapour-radiation and cloud-radiation feedbacks (Screen and Simmonds, 2010; Serreze and Barry, 2011; Pithan and Mauritsen, 2014; Bintanja and Krikken, 2016; Graversen and Burtu, 2016; Franzke et al., 2017; Stuecker et al., 2018).

Precipitation in the Arctic is dominated by snowfall, with rainfall present mostly during the summer period. Arctic climate is influenced by the North Atlantic Oscillation, the leading mode of atmospheric variability in the North Atlantic basin with a northward extension into the Arctic affecting temperature, precipitation and sea ice over the region, with ENSO and Atlantic Multidecadal Variability also affecting parts of the region (Annex IV). Further, the Greenland Ice Sheet contribution to sea-level results from the imbalance between mass gain by net snow accumulation and mass loss by meltwater runoff and ice discharge into the ocean (IMBIE team, 2020), highlighting that the ice sheet is a major contributor to sea level changes.

**Atlas.11.2.1.2 Findings from previous IPCC assessments**

The following summary from previous IPCC reports is derived from the SROCC (IPCC, 2019a) unless otherwise stated. Arctic surface air temperatures have increased from the mid-1950s, with feedbacks from loss of sea ice and snow cover contributing to the amplified warming (high confidence) (IPCC, 2018c), and have likely increased by more than double the global average over the last two decades (high confidence). Arctic snow cover in June has declined from 1967 to 2018 (high confidence). Arctic glaciers are losing mass (very high confidence) and this along with changes in high-mountain snow melt have caused changes in hydrology, including river runoff, that are projected to continue in the near term (high confidence). The rate of ice loss from the Greenland Ice Sheet has increased; during 2006–2015 the loss was 278 ± 11 Gt yr⁻¹ with the rate for 2012–2016 higher than for 2002–2011 and several times higher than during 1992–2001 (high confidence).

The Arctic sea-ice area is declining in all months of the year (very high confidence) with the September sea-ice minimum very likely having reduced by 12.8 ± 2.3% per decade during the satellite era (1979 to 2018) to levels unprecedented for at least 1000 years (medium confidence).

The high latitudes are likely to experience an increase in annual mean precipitation under RCP8.5 (IPCC, 2013c). Further, changes in precipitation will not be uniform. Autumn and spring snow cover duration are projected to decrease by a further 5–10% from current conditions in the near term (2031–2050). No further losses are projected under RCP2.6 whereas a further 15–25% reduction in snow cover duration is projected by the end of century under RCP8.5 (high confidence).
The Arctic has warmed at more than twice the global rate over the past 50 years with the greatest warming during the cold season (Davy et al., 2018; Boisvert et al., 2019; Przybylak and Wyszyński, 2020; Xiao et al., 2020) (high confidence). This is based on various Arctic amplification processes, in particular the combined effect of several related feedback processes including sea-ice and snow-cover albedo and water-vapour-cloud-radiation feedbacks as well as poleward energy transports. The annual average Arctic surface air temperature increased by 2.7°C from 1971 to 2017, with a 3.1°C increase in the cold season (October–May) and a 1.8°C increase in the warm season (June–September) (AMAP, 2019). Satellite-based data estimate the rate of annual warming for 1981–2012 over sea-ice covered regions to be 0.47°C per decade, whereas the trend was significantly higher at 0.77°C per decade over Greenland and amplified in the northern Barents and Kara seas (Comiso and Hall, 2014). The largest Arctic warming in 2003–2017 was reported over the Barents and Kara Seas with trends larger than 2.5°C per decade (Susskind et al., 2019) and Arctic temperatures from 2014 to 2018 have exceeded all previous records since 1900 (Blunden and Arndt, 2019).

Over the ARO, long-term temperature records are available from Spitsbergen (Svalbard Airport). For the period 1898–2018, the annual mean warming was 0.32°C per decade, about 3.5 times the global mean temperature for the same period and since 1991, 1.7°C per decade or about seven times the global average for the same period (Nordli et al., 2020). There is a positive trend in the annual temperature for all stations across Svalbard (Gjelten et al., 2016; Hanssen-Bauer et al., 2019; Dahlke et al., 2020) of 0.64°C–1.01°C per decade for 1971–2017 (Hanssen-Bauer et al., 2019) co-varying with regional changes in sea-ice conditions (Dahlke et al., 2020). The largest temperature trends very likely occur in winter, with Svalbard airport warming at 0.43°C per decade during 1898–2018 and 3.19°C per decade during 1991–2018 (Nordli et al., 2020) and Isaksen et al. (2016) reporting on substantial warming in western Spitsbergen, particularly in winter, while the summer warming is moderate.

A multi-data analysis for NEN shows a consistent warming (Rapais et al., 2015), with the largest annual temperature trend greater than 0.3°C per decade during 1981 to 2010 over eastern NEN and also significant warming over northern Quebec and most of the Canadian Arctic north of the treeline. For the longer 1950–2010 period, a consistent warming is found over central and western NEN, but no trend or no consensus is found over the Labrador coast. The latter is related with cooling of the North Atlantic region during the 1970s. For western Greenland, however, summer temperatures increased (2.2°C in June, 1.1°C in July) from 1994 to 2015 (Saros et al., 2019). For neighbouring Arctic regions of NEU, WSE and ESB, datasets show a consistent warming of annual mean temperature since the mid-1970s and 1980 (see Sections Atlas 8 and Atlas 5.2).

Along with the amplified warming, the Arctic has become moister (Rinke et al., 2019; Nygård et al., 2020). AMAP reported Arctic precipitation increases of 1.5–2.0% per decade, with the strongest increase in the cold season (October–May) (AMAP, 2019) (medium confidence). Also, for neighbouring Arctic regions for example NEU, EEU and Northern Asia, mean annual precipitation has increased since the early 20th century (see Sections Atlas 8 and Atlas 5.2). Estimated trends for precipitation and snowfall fraction are mixed for Arctic, with increases and decreases for different regions and seasons (Vihma et al., 2016). However, annual precipitation trends derived from different reanalyses do not agree, differ in sign and have low significance (Lindsay et al., 2014; Boisvert et al., 2018). Direct precipitation measurements are difficult and include uncertainties (among others measuring frozen precipitation), therefore precipitation estimates in the Arctic rely on climate models and reanalyses.

An average of five reanalyses for 2000–2010 suggests around 40% of Arctic Ocean precipitation falls as snow, though there is large uncertainty in this estimate (Boisvert et al., 2018). Rainfall frequency is estimated to have increased over the Arctic by 2.7–5.4% over 2000–2016 (Boisvert et al., 2018) with more frequent rainfall events reported for NEU and ARO (Svalbard) (Maturilli et al., 2015; AMAP, 2019), and winter rain totals and frequency have increased in Svalbard since 2000 (Lupikasza et al., 2019) (medium confidence). Rain-free winters have rarely occurred since 1998 (Peeters et al., 2019).

Observational records (1966 to 2010) for the RAR region show changing precipitation characteristics (Ye et
Do Not Cite, Quote or Distribute

Atlas.11.2.3 Assessment of model performance

Evaluating simulated temperature and precipitation is problematic in the Arctic due to sparse weather station observations. The lack of reliable observed precipitation datasets for the Arctic thus makes it very unlikely to be able to evaluate objectively the skill of models to reproduce precipitation patterns (Takhsha et al., 2018). The CMIP5 models reproduce the observed Arctic warming over the past century (Chylek et al., 2016; Hao et al., 2018; Huang et al., 2019) (medium confidence). The simulated mean Arctic warming for 1900–2014 averaged over 40 CMIP5 models is 2.7°C compared to the observed values of 2.2°C (NASA GISS data smoothed using a 1200-km radius) or 1.7°C (using a 250-km smoothing radius) (Chylek et al., 2016). However, there are large inter-model differences in the simulated warming which ranges from 1.2°C to 5.0°C. Although the CMIP5 models reproduce the spatially averaged observed warming over the past 50 to 100 years, the pattern is different from that of observations and reanalysis (Xie et al., 2016; Franzke et al., 2017; Hao et al., 2018). Zonal mean temperature trends in the CMIP5 models overestimate the warming in the cold season over high latitudes in the northern hemisphere (Xie et al., 2016). Overall, the amplified Arctic warming in the recent decades is overestimated by CMIP5 models (Huang et al., 2019). Possible reasons are modelled sea surface temperature biases and an overestimated temperature response to the Arctic sea-ice decline. Furthermore, some models, which have a warm or weak bias in their Arctic temperature simulations, closely relate the Arctic warming to changes in the large-scale atmospheric circulation. In other models, which show large cold biases, the albedo feedback effect plays a more important role for the temperature trend magnitude. This implies that the dominant simulated Arctic warming mechanism and trend may be dependent on the bias of the model mean state (Franzke et al., 2017). Compared to CMIP5 models, Davy and Outten (2020) found lower biases in CMIP6 models’ representation of sea-ice extent and volume with improved extents linked to a better seasonal cycle in the Barents Sea.

Rapid temperature changes, such as the pronounced increase of 2°C yr⁻¹ during 2003–2012 over the Kara and Barents Seas in March is well captured in Arctic CORDEX simulations (Kohmann et al., 2017). The models show adequate skill in capturing the general temperature patterns (Koenigk et al., 2015; Matthes et al., 2015; Hamman et al., 2016; Cassano et al., 2017; Brunke et al., 2018; Diaconescu et al., 2018; Takhsha et al., 2018), but tend to show a cold temperature bias which is largest in winter and depends on the reference dataset. Cassano et al. (2017) showed a large sensitivity of the simulated surface climate to changes in atmospheric model physics. In particular, large changes in radiative flux biases, driven by changes in simulated clouds, lead to large differences in temperature and precipitation biases.

The CMIP5 models perform well in simulating 20th-century snowfall for the northern hemisphere, although there is a positive bias in the multi-model ensemble relative to the observed data in many regions (Krasting et al., 2013b). Lack of sufficient spatial resolution in the model topography has a serious impact on the simulation of snowfall. The patterns of relative maxima and minima of snowfall, however, are captured reasonably well by the models.

Arctic CORDEX RCMs reproduce the dominant features of regional precipitation patterns and extremes (e.g., Glisan and Gutowski, 2014; Hamman et al., 2016). Due to their higher spatial resolution, RCMs simulate larger amounts of orographic precipitation compared to reanalyses. Overall, the simulated precipitation is within the reanalysis and global model ensemble spread, but the Arctic river basin precipitation is closer to observations (Brunke et al., 2018). However, Takhsha et al. (2018) show that the RCMs precipitation bias highly depends on the observational reference dataset used.

The annual mean precipitation pattern of ensemble global atmospheric simulations with a high horizontal resolution agrees well with the observations, with precipitation maxima over the Greenland and Norwegian Seas (Kusunoki et al., 2015). However, the simulated Arctic average annual precipitation shows a positive bias with excessive precipitation over Alaska and the western Arctic (Kattsov et al., 2017).
Regarding the Greenland Ice Sheet (region GIC), modelled surface mass balance (SMB) has decreased since the end of the 1990s (Fettweis et al., 2020). A multi-model inter-comparison study (Fettweis et al., 2020) emphasized a simulated positive annual SMB of $338 \pm 68 \text{ Gt yr}^{-1}$ between 1980 and 2012, with a decreasing average growth rate of $7.3 \pm 2.0 \text{ Gt yr}^{-2}$, mainly driven by an increase in meltwater runoff. Mouginot et al. (2019) stated that SMB played a strong role in the ice sheet mass loss, where SMB dominated in the last two decades. Mottram et al. (2019) found that SMB processes dominate the ice sheet mass budget over most of the interior, highlighting that the ice sheet is a contributor to global mean sea level rise between 1991 and 2015. More specifically, SMB models have improved (Fettweis et al., 2020; Hanna et al., 2021) due to increased availability and quality of remotely sensed (Koenig et al., 2016; Overly et al., 2016) and in-situ observations (Machguth et al., 2016; Fausto et al., 2018; Vandecrux et al., 2019, 2020). Fettweis et al. (2020) showed that the models’ ensemble mean provides the best estimate of the present-day SMB relative to observations. This is the case for the patterns in all seven regions (regional division after Mouginot et al., 2019) apart from the SE accumulation zone where large discrepancies in modelled snowfall accumulation occurred where the spread can reach 2 m water equivalent per year. Montgomery et al. (2020) confirmed this highlighting that RCMs (MAR and RACMO) are underestimating accumulation in southeast Greenland and that models misrepresent spatial heterogeneity due to an orographically forced bias in snowfall near the coast. Further, for northeast Greenland, Karlsson et al. (2020) found RCMs underestimate snow accumulation rates by up to 35%. The regional time series show that SMB has been gradually decreasing in all seven regions (1979–2017), although the trend is less strong in central-eastern and southeast regions. In the southwest, northeast and northwest, SMB turns negative or close to zero after 2000 and remains above zero in other regions (Figure 30) (medium confidence).

Atlas.11.2.4 Assessment and synthesis of projections

Mean surface annual warming in the Arctic is projected to continue to rise through the 21st century significantly higher than the global average (Figure 29 and Interactive Atlas). For the regions NWN and NEN, see Section Atlas.9. The Arctic is projected to reach a 2°C annual mean warming above the 1981–2005 baseline about 25 to 50 years before the globe as a whole under RCP8.5 and RCP4.5 (Post et al., 2019). The Arctic warming may be as much as 4°C in the annual mean and 7°C in late autumn under 2°C global warming, regardless of which scenario is considered (Post et al., 2019) (high confidence).

Projections from 40 CMIP5 models of the 2014–2100 Arctic annual warming under RCP4.5 vary from 0.9°C to 6.7°C, with a multi-model mean of 3.7°C (Chylek et al., 2016). All models agree on a projected Arctic amplification (of at least 1.5 times), but they disagree on the magnitude and spatial patterns. Arctic warming trends projected by models that include a full direct and indirect aerosol effect (‘fully aerosol-cloud interactive’) are significantly higher than those projected by models without a full indirect aerosol effect (Chylek et al., 2016).

Projected Arctic warming exhibits a very pronounced seasonal cycle, with exceptionally strong warming in the winter. In projections from 30 CMIP5 models, winter warming over ARO varies regionally from 3°C to 5°C by mid-century and 5°C to 9°C by late-century under RCP4.5 (AMAP, 2017) (high confidence). Averaged over the Arctic and based on 36 CMIP5 models, winter warming is 5.8 ± 1.5°C by mid-century and 7.1 ± 2.3°C by 2100 under RCP4.5 (Overland et al., 2019), and an exceptionally strong warming of up to 14.1 ± 2.9°C is projected in December under RCP8.5 (Bintanja and Krikken, 2016). Bintanja and Van Der Linden (2013) estimated the Arctic winter warming over the 21st century to exceed the summer warming by at least a factor of four, irrespective of the magnitude of the climate forcing.

Overland et al. (2014) highlighted the difference between the near-term ‘adaptation timescale’ and the long-term ‘mitigation timescale’ for the Arctic. Only in the latter half of the century do the projections under RCP4.5 and RCP8.5 noticeably separate. End-of-the-century warming is approximately twice as large under RCP8.5 demonstrating the impact of the lower emissions under RCP4.5 (AMAP, 2017) (high confidence). More specifically under the strong forcing scenario, annual mean surface air temperature in the Arctic is projected to increase by 8.5 ± 2.1°C over the course of the 21st century (Bintanja and Andry, 2017), and emerges as a ‘new Arctic’ climate being significantly different from that of the mid-20th century (Landrum...
and Holland, 2020). The end-of-the-century warming (2080–2099 relative to 1980–1999, RCP8.5) can exceed 15°C in autumn and winter over the Arctic Ocean (Koenigk et al., 2015). Projections averaged over the four best-performing CMIP5 models show an Arctic annual warming of 4.1°C (RCP2.6), 5.7°C (RCP4.5), and 10.6°C (RCP8.5) by 2100 compared to 1951–1980 (Hao et al., 2018). Also, for neighbouring Arctic regions, for example NEU, WSB and ESB, temperature is projected to increase towards the end of the century under both RCP4.5 and RCP8.5 (see Sections Atlas.8 and Atlas.5.2).

The ensemble of CMIP6 shows likely greater warming compared to CMIP5 (Figure Atlas.29). There is weak agreement among the models in projected temperature change over the Arctic North Atlantic under SSPs until the mid-century, but a robust warming signal clearly emerges even there by 2100 (Interactive Atlas). Generally, the largest annual warming is simulated over the Arctic Ocean, particularly over the Barents and Kara Seas. Future warming in CORDEX RCMs and the CMIP5 models are similar (Spinoni et al., 2020). The RCM warming over the AO is smaller, while the warming over land is larger in winter and spring but smaller in summer, compared with CMIP5 (Koenigk et al., 2015).

Mean precipitation in ARO, GIC and RAR is projected to rise in a warming climate (Figure Atlas.29), with different rates for the different seasons and scenarios. For NWN and NEN, see Section Atlas.9. The CMIP5 multi-model mean projected precipitation increase in the Arctic is likely of the order of 50% under RCP8.5 by the end of 21st century, which is among the highest globally (Bintanja and Selten, 2014). Over 70°–90°N, the precipitation increase is likely 62 ± 20% and 56 ± 13% for RCP4.5 and RCP8.5 respectively. For ARO (Svalbard), the increase in annual precipitation by 2100 is estimated to be about 45% for RCP4.5 and 65% for RCP8.5 (CMIP5 ensemble median) (Van der Bilt et al., 2019). However, importantly the simulated Arctic precipitation increase varies by a factor of three to four between models (Bintanja and Selten, 2014). The projected increase is strongest in late autumn and winter (Vihma et al., 2016). The interannual variability of Arctic precipitation will likely increase markedly (up to 40% over the 21st century), especially in summer (Bintanja et al., 2020) (medium confidence)

The CMIP6 projections confirm precipitation will likely increase almost everywhere in the Arctic (see the Interactive Atlas). The largest increase is simulated over the Barents and Kara Seas and East Siberian Sea regions, and over northeast Greenland. A pronounced uncertainty in the projection exists over the Arctic North Atlantic and south Greenland. There, the precipitation signal is not significant even by the end of the 21st century and under high-emission scenarios (RCP8.5, SSP5-8.5). Consistent with the generally higher warming in CMIP6, compared to CMIP5, the projected precipitation increase is also higher (Figure Atlas.29) (high confidence).

The Arctic mean annual precipitation sensitivity has been estimated at 4.5% increase per degree Celsius of temperature rise, compared to a global average of 1.6–1.9% per degree Celsius of temperature rise (Bintanja and Selten, 2014) based on a set of 37 CMIP5 GCMs. Koenigk et al. (2015) stress the different precipitation sensitivity in winter (0.8 mm per month per degree Celsius of temperature rise) and summer (2 mm per month per degree Celsius of temperature rise). Dobler et al. (2016) support the high precipitation sensitivity for the projected temperature changes. The pattern and amplitude of precipitation changes agree in CORDEX simulations with their driving CMIP5 models (Koenigk et al., 2015; Spinoni et al., 2020) (high confidence). However, more small-scale variations over land and coastlines and significantly larger precipitation changes in summer are obvious in the downscaling.

Rain is projected to become the dominant form of precipitation in the Arctic region by the end of the 21st century (Bintanja, 2018). The CMIP5 models show a decrease in annual Arctic snowfall under both RCP4.5 and RCP8.5 (Krasting et al., 2013b; Bintanja and Andry, 2017) (high confidence). In the central Arctic, the snowfall fraction barely remains larger than 50%, with only Greenland still having snowfall fractions larger than 80% (Bintanja and Andry, 2017). The most dramatic reductions in snowfall fraction are projected to occur over the North Atlantic and especially the Barents Sea.

With ongoing warming and polar amplification in the Arctic, the Greenland Ice Sheet SMB will inevitably continue to change ( Lenaerts et al., 2019) (high confidence). For the ice sheet, despite large differences between model scenarios, future projections and regions agree that increasing temperatures will increase.
runoff which will in turn dominate the future decrease of SMB (Rae et al., 2012; van Angelen et al., 2014; Mottram et al., 2017; Hofer et al., 2020), confirming the high sensitivity of the SMB to atmospheric warming. Changes in SMB will continue to dominate future mass loss from the ice sheet, and likely even more when marine terminating glaciers retreat onto land, and solid ice discharge is reduced (Vizcaíno, 2014; Lenaerts et al., 2019).

**Atlas.11.2.5 Summary**

It is very likely that the Arctic has warmed at more than twice the global rate over the past 50 years and likely that annual precipitation has increased with the highest increases during the cold season. This is based on various Arctic amplification processes, in particular combination of several feedback-related processes such as sea-ice and snow-cover albedo, poleward energy transports, and water-vapour-cloud-radiation feedbacks. The frequency of rainfall increased over the Arctic by 2.7 to 5.4% over the 2000–2016 period with more frequent rainfall events being reported for northern Europe and Svalbard (medium confidence).

The CMIP5 models reproduce the observed Arctic warming over the past century but overestimate the amplified Arctic warming in the recent decades (medium confidence). Arctic CORDEX simulations show adequate skill in capturing regional temperature and precipitation patterns and precipitation extremes (high confidence). SMB models have improved due to increased availability and quality of remotely sensed and in-situ observations and an ensemble mean of SMB model simulations provides the best estimate of the present-day SMB (medium confidence).

It is very likely that the Arctic annual mean temperature and precipitation will continue to increase, reaching around 11.5 ± 3.4°C and 49 ± 19% over the 2081–2100 period (with respect to a 1995–2014 baseline) under the SSP5-8.5 scenario or 4.0 ± 2.5°C and 17 ± 11% under the SSP1-2.6 scenario. These CMIP6 results show likely higher Arctic annual mean temperatures compared to CMIP5 for a given time-period and emissions scenario, though the projections are consistent for global warming levels.

**Atlas.12 Final remarks**

Developing from the WGI AR5 Atlas Annex (IPCC, 2013a), the Atlas is an innovation in the WGI contribution to the AR6, providing a region-by-region assessment of new knowledge on changes in mean climate and an online interactive tool, the Interactive Atlas. It demonstrates the diversity in the climate changes across these regions, in the evidence base for generating information on what changes have already occurred and why, and what further changes each region is likely to face in the future based on different emission scenarios. Finally, the Interactive Atlas allows for further exploration of the data underpinning assessment material generated by many of the other chapters.

The foundation of the regional information generated by the Atlas chapter is an assessment of the significant body of new literature on regional climate change though noting substantial heterogeneity in both its availability and the involvement of regional expertise. In many regions this allows for an in-depth assessment though in some the range of information that can be provided and/or the level of confidence in the information is limited. There is similar heterogeneity in the availability of observations to assess recent trends and evaluate model performance, with a lack of curated regional datasets in polar regions, northern South America and Africa.

Internal variability is a large contributor to the climate uncertainty at regional scales. Recent work has combined outputs of Single Model Initial-conditions Large Ensembles (SMILEs) with CMIP5 and CMIP6 to partition and gain insights on the modelled range and uncertainty arising from internal variability and from model response uncertainty for a given emission scenario (Deser et al., 2020; Lehner et al., 2020; Maher et al., 2021). The work highlights the notable role for internal variability at regional scales, particularly for precipitation in regions with weaker forced response, where internal variability can remain larger than model uncertainty or scenario uncertainty throughout the whole century. The Atlas (similar to the other regional
chapters) uses a single realization per model (CMIP6 models provide multiple realizations, but it is not the case for CORDEX and less so for CMIP5) which allows for the comparison of the different lines of evidence but at the expense of internal variability having a larger influence on the ability to detect or quantify changes.

The assessment produced in the Atlas is based on the individual results from the different lines of global and regional evidence and the consistency amongst them, as there is a lack of literature on methodologies that combine multiple lines of evidence to distil regional climate change information.

Figure Atlas.7: Evaluation of annual and seasonal air temperature and precipitation for the six North America subregions, NWN, NEN, WNA, CNA, ENA and NCA (land only) for CORDEX-NAM RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985-2005 relative to the observational reference (E5W5, see Section Atlas.1.4.2). Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Box Atlas.1, Figure 1: Temperature (left) and precipitation (right) climate change signals at the end of the century (2070–2099) for the entire CMIP5 ensemble (box-whisker plots) and the CORDEX-CORE driving GCMs (grey symbols) of the respective CORDEX-CORE results (non-grey symbols) in the South Asia (SAS) reference region. The shape of the grey symbols represents the climate sensitivity of the driving GCMs: triangles pointing upwards (low equilibrium), circles (medium equilibrium), triangles pointing downwards (high equilibrium). The corresponding RCM results are drawn using the same symbols, but in orange for REMO and in blue for RegCM. The bottom panels show the warming signal by 2070–2099 over the CORDEX regions for RCP2.6 (left) and RCP8.5 (right) (Teichmann et al., 2020).
Cross-Chapters Box Atlas.1, Figure 1: Illustration of the simple (top) and advanced (bottom) approaches (B and C in Cross-Chapters Box Atlas.1, Table 1) for uncertainty representation in maps of future projections. Annual multi-model mean projected precipitation change (%) from CMIP6 for the period 2040–2060 (left) and 2080–2100 (right) relative to the baseline periods 1995–2014 (a–d) and 1850–1900 (e–g) under a high-emission (SSP3-7.0) future. Diagonal and crossed lines follow the indications in Cross-Chapters Box Atlas.1, Table 1. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Cross-Chapter Box Atlas.1, Figure 2: Climate change signals are more separable from noise at larger spatial scales. The figure is showing the global warming level associated with the emergence of a significant increase in the probability due to anthropogenic forcing in the 1-in-20-year daily precipitation event using a 500-year sample from the CanESM2 large ensemble simulations. The left panel uses data analysed over a single grid box, with no spatial aggregation, while the right box uses data averaged over 25 grid boxes to represent the regional scale, with moderate spatial aggregation. Aggregation over 25 grid boxes reduces natural variability, resulting in a smaller warming required for a clear separation between the signal and noise. Adapted from Kirchmeier-Young et al. (2019).
The Interactive Atlas allows for flexible spatial and temporal analyses of essential climate variables, extreme indices and climatic impact-drivers including multiple lines of evidence to support the assessment of regional climate change:

- Observations
- CMIP5
- CMIP6
- CORDEX

CORDEX is available for 12 continent-wide domains.

Regional (aggregated) information for reference and typological regions:
(a) Time series
(b) Stripes
(c) Annual cycle plots
(d) Summary tabular information.
(e) Scatter plots (e.g. precip. vs temp.)

Dimensions of analysis include time periods for scenarios and global warming levels (1°C, 2°C, 3°C and 4°C).

**Figure Atlas.8:** Screenshots from the Interactive Atlas. (a) The main interface includes a global map and controls to define a particular choice of dataset, variable, period (reference and baseline) and season (in this example, annual temperature change from CMIP6 for SSP3-7.0 for the long-term 2081–2100 period relative to 1995–2014). (b–e) Various visuals and summary tables for the regionally averaged information for the selected reference regions.
Figure Atlas.9: Analysing robustness and uncertainty in climate change signals across spatial scales using the Interactive Atlas. The left panel shows projected annual relative changes for maximum 5-day precipitation from CMIP6 at 3°C of global warming level relative to the 1850–1900 baseline, through a map of the ensemble mean changes (panel top) and information on the regional aggregated signal over the South Asia reference region as time series (panel bottom). This shows non-robust changes (diagonal lines) at the grid-box level (due to the large local variability), but a robust aggregated signal over the region. The right panel shows projected surface wind speed changes from CMIP6 models for 2041–2060 relative to a 1995–2014 baseline under the SSP5-8.5 scenario, again with the ensemble mean changes in the map (panel top) and regionally aggregated time series over Central Africa for each model (panel bottom). This shows conflicting changes (crossed lines) at the grid-box level due to signals of opposite sign in the individual models displayed in the time series.
Figure Atlas.10: Schematic representation of the Interactive Atlas workflow, from database description, subsetting and data transformation to final graphical product generation (maps and plots).

Product-dependent workflow steps are depicted with dashed borders. METACLIP specifically considers the different intermediate steps consisting of various data transformations, bias adjustment, climate index calculation and graphical product generation, providing a semantic description of each stage and the different elements involved. The different controlled vocabularies describing each stage are indicated by the colours, with gradients indicating several vocabularies involved, usually meaning that specific individual instances are defined in ‘ipcc_terms’ extending generic classes of ‘datasource’. These two vocabularies, dealing with the primary data sources have specific annotation properties linking their own features with the CMIP5, CMIP6 and CORDEX Data Reference Syntax, taking as reference their respective controlled vocabularies. All products generated by the Interactive Atlas provide a METACLIP provenance description, including a persistent link to a reproducible source code under version control.
Figure Atlas.11: Observed linear trends of signals in annual mean surface air temperature (a, b) and precipitation (c, f) in the Berkeley Earth, CRU TS and GPCC datasets (see Section Atlas.1 for dataset details). Trends are calculated for the common 1960–2015 period and are expressed as °C per decade for temperature and relative change (with respect to the climatological mean) per decade for precipitation. Crosses indicate regions where trends are not significant (at a 0.1 significance level) and the black lines mark out the reference regions defined in Section Atlas.1. Panels c and d display the period in which the signals of temperature change in data aggregated over the reference regions emerged from the noise of annual variability in the respective aggregated data. Emergence time is calculated for (c) Berkeley Earth (as used in (a)) and CRUTEM5. Regions in the CRUTEM5 map are shaded grey when data are available over less than 50% of the land area of the region. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.12: Global temperature changes projected for the mid-century under SSP1-2.6 (left, top) and SSP3-7.0 (left, bottom) compared with a 2°C global warming level (right, top) and the end of the century under SSP3-7.0 (right, bottom) from the CMIP6 ensemble. Note that the future period warmings are calculated against a baseline period of 1995–2014 whereas the global mean warming level is defined with respect to the baseline period of 1851–1900 used to define global warming levels. The other three SSP-based maps would show greater warmings with respect to this earlier baseline. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.13: Changes in annual mean surface air temperature and precipitation averaged over the global (left) and global land areas (right) in each horizontal pair of panels. The top left two panels show the median (dots) and 10th–90th percentile range across each model ensemble for temperature change, for two datasets (CMIP5 and CMIP6) and two scenarios (SSP1-2.6/RCP2.6 and SSP5-8.5/RCP8.5). The first twelve bars represent the projected changes over three time periods (near-term 2021–2040, mid-term 2041–2060 and long-term 2081–2100) compared to the baseline period of 1995–2014 and the remaining four bars represent the additional warming projected relative to the same baseline to reach four global warming levels (GWL; 1.5°C, 2°C, 3°C and 4°C). The top right two panels show scatter diagrams of temperature against precipitation changes, displaying the median (dots) and 10th–90th percentile ranges for the same four GWLs, again representing the additional changes for the global temperature to reach the respective GWL from the baseline period of 1995–2014. In all panels the dark (light) grey lines or dots represent the CMIP6 (CMIP5) simulated changes in temperature and precipitation between the 1850–1900 baseline used for calculating GWLs and the recent past baseline of 1995–2014 used to calculate the changes in the bar diagrams and scatter-plots. Changes are absolute for temperature and relative for precipitation. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.14: Influence of major modes of variability (see Annex IV) on regional extreme events relevant to assessing multi-hazard resilience. Ribbon colours define the driver from which they originate and their width is proportional to the correlation. Crossed lines represent where there is conflicting evidence for a correlation or where the driver is not directly related to the hazard and dots represent drivers that have both a positive and negative correlation with the hazard. Figure is copied from Steptoe et al. (2018) / CCBY4.0.
Figure Atlas.15: Projected changes in sea surface temperature (top), sea level rise (bottom) for 2081–2100 under the SSP1-2.6 (left) and SSP5-8.5 (right) emission scenarios compared to a 1995–2014 baseline period from the CMIP6 ensemble. For sea surface temperature, diagonal lines indicate regions where 80% of the models do not agree on the sign of the projected changes. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.16: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Africa (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February-March (DJFM; middle panel) and June-July-August-September (JJAS; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.17: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Asia (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and
Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.18: Linear trends for the 1980–2015 period based on station data from the World Data Centre of the Russian Institute for Hydrometeorological Information (RIHMI-WDC) (Bulygina et al., 2014). (a) Snow season duration from 1 July to 31 December (days per decade); (b) snow season duration from 1 January to 30 June (days per decade); (c) maximum annual height of snow cover (mm per decade). Trends have been calculated using ordinary least squares regression and the crosses indicate nonsignificant trend values (at the 0.1 level) following the method of Santer et al. (2008) to account for serial correlation. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.19: The RCM projected changes in mean precipitation between the early (2011–2040), mid (2041–2070) and late (2071–2099) 21st century and the historical period 1976–2005. Data are obtained from the CORDEX-SEA downscaling simulations. Diagonal lines indicate areas with low model agreement (less than 80%). Adapted from Tangang et al. (2020).
Figure Atlas.20: Observed trends in mean annual temperature (a–b) and summer (DJF) and inter (JJA) precipitation (c–d) for Australia and New Zealand from high-quality regional datasets. Time series show anomalies from 1961–1990 average and 10-year running mean; maps show annual linear trends for 1960–2019; rainfall trends are shown in % per decade, crosses show areas and stations with a lack of significant trend and regions of seasonally dry conditions (<0.25 mm day$^{-1}$) are masked and outlined in red. Datasets are Australian Climate Observation Reference Network – Surface Air Temperature version 2.1 (ACORN-SATv2.1) for Australian temperature, the Australian Gridded Climate Data (AGCD) for Australian rainfall (Evans et al., 2020), and the 30-station high-quality network for New Zealand temperature and rainfall. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure 21: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Australasia (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.22: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Central America, the Caribbean and South America (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C).
and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions
(Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The
script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be
generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources
and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.23: (a) Mean 1980–2015 trend of annual mean surface air temperature (°C per decade) from E-OBS (Cornes et al., 2018). Data for non-European countries in the MED area are masked out. (b) Time series of mean annual temperature anomaly relative to the 1980–2015 period (shown with grey shading) aggregated for the land area in each of the four European subregions, from E-OBS, CRU, Berkeley and ERA5 (see Section Atlas.1.4.1 for description of global datasets). Mean trends for 1901–2015, 1961–2015 and 1980–2015 are shown for each data set in corresponding colours in the same units as panel (a) (see legend in upper panel). (c) As panel (a) for annual mean precipitation (mm day$^{-1}$ per decade). (d) as panel (b) for annual mean precipitation, and data sets E-OBS, CRU, GPCC and GPCP. Note that E-OBS data are not shown in panels b and d for region EEU. For the MED region data are aggregated over the European countries alone. Trends have been calculated using ordinary least squares regression and the crosses indicate nonsignificant trend values (at the 0.1 level) following the method of Santer et al. (2008) to account for serial correlation. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.24: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Europe (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.25: Grid-box trends (mm yr⁻¹) in annual maximum snow depth for cold season periods of 1960/1961 to 2014/2015. (Left) Numbers indicate number of stations available in that grid box. (Right) Boxes with ‘x’ indicate non-significant trends (at the p < 0.05 level of significance) (Kunkel et al., 2016).
Figure Atlas.26: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in North America (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.27: Changes (2070–2099 relative to 1970–1999) in the annual mean surface air temperature by three GCMs (GFDL ESM2M, MPI ESM-LR, HadGEM2-ES) and two RCMs (WRF and RegCM4) nested in the GCMs, for the RCP8.5 scenario (after Bukovsky and Mearns, 2020).
Figure Atlas.28: Regional mean changes in annual mean surface air temperature, precipitation and sea level rise relative to the 1995–2014 baseline for the reference regions in Small Islands (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlaying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). Bar plots in the right panel show the median (dots) and 5th–95th percentile range (bars) sea level rise from the CMIP6 ensemble (see Chapter 9 for details) for the same time periods and scenarios. The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively; for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.29: Regional mean changes in annual mean surface air temperature and precipitation relative to the 1995–2014 baseline for the reference regions in Arctic and Antarctica (warming since the 1850–1900 pre-industrial baseline is also provided as an offset). Bar plots in the left panel of each region triplet show the median (dots) and 10th–90th percentile range (bars) across each model ensemble for annual mean temperature changes for four datasets (CMIP5 in intermediate colours; subset of CMIP5 used to drive CORDEX in light colours; CORDEX overlying the CMIP5 subset with dashed bars; and CMIP6 in solid colours); the first six groups of bars represent the regional warming over two time periods (near-term 2021–2040 and long-term 2081–2100) for three scenarios (SSP1-2.6/RCP2.6, SSP2-4.5/RCP4.5, and SSP5-8.5/RCP8.5), and the remaining bars correspond to four global warming levels (GWL: 1.5°C, 2°C, 3°C, and 4°C). The scatter diagrams of temperature against precipitation changes display the median (dots) and 10th–90th percentile ranges for the above four warming levels for December-January-February (DJF; middle panel) and June-July-August (JJA; right panel), respectively, for the CMIP5 subset only the percentile range of temperature is shown, and only for 3°C and 4°C GWLs. Changes are absolute for temperature (in °C) and relative (as %) for precipitation. See Section Atlas.1.3 for more details on reference regions (Iturbide et al., 2020) and Section Atlas.1.4 for details on model data selection and processing. The script used to generate this figure is available online (Iturbide et al., 2021) and similar results can be generated in the Interactive Atlas for flexibly defined seasonal periods. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).
Figure Atlas.30: (Upper panels) Time series of annual surface mass balance (SMB) rates (in Gt a⁻¹) for Greenland ice sheet and its regions (shown in the inset map) for the periods 1972–2018 (Mouginot et al., 2019) and 1980–2012 (Fettweis et al., 2020) using 13 different models. (Lower panels) Time series of annual SMB rates (in Gt a⁻¹) for the grounded Antarctic ice sheet (excluding ice shelves) and its regions (shown in the inset map) for the periods 1979–2019 (Rignot et al., 2019) and 1980–2016 (Mottram et al., 2021) using five Polar-CORDEX regional climate models. The Antarctic inset map also shows the location of the stations discussed in section Atlas.11.1.2 where observations are available for at least 50 years. Colors indicate near surface air temperature trends for 1957-2016 (circles) and 1979-2016 (diamonds) statistically significant at 90% (Jones et al, 2019; Turner et al, 2020). Stations with an asterisk (*) are where significance estimates disagree between the two publications. Further details on data sources and processing are available in the chapter data table (Table Atlas.SM.15).

Atlas.SM.1  Tables of global (CMIP) and regional (CORDEX) models used in the Atlas chapter

The following tables present the global and regional models and the specific variables used in the Atlas chapter (and in the Interactive Atlas) from the ensembles of CMIP5, CMIP6 and CORDEX historical and scenario simulations. Detailed information and salient features of these models are described in IPCC AR5 Appendix 9.A for CMIP5, and Annexes AII.2 (Table AII.5) and AII.1 (Tables AII.1 to AII.4) for CMIP6 and CORDEX, respectively.

[START TABLE ATLAS.SM.1 HERE]

Table Atlas.SM.1: The CMIP5 models used in the Atlas for each of the historical and RCP scenario experiments. Salient features of these models are described in IPCC AR5 Appendix 9.A (model names are taken from Table 9.A.1). The first two columns indicate the model and the particular run used. Columns 4–7 indicate the availability of the different variables used in the Atlas. P: precipitation (pr); T: temperature (tas); X: tasmin and tasmax. A blank space indicates lack of data; usually because that scenario run was not available. P, T and X correspond to the atmosphere realm and daily frequency. Further details (including the specific ESGF versions used) are given in the Atlas GitHub repository (Iturbide et al., 2021).

[END TABLE ATLAS.SM.1 HERE]
Table Atlas.SM.2: The CMIP6 models used in the Atlas for each of the historical and SSP scenario experiments, and for the PMIP experiment. Salient features of these models are described in Table AII.5. The first two columns indicate the model and the particular run used. Columns 3–7 indicate the availability of the different variables from historical and scenario experiments used in the Atlas. P: precipitation (pr); T: temperature (tas); X: tasmin and tasmax; W: wind (sfcWind), S: snow (prsn); I: sea-ice area fraction (siconc); O: sea-surface temperature (tos); H: pH (ph). A blank space indicates lack of data, usually because that scenario run was not available. P, T, X, W and I correspond to the atmosphere realm; I, O and H correspond to the sea realm. Daily frequency has been used for P, T and X (to compute the derived indices, see Atlas.2.3), whereas monthly frequency is used for the others. The last column indicates the availability of data (precipitation and temperature) from the particular periods of the PMIP experiment used in the Interactive Atlas: piControl (c), midPliocene-eoi400 (p), midHolocene (h), lig127k (l), lgm (g); see Cross-Chapter Box 2.1 for details. Further details (including the specific ESGF versions used) are given in the Atlas GitHub repository (Iturbide et al., 2021). Note: Run r1i1p1f1 for CESM2 in PMIP.

Table Atlas.SM.5: Regional simulations from the CORDEX North America (NAM) domain (Figure Atlas.6) used in the Atlas for the historical and RCP scenario experiments. Column 2 indicates the domain and resolution. Columns 3–4 indicate the CMIP5 GCM (see Table Atlas.A.1) and RCM (see Table AII.2 for salient features of these models) pairs used in the simulations. Columns 5–8 indicate the availability of the different variables (with daily frequency) used in the Atlas. P: precipitation (pr); T: temperature (tas); X: tasmin and tasmax; W: wind (sfcWind); a blank space indicates lack of data. Further details (including the specific ESGF versions used) are given in the Atlas GitHub repository (Iturbide et al., 2021).

### Table Atlas.SM.8

Regional simulations from the CORDEX South Asia (WAS) domain (Figure Atlas.6) used in the Atlas for the historical and RCP scenario experiments. Column 2 indicates the domain and resolution. Columns 3–4 indicate the CMIP5 GCM (see Table Atlas.A.1) and RCM (see Table AII.2, for salient features of these models) pairs used in the simulations. Columns 5–8 indicate the availability of the different variables (with daily frequency) used in the Atlas. P: precipitation (pr); T: temperature (tas); X: tasmin and tasmax; W: wind (sfcWind); a blank space indicates lack of data. Further details (including the specific ESGF versions used) are given in the Atlas GitHub repository (Iturbide et al., 2021).

**Table Atlas.SM.13:** Regional simulations from the CORDEX Mediterranean (MED) domain (Figure Atlas.6) used in the Atlas for the historical and RCP scenario experiments. Columns 3–4 indicate the CMIP5 GCM (see Table Atlas.A.1) and RCM (see Table AII.2 for salient features of these models) pairs used in the simulations. The models selected in this domain are the coupled atmosphere-ocean regional models providing scenario simulations. Columns 5–8 indicate the availability of the sea surface temperature (with monthly frequency) used in the Atlas. Further details (including the specific ESGF versions used) are given in the Atlas GitHub repository (Iturbide et al., 2021).

**Table Atlas.SM.14:** Regional simulations from the CORDEX South-East Asia (SEA) domain (Figure Atlas.6) used in the Atlas for the historical and RCP scenario experiments. Column 2 indicates the domain and resolution. Columns 3–4 indicate the CMIP5 GCM (see Table Atlas.A.1) and RCM (see Table AII.2 for salient features of these models) pairs used in the simulations. Columns 5–8 indicate the availability of the different variables (with daily frequency) used in the Atlas. P: precipitation (pr); T: temperature (tas); X: tasmin and tasmax; W: wind (scfWind); a blank space indicates lack of data. Further details (including the specific ESGF versions used) are given in the Atlas GitHub repository (Iturbide et al., 2021).

Atlas.SM.2  Figures of regional (CORDEX) model evaluation

The following figures expand the illustrative evaluation results shown in Atlas 1.4.4 (Figure Atlas.7) for the CORDEX North America domain (NAM) to the other domains considered in the Atlas and the Interactive Atlas (see Figure Atlas.6 and Tables Atlas.SM.3 to Atlas.SM.14). Detailed information and salient features of these models are described in Tables AII.2 to AII.4.

**Figure Atlas.SM.1:** Evaluation of annual and seasonal air temperature and precipitation for the seven South America subregions NWS, NSA, SAM, NES, SWS, SES, and SSA (land only) for CORDEX-SAM (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).

[END TABLE ATLAS.SM.14 HERE]
Figure Atlas.SM.2: Evaluation of annual and seasonal air temperature and precipitation for the three Central America subregions NCA, SCA and CAR (land only) for CORDEX-CAM (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).
Figure Atlas.SM.3: Evaluation of annual and seasonal air temperature and precipitation for the nine African subregions MED, SAH, WAF, CAF, NEAF, SEAF, WSAF, ESAF, and MDG (land only) for the CORDEX-AFR (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).
Figure Atlas.SM.4: Evaluation of annual and seasonal air temperature and precipitation for the three European subregions NEU, WCE and MED (land only) for CORDEX-EUR11 (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).
Figure Atlas.SM.5: Evaluation of annual and seasonal air temperature and precipitation for the four Asian subregions WCA, TIB, ARP and SAS (land only) for CORDEX-WAS (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).
**Figure Atlas.SM.6:** Evaluation of annual and seasonal air temperature and precipitation for the three Asian subregions ECA, TIB and EAS (land only) for CORDEX-EAS (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).
Figure Atlas.SM.7: Evaluation of annual and seasonal air temperature and precipitation for the five Australasia subregions NAU, CAU, EAU, SAU, and NZ (land only) for CORDEX-AUS (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).
Figure Atlas.SM.8: Evaluation of annual and seasonal air temperature and precipitation for the Antarctic regions EAN and WAN (land only) for CORDEX-ANT (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (ESW5, see Section Atlas 1.4.2).
Figure Atlas.SM.9: Evaluation of annual and seasonal air temperature and precipitation for the Arctic regions GIC, RAR (land only), ARO for CORDEX-ARC (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (ESW5, see Section Atlas 1.4.2).
Figure Atlas.SM.10: Evaluation of annual and seasonal air temperature and precipitation for the Asian subregion SEA (land only) for CORDEX-SEA (see Figure Atlas.6) RCM simulations driven by reanalysis or historical GCMs. Seasons are June-July-August (JJA) and December-January-February (DJF). Rows represent subregions and columns correspond to the models. Magenta text indicates the driving historical CMIP5 GCMs (including ERA-Interim in first set of slightly separated columns) and the black text to the right of the magenta text represents the driven RCMs. The colour matrices show the mean spatial biases; all biases have been computed for the period 1985–2005 relative to the observational reference (E5W5, see Section Atlas 1.4.2).

2. **References** ..................................................................... 22
AI.1 Introduction

The purpose of this Annex is to document observational data sets used by Working Group I in the Sixth Assessment Report. This includes details of the types and versions of data sets, the time period they cover, the chapters in which they appear, and citations and (where available) web links to the data.

This list includes those observational data sets that contribute to values reported in the text or in figures, unless they are citing a specific result from a paper (as opposed to an ongoing data set for which that paper is a reference).

Reanalyses are within the scope of this Annex, but historical climate model simulations are not. Proxy data sets are also outside the scope of this Annex.

Data sets which are updated regularly on an operational basis are shown as ending in 2020, even if no 2020 data have yet been published at the time of writing.

Data sets are sorted alphabetically according to the data set name or, if there is no formal name, the name of the responsible institution or lead author.

Table AI.1: Observational products used by Working Group I in the Sixth Assessment Report.

Note: CRUTS, CRUTEM, and DCNet are datasets for climate variables such as temperature, precipitation, and sea level. CRU TS refers to the Climatic Research Unit TS dataset, which provides in situ monthly data with a resolution of 0.5° x 0.5°. CloudSat provides remote sensing data of cloud profiling radar (CPR) with horizontal resolution of 1.5 km and vertical resolution of 0.5 km. Cryosat provides Arctic sea ice thickness data. CSIRO atmospheric gas measurements dataset provides monthly data with a resolution of 1° x 1°. Mexican climate dataset provides in situ monthly data with a resolution of 30 arc sec. 3D-VAR regional reanalysis dataset provides monthly data with a resolution of 0.2° x 0.2°. Global sea level reconstruction dataset provides monthly data with a resolution of 1° x 1°. DCNet dataset provides hourly data. Ethiopian precipitation dataset provides sub-monthly data. Data of DYNAMED station in the Ligurian Sea provides point-based data. Eastern China spring phenology index provides annual data. European Climate Assessment provides daily and point-based data.

### AII.1 Regional Climate Models (RCMs) participating in CORDEX

The Coordinated Regional Climate Downscaling Experiment (CORDEX, (Gutowski Jr. et al., 2016)) coordinates regional downscaling activities worldwide over a number of defined domains. Regional downscaling is performed using Regional Climate Models (RCMs) run over limited geographical regions, driven at the boundaries by the output from CMIP global model simulations. CORDEX relies on the same infrastructure as the Coupled Model Intercomparison Project (CMIP) to make the multi-model output publicly available in a standardized format: the data is disseminated via the Earth System Grid Federation (ESGF, Williams et al. 2016).

Table AII.1 lists the current CORDEX domains, displaying the different resolutions (from the lowest 0.44°, to the highest 0.11°, typically in rotated coordinates), with data available through the ESGF. Figure Atlas 7 provides a geographical map of the domains. Note that 0.44° and 0.22° are the prioritized resolution in the CORDEX and CORDEX-CORE experimental designs, respectively, and only some domains provide information for higher resolution (0.11°); see Atlas, Section Atlas 1.4.4 and https://cordex.org for further details. Table AII.1 also displays the number of simulations available for the following experiments: "evaluation" (ERA-Interim driven simulations), and the "historical", "RCP26", "RCP45" and "RCP85" CMIP5-driven simulations (Taylor et al., 2012). This table illustrates the heterogeneity of information available across the different domains which limits the assessment of some scenarios in some regions.

The RCMs contributing to CORDEX (as available from ESGF) are listed in Table AII.2, including the main references and details on model components relevant for the WGI AR6 assessment.

Finally, Tables AII.3 and AII.4 provide information on the CMIP5 and RCM models used in the different CORDEX domains, respectively (the numbers in each cell indicate the number of available simulations for each scenario). Note that CORDEX information is complex to describe since each particular simulation is produced by a single combination of a CMIP5 boundary forcing, or “driving model” (or reanalysis for the evaluation experiment) and an RCM model from Table AII.2. These two tables together provide comprehensive information on the GCM/RCM composition of the ensembles available in each domain, which is key to understanding the assessment done in WGI chapters (in particular the regional Chapters 10, 11, 12 and Atlas).

**Table AII.2:** Regional Climate Models contributing to CORDEX experiments.

Salient features of the Regional Climate Models (RCMs) participating in CORDEX scenario experiments (CMIP5-driven). Column 1: sponsoring institution(s). Column 2: name of the model (and versions); subsequent columns for each of the model components with main references. Column 3: atmospheric component with number of vertical levels and main reference. Column 4: aerosols component (interactive or prescribed, with component details when interactive). Column 5: land component (number of levels and component name). Column 6: ocean component (prescribed or interactive, with model details when interactive). Column 7: additional components (lake, urban, river models) and comments on versions and/or different configurations of the same model. See Table AII.1 for the codes of CORDEX domains.

| KNMI (Netherlands) | RACMO21P_v1 | RACMO21P_v2 | 1) Prescribed (Tegen et al., 1997) four classes (land, maritime, dust, urban) + stratospheric + optionally volcanic  
1) 4  
2) baseline LSM TESSEL (van den Hurk et al., 2000); Land-ice tile added for ice-sheet modelling.  
Multi-layer snow-ice-refreezing scheme (Ettema et al., 2010); snow albedo scheme (Kuipers Munneke et al., 2011); snow drift scheme (Lenaers et al., 2012)  
1) Prescribed SST and sea-ice concentration; inferred from re-analysis or GCM  
Model versions: Simulations with RACMO21P_v2 are straight reruns of RACMO21P_v1 employing the same model system and parameter settings. In ANT-44 simulations, v2 is only used with MOHC-HadGEM2-ES forcing to fix the remapping of SST to the RACMO grid in the v1-simulation |
| KNMI (Netherlands) | RACMO22E_v1 | RACMO22E_v2 | 1) Prescribed; inferred from CAM inventory (except volcanic); historical and CEP pathways (Lamarque et al., 2010, 2011; van Vuuren et al., 2011); also used in evaluation. Sulfate, particulate organic matter black carbon, sea-salt, desert dust stratospheric aerosols, volcanic aerosol. Spatial maps and vertical profiles per species. Monthly variations and decadal trends.  
1) 4  
2) HTESSEL (Balsamo et al., 2009)  
1) Prescribed SST and sea-ice concentration; inferred from re-analysis or GCM  
Model versions: Simulations with RACMO22E_v2 are straight reruns of RACMO22E_v1 employing the same model system and parameter settings. Meaning of v2 depends on forcing GCM:  
i) MOHC-HadGEM2-ES: remapping of GCM-SST to RACMO grid erroneous in v1, corrected in v2  
ii) CNRM-CERFACS-CNRM-CM5: atmospheric forcings derived from pressure level fields, because of error in CNRM-CM5 model level fields |
| KNMI (Netherlands) | RACMO22T_v1 | RACMO22T_v2 | 1) Prescribed, as in RACMO22E  
1) 4  
2) HTESSEL (Balsamo et al., 2009)  
1) Prescribed SST and sea-ice concentration; inferred from re-analysis of GCM  
Model versions: Simulations with RACMO22T_v2 are straight reruns of RACMO22T_v1 employing the same model system and parameter settings. In AFR-44, v2 is only used with MOHC-HadGEM2-ES forcing to fix the remapping of SST to the RACMO grid in the v1-simulation |
| SMHI (Sweden) | RCA4_v1 | RCA4_v1a | RCA4_v2 | 1) Prescribed: single integrated class, parameterized aerosol effect on radiation fluxes, spatially uniform, static.  
1) 3  
2) a tile-based scheme with physiography based on ECOCLIMAP (Samuelsson et al., 2015)  
1) Prescribed SST and sea-ice from daily driving GCMS/reanalysis  
Model versions: i) RCA4_v1a is simply a rerun because a restart file to start the scenario experiment was taken from another  
LK: Flake (pronostic lake ice). (Mironov et al., 2010)  
Model versions: Simulations with RCA4_v2 are straight reruns of RCA4_v1 employing the same model system and parameter settings. In AFR-44, v2 is only used with MOHC-HadGEM2-ES forcing to fix the remapping of SST to the RACMO grid in the v1-simulation |

**[END TABLE AII.2 HERE]**
Climate models participating in CMIP5 (rows) used as boundary conditions for the CORDEX regional simulations in the different domains (columns). Each cell indicates the number of simulations available for the historical, RCP26, RCP45 and RCP85 experiments (see the color legend). Salient features of these models are described in IPCC-AR5 Appendix 9.A (model names are taken from table 9.A.1). Further details on these simulations (e.g. particular GCM-RCM combinations in each cell) are given in the November 2021 list of simulations available in the CORDEX website https://cordex.org. (*) For the Mediterranean domain, only the coupled atmosphere-ocean simulations are listed.

Table AII.4: Regional models used for downscaling in the different CORDEX domains

Regional simulations contributed by the different models participating in CORDEX (rows, grouped by model families, see Table AII.2) in the different domains (columns). Each cell indicates the number of simulations available for the historical, RCP26, RCP45 and RCP85 experiments (see the color legend). Further details on these simulations (e.g. particular GCM-RCM combinations in each cell) are given in the November 2021 list of simulations available in the CORDEX website [https://cordex.org](https://cordex.org). (*) For the Mediterranean domain, only the coupled atmosphere-ocean simulations are listed.

[END TABLE AII.4 HERE]
AII.2 Earth System Models and General Circulation Models for climate projections

Detailed and structured information about climate models, simulations and their conformance to common experimental protocols is not only important for scientific interpretation but, under increased scrutiny from society, it is also demanded of climate science that purports to be mature, credible, open, transparent and reproducible (Guilyardi et al., 2013). Scientific publications remain an essential way of documenting models but remain largely scattered and not easily accessible by the growing community of users of model output. To address these challenges, the Earth System Documentation (ES-DOC) project offers an eco-system of tools and services in support of Earth System modelling documentation creation, analysis and dissemination. ES-DOC is coordinated with other community efforts such as the Coupled Model Intercomparison Project (CMIP) via the World Climate Research Programme work group on Climate Modelling (WGCM) and its Infrastructure Panel WIP (Balaji et al., 2018).

The objective of CMIP is to better understand past, present and future global climate changes arising from natural, unforced variability or in response to changes in radiative forcing in a multi-model context (Chapter 1, Section 1.5.4). This understanding includes assessments of model performance during the historical period (Chapter 3) and quantifications of the causes of the spread in future projections (Chapters 4, 7). Idealised experiments are also used to increase understanding of the model responses. In addition to these long-time scale responses, experiments are performed to investigate the predictability of the climate system on various time and space scales as well as making predictions from initialised climate states. The different activities (MIP) endorsed by CMIP6 are listed in Chapter 1, Table 1.3 (Eyring et al., 2016). A set of common experiments, the DECK (Diagnostic, Evaluation and Characterization of Klima) and CMIP historical simulations (1850–2014) were introduced that will maintain continuity with previous CMIP phases and help document basic and evolving characteristics of models. ScenarioMIP is the framework for future climate projections (O’Neill et al., 2016). The infrastructure panel of the World Climate Research Programme coordinates framework developments and defines data standards for CMIP. A key aspect is the dissemination of the data via the Earth System Grid Federation, ESGF (Williams et al., 2016; Petrie et al., 2021).

A new online service, ES-DOC, provides information about all aspects of CMIP6. Building on the Common Information Model concepts and standards (Lawrence et al., 2012), a number of documents are created for the CMIP6 Project, as illustrated on https://es-doc.org/c mip6/. These include documents to describe experiments, ensembles simulations, models, conformance to the numerical requirements of the CMIP6 protocol (see Pascoe et al., 2019) for CMIP6 experiments) and other important aspects of the CMIP6 model archive. These different documents are either produced automatically or provided in a standard way by modelling groups. Hundreds of clearly structured properties are harvested and stored on a database to be used by clients and portals (e.g. https://search.es-doc.org/ and https://explore.es-doc.org/). Another entry point to the database is provided by the one-stop-shop “further info url" global attribute in each CMIP6 netcdf data file. ES-DOC also includes the CMIP6 errata system (https://errata.es-doc.org), which tracks issues with the model data and the potential corrections made. ES-DOC includes information at the model level and the experiment level.

Model datasets shared on ESGF are characterized by their institution, model, experiment, variable, and ensemble member (the different types of ensemble strategies are introduced in Chapter 1, Section 1.4). Each ensemble member is designated by a label of four letters, each associated with a number: “r” for realization, “i” for initialization, “p” for physics, and “f” for forcing. For example, Table Atlas.A.2 lists the ensemble member label of each CMIP6 dataset used in the Atlas. In the future, ES-DOC will document in more detail how each individual member differs from the other members of a given ensemble.

The key new model developments since AR5 are summarized in Chapter 1, Section 1.3.5, and model results are assessed in multiple chapters of this report. In this Annex, Table AII.5 presents the main features of the CMIP6 coupled models, in a format comparable with AR5 table 9.A.1 for CMIP5 (Flato et al., 2013). At the date of March 2021, 136 models had registered for CMIP6, including the 23 CMIP6-endorsed MIPs (Chapter 1, Table 1.3). For conciseness, Table AII.5 documents only the coupled models used in the CMIP6 "DECK" experiments and ScenarioMIP, excluding atmosphere-only and ocean-only components (AMIP and

Do Not Cite, Quote or Distribute AII-15 Total pages: 57
OMIP), radiative transfer models (RFMIP), etc. Registered coupled model that have not submitted data in time to be used in this report are not included. The high-resolution models used for HighResMIP (Haarsma et al., 2016) are listed in Table AII.6, and ice sheet models are documented in section AII.3. The citation information for all CMIP6 model datasets is compiled in section AII.4, Table AII.10.
Table AII.5: Coupled Climate and Earth System Models participating in CMIP6 DECK, historical simulation, and ScenarioMIP

<table>
<thead>
<tr>
<th>Column 1 (Sponsoring Institution(s))</th>
<th>Column 2 (Model Configurations)</th>
<th>Column 3 (Main Reference(s))</th>
<th>Subsequent Columns (Model Components)</th>
</tr>
</thead>
</table>

Salient features of the coupled General Circulation Models (GCMs) and Earth System Models (ESMs) participating in the CMIP6 DECK, historical simulation, and ScenarioMIP. Column 1: sponsoring institution(s), Column 2: names of model configurations; Column 3: main reference(s); subsequent columns for each of the model components, with names and main component reference(s). In addition, there are standard entries for the atmosphere component: horizontal grid resolution, number of vertical levels, grid top; and for the ocean component: horizontal grid resolution, number of vertical levels, vertical coordinate type. The horizontal resolution (rounded to 10km) is the square root of the number of grid points divided by the surface area of the Earth, or the number of surface ocean grid points divided by the area of the ocean surface, for the atmosphere and ocean respectively. When reported in hPa, the atmosphere top heights are converted into km assuming standard atmosphere (ISO 2533:1975, 1975). Aerosols are either prescribed or computed from emissions (emission-driven). For land carbon, a list of active processes is provided among: active land carbon cycle (Land carbon), active nitrogen cycle (N cycle), prognostic biogeography of vegetation (Prog. veg.), carbon included in a permafrost pool (Permafrost), and dynamic fires (Fires). A blank entry indicates that information was not available. The information contained in the table is consistent with version 6.2.55.10 of the CMIP6 Controlled Vocabularies (https://github.com/WCRP-CMIP/CMIP6_CVs).

[END TABLE AII.5 HERE]
Table AII.6: High resolution coupled models participating in HighResMIP. Full names of the institutions are found in table AII.5. The horizontal resolution (rounded to 10 km, when larger than 10 km) is the square root of the number of grid points divided by the surface area of the Earth, or the number of surface ocean grid points divided by the area of the ocean surface, for the atmosphere and ocean respectively. When reported in hPa, the atmosphere top heights are converted into km assuming standard atmosphere (ISO 2533:1975, 1975).

AII.3 Models used in Ice sheet and glacier model intercomparison studies

Ice sheet and glacier models are used to assess the contribution of ice sheets and glaciers to future sea level rise as described in Section 9.6.3. New to AR6, the projections of the future sea level contribution from ice sheets and glaciers comes from the ensemble of model intercomparison studies (Box 9.3; Section 9.4.1.2; Section 9.4.2.2; Section 9.5.1.3). The tables here describe the models used for Greenland ISMIP6 (Table AII.7), Antarctica ISMIP6 and LARMIP-2 (Table AII.8) and GlacierMIP (Table AII.9).

More specific information on the model capabilities and parameter choices used for each ice sheet and glacier MIPs are presented in the following papers: ISMIP6 initMIP-Greenland (Goelzer et al., 2018), ISMIP6 projection-Greenland (Goelzer et al., 2020), ISMIP6 initMIP-Antarctica (Seroussi et al., 2019), ISMIP6 Antarctica projection (Seroussi et al., 2020), LARMIP-2 Antarctica projections (Levermann et al., 2020), and GlacierMIP (Hock et al., 2019; Marzeion et al., 2020).

This document is subject to copy-editing, corrigenda and trickle backs.
AIII.1 Introduction

Annex III presents, in tabulated form, data related to historical and projected changes in greenhouse gas (GHG) mixing ratios and effective radiative forcing (ERF) of all climate forcers as assessed and used throughout Chapters 1-7. Where available 90% confidence level uncertainties on observed GHG mixing ratios are given. For each species, the abundance is given as dry air mole fraction: \( \text{ppm} = \text{micromoles per mole} \times 10^{-6} \); \( \text{ppb} = \text{nanomoles per mole} \times 10^{-9} \); and \( \text{ppt} = \text{picomoles per mole} \times 10^{-12} \). ERF is given in W m\(^{-2}\) for CO\(_2\), N\(_2\)O, and CH\(_4\) and mW m\(^{-2}\) for other components.

Pre-instrumental mixing ratios are estimated from ice core and firm air records that are described in Ahn et al., 2012; Bauska et al., 2015; Flückiger et al., 1999; Machida et al., 1995; Meinshausen et al., 2017; Mitchell et al., 2013; Rubino et al., 2020; Ryu et al., 2020; Siegenthaler et al., 2005; Sowers, 2001.

Observed (instrumental) mixing ratios are described in Dlugokencky et al., 2011; Hall et al., 2011; Laube et al., 2016; Masarie and Tans, 2004; Montzka et al., 2009; Naus et al., 2019; Prinn et al., 2018; Rigby et al., 2014; Trudinger et al., 2004; Worton et al., 2006; Adcock et al., 2018; Droste et al., 2020; Leedham Elvidge et al., 2018; Mühle et al., 2019; Simmonds et al., 2017.

Projected concentrations for the 5 core scenarios discussed in the report (Section 1.6.1) are from (Gidden et al., 2019; Meinshausen et al., 2017, 2020; Velders et al., 2015). These scenarios span a wide range of plausible societal and climatic futures from potentially below 1.5°C best-estimate warming to over 4°C warming by 2100 (Section 4.3.4). Computational methods and assumptions to calculate historical and projected ERF are described in Chapter 7 and detailed information can be found in Chapter 7 Supplementary Material 7.SM.1.3 and 7.SM.1.4.

Extended datasets and further auxiliary data are made available via https://zenodo.org/xxxx

Notes: ¹ 1750-1850 CO₂, CH₄, N₂O from multiple ice cores assessed in Chapter 2. Uncertainties (90 % CI) for 1750 are 2.9 ppm, 9.4 ppb and 6.0 ppb for CO₂, CH₄ and N₂O, respectively. Uncertainties for 1850 are 2.1 ppm, 13.8 ppb and 5.7 ppb, based on variations of ice cores. ² Mixing ratios from 1851-1980/1984 are updated from the CMIP6 (Meinshausen et al., 2017) dataset, using a linear time-dependent offset correction function. ³ CO₂ from NOAA network; CH₄, N₂O from merged NOAA and AGAGE networks. Uncertainties (90 % CI) in 2019, derived from multiple global networks, are 0.36 ppm, 3.3 ppb and 0.4 ppb for CO₂, CH₄ and N₂O, respectively, and do not include estimates of analytical accuracy. Uncertainties for other years may differ. ⁴ ERF(2019-1750) from Chapter 7.

Notes: Data merged from AR5 (1750;1850); CMIP6 compilation by Meinshausen et al. (2017) until ca. 1995, and data directly taken from merged AGAGE and NOAA networks, depending on date of availability. Perfluorocarbons from CMIP6 dataset (Meinshausen et al., 2017) or estimated from Droste et al. (2020), with CMIP6 n-C\(_4\)F\(_{14}\) and C\(_5\)F\(_{18}\) scaled to account for calibration changes in Droste et al. (2020). Uncertainties pertain to 2019, derived from observations made by global networks and literature, and do not include estimates of analytical accuracy. Uncertainties are not available for c-C\(_2\)F\(_8\), n-C\(_3\)F\(_{10}\), n-C\(_3\)F\(_{12}\), n-C\(_4\)F\(_{10}\), i-C\(_4\)F\(_{10}\), C\(_5\)F\(_{18}\), and ERF (2019-1750) from Chapter 7, except for c-C\(_4\)F\(_8\), n-C\(_4\)F\(_{10}\), n-C\(_3\)F\(_{12}\), n-C\(_4\)F\(_{14}\), i-C\(_4\)F\(_{14}\), C\(_5\)F\(_{18}\) use 2015 abundances and C\(_4\)F\(_{18}\) which uses 2014 abundance. \(^{\text{(b)}}\)below <0.5 mWm\(^{-2}\)

Notes: 1750/1850 from AR5.; 1900-1970 from CMIP6 dataset in Meinshausen et al. (2017); 1980-1995 AGAGE, or data directly taken from merged AGAGE and NOAA networks, depending on date of availability for various components; CFC-13 from Vollmer et al. (2018) until 2015 then AGAGE; CFC-114 and CFC-114a from AGAGE and Laube et al. (2016); CFC-112 from Laube et al. (2014); CFC-112a from Adcock et al. (2018). Uncertainties pertain to 2019, derived from observations made by global networks, and do not include estimates of analytical accuracy. For CFC-112, CFC-112a, CFC-113a, and CFC-114a abundances and uncertainties for 2019 are not available. ERF(2019-1750) from Chapter 7, except for CFC-112, CFC-112a, CFC-113a, and CFC-114a for 2015

Note: O\(_3\) includes tropospheric and stratospheric O\(_3\), dominated by tropospheric O\(_3\). Stratospheric water vapour from methane oxidation is a linear function of the methane ERF (Section 7.3.2.6). Contrail forcing is a linear scaling of aviation NO\(_x\) emissions, scaled to ERF in 2018 (Lee et al., 2021). Present-day aerosol forcing is assessed in Section 7.3.3 as -0.3 (-0.6 to 0.0) W m\(^{-2}\) for aerosol-radiation interactions and -1.0 (-1.7 to -0.3) W m\(^{-2}\) for aerosol-cloud interactions for the 2005-2014 mean relative to 1750. Land use change considers albedo and irrigation effects (Section 7.3.4.1). BC on snow forcing is linear with emissions of BC (Section 7.3.4.3). Volcanic forcing is positive in years without large volcanic eruptions such that the long-term pre-industrial (500 BCE to 1749 CE) mean volcanic forcing is zero. Solar forcing is derived from the \(^{14}\)C reconstruction of total solar irradiance in the combined PMIP4/Cmip6 dataset (Jungclaus et al., 2017; Matthes et al., 2017). Present-day solar forcing is assessed in Section 7.3.4.4 as +0.01 (-0.06 to +0.08) W m\(^{-2}\), based on the mean total solar irradiance from solar cycle 24 (2009-2019) compared a long pre-industrial baseline period (6754 BCE - 1744 CE); the 2019 ERF value differs from this as it represents a single year near the solar minimum. Natural is the sum of volcanic and solar forcing, while anthropogenic includes all others. Further details on methods for computing ERF are in Chapter 7 Supplementary Material 7.SM.1.3.

Note: ERF based on future abundancies of WMGHGs listed in AIII.2. See notes of AIII.3. Future ozone forcing uses projected emissions of carbon monoxide, volatile organic carbon, nitrogen oxides, and concentrations of methane, nitrous oxide and halogenated compounds with relationships to forcing derived from Thornhill et al. (2021b, 2021a). Future contrail forcing is a linear scaling of future NOx emissions (Smith et al., 2018) and scaled to year-2018 ERF (Lee et al., 2021). Future aerosol forcing is based on emissions of black carbon, organic carbon, sulphur dioxide and ammonia using method described in Smith et al. (2018). Land use forcing scales with cumulative emissions of future land-use CO$_2$ (Smith et al., 2018). Future volcanic forcing set to zero from a 10-year linear transition from the end of the historical period following Eyring et al. (2016). Solar forcing is set to zero from 2300 CE. Further details on methods for computing SSP projection ERF are in Chapter 7 Supplementary Material 7.SM.1.4.

AIV.1 Introduction

This Annex describes the fundamental features of the main modes of large-scale climate variability assessed across chapters in the AR6 WGI report. Modes are defined as recurrent space-time structures of variability of the climate system with intrinsic spatial patterns, seasonality and timescales. They can arise through the dynamical characteristics of the atmospheric circulation but also through coupling between the ocean and the atmosphere, with some interactions with land surfaces and sea ice. The variability of the climate system at ocean- or continental-basin scales, and in particular on seasonal-to-multidecadal timescales, can be described to a large extent by the occurrence and often combination of several modes of climate variability which lead to local impacts and remote responses through teleconnection processes on top of externally forced trends. More precisely, the concept of “teleconnection” refers to the ability of modes of variability to relate climate in remote regions through associated atmospheric or oceanic pathways. Regional climate variations are thus the complex outcome of local physical processes, such as thermodynamical and land-atmosphere feedback processes, and non-local large-scale phenomena.

Historically, modes have been identified based on evidence of correlations between regional climate variations at widely separated, mostly geographically fixed spatial locations. One of the oldest known space-time structured patterns of variability is the North Atlantic Oscillation (NAO, Section AIV.2.1), with some early description from seafaring activities available since several centuries ago (Stephenson et al., 2003). Similarly, empirical, albeit remarkably precise, documentation of trans-Paciﬁc coherent variability in atmospheric and oceanic conditions can be traced back to the 19th century for the El Niño-Southern Oscillation (ENSO, Section AIV.2.3). The Southern Oscillation was named in 1924 and the first use of the name ‘El Niño’ to describe a climatic phenomenon appeared in South America in 1893 (see for instance Philander, 1983 for ENSO history). Since then, the increased spatial coverage of observations and the measurement of new climatic parameters have improved signiﬁcantly. These advancements, along with the development of new theoretical background and statistical methods for combining different sources of information, have allowed substantial improvements in our understanding of the characteristic spatial scale of the coherent structures of variability as well as of the characteristic temporal expression of the modes.

There are several ways to document and describe the modes of climate variability based on more or less sophisticated statistical techniques and dynamical nature, interpretation and understanding of the variability (i.e., Feldstein and Franzke, 2017; Hannachi et al., 2017; Franzke et al., 2020; Ghil and Lucarini, 2020). The simplest method to evaluate the temporal evolution of a spatially coherent phenomenon is to take one or more spatial averages of a climate variable such as sea surface temperature (SST) or sea level pressure (SLP), as examples, within a latitude-longitude box. Another classical technique relies on principal component analysis (PCA), also known as empirical orthogonal function (EOF) analysis, to extract the patterns in the chosen climate variable with maximal spatial covariance. The method also extracts an associated climate index timeseries, i.e. principal component (PC), describing the temporal evolution tied to the spatial pattern. PCA/EOF is widely used with gridded datasets and model outputs. Correlation or regression maps between the climate index timeseries and other space-time variables, such as precipitation, temperature or wind, are then calculated to quantify the teleconnection patterns. Altogether, beyond their physical relevance, modes of climate variability and their teleconnection patterns provide a simplified representation of climate variation affecting weather, from regional (i.e. oceanic or continental scale) to worldwide scales (i.e. for some specific phenomena like ENSO), having important impacts on human activities and ecosystems. Modes are often associated with climatic impact-drivers (CIDs, as defined in Chapter 12, Section 12.1) including droughts, heavy rains, storms, heat waves and cold spells, affecting agriculture, water resources, availability and consumption of energy, ﬁre risks, etc.

Many modes of variability are driven by internal climate processes and are a critical potential source of climate predictability on sub-seasonal to decadal timescales. It is essential to understand the physical processes behind the past evolution of the modes of climate variability in order to assess, with conﬁdence, their future changes. External forcing may affect their temporal (occurrence, variance, seasonality, persistence etc.) or spatial properties and associated teleconnections.

Previous IPCC reports have described the observed and modelled behaviour of a large number of modes of
variability over the instrumental period and in a paleoclimate context. The projected evolution of those
modes has been also documented based on future climate scenarios. In AR5, large-scale modes of variability
and teleconnections were assessed in depth in Chapter 14, setting the physical basis of future regional
climates changes contingent on global mean temperature increase. Modes were defined through so-called
“indices of climate variability” in AR5 Chapter 2, dedicated to observed atmospheric and surface changes.
Two boxes (AR5 Box 2.5 and AR5 Box 14.1) introduced the main concepts. AR4 had a similar structure,
with a specific section on modes in the chapter dedicated to the observations (Chapter 3). In AR6, a different
perspective has been adopted, as the modes are discussed in various chapters and assessed with respect to the
specific objectives of each of them. Space-time past changes of the modes using proxy records and
instrumental data are assessed in Chapter 2. Human influence on modes is assessed in Chapter 3 over the
instrumental period, while their future changes are addressed in Chapter 4. Their influence at regional scale
through large-scale teleconnection is assessed in Chapters 10, 11, 12 and Atlas, while the contribution of the
modes in past and future hydrological changes and related uncertainties are assessed in Chapter 8. Chapter 9
focuses on oceanic expression of the modes. The aim of this Annex is to set a common background for the
assessment of the modes of climate variability and related regional climate anomalies for all the AR6 WG1
Chapters, and to provide this information for the readers of the report. In doing so, the Annex provides a
more accessible summary of the main modes of variability allowing a more coherent assessment of this
important aspect of the climate system.

The Annex summarizes the fundamental features of spatial structure, seasonality and teleconnections for a
selection of modes of climate variability corresponding to those addressed in the report, namely: the NAO
and Northern Annular Mode, the Southern Annular Mode, ENSO, the Indian Ocean Basin and Dipole
Modes, the Atlantic Meridional and Zonal Modes, the Pacific Decadal Variability, the Atlantic Multidecadal
Variability, and the Madden-Julian Oscillation. For each mode, the description follows a common structure,
starting with a short definition of the mode (based on simple box-averaged indices and EOF) and related key
physical mechanisms, then a description of the associated teleconnections (based on regression techniques),
and when relevant, finishes with a short summary of paleoclimate reconstruction of the mode based on
proxy-based records. An illustrative figure including patterns and timeseries is also provided for each mode.

AIV.2 The main modes of climate variability assessed in AR6

AIV.2.1 North Atlantic Oscillation and Northern Annular Mode

AIV.2.1.1 Definition of the mode

The North Atlantic Oscillation (NAO) is the leading mode of large-scale atmospheric variability in the North
Atlantic basin. It is characterized by alternating (seesaw) variations in SLP between the Azores High in the
subtropics and the Icelandic Low in the mid- to high latitudes, with some northward extension deep into the
Arctic (Hurrell et al., 2003). The positive phase of the NAO corresponds to an anomalously strong Azores
High and concomitant deepening of the Icelandic Low with some penetration in the subarctic basin
(Greenland/Norwegian/Barents Sea), accompanied by a reinforced and northward shifted jet and storm track
over a broad North Atlantic-European sector (Figure AIV.1a). The opposite, notwithstanding marginal
spatial asymmetries, occurs for the negative phase.

The NAO is the main mode of climate variability over a broad North Atlantic-Europe region in all seasons
(Hurrell and Deser, 2009) for intra-seasonal to multidecadal timescales, albeit with seasonally-dependent
physical characteristics (fraction of explained variance, latitudinal shift and intensity of the related
anomalous atmospheric circulation and SST fingerprint, etc.; Folland et al., 2009a; Woollings et al., 2015a).
The phases of the NAO control a significant fraction of the variance of temperature and precipitation over
the North Atlantic and surrounding continents and of the prevailing westerly winds and the related storm
tracks (Woollings et al., 2014). It is also strongly related to the occurrence and intensity of blocking
conditions especially over Greenland (Woollings et al., 2010; Davini et al., 2012) and controls a large part of
the incidence of extremes (cold waves, very strong wind episodes related to explosive storminess, heavy
precipitation events, etc.) over Europe (Matthews et al., 2014; Yiou et al., 2017) and eastern North America
The NAO/NAM can be viewed as the regional expression of a hemispheric-scale mode of atmospheric variability that was identified in the late 1990s known as the Arctic Oscillation (AO; Thompson and Wallace, 1998) or Northern Annular Mode (NAM) (Thompson and Wallace, 2000a; Ambaum et al., 2001) to reflect the longitudinal scale that transcends the entire hemisphere. An additional centre of action is present for NAM over the North Pacific, albeit much weaker than its Atlantic counterpart, with a slackened Aleutian Low in the positive phase (Figure AIV.1b). The AO/NAM can be defined as the leading mode of variability across a range of atmospheric levels from the surface to the stratosphere (Baldwin and Dunkerton, 1999; Gerber et al., 2010). In the stratosphere, the AO/NAM corresponds to fluctuations in the strength of the boreal winter polar vortex over the Arctic. In the troposphere, the AO/NAM primarily corresponds to fluctuations in the position of the midlatitude westerly jet stream. Interactions between the stratospheric and tropospheric annular modes have been extensively studied and are important for the variability and predictability of the mode at intra-seasonal timescales (i.e. see Domeisen, 2019).

Despite the fact that NAM and NAO indices are strongly correlated (Figure AIV.1c), the debate on the relevance of the NAM as a mode of variability persists (Deser, 2000; Honda and Nakamura, 2001; Itoh, 2008) is not closed yet, despite progress in understanding the dynamical mechanisms linking the Pacific and Atlantic SLP cores on the basis of wave breaking theory that prevails at intra-seasonal timescales (e.g. Riviére and Drouard, 2015). Consequently, NAO and NAM are treated as indistinguishable in some studies (Feldstein and Franzke, 2006) while others still consider the NAO as a stand-alone mode even if associated circumpolar patterns exist (García-Serrano and Haarsma, 2017). In the latter case, the NAM is interpreted as a statistical artefact of two regional independent modes namely the NAO and the Pacific-North American pattern (Ambaum et al., 2001; Douville et al., 2017). Throughout the report, NAO and NAM are often considered as the same entity because the NAO explains most of the variance on the zonally-averaged hemispheric circulation and because the associated timeseries are highly correlated.

The NAO/NAM arise as large-scale signals primarily driven by internal atmospheric variability of midlatitude dynamics (e.g., Lorenz and Hartmann, 2003). By nature, these signals correspond to barotropic phenomena being partly controlled by eddy-mean flow interaction (Feldstein and Franzke, 2017). Their fingerprint can be found along the entire atmospheric column with maximum amplitude in the winter season when storminess is the most pronounced. In addition, the tropospheric NAO/NAM variability has been shown in boreal winter to be linked to the strength of the stratospheric polar vortex (Baldwin and Dunkerton, 1999) including sudden stratospheric warmings (Domeisen, 2019). On intra-seasonal timescales, downward propagation of associated geopotential height anomalies occurs from the lower stratosphere to the troposphere through wave-mean flow interaction resulting in some predictability at the surface for CIDs, through temperature, precipitation and wind anomalies at large spatial scales (e.g. Karpechko et al., 2017 over Europe).

The NAO/NAM includes a forced component arising from SST anomalies: key oceanic regions are identified but are dependent on the timescale of variability that is investigated (Baker et al., 2019). There is also growing evidence for the importance of cryosphere-atmosphere coupling to explain part of the observed variability of the NAO in response to recent Arctic sea-ice decline (Cohen et al., 2014), even if discrepancies remain in model estimates (Screen et al., 2018) and may not be stationary in time (Blackport and Screen, 2020). Finally, part of the NAO/NAM variability has also been documented to be influenced by external forcing such as volcanic eruptions (Swingedouw et al., 2017) and solar forcing (Ineson et al., 2011; Gray et al., 2016; Le Mouël et al., 2019) as well as anthropogenic factors (Gillett et al., 2003). However, internal variability is predominant and, because of signal-to-noise issues, very long observational records and large ensembles of climate simulations are needed to clearly evaluate the fraction of the forced component in the observed NAO/NAM, as assessed in detail in Sections 2.4.1.1 and 3.7.1. Sea ice-NAO/NAM coupling is comprehensively assessed in Cross-Chapter Box 10.1.

Given their equivalent barotropic structure, the NAO/NAM is usually defined from SLP fields or geopotential height anomalies at various levels (Fu et al., 2016). The NAO/NAM can be defined using pattern-based statistical techniques such as EOF or clustering techniques applied to seasonal gridded
atmospheric circulation fields (SLP or geopotential height anomalies) from observations or reanalysis data. The NAM pattern is traditionally defined as the leading EOF of pressure fields computed over the entire hemisphere, northward of 20°N (Figure AIV.1b) and its related PC defines the NAM index (Figure AIV.1c). Similarly the NAO index can be defined as the PC of the leading EOF of the pressure field over the North Atlantic sector (Figure AIV.1a) or the temporal occurrence of the seasonal weather regimes extracted from clustering (Corti et al., 1999; Cassou et al., 2011; Hamachi et al., 2017).

An alternative and simpler estimate of the NAM/NAO uses differences in SLP between fixed locations. The NAM index can be calculated from the difference in normalized zonally averaged SLP between 35°N and 65°N (Li and Wang, 2003), which reflects the latitudinal fluctuation of the position and strength of the midlatitude westerlies at the hemispheric scale. Similarly, for the NAO, a weather station-based index is traditionally calculated as the difference of normalized SLP anomalies located in the Azores (Ponta Delgada) or continental Iberia (Lisbon/Gibraltar) minus those along the northern centre of action around Iceland (Stykkisholmur/Reykjavik) (Jones et al., 1997). Cornes et al. (2013) alternatively uses the Paris-London difference because of data availability back to the 17th century. The station-based NAO index is simple to compute, extends the longest over the instrumental period, and can be used year round, but caveats stand in its limitation to capture the seasonal latitudinal migration of the NAO variability pattern as well as potential shifts in the North Atlantic pressure centres of action at interannual to decadal timescales (Ulbrich and Christoph, 1999). Because it uses fixed locations, the index captures part of the variability that is not directly related to the latitudinal seesaw pressure balance and associated large-scale fluctuations of the zonal flow that characterize the NAO dynamics, and it also fails representing the spatial asymmetries between the positive and negative phases of the mode (Cassou et al., 2004).

The temporal correlation between the EOF and fixed latitude-based zonal NAM estimations is equal to 0.91 for December-January-February average and both are strongly correlated with the NAO indices (Figure AIV.1c). Correlations between all the NAO estimates are spatially and temporally very high in all the observational products over the modern reanalyses period (Gerber and Martineau, 2018); for instance, the correlation between the station-based and EOF-based NAO indices over 1959-2018 in boreal winter using JRA-55 is equal to 0.89 (Figure AIV.1c). EOF-based NAO and NAM indices are used in Section 3.7.1 for model evaluation. The fixed-latitude NAM index is used in Sections 2.4.1.1, 4.3.3.1, 4.4.3.1 and 4.5.3.1, and in Section 3.7.1 for attribution of past changes.

[START FIGURE AIV.1 HERE]

Figure AIV.1: The boreal wintertime NAO and NAM modes extracted as the leading EOF of December-January-February SLP anomalies over the North Atlantic-Europe Sector (20°N-80°N, 90°W-30°E, materialized by the red box, a) and the Northern Hemisphere (north of 20°N, black domain, b), respectively, based on JRA-55 reanalysis over 1959-2019. (a,b) SLP anomalies regressed onto the leading principal component (PC) time series shown in (c). The NAO-PC is represented by red and blue bars, the NAM-PC by the black curve in (c); their variance explained is given in the legend. The NAO index based on weather stations (cyan dots in a) is given in cyan and the zonal-NAM index (latitude circles in b) is given in magenta. Correlation between each index and the NAO-PC timeseries is given in the legend. (d,e) Regression maps of blended SST and SAT over land from ERSST and BerkeleyEarth dataset, respectively, over for 1959-2019 (d) and of precipitation anomalies (e, shading based on GPCC for 1959-2016 and contours based on CMAP for 1979-2019 for every 0.1 mm/day). On maps, no overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (e). All fields have been linearly detrended prior to computation.

[END FIGURE AIV.1 HERE]

AIV.2.1.2 Teleconnections and regional influence

Large-scale changes in the position and strength of the North Atlantic jet stream and storm tracks associated
with the NAO/NAM, as well as the related incidence in blocking episodes traditionally linked to extreme
events, affect surface climate conditions over the entire North Atlantic and surrounding landmasses from
daily to multidecadal timescales (Hurrell, 1995). Warmer and wetter weather over Northern Europe
extending eastward in western Siberia with simultaneous cooler and drier conditions over a broad
Mediterranean basin are distinct features of the positive boreal winter NAO/NAM (Figure AIV.1.d,e). Over
North America, regions around the Labrador Sea are significantly colder with excess sea-ice formation while
milder conditions dominate the Great Plains forming altogether a typical quadrupolar anomaly pattern for
temperature linked to the winter NAO/NAM. The latter structure is tightly related to the latitudinal shift of
the storm tracks that is particularly marked in precipitation over the ocean (Figure AIV.1.e). More remotely,
changes in North Atlantic storm track position and transient eddy activity associated with the positive
(negative) phase of the NAO contribute downstream to negative (positive) SLP anomalies in north-eastern
East Asia during boreal summer (Linderholm et al., 2011).

Related changes in both westerly winds at midlatitudes and trade winds in the tropics over the North Atlantic
result in anomalous fluxes of sensible and latent heat at sea surface, which create ocean temperature
anomalies that extend down to the base of the deep mixed layer during boreal winter (Deser and Timlin,
1997; Seager et al., 2000). The SST imprint of the NAO has a tripolar shape with positive anomalies at
midlatitudes straddled by colder surface ocean in the subtropics and along the entire subpolar gyre (Figure
AIV.1d). Weak feedbacks from SST on boreal winter NAO are found through forced Rossby wave
mechanism (Baker et al., 2019) and local phenomena such as oceanic re-emergence in the North Atlantic
Nordic seas (Cassou et al., 2007). Negative NAO phases are characterized by a wavier jet stream and a
southward shift of storm tracks, which favours cold outbreaks over Northern Europe (Cattiaux et al., 2010)
and reinforced storminess along the Mediterranean basin leading to heavy precipitation events (Sanchez-
Gomez et al., 2008) and storm surge in southern Europe (Cid et al., 2016). Those are also often related to a
collapse/split/displacement of the low-level stratospheric polar vortex and the occurrence of Stratospheric
Sudden Warming (Sections 2.3.1.4.5 and 3.3.3.4). In boreal winter, NAM and NAO teleconnections are very
similar over the Atlantic surrounding continents.

There is a strong seasonal asymmetry in observed NAO teleconnection patterns and NAO temporal
evolution. Impacts over Europe are opposite between summer and winter months with dominant warmer and
drier weather conditions over north-western Europe in summertime concurrently with wetter conditions over
Southern Europe during positive NAO phases (Folland et al., 2009; Bladé et al., 2012). Extreme events (heat
waves occurrence, droughts, etc.) are also linked to NAO phases (Cassou et al., 2005; Drouard et al., 2019)
due to the related latitudinal shift of the North Atlantic storm tracks (Dong et al., 2013). Summer NAO
trends also affect Arctic climate as assessed in Sections 3.4.1 and 9.4.1. The NAO is associated with storms
or persistent mild wind period and dry/sunny spells affecting availability and power consumption (Jerez et
al., 2013; Zubiate et al., 2017).

NAO fluctuations generate ocean responses due to altered buoyancy fluxes and wind stress anomalies
(Barrier et al., 2014). Signatures of the NAO can be found in the gyre circulations (Marshall et al. 2001) and
in the Atlantic Meridional Overturning Circulation (AMOC; Yeager and Danabasoglu, 2014), with a sea
level imprint in observations (Han et al., 2017). The oceanic response is dependent on the timescale of the
NAO variability (Delworth and Zeng, 2016) especially for AMOC in connection with the so-called Atlantic
Multidecadal Variability (Section AIV.2.7). This is assessed in Section 9.2.3.1.

Implications of NAO/NAM variability in terms of observed and projected precipitation at a regional scale
(Europe, Mediterranean basin, etc.) is comprehensively assessed in Sections 8.3.2.9, 8.4.2.9, and 8.5.2. NAO
implications on extremes are assessed in Sections 11.3.1 and 11.4.1, and regional manifestations of
NAM/NAO are further assessed in Sections Atlas.5, Atlas.7, Atlas.8 and Atlas.9 and Cross-Chapter Box
Atlas.2.

AIV.2.1.3 Available proxy-based reconstruction

Sea level pressure records from Stykkisholmur, Akureyri, Reykjavik and from Gibraltar, Lisbon and Ponta

Do Not Cite, Quote or Distribute AIV-8 Total pages: 60
Delgado weather stations, all located close the NAO centres of action (i.e. Islandic Low and Azores high), allowed the reconstruction of the NAO index back to the mid-19th Century (Cropper et al., 2015; Hernández et al., 2020). The Paris-London sea level pressure difference used by Comes et al. (2013) extends back to 1692, but it captures only part of the large-scale NAO phenomena because of the spatial proximity of the weather stations used. More reliable NAO reconstructions were recently developed based on the reconstruction of the sea level pressure field all over the North Atlantic and Europe (Delaygue et al., 2019; Mellado-Cano et al., 2019). Other long-term reconstructions involve proxy-based information from documents (Barriopedro et al., 2014), tree rings (Cook et al., 2019), ice cores (Sjolte et al., 2018), stalagmites (Baker et al., 2015), sediments (Faust et al., 2016) and a combination of multi-proxy information (Ortega et al., 2015), with large uncertainties due to diverse methodological approaches used for reconstruction (Michel et al., 2020) and disparate correlations between proxies and associated temporal resolution (Hernández et al., 2020). An additional difficulty for reconstruction lies on the fact that the spatial structure of North Atlantic variability might be time-scale dependent (Woollings et al., 2015). It is shown that on the shorter timescale (interannual), the NAO is dominated by variations in the latitude of the North Atlantic jet and storm track, whereas on the longer timescale (multidecadal and beyond) it represents changes in their strength instead. The two timescales also exhibit different regional impacts on temperature and precipitation and different relationships to sea surface temperatures, which makes proxy reconstructions of the NAO problematic.

Most of the reconstructed NAO/NAM indices describe the winter patterns of the last 500 years because the variability is the most pronounced and on larger-scale for that season (Luterbacher, 2001; Dezileau et al., 2011). Tree rings can however allow NAO boreal summer reconstruction back to the 16th century (Folland et al., 2009; Linderholm et al., 2009). Recent efforts to develop reconstructions of the NAO phases using pollen data (Mauri et al., 2014), speleothems (Ait Brahim et al., 2019) and lake sediments (Olsen et al., 2012) provide new evidence for multi-centennial NAO-type of variability along the Holocene (Hernández et al., 2020). A detailed description of the latest proxy-based reconstructions of the NAO and related conclusions placing the observations since the pre-industrial in a broader context of variability are given in Section 2.4.1.1.

AIV.2.2 Southern Annular Mode

AIV.2.2.1 Definition of the mode

The Southern Annular Mode (SAM), sometimes called the Antarctic Oscillation (AAO), is the leading mode of large-scale atmospheric circulation variability in the Southern Hemisphere extra tropics in all seasons and at intra-seasonal to multidecadal timescales, albeit with season-dependent physical characteristics such as fraction of explained variance, latitudinal shift and intensity of the related anomalous atmospheric circulation and SST fingerprint. It is characterized by synchronous SLP or geopotential height anomalies of opposite signs between the mid- and high latitudes, modulating the mean westerly winds near 50°S. The SAM affects the frequency, strength, and position of cold fronts, and extratropical synoptic to mesoscale weather systems (Thompson and Wallace, 2000b; Manatsa et al., 2016; Mariani and Fletcher, 2016; Cerrone and Fusco, 2018). It controls a significant fraction of seasonal to multi-annual variance of the zonal mean precipitation in the Southern Hemisphere sub-tropics and extratropics (Kang et al., 2011). The SAM is also tightly linked to the fluctuations in the thermohaline properties of the Southern Ocean as well as its dynamics (Sen Gupta and England, 2006; Spence et al., 2014), and it modulates the Antarctic sea ice extent from interannual to multidecadal timescales (Ferreira et al., 2015).

Given its equivalent barotropic structure, the SAM is commonly quantified as the first EOF mode of extratropical geopotential height anomalies at various tropospheric levels or of SLP anomalies. However, it extends into the stratosphere, coupling lower and middle-atmosphere dynamics. As it essentially represents a meridional atmospheric mass transfer, an alternative definition is the difference in normalized zonal mean SLP at middle (40°S) and high (65°S) southern latitudes (Gong and Wang, 1999; Marshall, 2003). The polarity of the SAM is defined such that it is positive when pressure over Antarctica is anomalously low, and vice versa. While the SAM pattern is more zonally symmetric than its Northern Hemisphere counterpart (NAM, Section AIV.2.1), it does exhibit some asymmetries particularly in the midlatitude node over the
Pacific and Indian Ocean sectors (Fogt et al., 2012). Alternative interpretations of the SAM as a regional
variability pattern in the South Pacific are also considered (Spensberger et al., 2020). The zonal asymmetries
are present for all seasons, and illustrated in Figure AIV.2a for austral summer, to support the assessment in
Section 3.7.2. A number of different SAM indices have been produced, and several are compared by Ho et
al. (2012) and Barrucand et al. (2018), showing good agreement after the second half of the 20th century.
Over the 1979-2019 period, the correlation between the EOF-based and zonal SLP-based indices for the
summertime SAM reaches 0.94 (Figure AIV.2b).

During the positive phase of the SAM, the Antarctic air mass is isolated by an enhanced westerly jet that is
located further south than during the negative phase. This leads to colder conditions over the entire continent
and negative SST anomalies along the surrounding ocean (Figure AIV.2). During the opposite, negative
phase, an equatorward displacement of the jet and related storm track brings low pressure systems toward the
north with a strong effect on southern tip of South America (Mariani and Fletcher, 2016). The SAM is often
used as a proxy for the location of the midlatitude westerly wind belt at seasonal to interannual timescales.
However, Swart et al. (2015) noted that trends in the SAM and the Southern Hemisphere surface westerly jet
are not directly interchangeable because multiple factors other than SAM can affect trends in the position,
width and strength of the jet and surface wind.

The SAM is mainly driven by extratropical atmospheric dynamics, but its phase is affected by remote SST
anomalies such as ENSO (Section AIV.2.3) and anthropogenic forcing as assessed in Section 3.7.2.

The EOF-based SAM index is used for model evaluation in Section 3.7.2. The fixed-latitude SAM index is
used for the attribution assessment of the observed positive trend of the SAM that is maximum over the
second half of the 20th century but reduced since about 2000 (Section 2.4.1.2) due to slackened ozone
influence (Section 3.7.2). The fixed-latitude SAM index is also used in Sections 4.3.3.1, 4.4.3.1 and 4.5.3.1
to assess the future changes in Southern Hemispheric zonal circulation as a function of emissions scenarios
and lead times.

[START FIGURE AIV.2 HERE]

Figure AIV.2: The austral summertime SAM extracted as the leading EOF of December-January-February SLP
anomalies over the Southern Hemisphere (south of 20°S, a) based on JRA-55 reanalysis over 1979-
2019. (a) SLP anomalies regressed onto the leading principal component (PC) time series shown in
(b); the variance explained is given in the legend in (b). The SAM-PC is represented by red and blue
bars and the zonal-SAM index (latitude circles in a) is given in magenta. Correlation between the
zonal SAM index and the SAM PC timeseries is given in the legend. (c, d) Regression maps of SST
and SAT over land from ERSST and BerkeleyEarth dataset, respectively, over for 1979-2019 (d) and
of precipitation anomalies (e, shading based on CMAP for 1979-2016 and contours based on GPCP
for 1979-2019 for every 0.1 mm/day). On maps, no-overlay indicates regions where the regressions
are significant based on t-test accounting for false detection rate at 10% and crosses indicates no
significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields
have been linearly detrended prior computation.

[END FIGURE AIV.2 HERE]

AIV.2.2.2 Teleconnections and regional influence

Recent observational studies have enriched our understanding of the widespread influence of SAM
variability on mean climate and related environmental parameters of the entire Southern Hemisphere
extratropics (e.g. Holz et al., 2017; Jones et al., 2016; Kostov et al., 2017; Manatsa et al., 2013; Marshall et
al., 2017; Raut et al., 2014; Waugh et al., 2013). The influence of the SAM extends over the midlatitude
continental land masses with precipitation anomalies over Southern Australia (Cai and Wattersen, 2002) and
south-eastern South America (Silvestri and Vera, 2003) in link with the latitudinal migration and strength of
the extratropical storm and mean westerly circulation. Consistently with NAM/NAO (Section AIV.2.1),

Do Not Cite, Quote or Distribute AIV-10 Total pages: 60
there is a strong seasonality in the teleconnection associated with SAM. In austral summer, during a positive phase of the SAM, drier conditions affect most of the southern Patagonia region and the southernmost tip of South America, while wetter conditions are found in South Africa and Madagascar, as well as in Southeast Australia where colder temperatures also prevail (Figure AIV.2c,d). Positive temperature anomalies are found in New Zealand, Tasmania and Southern tip of South America. These anomalies appear as the continental fingerprint of a warmer belt located around 40oS that is characterized by significant hemispheric-scale SST changes in consistency with the southern shift of the summertime storm track.

Moreover, several studies have described equatorward teleconnections linking the SAM to Asian precipitation across the equator (e.g., Liu et al., 2018; Prabhu et al., 2017). Coupling of seasonal stratospheric anomalies to the SAM can influence spring-time heat extremes in eastern Australia (Lim et al., 2019). Marshall et al. (2013) described a reversal in the relationship between the SAM and East Antarctic temperatures during austral summer/autumn in the first decade of the 21st century, due to regional variability of the pressure pattern associated with the zonal wavenumber 3. Other studies have analysed the temporal variability in the interactions between the SAM and ENSO at different timescales (e.g. Clem et al., 2016; Yu et al., 2015), being positive and significant during 1986-2014 (Vera and Osman, 2018).

Implications of SAM on observed and projected changes in water cycle and specific regional influences are assessed in Sections 8.3.2.9 and 8.4.2.9 and in Sections 12.4, Atlas.7 and Atlas.11, respectively.

AIV.2.2.3 Available proxy-based reconstruction

The regional influence of the SAM is recorded in tree rings (Holz et al., 2017; Dätwyler et al., 2018), lake sediments (Fletcher et al., 2018; Moreno et al., 2018), ice cores (Goodwin et al., 2004) and corals (Goodwin and Harvey, 2008) across the Southern Hemisphere extratropics. Multiproxy-based reconstructions of the SAM have been developed using temperature-sensitive proxy records that cover the last millennium (Villalba et al., 2012; Abram et al., 2014; Dätwyler et al., 2018). Villalba et al. (2012) used tree ring records to reconstruct the summertime SAM since 1409, while Abram et al. (2014) combined ice core records with tree ring data to derive a weighted composite-plus-scale reconstruction of the annual SAM index for the past millennium. Dätwyler et al. (2018) further included proxies from corals, speleothems and lake sediments using different stationarity criteria for the proxy record selection to build an austral summer SAM reconstruction. Hessl et al. (2017) compared three paleoclimatic reconstructions of the SAM, highlighting the need for additional proxy records over the Indian Ocean sector, to fully account for the annular structural properties of this mode of variability. Uncertainties also arise from the lack of proxy data related to cold season conditions, given that reconstructions relying on tree rings might be biased towards summertime thus accounting only for SAM austral summer variability (Hernández et al., 2020). Several studies attempted to reconstruct the SAM behaviour during the Holocene, inferred through changes in the Southern Hemisphere westerly wind belt, but uncertainties remain large without consensus in the SAM phases for most of the periods at multidecadal timescales (Hernández et al., 2020). These SAM reconstructions are assessed in Section 2.4.1.2 and compared with simulations in Section 3.7.2.

AIV.2.3 El Niño-Southern Oscillation

AIV.2.3.1 Definition of the mode

The El Niño-Southern Oscillation (ENSO) refers to the large-scale alternation between anomalous warming and cooling of central/eastern equatorial Pacific SSTs that coincide with changes in the overlying winds and precipitation (Philander, 1990; Neelin et al., 1998; Wang, 2018). The main features of ENSO are displayed in Figure AIV.3. ENSO is the primary mode of tropical variability on interannual timescales and is considered as an internally occurring coupled ocean-atmosphere phenomenon. Whilst the ENSO phenomenon itself largely occurs in the tropical Pacific, it triggers climate teleconnections over the entire basin and in many other parts of the world (Figure AIV.3c,d). ENSO is consistently the main modulator of the global surface temperature at interannual timescales (Pan and Oort, 1983; Trenberth et al., 2002). ENSO
is the main source of climate predictability on seasonal to interannual timescales (Philander, 1990; Smith et al., 2012) and its status is consequently closely monitored by meteorological institutes around the globe. El Niño events are typically identified by warmer than normal central/eastern equatorial Pacific SSTs, negative SLP anomaly difference between the eastern and western portions of the tropical Pacific Ocean, anomalous westerly surface winds, and increases in cloudiness and precipitation over the central and eastern equatorial Pacific and adjacent land areas. By contrast, La Niña events are typically identified by cooler than normal central/eastern equatorial Pacific SSTs, positive surface pressure anomaly difference between the eastern and western portions of the tropical Pacific Ocean and anomalous easterly surface winds reflecting altogether an intensification of the climatological east-west thermal gradient across the equatorial Pacific Ocean.

ENSO has been monitored through a range of indices, which are based on SST or SLP anomalies during the instrumental period, and various proxies on longer timescales. Differences between indices and thresholds used to define the occurrence of an El Niño or La Niña event imply that no commonly accepted list of events and their magnitudes exists. The three most prominent (L’Heureux et al., 2017; Pepelet, 2016) indices used to monitor ENSO are the averaged SST anomalies over the so-called NINO3 (5°S-5°N, 150°W-90°W) or NINO34 (5°S-5°N, 170°W-120°W) regions and the Southern Oscillation Index (SOI) based on the normalized SLP difference between Darwin and Tahiti (Troup, 1965). Decomposition into EOFs of the tropical SST is also used in the literature. Those indices are highly correlated, as shown in Figure AIV.3b. The correlation between NINO3 SST and EOF-SST index is about 0.97, and between NINO34 and SOI is about 0.89 over the 1959-2019 period.

SST anomalies from the NINO3 and NINO34 regions provide a direct measure of the events via its surface ocean fingerprint, while the SOI provides a measure in terms of atmospheric perturbation. Data are available back to 1876 for the SOI computation, whilst the uncertainty in SST-based indices, particularly those associated with the central equatorial Pacific, is large prior to the 1950s when the number of SST observations was much lower (Kennedy et al., 2019). The complexity of ENSO is at least partly demonstrated by the observed events, which are all different in the magnitude, spatial structure and/or seasonal timing. As a direct consequence, it is difficult to accurately represent ENSO with one single index. Over time, further indices have been introduced to monitor ENSO event evolution (i.e., Trans Niño Index – TNI, Trenberth and Stepaniak, 2001) and spatial structure (i.e., El Niño Modoki Index – EMI, Li et al., 2010). The limited length and quality of the observational records may further affect the choice of the index, whose relevance can depend on the specific application. The variety in ENSO indices also explains the non-universality in the qualification of ENSO status delivered by meteorological agencies responsible for operational monitoring, operational forecast and climate services for users.

A particular aspect of ENSO diversity is whether the event is centred in the eastern Pacific (EP events) or central Pacific (CP or “Modoki” events). This distinction is important as the type of event leads to different large-scale teleconnections and worldwide climatic impacts (e.g. Ashok et al., 2007; Ratnam et al., 2014; Capotondi et al., 2015; Timmermann et al., 2018; Taschetto et al., 2020). Differences can be significant at regional scale because of displaced source of diabatic heating associated with the position of the main SST anomalies. For instance, stronger precipitation teleconnections occur over Australia during CP than during EP events (Wang and Hendon 2007; Taschetto et al. 2009). It is noteworthy that central and eastern Pacific SST indices are more highly correlated with each other during La Niña than during El Niño events. This indicates that La Niña events have less geographic diversity than El Niño events (Kug and Ham, 2011) and that the CP/EP distinction is therefore more relevant for the latter. In the historical instrumental records, Banholzer and Donner (2014) found that CP events had a weaker influence on global surface temperature than EP events did.

However, the distinction between CP and EP events is not necessarily clearly defined, as different methods yield an inconsistent classification of the events, which implies that no robust consensus on the classification of CP or EP events is possible (Wiedermann et al. 2016). Furthermore, Giese and Ray (2011) found that the central longitude of peak SST anomalies associated with individual El Niño events had a distribution indistinguishable from a Gaussian distribution peaked at 140°W, as opposed to a bimodal distribution implied by the EP/CP paradigm. There are also occasional “coastal Niño” events, such as those of 1925 (Takahashi and Martinez, 2019) or 2017 (Rodriguez-Marata et al., 2019), where abnormally warm waters are
confined to the South American coast. Even though these events are not conventionally classified as El Niños, they have some El Niño-like teleconnections in South America. Instrumental data have historically been of limited value in assessing the classification of events before 1955, because of the almost total lack of SST measurements in the western half of the NINO34 region (L’Heureux et al., 2013). It is not yet known whether newer SST data set versions, which benefit from improved data archives (Section 2.3.1.1), have reduced this uncertainty.

The description of ENSO in this Annex supports the assessments of Sections 2.4.2, 3.7.3, 4.3.3.2, 4.4.3.2 and 4.5.3.2. ENSO’s influence on ocean circulation, heat transport and sea levels are assessed in Sections 9.2 and 9.6.

[START FIGURE AIV.3 HERE]

Figure AIV.3: The boreal wintertime ENSO mode defined by December-January-February SST anomalies averaged over the NINO34 region (5ºS-5ºN, 170ºW-120ºW, cyan box) or extracted as the leading EOF mode over the Tropical Pacific Ocean (the region denoted by the black box in a) for 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the NINO34 time series, which is shown in (b) as red and blue bars. Black curve in (b) represents the standardized leading principal component and the magenta curve stands for the SOI index. The percentage of explained variance of the leading EOF is given in the legend as well as the correlation between all indices and the NINO34 timeseries. (c) Same as (a) but for land SAT (shading; based on Berkeley/Earth) and 10-m level wind (arrows; based on JRA-55) anomalies over 1958-2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for every 0.5 mm/day). Magenta dots in (c,d) stands for the Darwin and Tahiti weather station used for the SOI computation. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

[END FIGURE AIV.3 HERE]

AIV.2.3.2 Teleconnections and regional influence

ENSO has a broad range of teleconnections, both in and outside the Pacific region (Figure AIV.3c,d). Amongst the best-known teleconnections are the association of El Niño events with increased precipitation in the southwestern and southeastern United States, eastern Africa, coastal Ecuador and Peru, and northern Argentina, and with decreased precipitation in eastern Australia and the Maritime Continent, southern Africa, the Amazonian basin and much of the Indian subcontinent. A general reverse association is found during La Niña events although there are some asymmetries (Cai et al., 2010; Taschetto et al., 2020). ENSO also has a substantial impact on tropical cyclone occurrence (Wang and Chan, 2002; Chu, 2004; Kuleshov et al., 2008), with El Niño typically being associated with reduced tropical cyclone activity in the North Atlantic, and an eastward displacement of Northwest and South Pacific tropical cyclone genesis away from the Philippine Sea and the Australian continent and into the central Pacific. ENSO have been shown to control part of the interannual variability of fire, including wildfire and human-triggered fires, in many regions of the world including all the continents surrounding the Pacific (see for instance the devastating extreme fire emissions in Indonesia in 2015, Chisholm et al. 2016) but also remotely, e.g. over the Arctic (Monks et al., 2012).

Tropical climate impacts during ENSO events are largely driven by a reorganisation of the zonal Walker circulation that result from anomalous diabatic heating associated with deep atmospheric convection changes (e.g. Chiang and Sobel, 2002; Choi et al., 2015; Gill, 1980; Klein et al., 1999). The latter are also responsible for atmospheric teleconnections to higher latitudes (Yeh et al., 2018), acting as a source of forced large-scale Rossby waves (Hoskins and Karoly, 1981). Specific phases of the Pacific-North American (PNA) pattern (Horel and Wallace, 1981) and Pacific-South American (PSA) pattern (Karoly, 1989) are then favoured in the Northern and Southern Hemispheres, respectively, and are associated with shift and modulation of the
mean storm tracks. These teleconnections influence temperature and rainfall around the globe including extreme events (King et al., 2014). For instance, mild winter conditions dominate Alaska/Canada connected to the southeastward displacement and reinforcement of the Aleutian Low during El Niño, which generates anomalous southerlies and advects warmer air northward. By contrast, the anomalous cyclonic circulation favours cold outbreaks over the far-east Siberian region and Kamtchaka (Figure AIV.3c,d).

Being the dominant actor of variability at interannual timescale, ENSO is linked to many other modes of variability both in the tropics and midlatitudes, either in phase or with some seasonal lag. For instance, connection has been documented between EP ENSO events and SAM during austral summer (Ciasto et al., 2015). Relationship exists between ENSO and the NAO/NAM in boreal wintertime though various mechanisms such as stratosphere-troposphere coupling (Domeisen et al., 2015) and tropospheric pathways, including the eastward extension of the PNA during El Niño event and also through the alteration of the propagation of tropical Rossby wave trains from the Pacific to the Atlantic (Drouard et al., 2015). The tropical-extratropical teleconnection is not symmetrical with the phase of ENSO and nonstationary with considerable dependence on epochs being modulated by the inherent strong internal variability (Deser et al., 2017; Drouard and Cassou, 2019). In the Atlantic, relationship between ENSO and Atlantic Niño (Section AIV.2.5) is found in boreal spring (Tokinaga et al., 2019) while the South Atlantic Subtropical Dipole mode is mostly connected to ENSO in austral summer (Rodrigues et al., 2015).

Implications of ENSO in water cycle changes are further assessed in Sections 8.3.2.9 and 8.4.2.9. Association of ENSO with extremes and specific regional climate anomalies are assessed in Sections 11.4, 11.6, 11.7, 12.4, Atlas.4, Atlas.5, Atlas.6, Atlas.7, and Atlas.9 and Box 11.4.

AIV.2.3.3 Available proxy-based reconstruction

Model evidence suggests that ENSO characteristics vary on decadal to centennial timescales (e.g. Lewis and LeGrande, 2015; Deser et al., 2017), implying that a minimum of several hundred years of observations, which is much longer than the instrumental record, are required to determine the full natural range of ENSO complexity (Wittenberg, 2009). Thus, one way to understand if anthropogenic forcing has modulated ENSO is to understand ENSO behaviour prior to the observational record. Paleoclimate archives can be used to fill this gap as they provide quantitative estimates of ENSO behaviour during the pre-industrial era, while also providing information of ENSO characteristics under a variety of past natural climate background states controlled by external forcings. Extensive proxy-based studies, using a range of ENSO-sensitive records, have been carried out to assess the ENSO changes on various paleoclimate timescales, specifically the last few hundred years and back to the mid-Holocene (see Section 2.4.2).

Reconstructions of past ENSO behaviour traditionally merges information from multiple proxies that are considered sensitive to ENSO (Lu et al., 2018). This merging process may have multiple purposes, but is generally used to extend the reconstruction length and also to increase its signal to noise ratio. The resulting reconstructions can be broadly placed into two main categories: (i) those that utilise proxies in the central and eastern equatorial Pacific itself; and (ii) those that utilise proxies from other regions impacted through teleconnections, along with those that mix both categories. ENSO reconstructions from category (i) are considered to be a more accurate measure of ENSO behaviour. However, proxies from the central and eastern equatorial Pacific are generally rarer than those outside the region, due to the small number of land/reefs, and they also tend to be of shorter duration. Thus, the ideal case is a combination of both categories to get a robust quantitative estimates of ENSO behaviour in the past.

AIV.2.4 Indian Ocean Basin and Dipole Modes

AIV.2.4.1 Definition of the mode

The Indian Ocean basin (IOB) and Indian Ocean dipole (IOD) modes are the two dominant modes of interannual climate variability in the Indian Ocean. The IOB mode features the temporal alternation of basin-
wide warming and cooling of sea surface in the positive and negative phases, respectively (Figure AIV.4), while the IOD mode is characterized by a zonal dipole of SST anomalies in the tropics, with one lobe centred off Sumatra and Java and the other covering a large portion of the western basin (Figure AIV.5). The two modes mostly vary on interannual timescales and are both correlated positively with ENSO. In particular, the IOD tends to emerge during ENSO development from boreal summer to autumn (Stuecker et al., 2017), followed by the IOB which grows in ENSO peak season and persists for a few subsequent seasons (Tokinaga and Tanimoto, 2004).

The IOB mode is considered primarily as a response to ENSO associated with large-scale alteration of the Walker circulation, and thus matures in boreal spring, a season after the typical ENSO peak (Klein et al., 1999; Lau and Nath, 2000, 2003). By contrast, the Bjerknes feedback is key to the formation of the IOD. This feedback requires background surface easterlies and thermocline shallowing in the eastern part of the basin along the equator, and this condition sets in boreal spring and persists until autumn, then dissipating by early winter in association with climatological monsoon wind swing. The IOD mode therefore develops in boreal summer and reaches its maximum amplitude in autumn, then rapidly terminates before winter (Schott et al., 2009). Differently from the IOB, strong internal feedbacks enable the IOD mode to develop also without influence from ENSO, as noted for some specific events (Saji and Yamagata, 2003a; Meyers et al., 2007).

The IOB and IOD are identified as the first and second EOF modes, respectively, of monthly SST variability in the tropical Indian Ocean (Weare, 1979; Saji et al., 1999). The IOB can be extracted also as the first EOF of SST variability in boreal autumn, although the pattern depends on the analysis period (Pillai et al., 2019). The IOB mode has a subsurface signature and can be also calculated as the leading EOF mode of the 20°C isotherm depth of the Indian Ocean seawater temperature (Saji et al., 2006). Apart from the EOF definitions, the Tropical Indian Ocean averaged SST (20ºS-20ºN, 40ºE-100ºE or 40ºE-120ºE) is often used as the IOB mode index (Figure AIV.4a). For March-April-May, its correlation with the leading PC of Indian Ocean SST (Figure AIV.4b) reaches 0.98. For the IOD, SST anomaly difference between the western (10ºS-10ºN, 50ºE-70ºE) and eastern (10ºS-0º, 90ºE-110ºE) equatorial Indian Ocean is a widely used index (Saji et al. 1999; Figure AIV.5). It is highly correlated (at 0.76) with the leading principal component of the Indian Ocean September-November SST when assessed over 1958-2019 (Figure AIV.5b).

The IOB (Han et al., 2014) and IOD (Ashok et al., 2004a; Tozuka et al., 2007) -like variability can also be identified at decadal timescales. The decadal IOB mode is defined as the leading EOF mode of linearly detrended monthly SST after decadal time filtering (Han et al., 2014; Dong and McPhaden, 2017). 10-year low pass filtered Indian Ocean basin-mean SST is an alternative index for the decadal IOB mode (Dong et al., 2016), with the global-mean SST subtracted in some cases as an estimation of the response component to radiative forcing (Huang et al., 2019). The decadal IOD mode can be extracted as the second EOF mode of 10-year low-pass filtered Indian Ocean SST in boreal autumn (Yang et al., 2017), while other studies use the 10-year low-pass filtered SST anomaly difference between the western and eastern equatorial Indian Ocean (Ashok et al., 2004a; Tozuka et al., 2007).

Paleo fluctuations of IOB and IOD as well as the changes over the instrumental record period are assessed in Section 2.4.3, while their model representations are assessed in Section 3.7.4. Future variations under global warming are assessed in Sections 4.4.3.3 (near-term) and 4.5.3.3 (mid- to long terms).

Figure AIV.4: The boreal springtime IOB mode defined by March-April-May SST anomalies averaged over the Indian Ocean (the region denoted by the cyan box in a) or extracted as the leading EOF mode over the same domain (black contour) for 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the IOB index timeseries shown in (b) in red and blue bars, while the black curve in (b) represents the leading principal component timeseries. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth) and 10-m level wind (arrows; based on JRA-55) anomalies for 1958-2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for

[START FIGURE AIV.5 HERE]

Figure AIV.5: The boreal autumn IOD mode defined by September-October-November standardized SST difference between the western (10°S–10°N, 140°E–170°E) and eastern (10°S–0°, 90°E–110°E) equatorial Indian Ocean denoted by cyan boxes in (a) or extracted as the leading EOF mode over the Indian Ocean (the region denoted by black contour in a) over 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the IOD index timeseries shown in (b) in red and blue bars while the black curve represents the leading principal component timeseries. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth) and 10-m level wind (arrows; based on JRA-55) anomalies for 1958-2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for every 0.3 mm/day. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.

[END FIGURE AIV.5 HERE]

AIV.2.4.2 Teleconnections and regional influence

Since the IOB mode is tightly associated with ENSO, related climate anomalies can be viewed as part of ENSO’s influence from boreal winter to subsequent spring. Still, the IOB mode plays an important role in modulating the ENSO influence on several regions. The positive phase of the IOB plays a major role in suppressing precipitation in the Maritime Continent from boreal winter to spring (Watanabe and Jin, 2002; Annamalai et al., 2005) and Northern Australia in austral summer (Taschetto et al., 2011) in concomitance with El Niño event (Figure AIV.3d). An anomalous surface anticyclone then forms over the Philippine Sea linked to the precipitation reduction in the tropical western Pacific and brings more precipitation to East Asia during El Niño winter and spring (Figure AIV.3d; Wang et al., 2000).

ENSO’s equatorial Pacific SST anomalies typically dissipate by boreal summer, when the lingering IOB then plays the leading role in exerting climate anomalies in Asia and the Northwest Pacific (the Indian Ocean capacitor effect; Xie et al. 2009). The boreal summer IOB induces meridionally dipolar anomalies of precipitation and surface air temperature in Southeast and East Asia, with wetter and cooler summer in midlatitude East Asia and drier and warmer summer in Southeast Asia during positive IOB events (Kosaka et al., 2013; Wang et al., 2013). These conditions affect the occurrence of extremes such as heavy rainfall (often caused through atmospheric rivers; Kamae et al. 2017) and heat waves (Hu et al., 2012; Deng et al., 2019). The positive IOB suppresses summertime tropical cyclone formation in the Northwest Pacific (Du et al., 2011; Ueda et al., 2018), leading to a delayed onset of the typhoon season (Zhao et al., 2019). These regional influences are already present in the spring season (Figure AIV.4c,d) but tend to persist and even get reinforced due to the persistence of the IOB, while following the seasonal climatological displacement of tropical dynamics (monsoon etc.). In South Asia, tripolar precipitation anomalies form in boreal summer, with precipitation increase along the Western Ghats and in Bangladesh and decrease around the Ganges Delta during the positive IOB (Chowdary et al., 2013, 2019).

The IOB is associated with climate anomalies in broad regions (Figure AIV.5c,d). However, the related anomalies are interfered with influences from concomitant ENSO. The IOB affects rainfall in eastern Africa, South Asia, Indonesia and Australia (Figure AIV.5c,d). The IOD in the positive phase increases rainfall in eastern tropical Africa in boreal autumn to early winter (Figure AIV.5d), while the negative phase induces...
the opposite anomalies. These anomalies are also found in association with ENSO (Figure AIV.3d), but the explained variance by IOD is larger (Saji and Yamagata, 2003b). Both positive IOD and El Niño events reduce precipitation and temperature over the entire Maritime Continent (Figure AIV.5c,d and Figure AIV.3c,d) because of strong low-level divergence coupled with upper-level convergence related to diminished convection, while the opposite anomalies are induced by negative IOD and La Niña episodes (Saji and Yamagata, 2003b). The positive phase of the IOD also decreases rainfall in western to south-eastern Australia (Ashok et al., 2003; Risbey et al., 2009) acting as preconditioning for fires (Cai et al., 2009). The rainfall anomalies cover the entire Australia when combined with simultaneous ENSO with the same polarity (Risbey et al., 2009). The IOD influences South Asian summer monsoon rainfall either directly through moisture transport over the western Indian Ocean or modification of the local Hadley cell (e.g., Ashok et al., 2001; Gadgil et al., 2004; Ashok and Saji, 2007; Behera and Ratnam, 2018), or indirectly in the framework of the tropospheric biennial oscillation (e.g., Meehl et al., 2003; Li et al., 2006; Webster and Hoyos, 2010). IOD and ENSO often interfere in their influence on the south Asian summer monsoon (e.g., Ashok et al., 2001, 2004b; Pepler et al., 2014; Cretat et al., 2017). Opposing influence of IOD and ENSO has been found on surface temperature in summertime Northeast Asia (Saji and Yamagata, 2003b).

Implications of these modes on water cycle changes and specific regional influences are further assessed in Sections 8.3.2.9 and 8.4.2.9 and in Sections 12.4, Atlas.5, Atlas.6, Atlas.7 and Cross-Chapter Box Atlas.2, respectively.

AIV.2.4.3 Available proxy-based reconstruction

Corals record interannual and longer variability in the Indian Ocean (Zinke et al., 2005, 2009). Several studies have developed IOD reconstructions based on oxygen isotope ratios from corals. These reconstructions include those based on samples from Kenya since 1887 (Kayanne et al., 2006), from the Mentawai Islands in western Indonesia for the last 6,500 years (Abram et al., 2007) and in combination with samples from Bali in southern Indonesia and the Seychelles since 1846 (Abram et al., 2008). Abram et al. (2020) developed a coral-based reconstruction of the IOD for the last millennium, albeit with some discontinuity. Niedermeyer et al. (2014) use isotope compositions in terrestrial plant wax to reconstruct rainfall changes over Northwest Sumatra, which is highly correlated with the IOD. Compared to the IOD, proxy-based IOB reconstruction is limited. Yet, Du et al. (2014) find that coral oxygen isotope records from the Seychelles are well correlated with the IOB, suggesting that they can be used as an IOB proxy. Evidence from other proxies that are potentially associated with the Indian Ocean variability is assessed in Section 2.4.3.

AIV.2.5 Atlantic Meridional and Zonal Modes

AIV.2.5.1 Definition of the mode

The Atlantic Zonal Mode (AZM), also commonly referred to as the Atlantic Niño, and the Atlantic Meridional Mode (AMM) are the two dominant modes of tropical Atlantic climate variability on interannual to decadal time scales. The AZM peaks during the boreal summer upwelling season with maximum SST anomalies in the eastern equatorial Atlantic and is commonly regarded as the Atlantic counterpart of the Pacific El Niño (Zebiak, 1993; Keenlyside and Latif, 2007; Lübbecke et al., 2018; Foltz et al., 2019). The AMM, which is more active on longer time scales, peaks during boreal spring and exhibits a cross-equatorial gradient of SST with opposite signs in the northern and southern portion of the Atlantic. Both modes are associated with changes in the Intertropical Convergence Zone (ITCZ) and related winds and exert a strong influence on the climate in adjacent and remote regions.

The AMM is thought to be primarily driven by air-sea heat fluxes and therefore thermodynamic in nature (Chang et al., 2000; Foltz and McPhaden, 2010), while various mechanisms for generating AZM events have been discussed. They mainly concern fluctuations in the wind field over the equatorial Atlantic. These wind stress anomalies can be excited by local SST changes, as part of Bjerknes feedback (i.e. weakening of trade
winds and thermocline slope adjustments via oceanic equatorial Kelvin wave propagation; Keenlyside and Latif, 2007; Deppenmeier et al., 2016). They can also be excited by meridional advection of temperature anomalies (Richter et al., 2013), generated remotely as a response to ENSO (Latif and Grötzner, 2000; Tokinaga et al., 2019) or to variations in the South Atlantic subtropical high (Lübbecke et al., 2014), or occur as stochastic wind variability (Richter et al., 2014). In contrast to previous mechanisms involving coupled atmosphere-ocean dynamics, Bellomo et al. (2015) and Nnamchi et al. (2015) suggested that a large part of the SST variability in the eastern equatorial Atlantic can be explained by thermodynamic feedbacks excited by stochastic atmospheric perturbations. A recent study based on observational and reanalysis products by Nnamchi et al. (2021) indicates that the seasonality of AZM is indeed largely controlled by the variability of the atmospheric diabatic heating. However, the balance between thermodynamic and dynamic processes determining SST variability in the equatorial Atlantic is subtle, and other studies (e.g. Jouanno et al., 2017; Dippe et al., 2018) conclude that, even if the thermodynamic component is not negligible, the dynamics is the dominant driver of the AZM.

The AZM and AMM represent the first and second EOF patterns of the tropical Atlantic variability identified using SST anomalies in this region (Figure AIV.6a and Figure AIV.7a). These modes may also be defined using box averages, with the AZM defined as SST anomalies averaged over the equatorial Atlantic region called ATL3 (3ºS-3ºN, 0º-20ºW) and the AMM defined as the difference between the SST anomalies averaged over the tropical North Atlantic and tropical South Atlantic (i.e. 5ºN-30ºN, 20ºW-60ºW minus 5ºN-20ºS, 5ºE-25ºW). In boreal summer, the ATL3 and the EOF-AZM PC are correlated at 0.87 during 1958-2019 (Figure AIV.6b). The correlation between the AMM-box index and the EOF-AMM PC is lower, i.e. 0.39 (Figure AIV.7b), but increases to 0.67 over 1900-2019.

For the AMM, the latitudinal polarity in SST anomalies is associated with wind gradient and flow from the cooler to the warmer hemisphere (Ruiz-Barradas et al., 2000; Chiang and Vimont, 2004; Lübbecke et al., 2018; Foltz et al., 2019; Figure AIV.7c). For the AZM, similarly to ENSO in the Pacific Ocean, anomalous westerlies lead to low-level convergence over warmer SST along the climatological cold tongue (Figure AIV.6c).

The temporal evolution of the Atlantic modes of variability and their model representation are assessed in Sections 2.4.4 and Section 3.7.5, respectively. Their near-term and long-term evolution is assessed in Sections 4.4.3.4 and 4.5.3.4, respectively.

AIV.2.5.2 Teleconnections and regional influence

The tropical Atlantic variability has robust teleconnections with climate variability across the global tropics and beyond. There is evidence for two-way teleconnections between the tropical Atlantic and Pacific on interannual to decadal timescales such that the tropical Atlantic variability responds and feeds back to the Pacific ENSO (Section AIV.2.3) and Pacific Decadal Variability (Section AIV.2.6). A number of studies suggest the existence of a possible connection between the tropical North Atlantic and tropical Pacific variability (Wu et al., 2007; Ham et al., 2013a, 2013b; Wang et al., 2017b) at interannual timescales. This teleconnection appears to be modulated at decadal timescale by the AMV phases (Wang et al., 2017b) and it is also affected by global warming (Dong and Zhou, 2014).

The AZM-related boreal summer variability is linked with ENSO in the following boreal winter (Polo et al., 2007; Rodriguez-Fonseca et al., 2009; Ding et al., 2012; Keenlyside et al., 2013; Martin - Rey et al., 2015; Cai et al., 2019). This relationship is strongest during negative AMV phases due to enhanced equatorial Atlantic variability (Martin-Rey et al., 2014; 2018; Polo et al., 2015). On the other hand, the persistence of SST anomalies during multi-year ENSO events affects the equatorial Atlantic variability through modifications of the Walker circulation (Tokinaga et al., 2019). An exhaustive analysis of the AZM characteristics and related teleconnections is given by Lübbecke et al. (2018b) and by Cabos et al. (2019).

The AZM affects the Indian summer monsoon (ISM), altering the ENSO-ISM connection (Kucharski et al., 2007, 2008; 2007; Rodriguez-Fonseca et al., 2009; Ding et al., 2012; Keenlyside et al., 2013; Martin - Rey et al., 2015; Cai et al., 2019). This relationship is strongest during negative AMV phases due to enhanced equatorial Atlantic variability (Martin-Rey et al., 2014; 2018; Polo et al., 2015). On the other hand, the persistence of SST anomalies during multi-year ENSO events affects the equatorial Atlantic variability through modifications of the Walker circulation (Tokinaga et al., 2019). An exhaustive analysis of the AZM characteristics and related teleconnections is given by Lübbecke et al. (2018b) and by Cabos et al. (2019).

On the western side of the basin, a warm equatorial Atlantic delays the northward migration of the ITCZ and can thus influence rainfall over northeastern South America (Nobre and Srukla, 1996), even before the peak of the AZM (Losada et al., 2010; Mohino et al., 2011; Martin-Rey et al., 2018). When the Atlantic and Pacific basins act together, the response over northeastern South America is found to be strongly enhanced (Torralba et al., 2015). In the extratropics, the decaying phase of the AZM in boreal fall can modify the atmospheric circulation over Europe via a circum-global teleconnection pattern (Haarsma and Hazeleger, 2007; García-Serrano et al., 2011), and can remotely affect the NAO (Drévillon et al., 2003; Peng et al., 2005). AZM can also increase precipitation over southern Europe and the Mediterranean Sea during boreal summer through extra-tropical Rossby waves (Losada et al., 2012).
The fluctuation of the meridional SST gradient in the tropical Atlantic modulates the seasonal march of the ITCZ, thus influencing regional rainfall over northeast Brazil and Sahel (Hastenrath and Heller, 1977; Folland et al., 1986; Foltz et al., 2012). During a negative phase of the AMM, northerly wind anomalies are associated with a southward shift of the ITCZ (Cabos et al., 2019). During boreal spring, warmer SST over the tropical North Atlantic modulate winds over the western Indian Ocean and may strengthen the monsoon circulation over India, affecting the continental rainfall (Vittal et al., 2020). The AMM is also well known to affect the Atlantic hurricane activity (Vimont and Kossin, 2007; Patricola et al., 2014) and tropical cyclones over the western North Pacific (Zhang et al., 2017).

**AIV.2.5.3 Available proxy-based reconstruction**

Only a few paleo-reconstructions of AMM and AZM are available. Interhemispheric cross-equatorial SST gradients linked to changes in ITCZ locations characteristic of the AMM has been found during LGM, Heinrich Stadial 1 and the mid-Holocene (McGee et al., 2014). Similarly, the dipole-like SST pattern in the South Atlantic subtropics, which is related to the AZM (Lübbecke et al., 2018; Foltz et al., 2019), has been reconstructed with SST proxies from marine sediment cores during the past 12 kyr (Wainer et al., 2014).

Evidence from proxies associated with the AZM and AMM is assessed in Section 2.4.4.

**AIV.2.6 Pacific Decadal Variability**

**AIV.2.6.1 Definition of the mode**

The Pacific Decadal Variability (PDV) describes the large-scale fluctuations typically observed beyond ENSO timescales in a variety of instrumental records and proxy reconstructions over the entire Pacific Ocean and surrounding continents.

Historically, climate variability of the Pacific Ocean on timescales longer than 8-10 years has been described in terms of statistical modes, usually assessed through the decomposition into EOFs of the SST over oceanic sub-basins. The leading EOF mode of SST decadal variability in the extratropical North Pacific is called the Pacific Decadal Oscillation (PDO, Mantua et al., 1997; Mantua and Hare, 2002). The PDO is recognized to correspond to a collection of multiple processes (Newman et al., 2016). On interannual-to-decadal timescales, the PDO is thought to be driven by atmospheric forcing linked to stochastic changes in the Aleutian Low integrated by ocean mixed layer dynamics and related re-emergence processes, as well as to ENSO-forced teleconnections (Schneider and Cornuelle, 2005; Nidheesh et al., 2017). On decadal-to-interdecadal timescales, subpolar-subtropical gyre dynamics and related zonal advection of temperature anomalies in the Kuroshio-Oyashio extension and westward-propagating oceanic Rossby waves are thought to be key mechanisms (Qiu et al., 2007; Taguchi et al., 2007; Wills et al., 2019).

The PDO's South Pacific counterpart, called the South Pacific Decadal Oscillation (SPDO; Chen and Wallace 2015) is defined as the leading EOF mode of SST in the extratropical South Pacific. As for the PDO, the SPDO is thought to be driven by internal climate variability associated with extratropical atmospheric modes (e.g. SAM, Section AIV.2.2), ENSO teleconnections (Section AIV.2.3) and ocean dynamics through gyre circulation (Shakun and Shaman, 2009; Zhang et al., 2018).

In the tropical Pacific, while ENSO has a clear interannual spectral peak, decadal variability is also present with a similar spatial structure (Zhang et al., 1997), called tropical Pacific Decadal Variability (TPDV) or decadal ENSO. Relative occurrence of El Niño and La Niña events in a given decade correlates with the phase of the TPDV (Power and Colman, 2006).

Despite the PDO, SPDO and TPDV being considered to be physically distinct modes (Newman et al., 2016), they are highly correlated in observations (Chen and Wallace 2015) and they collectively constitute an equatorially symmetric pattern of basin-wide variability, often called the Interdecadal Pacific Oscillation.
(IPO) (Power et al., 1999; Folland et al., 2002; Henley et al., 2015). There is evidence that ENSO and the TPDO drive the PDO and SPDO in the North and South Pacific through tropical-extratropical teleconnections and the “reddening” (i.e. selective retainment of decadal and longer variability) in the ocean, ensuring the synchronization of decadal variability in both hemispheres (Newman et al., 2016). Besides, positive feedbacks are suggested between the TPDO and the extratropical North Pacific through the Pacific Meridional Mode (Stuecker, 2018), which is the Pacific analogue of the AMM (Section AIV.2.5; Chiang and Vimont, 2004), and modulations of the shallow subtropical cell of the Pacific ocean circulation (Farneti et al., 2014).

Whether the IPO is a distinct mode of climate variability (Henley et al., 2017) or not (Tung et al., 2019) remains to be further assessed and clarified. However, since the PDO, SPDO, TPDO and IPO modes are highly correlated both spatially and temporally, they can be referred collectively as the Pacific Decadal Variability mode (PDV; Henley 2017b; Liu and Di Lorenzo 2018), similarly to the Atlantic (Section AIV.2.7). Besides, it is noteworthy that none of these modes are actually oscillations with clear spectral peaks in the instrumental period (Mann et al., 2020), which advocates for the use of the PDV acronym across the report.

De facto, there is no unique way to assess the PDV. It can be extracted from the IPO, defined as the leading EOF mode of decadal low-pass filtered SST variability over the entire Pacific to remove the overwhelming influence of ENSO at interannual timescales. Henley et al. (2015) introduced the tripole index (TPI) as the difference of SST anomalies between an equatorial Pacific domain (10°S-10°N, 170°E-90°W) and an average of midlatitude North (25°N-45°N, 140°E-145°W) and South (50°-15°S, 150°E-160°W) Pacific domains (Figure AIV.8a). Section 2.4.5 describes the changes in the PDV phases over the instrumental record using a variety of SST products.

A positive phase of the PDV is characterized by warm conditions in the central-eastern tropical Pacific from the dateline to the coasts of the Americas, encircled to the west in the midlatitudes by negative SST anomalies forming a so-called horseshoe pattern. The pattern has a certain similarity with ENSO and related anomaloust SST fingerprints through atmospheric teleconnections. However, the PDV features meridionally broader SST anomalies in the tropical Pacific extending to the subtropics compared to ENSO, and relatively stronger extratropical SST anomalies. Alternatively, the low-pass filtered SST regression on the PDO index defined as the leading principal component of SST (Mantua et al., 1997) or sea surface height (Di Lorenzo et al., 2008) over the extratropical North Pacific north of 20°N are used in literature for PDV. Their corresponding spatial patterns are, by definition, weighted to the respective hemisphere of the Pacific. Figure AIV.8b provides evidence that they are all highly correlated to each other. The correlation value between TPI and the PDO index is equal to 0.76, and when low-pass filtered, it is greater than 0.9 for all the combination of indices.

In the following, and in Section 3.7.6 evaluating the model performance in reproducing PDV and assessing the human influence on the mode evolution, the TPI index is preferred. The latter definition is found to be less sensitive than classical EOF analysis to the possible interplay between internal processes that intrinsically drive the PDV (Wills et al., 2018) and the externally-forced SST response simulated in historical simulations. There is no unique way to remove the impact of the external forcing in the observations at decadal to multidecadal timescales, and the chosen method may have significant implications for the interpretation of the PDV expression during the instrumental era.

Since AR5, there has been considerable progress in the understanding of PDV itself but also in its critical role in modulating the evolution of observed global surface temperature (Cross-Chapter Box 3.1) as well as regional climate through teleconnections. On interannual time scales, ENSO is the leading internal driver of global surface temperature variability (Section AIV.2.3). Since PDV encompasses decadal modulations of El Niño versus La Niña occurrences, PDV affects global surface temperature on decadal timescales, with its positive and negative phases tied to higher and lower global surface temperature, respectively. Indeed, studies identify PDV as the leading mode of variability associated with unforced decadal global surface temperature fluctuations in observations and a majority of CMIP5 models (Brown et al., 2015; Dai et al., 2015), with additional influence from Atlantic Multidecadal Variability (AMV, Section AIV.2.7) (Tung and Zhou, 2019).
2013). PDV thus plays an important role in decadal acceleration and slowdown of global surface temperature trends (Cross-Chapter Box 3.1). So far, little predictability has been found for decadal PDV, despite its global relevance and decadal prediction in the Pacific remains challenging with the current decadal forecast system (Section 4.4.3.5). Finally, there is an increasing body of evidence about the existence of a network of teleconnections related to decadal climate variability phenomena (Cassou et al., 2018; Cai et al., 2019). For instance, AMV has been hypothesized to influence part of the phase of the PDV (McGregor et al., 2014; Ruprich-Robert et al., 2017) and consistently, there is a significant negative correlation between PDV and AMV. Other studies suggest that the PDV may be the main driver of the decadal IOB and IOD modes (Section AIV.2.4), while influence from the Indian Ocean SST on PDV has also been suggested (Luo et al., 2012; Mochizuki et al., 2016).

The temporal evolution of PDV in the instrumental records and its model representation are assessed in Sections 2.4.5 and 3.7.6, respectively. Skill in predicting near-term temporal evolution of the PDV and mid- to long term PDV changes are assessed in Sections 4.4.3.5 and 4.5.3.5, respectively.

**[START FIGURE AIV.8 HERE]**

**Figure AIV.8:** The PDV based on TPI for 1900-2014 after 10-year low-pass filtering. (a) SST anomalies regressed onto TPI based on ERSSTv5. The cyan boxes indicate regions for the TPI definition. (b) Temporal evolution of the raw TPI (bars), the 10-year low-pass filtered TPI (cyan curve), the EOF-based PDO index (dashed black) and two estimations of the IPO EOF-based indices. In solid black, linear detrending is applied to annual data prior to the computation of the EOF of the low-pass filtered SST to remove the forced component in the SST field. In orange, the forced signal is estimated from CMIP5 historical simulations following Ting et al. (2009). The latter metric is used in CMIP6 DCPP-C sensitivity experiments (Boer et al. 2016). The correlation between the low-pass filtered TPI and all PDV indices is given in the legend. (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth for 1900-2014) and 10-m level wind (arrows; based on JRA-55 for 1958-2014) anomalies. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1900-2014). All are based on annual mean. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance.

**[END FIGURE AIV.8 HERE]**

**AIV.2.6.2 Teleconnections and regional influence**

Due to the similarity of the SST anomaly pattern with ENSO in the tropical Pacific, atmospheric teleconnections associated with the PDV are rather similar to those of ENSO but with a longer temporal expression. This includes the long-term alteration of the Walker circulation, the modification of the extratropical background driven by tropically-forced Rossby waves then favouring particular phases of the Pacific-North American (PNA) and Pacific-South American (PSA) patterns of atmospheric internal variability that are responsible for persistent influences over the continents (e.g. persistent drought over California and Australia, etc.). Those atmospheric patterns imprint a PDO-like and SPDO-like SST patterns with a reddening by the extratropical oceans, forming the pan-Pacific SST anomaly pattern of the PDV as described above (Newman et al., 2016; Henley, 2017; Liu and Di Lorenzo, 2018).

A positive phase of the PDV brings anomalously warm conditions in the northwestern corner of North America, with maximum loading over Alaska linked to reinforced and eastward displaced Aleutian Low and related anomalous southerlies (Figure AIV.8c). In contrast, concurrent cold conditions dominate far-eastern Siberia due to strengthened advection of Arctic air. The tail end of the storm track is strengthened leading to more precipitation along the Pacific coast of North America, especially in boreal winter. A positive PDV also induces a cooler and wetter climate in the southern part of the North American continent, with the wet anomalies being the most pronounced in boreal summer (Figure AIV.8d). The negative phase of the PDV is an important cause of droughts in the western and central United States (Dai, 2013). Besides the direct
influence of atmospheric teleconnections from the tropical branch of the mode, extratropical SST anomalies have been shown to modulate the amplitude of the precipitation anomalies in North America (Burgman and Jang, 2015).

In the tropics, a positive PDV is associated with warm and dry anomalies in the Maritime Continent and Amazon (Meehl and Teng, 2014; Figure AIV.8c,d). The Indian and African monsoons also tend to weaken (Meehl and Hu, 2006; Figure AIV.8d). Warm and dry anomalies also cover most of Australia while wet anomalies dominate in South America south of 15°S. In particular, a positive PDV increases drought risk in Australia (Power et al., 1999; Vance et al., 2015). In the oceans, a positive PDV increases the occurrence of marine heat waves in the Bering Sea and subtropical Eastern Pacific, while a negative PDV increases ocean heat waves in the Kuroshio-Oyashio extension, Melanesia and over the tropical Indian Ocean (Holbrook et al., 2019). PDV also modulates tropical cyclone activity: a positive PDV increases tropical cyclone genesis over the Philippine Sea and the tropical eastern North Pacific and decreases it over the tropical North Atlantic and western South Pacific (Grant and Walsh, 2001; Liu and Chan, 2008; Li et al., 2015; Zhao et al., 2018, 2020). PDV, together with ENSO, have been shown to control part of the interannual to multidecadal wildfire variability, PDV-related persisting droughts and severe heatwave acting as preconditioning in many regions (see for instance Kitzberger et al., 2007; Ward et al., 2016).

Implications of PDV on water cycle changes are further assessed in Sections 8.3.2.4 and 8.4.2.4. Section 10.4 highlights the importance of PDV in regional climate change attribution, with an example in Section 10.6. Influence of PDV climate anomalies in specific regions, including extremes, are assessed in Sections 11.3, 11.4, 11.6, 11.7, Atlas.4, Atlas.5, Atlas.7 and Cross-Chapter Box Atlas.2. Its implications for ocean circulation and sea levels are assessed in Sections 9.2 and 9.6.

AIV.2.6.3 Available proxy-based reconstruction

PDV reconstructions have been developed with tree rings in North America and Asia (Biondi et al., 2001; D’Arrigo et al., 2001; Gedalof and Smith, 2001; MacDonald and Case, 2005; D’Arrigo and Wilson, 2006; D’Arrigo and Ummenhofer, 2015; Buckley et al., 2019), corals in the Pacific (Linsley et al., 2015; Williams et al., 2017) and Indian Ocean (Crüger et al., 2009), historical documents in China (Shen et al., 2006), ice cores (Vance et al., 2015), and multiproxy approaches (Verdon and Franks, 2006; Mann et al., 2009; McGregor et al., 2010) covering the past several centuries up to a millennium. Comparing 12 of these reconstructions, it has been found that respective correlations are generally low (Henley, 2017b), indicating large uncertainty in the PDV temporal history before instrumental records. On longer timescales, a variety of proxies consistently capture the variations of the Aleutian Low intensity throughout the Holocene, which can be used to reconstruct the PDV (see Section 2.4.5).

AIV.2.7 Atlantic Multidecadal Variability

AIV.2.7.1 Definition of the mode

The Atlantic Multidecadal Variability (AMV) describes the large-scale slow fluctuations observed from one decade to the next in a variety of instrumental records and proxy reconstructions over the entire North Atlantic Ocean and surrounding continents. Fingerprints of the AMV can be found at the surface ocean, which is characterized by swings in basin-scale SST anomalies reflecting the interaction with the atmosphere, with a nominal period in the order of 70 years (Deser et al., 2010). AMV markers can be also tracked at the subsurface ocean in terms of heat content and density anomalies. The latter have been traditionally linked to the low-frequency fluctuations in the Atlantic Meridional Overturning Circulation (AMOC) and related oceanic meridional heat/salinity transport and water masses formation through deep convection in the Subarctic Seas (Zhang, 2017).

The positive phase of the AMV is characterized by anomalous warming over the entire North Atlantic, with the strongest amplitude in the subpolar gyre and along sea-ice margin zones in the Labrador Sea and...
Greenland/Barents Sea (approximately +0.5°C) and in the subtropical North Atlantic basin to a lower extent (Figure AIV.9a). Concurrent, albeit weaker, anomalous cooling is found over the South Atlantic but also along the Pacific cold tongue sandwiched by warmer SST, a pattern reminiscent of the PDV (Section AIV.2.6). What stands out is the apparent inter-basin connectivity in AMV related SST anomalies, which is strongly indicative of the existence of a network of teleconnections linking neighbouring ocean basins, the tropics and the extra tropics, including Northern Hemisphere polar regions, and the oceans and land regions (Cassou et al., 2018). The AMV, together with the PDV, has been shown to modulate the observed time-evolving global surface temperature on multidecadal timescales since pre-industrial time (Cross-Chapter Box 3.1), whilst the level of their respective influence remains difficult to quantify because of their inter-connectivity (Tung and Zhou, 2013; Wu et al., 2019; Li et al., 2020).

The term “Atlantic Multidecadal Oscillation” (AMO) has been introduced in the literature (Kerr, 2000) and used in previous IPCC reports to describe this phenomenon and in particular to make the distinction with the so-called North Atlantic tripole pattern connected to the NAO (Section AIV.2.1) at interannual timescales (Enfield et al., 2001). However, since the observed slow variations of the North Atlantic SSTs consist of a broad band of low-frequency signals (Zhang, 2017; Sutton et al., 2018) rather than a single preferred timescale, as also confirmed from last-millennium reconstructions (e.g., Singh et al., 2018), the denomination “Atlantic Multidecadal Variability” wherein a distinct oscillatory timescale is less clearly implied, appears more appropriate to describe decadal climate variability phenomena as also suggested for the Pacific (Section AIV.2.6). The term AMV will be accordingly used subsequently and throughout the entire report.

The observed AMV is interpreted as the regional residual imprint in SST anomalies after removal of the externally-forced signal. There is no unique and preferred way to remove the impact of external forcing in observations. Linear detrending is used in the traditional definition of the AMV index, which corresponds to the average over the entire North Atlantic basin of the linearly detrended SST yearly anomalies on which a 10-year running mean is applied, as proposed by Enfield et al. (2001). To remove the residual nonlinear global-scale signal from the North Atlantic mean SST, different approaches have been proposed either based on observations applying specific statistics (e.g., Trenberth and Shea, 2006; Frajka-Williams et al., 2017; Frankignoul et al., 2017; Sutton et al., 2018; Yan et al., 2019) or based on model estimates of the externally-forced signal including both natural (solar and volcanoes) and anthropogenic (greenhouse gases and aerosols) influence assessed from historical simulations (Ting et al., 2009; Terray, 2012; Steinman et al., 2015; Tandon and Kushner, 2015). More specifically, in Trenberth and Shea (2006), the annual observed global-mean SST anomaly timeseries is subtracted from the observed annual North Atlantic spatially averaged timeseries to obtain the raw unfiltered AMV index. In Ting et al. (2009), a signal-to-noise maximizing EOF analysis is applied to global annual mean SSTs derived from the CMIP5 multi-model ensemble to extract an estimation of the forced component, which is a priori removed before computation of the AMV index, then defined as a low-frequency residual. The latter technique has been retained in the so-called CMIP6 DCPP-C sensitivity experiments (Boer et al., 2016) aimed at furthering a better understanding of the teleconnections associated with the AMV. The two latter indices are shown in Figure AIV.9b and compared to the traditional AMV index.

All AMV timeseries consistently show a few distinct phases over the approximately 120-year instrumental record, namely warm periods over 1930-1965 and since 1995, and cool periods between 1900 and 1925 and over 1965-1995 (Figure AIV.9b). The uncertainty introduced by the different definitions of the index is mainly related to the strength of the phase of the AMV and in particular the most recent ones, which are the most sensitive to the estimation of the externally-forced signal.

The temporal evolution of AMV in the instrumental records is assessed in Section 2.4.6. The transition between phases has been shown to involve various atmospheric and oceanic processes, leading to some predictability, but also influences from external forcing (both anthropogenic and natural), whose respective weight and interplay remain outstanding issues, as assessed in detail in Section 3.7.7 and Section 9.2.3.
[START FIGURE AIV.9 HERE]

**Figure AIV.9:** The AMV based on the AMV index defined from Trenberth and Shea (2006) for 1900-2014 after 10-year low-pass filtering. The index corresponds to the annual SST averaged over the North Atlantic domain (cyan box) minus near-global average [60°N-60°S]. (a) SST anomalies regressed onto the AMV index based on ERSSTv5. (b) The cyan curve indicates the 10-year low-pass filtered AMV index shown in bars. The orange curve stands for the AMV index used for the CMIP6 DCPP-C sensitivity experiments (Boer et al. 2016). (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth for 1900-2014) and 10-m level wind (arrows; based on JRA-55 for 1958-2014) anomalies. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1900-2014). All is based on annual mean. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance.

### AIV.2.7.2 Teleconnections and regional influence

The important role of the AMV in observed low-frequency climate signals at a regional scale has been recognized for decades. The AMV is a key driver of temperature and precipitation anomalies along the North Atlantic surrounding continents but also remotely through global atmospheric teleconnections (e.g. monsoons). Considering AMV-induced regional influence is crucial because the AMV acts as a pronounced modulator of the impacts driven by external natural and anthropogenic forcings. For instance, the AMV can have a pronounced fingerprint in time-integrating processes, such as river flows, and could explain the largest fraction of observed variance in some specific local areas since the 1900s (e.g. Bonnet et al., 2020). It is thus a key phenomenon for regional-scale or process-based attribution of past observed climate variations as introduced in Cross-Chapter Box 1.4 and extensively developed in Section 10.4.1.

Positive AMV is associated with much warmer conditions over the north-western corner of the Atlantic, with marked positive anomalies on land around the Labrador Sea (Figure AIV.9c). There is a strong seasonality in the AMV teleconnection and this pattern is mostly explained by boreal winter atmospheric dynamics and a local reduction of sea-ice formation. There is a large-scale decrease of the wintertime midlatitude westerlies and, concurrently, a weakening of the trade winds in the North Atlantic tropical basin, which is reminiscent of a negative phase of the NAO (Peings and Magnusdottir, 2014; Gastineau and Frankignoul, 2015). Over Europe, AMV-related signals are weak on yearly average (Figure AIV.9c) but mask a pronounced seasonality of the teleconnection as well as some interplay between dynamical (i.e. atmospheric circulation) versus thermodynamical changes controlled by the AMV (O’Reilly et al., 2017; Ruprich-Robert et al., 2017, Qasmi et al. 2020). Summer tends to be warmer during positive AMV in Europe (Sutton and Dong, 2012; Nicoli et al., 2020) with constructive contribution of both dynamical and thermodynamical responses while destructive interference prevails in boreal winter leading to colder conditions with a reinforced occurrence of blocking (Rihibu et al., 2014; Davini et al., 2015) and a southward shift of the jet (Simpson et al., 2018). Anomalies are positive all year round over a broad Mediterranean region, including North Africa and the Middle East. Reduction of Arctic Sea Ice is also found during positive AMV with local warming extension over the adjacent polar land (Day et al., 2012; Yu et al., 2017; Castruccio et al., 2018).

In terms of precipitation (Figure AIV.9d), positive AMV is associated with a northward shift of the Atlantic ITCZ in response to changes in the meridional SST gradient with respect to the equator (Martin and Thorncroft, 2014; Friedman et al., 2017; Green et al., 2017). The AMV influence is the strongest in the boreal summer affecting the West African Monsoon, leading to reinforced Sahel rainfall, and wetter conditions in the Caribbean basin through the modulation of the occurrence of hurricanes (Dunstone et al., 2011; Hermanson et al., 2014). By contrast, dry conditions prevail in the Northeast Brazil and in the south-eastern corner of South America as well as in the Great Plains in North America. The signal of the positive AMV lead to an intensified precipitation and river runoff over Northern Eurasia (Nicoli et al., 2020) and controls the multidecadal variations in river flows over much of Europe (Boé and Habets, 2014; Hodgkins et al., 2017). Because of global teleconnections, especially in the tropics, the AMV also affects the other
monsoon systems with signals found over India, South East Asia, and the Maritime Continent and, more broadly, over the entire tropical Pacific (Chylek et al., 2014; Kucharski et al., 2016; Ruprich-Robert et al., 2017).

The weight of the AMV in observed low-frequency variations is assessed in detail in Section 10.4.2 for specific regional case studies, including the sectors listed above. Because of its long timescale due to persistent heat content anomalies, the AMV can be considered as a potential source of near-term climate predictability. Skill of the current decadal forecast systems in predicting the AMV temporal evolution and associated teleconnection at various lead time is assessed in Section 4.4.3.6, while long-term changes are assessed in Section 4.5.3.6.

**AIV.2.7.3 Available proxy-based reconstruction**

Paleoclimate reconstructions of AMV-related signals have been developed using terrestrial, marine and ice-core proxies. The AMV reconstruction in the last 1200 years by Wang et al. (2017a), using terrestrial proxy records, shows a clear broad band of enhanced spectral power at multidecadal timescales but no evidence of a distinct multidecadal or centennial spectral peak (Singh et al., 2018). This is largely consistent with the record of the instrumental period and with previous proxy-based studies (Gray et al., 2004; Mann et al., 2009) in the overlapping periods. Studies focusing on marine proxies also show persistent multidecadal variability over the last three centuries (Kilbourne et al., 2014; Svendsen et al., 2014; Moore et al., 2017).

Multidecadal Arctic temperature variability related to the AMV is also evident in ice core records over the last millennium (Chylek et al., 2011; Zhou et al., 2016) and beyond (Knudsen et al., 2011). High resolution sedimentary records from the Arctic were recently analyzed to reconstruct the AMV over the last 2900 years (Lapointe et al., 2020). However, this new reconstruction refers to the raw North Atlantic SST variability rather than to the residual of the Atlantic signal obtained after removal of the estimation of the external forcing influence. A multi-perspective assessment of the North Atlantic variability is thus necessary for understanding the origin of the AMV, its physics and its climatic implications over the paleoclimatic period.

The temporal evolution of the AMV is described and assessed in detail in Section 2.4.6.

**AIV.2.8 Madden-Julian Oscillation**

**AIV.2.8.1 Definition of the mode**

The Madden-Julian Oscillation (MJO) is the leading mode of tropical intra-seasonal variability with 20–90 days’ timescale (Madden and Julian, 1994) and an important source of regional climate variability and predictability across the globe at subseasonal timescales from a week to months (Madden and Julian, 1994; Zhang, 2005; Vitart, 2017; Wheeler et al., 2017; Kim et al., 2018). It is characterized by planetary-scale disturbances (zonal wavenumber 1–3) of pressure, wind, clouds and rainfall moving predominantly eastward along the equator at average speed of 5 m s\(^{-1}\) (Roxy et al., 2019). More precisely, the MJO is characterized by alternating regions of suppressed and enhanced convection coupled to an anomalous zonal overturning circulation of the atmosphere (Zhang, 2005). The MJO is driven by internal ocean-atmosphere processes that occur all year round but exhibits prominent seasonality with more pronounced signals in boreal winter.

During boreal summer, centres of convective activity associated with the MJO are shifted away from the equator to 10\(^\circ\)N–20\(^\circ\)N and propagate northward in the Asian monsoon region (Yasunari, 1980; Madden, 1986) in addition to eastward propagation, often called as the boreal summer intra-seasonal oscillation (BSISO; Madden, 1986; Kikuchi et al., 2012). Whereas the MJO is considered present in all seasons, albeit with weaker amplitude in boreal summer, the BSISO tends to prevail during boreal summer, with influences on monsoons, tropical cyclones and other water cycle aspects (Kikuchi et al., 2012; Lee et al., 2013).

The real-time multivariate MJO (RMM) index has been widely used to detect the MJO, based on the first two combined EOF modes of daily outgoing longwave radiation (OLR) and zonal winds at 850 and 200 hPa averaged over 15\(^\circ\)N-15\(^\circ\)S (Wheeler and Hendon, 2004). The OLR represents convective activity and zonal...
winds at the lower and upper troposphere depict the overturning zonal circulation along the equator. The composite maps of convective activity and atmospheric circulation (Figure AIV.10a) and the phase diagram (Figure AIV.10b) based on eight phases constructed by the two PCs timeseries provide effective ways to understand and monitor spatial and temporal evolution of the MJO event. In general, the MJO disturbance are initiated in the equatorial western Indian Ocean and travel eastward mainly over the Indo-Pacific warm pool region. However dynamical fields in composite maps indicate that the MJO also propagates over climatological non-convective regions (e.g., the eastern Pacific, part of the tropical Atlantic) (Figure AIV.10a), then manifesting the planetary nature of the tropical intra-seasonal oscillation (Cassou, 2008). Each phase has a nominal persistence of about 7-8 days and the anti-clockwise rotation in this 2-dimensional diagram materializes the propagation of the MJO packets from west to east. Figure AIV.10b provides an example of that RMM index computed for the year 1997, with months highlighted in colours. When the value of the index lies in the centre of the diagram, the MJO is considered to be inactive; outside the circle, its distance from the centre quantifies the amplitude and spatial coherence of the MJO episode.

The evaluation of the MJO in climate models is done through phenomenological (Waliser et al., 2009) and process-oriented (Xavier, 2012) diagnostics. MJO simulation remains a challenge in both CMIP3 and CMIP5 models, even though overall improvements have been reported in the most recent model versions (Waliser et al., 2003; Lin et al., 2006; Sperber and Annamalai, 2008; Kim et al., 2009; Xavier et al., 2010; Jiang et al., 2016). Poor MJO simulation in coupled climate models has been attributed to many factors, including an insufficient build-up of atmospheric moisture for large-scale organized convection to occur (Kim et al., 2012; Mizuta et al., 2012), biases in models mean state (Inness et al., 2003; Hahnah et al., 2015; Kim, 2017), coupling frequency with the ocean and representation of air-sea interactions (Bernie et al., 2008; DeMott et al., 2015). In CMIP5 simulations, the eastward propagation of boreal winter MJO convection from the Indian Ocean into the western Pacific (Hung et al., 2013) and the northward propagation during boreal summer (Sperber et al., 2013) are slightly better represented, even if major biases persist and still affect the monsoon systems. These improvements have been attributed to advances in parametrizing moist turbulence and convection (Hohenegger and Bretherton, 2011; Mapes and Neale, 2011; Del Genio et al., 2012; Kim et al., 2012; Hourdin et al., 2013), leading to greater MJO predictive skill of up to four weeks in operational subseasonal prediction centres (Vitart, 2014). Super-parametrized models (Benedict and Randall, 2009), global cloud system-resolving models (Miyakawa et al., 2014) and high-resolution global climate models with an improved seasonal cycle (Mizuta et al., 2012) have been shown to produce a more realistic simulation of the MJO. Progresses in the representation of the MJO across model generations are assessed in Section 1.5.4.6 and Section 8.3.2.9.1.

The assessment of changes in the MJO and related processes, mostly in terms of its implication for water cycle changes in the recent past and in future projections is provided in Sections 8.3.2.9 and 8.4.2.9, respectively. The MJO influence over south East Asia and Central and South America is further assessed in Sections Atlas.4, Atlas.5, Atlas.7. and Cross-Chapter Box Atlas.2.

[START FIGURE AIV.10 HERE]

**Figure AIV.10:** (a) The spatio-temporal properties of the MJO. Daily composites of Outgoing Longwave Radiation (OLR, W m$^{-2}$, shaded) anomalies and streamfunction anomalies at 300 hPa (STF, contours every 0.5 10$^{-4}$ m$^{2}$ s$^{-1}$) for the 8 MJO phases in boreal winter (1$^{st}$ Dec. to 31$^{st}$ March) based on NOAA interpolated satellite products and NCEP-NCAR reanalyses over 1979-2019, respectively. Greenish (brownish) colours indicate enhanced (reduced) convective activity associated with wet (dry) conditions. Solid (dashed) contours show for positive (negative) STF anomalies which stand for anomalous anticyclonic circulation in the Northern (Southern) Hemisphere. (b) Phase diagram of the MJO constructed from the two leading principal components drawn from empirical orthogonal decomposition of combined wind@300hPa+OLR fields following Wheeler and Hendon (2004) for the winter 2007-2008 chosen as an example of active MJO years. (c) Schematic representation of MJO-related tropical—Northern Hemisphere interactions and teleconnections inferred from observational and numerical studies (adapted from Stan et al. (2017)). Because the interactions and teleconnections of the Southern Hemisphere are not as well understood but SAM, they are not included in the current schematic.
AIV.2.8.2 Teleconnections and regional influence

In AR5, the MJO has been described as a tropical phenomenon, yet with prominent impacts across the globe through teleconnections. The MJO exerts a strong influence on occurrences of extreme weather events in the tropics, including tropical cyclones, droughts, flooding, heat waves, fires, among others (Zhang, 2013), as well as those in the extratropics via teleconnections (Stan et al., 2017). This has opened new opportunities and scientific endeavours in the emerging field of sub-seasonal to seasonal forecasts of extremes (Vitart and Robertson, 2018) and for the development of new observational networks needed to initialize the forecast systems (Subramanian et al., 2019). The MJO can also impact the atmospheric composition, such as ozone, CO, CO$_2$, and aerosols (Tian et al., 2007, 2011; Li et al., 2010b; Lau et al., 2012).

The schematic in Figure AIV.10c shows the main regions of influence of the MJO. During boreal winter, the MJO fingerprint is mostly confined to the deep tropics with a zonal alternation of wet and dry zones depending on the MJO phase. For instance, in phase 4, enhanced rainfall is found over the Maritime Continent while suppression of convection is present over the central Pacific, northeast Brazil and equatorial Africa (Figure AIV.10a). The opposite is found during phase 8. Anomalous upper-level divergence in the deep tropics associated with altered convection and diabatic heating leads to anomalous vorticity in the subtropics (shown by streamfunction dipoles straddling the equator in Figure AIV.10a) acting as an efficient and primary source of teleconnections outside the tropics (L’Heureux and Higgins, 2008; Lin et al., 2009; Lukens et al., 2017). The extratropical influence of the MJO may occur via the excitation of forced tropospheric Rossby waves (Ferranti et al., 1990; Matthews et al., 2004; Cassou, 2008; Stan et al., 2017) that affect the climate variability over the North Pacific (Ferranti et al., 1990; Higgins and Mo, 1997), the North Atlantic (Ferranti et al., 1990; Cassou, 2008) and the Arctic (Zhou and Miller, 2005). For example, tropical convective heating associated with MJO phase 5 contributes to Arctic warming, while the opposite occurs for the MJO phase 1 (Yoo et al., 2011, 2012). Phase 2-3 of the MJO is clearly associated with the prevalence of the positive phase of the NAO with a 10 to 15 days lag after the MJO forcing. Stratospheric pathways are also reported to support tropical-extratropical teleconnections though the modified occurrence of sudden stratospheric warming (Liu et al., 2014; Garfinkel and Schwartz, 2017) with a 15 to 20 days delay leading to sub-seasonal predictability.

During boreal summer, the MJO/BSISO convective activities and related impacts propagate northward/northeastward over the Indian Ocean-South Asia region (Yasunari, 1980; Annamalai and Sperber, 2005) and northward/northwestward over the western North Pacific-East Asia region (Kemball-Cook and Wang, 2001; Lee et al., 2013). The MJO/BSISO significantly modulate occurrences of extreme rainfall and heat waves over Asia (Hsu et al., 2016, 2017; Chen and Zhai, 2017; Diao et al., 2018) and North America (Moon et al., 2013; Lee and Grotjahn, 2019). They also regulate tropical cyclone activities in Indian (Frank and Roundy, 2006), Pacific (Maloney and Hartmann, 2000; Diamond and Renwick, 2015; Zhao et al., 2015) and Atlantic (Klotzbach and Oliver, 2015) tropical oceans. They contribute to the intra-seasonal fluctuations of monsoons, including timing of its onset and termination during summer (Maloney and Shaman, 2008; Wheeler et al., 2009; Lee et al., 2013; Grimm, 2019) and its active/break phases (Pohl and Camberlin, 2006; Maloney and Shaman, 2008; Joseph et al., 2009; Lee et al., 2017).

The Southern Annular Mode (SAM)

Figure AIV.2: The austral summertime SAM extracted as the leading EOF of December-January-February SLP anomalies over the Southern Hemisphere (south of 20°S, a) based on JRA-55 reanalysis over 1979-2019. (a) SLP anomalies regressed onto the leading principal component (PC) time series shown in (b); the variance explained is given in the legend in (b). The SAM-PC is represented by red and blue bars and the zonal-SAM index (latitude circles in a) is given in magenta. Correlation between the zonal SAM index and the SAM PC timeseries is given in the legend. (c, d) Regression maps of SST and SAT over land from ERSST and BerkeleyEarth dataset, respectively, over for 1979-2019 (d) and of precipitation anomalies (e, shading based on CMAP for 1979-2016 and contours based on GPCP for 1979-2019 for every 0.1 mm/day). On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior computation.
Figure AIV.3: The boreal wintertime ENSO mode defined by December-January-February SST anomalies averaged over the NINO34 region (5°S-5°N, 170°W-120°W, cyan box) or extracted as the leading EOF mode over the Tropical Pacific Ocean (the region denoted by the black box in a) for 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the NINO34 time series, which is shown in (b) as red and blue bars. Black curve in (b) represents the standardized leading principal component and the magenta curve stands for the SOI index. The percentage of explained variance of the leading EOF is given in the legend as well as the correlation between all indices and the NINO34 timeseries. (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth) and 10-m level wind (arrows; based on JRA-55) anomalies over 1958-2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for every 0.5 mm/day). Magenta dots in (c,d) stands for the Darwin and Tahiti weather station used for the SOI computation. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.
Figure AIV.4: The boreal springtime IOB mode defined by March-April-May SST anomalies averaged over the Indian Ocean (the region denoted by the cyan box in a) or extracted as the leading EOF mode over the same domain (black contour) for 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the IOB index timeseries shown in (b) in red and blue bars, while the black curve in (b) represents the leading principal component timeseries. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth) and 10-m level wind (arrows; based on JRA-55) anomalies for 1958-2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for every 0.3 mm/day). On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.
The Indian Ocean Dipole Mode (IOD)

The boreal autumn IOD mode defined by September-October-November standardized SST difference between the western (10°S-10°N, 50°E-70°E) and eastern (10°S-0°, 90°E-110°E) equatorial Indian Ocean denoted by cyan boxes in (a) or extracted as the leading EOF mode over the Indian Ocean (the region denoted by black contour in a) over 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the IOD index timeseries shown in (b) in red and blue bars while the black curve represents the leading principal component timeseries. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth) and 10-m level wind (arrows; based on JRA-55) anomalies for 1958-2018. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for every 0.3 mm/day. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.
Figure AIV.6: The boreal summertime AZM defined by June-July-August box-averaged SST anomalies over the ATL3 region (3°S-3°N, 0°-20°W, cyan box in a) or estimated as the leading EOF over the tropical Atlantic Ocean (the region denoted by the black box in a) for 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the ATL3 time series, which is shown in (b) as red and blue bars, while the black curve represents the leading principal component timeseries. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land SAT and 10-m level wind (arrows; based on JRA-55 for 1958-2019) anomalies. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1958-2016 and contours based on CMAP for 1979-2019 for every 0.2 mm/day). On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.
The Atlantic Meridional Mode (AMM)

a. SST spatial pattern for AMM in June-Aug (JJA)

Figure AIV.7: The boreal summertime AMM defined by June-July-August standardized SST difference between the north (5°N-30°N, 20°W-60°W) and south (5°N-20°S, 5°E-25°W) tropical Atlantic Ocean shown by the cyan boxes in (a) or estimated as the leading EOF over the tropical Atlantic Ocean (the region denoted by the black box in a) for 1958-2019 using ERSSTv5. (a) SST anomalies regressed onto the AMM time series, which is shown in (b) as red and blue bars, while the black curve represents the leading principal component timeseries. Explained variance and correlation between indices are given in the legend in (b). (c) Same as (a) but for land SAT and 10-m level wind (arrows; based on JRA-55 for 1958-2019) anomalies. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1979-2019 for every 0.2 mm/day). On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance. Significance for CMAP precipitation is materialized by red contours in (d). All fields have been linearly detrended prior to computation.
The Pacific Decadal Variability (PDV)

a. SST spatial pattern for PDV (annual mean)

Figure AIV.8: The PDV based on TPI for 1900-2014 after 10-year low-pass filtering. (a) SST anomalies regressed onto TPI based on ERSSTv5. The cyan boxes indicate regions for the TPI definition. (b) Temporal evolution of the raw TPI (bars), the 10-year low-pass filtered TPI (cyan curve), the EOF-based PDO index (dashed black) and two estimations of the IPO EOF-based indices. In solid black, linear detrending is applied to annual data prior to the computation of the EOF of the low-pass filtered SST to remove the forced component in the SST field. In orange, the forced signal is estimated from CMIP5 historical simulations following Ting et al. (2009). The latter metric is used in CMIP6 DCPP-C sensitivity experiments (Boer et al. 2016). The correlation between the low-pass filtered TPI and all PDV indices is given in the legend. (c) Same as (a) but for land SAT (shading; based on BerkeleyEarth for 1900-2014) and 10-m level wind (arrows; based on JRA-55 for 1958-2014) anomalies. (d) Same as (a) but for precipitation anomalies (shading based on GPCC for 1900-2014). All are based on annual mean. On maps, no-overlay indicates regions where the regressions are significant based on t-test accounting for false detection rate at 10% and crosses indicates no significance.
The Atlantic Multidecadal Variability (AMV)

AV.1 Introduction

A monsoon refers to a seasonal transition of regimes in atmospheric circulation and precipitation in response to the annual cycle of solar insolation and the distribution of moist static energy (Wang and Ding, 2008; Wang et al., 2014; Biasutti et al., 2018). A global monsoon can be objectively identified based on precipitation contrasts in the solstice seasons to encompass all monsoon regions (Wang and Ding, 2008). In AR5, regional monsoon domains were identified starting from the definition of the global monsoon tailored over the continents and adjacent oceans, as in Kitoh et al. (2013). This Annex contains the definition of the global monsoon as used in AR6 (Section AV.2), it explains the rationale for the different definition of AR6 regional monsoons compared to AR5 (Section AV.3) and provides the definition and basic characteristics of each regional monsoon assessed (Section AV.4).

AV.2 Definition of the global monsoon

The concept of global monsoon (GM) emerged during the second half of the 20th century, representing the leading empirical orthogonal function (EOF) mode of the annual variations of precipitation and circulation in the global tropics and subtropics as a forced response of the coupled climate system to the annual cycle of solar insolation (Wang and Ding, 2008; An et al., 2015; Wang et al., 2017). GM variability represents, to a large extent, changes in the ITCZ and associated Hadley circulation (Wang et al., 2014). Changes in GM have been attributed to both internal variability and external forcings, ranging from interannual to millennial and orbital time scales (Wang et al., 2014, 2017; An et al., 2015; Geen et al., 2020). In AR6, the global monsoon is defined as the area in which the annual range (local summer minus local winter) of precipitation is greater than 2.5 mm/day (Kitoh et al. et al., 2013), and the domain is represented by the black contour in Figure AV.1. Simulation of the global monsoon and its variability is the subject of coordinated modelling experiments in the Global Monsoon Model Intercomparison Project (GMMIP; Zhou et al., 2016). Past changes, simulation and attribution, and projections of the GM are assessed in Sections 2.3.1.4.2, 3.3.3.2 and 4.4.1.4, respectively.

[START Figure AV.1 HERE]

Figure AV.1: Global and regional monsoons domains. AR6 global monsoon area is represented by the black contour. AR6 regional monsoons are: North American monsoon (shaded magenta), South American monsoon (shaded dark-orange), West African monsoon (shaded grey), South and Southeast Asian monsoon (shaded pink), East Asian monsoon (shaded purple) and Australian-Maritime Continent monsoon (shaded yellow). Areas over Equatorial America and South Africa (dotted red and magenta, respectively) are highlighted but not identified as specific regional monsoons (see explanation in the main text). For each regional monsoon, the seasonal characteristics associated with each domain are specified in the main text.

[END Figure AV.1 HERE]

AV.3 Rationale for regional monsoons definitions in AR6

The definition of the regional monsoons has been slightly modified in AR6 with respect to AR5, starting from the consideration that some of the continental areas identified using the global metric have a seasonality in precipitation that is not necessarily of monsoon origin. In particular, the dotted regions in Figure AV.1 located over South Africa, Central America and equatorial South America have a strong seasonality in precipitation but their qualification as monsoons is a subject of discussion. In the assessment of the regional monsoons in Sections 8.3.2.4 and 8.4.2.4, these regions are not considered as distinct regional monsoons, but they are discussed in Box 8.2 that is dedicated to changes in water cycle seasonality. The domains of the regional monsoons in AR6 are defined based on published literature and expert judgement, and accounting Do Not Cite, Quote or Distribute
for the fact that the climatological summer monsoon rainy season varies across the individual monsoon regions. As shown in Figure AV.1, AR6 regional monsoons are: South and Southeast Asian (Section AV.4.1), East Asian (Section AV.4.2), West African (Section AV.4.3), North American (Section AV.4.4), South American (Section AV.4.5) and Australian-Maritime Continent (Section AV.4.6). For each region the definition, regional justification and key features are provided, along with cross references to the main areas of assessment in AR6.

AV.4 Definition of regional monsoons

AV.4.1 The South and Southeast Asian monsoon

The South and Southeast Asian monsoon (SAsiaM) is characterized by pronounced seasonal reversal of wind and precipitation. It covers vast geographical areas and several countries including India, Bangladesh, Nepal, Myanmar, Sri Lanka, Pakistan, Thailand, Laos, Cambodia, Vietnam and the Philippines (Pant and Rupa Kumar, 1997; Goswami, 2006; Gadgil et al., 2010; Shige et al., 2017), with a domain roughly extending across 60°-110°E and 10°S-25°N as shown in Figure AV.1 (shaded pink). The SAsiaM is unique in its geographical features because of the orography surrounding the area (i.e., the Himalayas, Western Ghats and Arakan Yoma mountains, and Tibetan Plateau to the north) and the adjacent Indian Ocean.

The SAsiaM rainy season from June to September contributes to more than 75% of the annual rainfall over much of the region, including the southern slopes of the central and eastern Himalayas (Krishnan et al., 2019b). Considering the spatial domain of the SAsiaM, monsoon precipitation maxima are located over the west coast, northeast and central north India, Myanmar and Bangladesh, whereas minima are located over northwest and south-eastern India, western Pakistan, and south-eastern and northern Sri Lanka (Pant and Rupa Kumar, 1997; Gadgil et al., 2010). Prior to the SAsiaM rainy season, areas in the north-western Himalaya receive precipitation during winter and early spring from so-called “western disturbances”, which are extratropical synoptic systems originating over the Mediterranean region and propagating eastward along the sub-tropical westerly jet (Madhura et al., 2014; Cannon et al., 2015; Dimri et al., 2015; Hunt et al., 2018; Krishnan et al., 2019a, 2019b).

The climatological onset of the SAsiaM occurs around 20 May over the Andaman and Nicobar Islands and covers the central Bay of Bengal around 25 May, while it simultaneously advances into mainland India from the south through Kerala (Pai et al., 2020). The normal date of monsoon onset over Kerala is 1 June and the monsoon rains progress into India both from south to north and east to west, so as to cover the entire country by 15 July (Pai et al., 2020), although with large interannual and interdecadal variations (Ghanekar et al., 2019). Retreat of the SAsiaM typically begins from far northwest India around 1 September and withdraws completely from the country by 15 October; this is followed by establishment of the northeast monsoon rainy season over south peninsular India from October through December (Pai et al., 2020).

The SAsiaM exhibits prominent rainfall variability on subseasonal, interannual and interdecadal time scales with teleconnections to modes of climate variability (see Webster et al., 1998; Turner and Annamalai, 2012). While the gross features of the SAsiaM are simulated in GCMs, there are several large biases that have persisted over generations of climate models, in CMIP3 and CMIP5, including a large dry bias over India coupled to a lower-tropospheric circulation that is too weak (Sperber et al., 2013) and a related wet bias over the western equatorial Indian Ocean (Bollasina and Ming, 2013). In CMIP5, cold Arabian Sea SST biases in coupled GCMs were shown to worsen the monsoon dry bias by limiting the available moisture (Levine et al., 2013; Sandeep and Ajayamohan, 2015). Some improvements to the spatial pattern have been noted in CMIP6, particularly near orography (Gusain et al., 2020). The teleconnection to the El Niño-Southern Oscillation (ENSO) provides the main prospect for seasonal prediction and was too weak in CMIP5 (Sperber et al., 2013). The boreal summer intraseasonal oscillation (BSISO) controls the majority of subseasonal variations in SAsiaM rainfall, as well as affecting the East Asian monsoon region. While CMIP5 models better represented the BSISO than CMIP3 (especially its characteristic northward propagation), the spatial
pattern is still poorly simulated in most models (Sabeerali et al., 2013).

The SAsiA monsoon is assessed in Sections 8.3.2.4.1, 8.4.2.4.1, Atlas.5.3.2 and Atlas.5.3.4. One of its main components, the Indian summer monsoon, is assessed in Section 10.6.3 as a case study on the construction of regional climate information from the distillation of multiple lines of evidence. Climate change over the Hindu Kush-Himalaya is assessed in CCB10.4.

**AV.4.2 The East Asian monsoon**

The East Asian monsoon (EAsiaM) is the seasonal reversal in wind and precipitation occurring over East Asia, including eastern China, Japan and the Korean Peninsula. The continental area influenced by this monsoon is roughly bounded by 102.5°-140°E and 20°-40°N (e.g., Wen et al., 2000; Wang and LinHo, 2002; Wang et al., 2010), and is shaded purple in Figure AV.1. Unlike other monsoons, it extends quite far north, out of the tropical belt, and it is largely influenced by subtropical systems, such as the Western North Pacific subtropical high, East Asian subtropical westerly jet, and by disturbances from the mid-latitudes (Chang et al., 2000; Lee et al., 2006, 2013b; Yim et al., 2008; Zhou et al., 2009).

The EAsiA monsoon manifests during boreal summer with warm and wet southerly winds, but also during boreal winter with cold and dry northerly winds (Ha et al., 2012). The winter component has been linked to the subsequent summer (i.e., Wen et al., 2000, 2016; Ge et al., 2017, Yan et al., 2020).

**AV.4.2.1 The summer EAsiA monsoon**

The summer EAsiaM is a subtropical monsoon system (e.g., Wang and LinHo, 2002; Ding et al., 2007). It is characterized by low-level southerly winds prevailing over eastern China, Korea and Japan in boreal summer. The monsoon flow brings abundant water vapour into East Asia that converges and forms the Meiyu/Baiu/Changma rain belt over the region (Zhou et al., 2009; Jin et al., 2013; Lee et al., 2017). In late April/early May, rainfall onsets in central Indochina Peninsula, and in mid-June the rainy season arrives over East Asia with the formation of the Meiyu front along the Yangtze River valley, Changma in Korea and Baiu in Japan. Later in July, the monsoon advances up to North China, the Korean peninsula and central Japan (Zhang et al., 2004; Yihui and Chan, 2005; Zhou et al., 2009).

Intraseasonal variability of the EAsiA monsoon has been mostly related to the Madden Julian Oscillation (MJO) (Yasunari, 1979; Zhang et al., 2009; Chen et al., 2015), to the phase of the Pacific-Japan mode (Nitta, 1987) or the Indian summer monsoon (Li et al., 2018) and to the BSISO (Kikuchi et al., 2012; Chen et al., 2015), particularly for its onset (Lee et al., 2013a). At interannual time scales, changes in summer EAsiA monsoon intensity lead to a position shift of the monsoon rain belt under the influence of ENSO (Wang et al., 2000) and the western Pacific subtropical high (Kosaka et al., 2013; Wang et al., 2013), Arctic sea ice (Guo et al., 2014) and solar and volcanic forcing (Peng et al., 2010; Man et al., 2012; Cui et al., 2014). Variability at interdecadal timescales is more prominent in the second half of the 20th century (Jiang, 2005; Ding et al., 2008; Wang et al., 2018), and a specific assessment about this aspect is provided in Section 8.3.2.4.2.

The basic features and interannual variations of the summer EAsiA monsoon are well reproduced in climate models. For example, the climatological circulation structure is well reproduced in both atmospheric and coupled GCMs (Song and Zhou, 2013; Song et al., 2013; Jiang et al., 2016, 2020), and the relationship between the monsoon and ENSO is well represented (Sperber et al., 2013; Fu and Lu, 2017). In CMIP5 models, the main shortcomings relate to missing rainfall bands around 30°N and the northward shift of the western North Pacific subtropical high (Huang et al., 2013). Most coupled models show an inadequate strength of monsoon circulation over southern East Asia, and with little change in model performance from the TAR to AR6 (Jiang et al., 2016, 2020). In coupled model simulations, air-sea coupling helps improve the climatology and interannual variability of rainfall over the East Asia monsoon region (Wang, 2005; Song and Zhou, 2014).
The summer (June-July-August) component of the EAsiaM is assessed in Sections 8.3.2.4.2, 8.4.2.4.2, Atlas.5.1.2 and Atlas.5.1.4.

**AV.4.2.2 The winter EAsiaM**

The winter EAsiaM is characterized by strong north-westerlies over northeast China, Korea and Japan, and by strong north-easterlies along the coast of East Asia (Huang et al., 2003). The northerly wind extends from midlatitude East Asia to the equatorial South China Sea (Wen et al., 2000; Wang et al., 2010). The winter EAsiaM has one component mostly linked to mid-to-high latitude circulation systems and another mostly linked to the tropical circulation and largely controlled by ENSO (Ge et al., 2012; Chen et al., 2014a). The mid-latitude component has a close relationship with autumn Arctic sea-ice concentration changes (Chen et al., 2014b).

The winter EAsiaM exhibits significant variability ranging from intra-seasonal to interdecadal timescales. Its intra-seasonal variability is suggested to be influenced by both high-latitude and subtropical Eurasian wave trains (Jiao et al., 2019). At the interannual timescale, ENSO is an important factor modulating the winter EAsiaM (Wang et al., 2000), while the relationship between them is not stable (Wang and He, 2012; Fan et al., 2020). In addition, Arctic Oscillation (Gong et al., 2001), Arctic sea ice (Ge et al., 2012), Eurasian snow (Luo and Wang, 2019), and strong volcanic eruptions (Miao et al., 2016) also play vital roles in changing the winter EAsiaM intensity. At the interdecadal timescale, the winter EAsiaM weakened significantly in the mid-1980s, which resulted from atmospheric intrinsic quasi-stationary planetary waves (Wang et al., 2009) and external forcings (Miao et al., 2018). In the mid-2000s, the winter EAsiaM was observed to recover from its weak epoch (Wang and Chen, 2014).

The large-scale features of the winter EAsiaM are well reproduced by climate models, although the strength of monsoon circulation is underestimated. The ability of coupled models to simulate the winter EAsiaM shows little difference through the TAR to AR5, but has improved from AR5 to AR6 (Jiang et al., 2016, 2020). In CMIP5 models, reasonable simulations of the Siberian high and Aleutian low intensities and the ENSO-winter EAsiaM relationship help improve the climatology and interannual variability of the winter EAsiaM (Gong et al., 2014).

Model simulations of the winter component of the EAsiaM are assessed in chapter Atlas.5.1.3.

**AV.4.3 The West African Monsoon**

The West African monsoon (WAfriM) is a seasonal reversal in wind and precipitation extending over a vast and contrasted geographical region, from the Equator to the margins of the Sahara, and from the Atlantic coast inland. The WAfriM domain includes Togo, Guinea Bissau, Gambia, Senegal, Mauritania, Guinea, Sierra Leone, Liberia, Mali, Ivory Coast, Burkina Faso, Ghana, Benin, Chad, Cape Verde, northern Cameroon, Niger, Nigeria and northern Central African Republic. It can thus be roughly bounded by 18°W-30°E, 5°-18°N and is grey shaded in Figure AV.1 (e.g., Adedokun, 1978). The West African monsoon and Sahel are sometimes considered interchangeably. However, the Sahel lies in the northern part of the WAfriM region, often limited to the west and central north Africa (e.g., Nicholson et al. (2018) considered the domain to be 20°W-30°E, 10°-20°N) or sometimes extended to the east (e.g., Giannini and Kaplan (2019) considered the domain to be 20°W-40°E, 10°-20°N). The East African region with the Greater Horn of Africa, which includes Ethiopia, Sudan, and South Sudan, lies on the fringes of both the West African and Indian monsoons (Nicholson, 2017).

The WAfriM is characterized by the northward progression from May to September of moist low-level south-westerlies from the Gulf of Guinea, meeting the dry north-easterlies (Harmattan) from the Saharan heat low at the intertropical discontinuity (e.g., Hamilton et al., 1945; Omotosho, 1988). In May and June,
rainfall remains essentially along the Guinean coast with a maximum occurring near 5°N, then the rainfall maximum jumps suddenly over the Sudan-Sahel zone near 12°N, followed by a “little dry season” over the Guinea coast (Adejumon and Odekunle, 2006). This apparent shift is known as the West African monsoon jump and it is concomitant with the monsoon onset over the Sahel (Sultan and Janicot, 2003; Cook, 2015). Rainfall continues to progress towards the north up to about 18-20°N. The rainfall maximum occurs in the Sahel in August/September, followed by a rapid retreat of rainfall to the Guinean Coast and a second maximum occurs over this region in October/November.

The WAfriM features variability at different timescales. Unprecedented droughts occurred in West Africa and particularly over the Sahel from the late 1960s to the mid-1990s, and a specific assessment of the understanding of mechanisms related to these changes is provided in Sections 8.3.2.4.3 and 10.4.2.1.

At interannual time scales, tropical oceans (Atlantic, Pacific and Indian) appear to be the major drivers with their SSTs anomalies leading to variations in the accumulated seasonal rainfall (e.g., Lamb, 1978; Diakhate et al, 2019). At intraseasonal time scales, equatorial waves (e.g., Mekonnen et al., 2008; Janicot et al., 2010) and interactions with mid-latitudes and the Mediterranean (e.g., Vizy and Cook, 2009; Roehrig et al., 2011) have an effect on WAfriM activity. African Easterly Waves (AEWs) and mesoscale convective systems (MCSs), including squall lines, are the prominent weather synoptic scale aspects of the WAfriM, supplying almost all rainfall in the Sahel. The strong coupling between AEWs and MCSs has been investigated in depth, as well as their interactions with the Saharan Heat Low, the moisture supply from East Africa and the Mediterranean region or from near the equator (e.g., Diougou et al., 2002; Brammer and Thorncroft, 2017; Lafore et al., 2017). Land surface processes are known to influence WAfriM precipitation (Boone et al., 2016).

Simulation of West Africa climate, including the monsoon, has received specific attention under coordinated programmes in the recent past: the African Multidisciplinary Monsoon Analysis Model Intercomparison Project (AMMA-MIP), the AMMA Land-surface Model Intercomparison Project (ALMIP), the West African Monsoon Modelling and Evaluation (WAMME) project and the Coordinated Regional Downscaling Experiment (CORDEX) (Raj et al., 2019). CMIP5 and CMIP6 struggle to reproduce the amplitude of observed decadal variability in the twenty century and to represent the mean climatology including the northward propagation of the monsoon (Roehrig et al., 2013; Monerie et al., 2020; Sow et al., 2020). A higher horizontal resolution improves the representation of the intensity and spatial distribution of WAfriM rainfall and related circulation, because of the effects of vegetation, orography and coastlines (Hourdin et al., 2010; Sylla et al., 2010; Xue et al., 2010; Raj et al., 2019).

The WAfriM is assessed in Sections 8.3.2.4.3 and 8.4.2.4.3. The observed Sahel and West African monsoon drought and recovery is assessed as a regional climate change attribution example in Section 10.4.2.1.

**AV.4.4 The North American Monsoon**

The North American monsoon (NAmerM) is a regional-scale atmospheric circulation system dominated by boreal summer precipitation over northwestern Mexico and southwest United States, where it contributes to almost 70% and 40% of the total annual precipitation, respectively (Douglas et al., 1993; Higgins et al., 1997). The NAmerM domain is shaded magenta in Figure AV.1, roughly bounded by 15°-35°N, 100°-115°W and defined where the July-August-September minus June mean precipitation exceeds 25mm/mon (Douglas et al., 1993; Adams and Comrie, 1997; Barlow et al., 1998; Cook and Seager, 2013).

The identification of a regional monsoon regime in North America dates back to the 1990s (Douglas et al., 1993; Adams and Comrie, 1997; Higgins et al., 1997; Barlow et al., 1998), although consideration of the monsoonal character of the southwestern United States precipitation goes back considerably further (e.g.,
Bryson and Lowry, 1955). The monsoonal characteristics of the region include a pronounced annual maximum of precipitation in boreal summer (June-July-August) accompanied by a surface low pressure system and an upper-level anticyclone, although the seasonal reversal of the surface winds is primarily limited to the northern Gulf of California. In particular, the summertime precipitation in the NAmerM region is dictated by the location of the upper-level anticyclone (Reed, 1933; Castro et al., 2001). The decay phase of the NAmerM is typically observed during late September-October, when convection migrates from Central to South America (Vera et al., 2006).

Mesoscale variability of the NAmerM comes from the pulsing of the Gulf of California low-level jet, the intensification/reduction of the land-sea contrast (Torres-Alavez et al., 2014) and moisture surges over the Gulf of California (Vera et al., 2006). Synoptic variability of the NAmerM is mainly associated with the activity of tropical cyclones and of easterly waves (Stensrud et al., 1997; Fuller and Stensrud, 2000). In addition, the NAmerM is strongly influenced by the ENSO variability at both the interannual (Higgins et al., 1999; Higgins and Shi, 2001) and decadal (e.g., Castro et al., 2001) time scales.

The region is challenging for climate modeling for several reasons, including complex topography, the importance of Mesoscale Convective Systems (MCSs), and sensitivity to SST bias (e.g., Pascale et al., 2019). Many CMIP3 and CMIP5 models with resolutions coarser than 100 km are unable to realistically resolve the topography of the NAmerM region, thus inducing biases in simulating the monsoon (Geil et al., 2013). Among other factors, these biases are due to biases in the simulation of the Gulf of California summertime low-level flow (Kim et al., 2008; Pascale et al., 2017) and to failures in representing properly the diurnal cycle (Risanto et al., 2019) and the decay (Bukovsky et al., 2015) of the NAmerM precipitation. Simulations at higher horizontal resolution (i.e. with at least 0.25° grid) exhibit an improved representation of the regional topography, which provides a better representation of the regional circulation and therefore of the NAmerM (Varuolo-Clarke et al., 2019).

The NAmerM is assessed in Sections 8.3.2.4.4 and 8.4.2.4.4.

**AV.4.5 The South American Monsoon**

The South American monsoon (SAmErM) is a regional circulation system characterized by inflow of low-level winds from the Atlantic Ocean toward South America, involving Brazil, Perú, Bolivia and northern Argentina, associated with the development of surface pressure gradients (and intense precipitation) during austral summer (December-January-February). Based on climatological precipitation intensity, the SAmErM region is roughly bounded by 5°-25°S and 70°-50°W (Zhou and Lau, 1998; Vera et al., 2006; Raia and Cavalcanti, 2008) and is dark-orange shaded in Figure AV.1.

During austral spring (September-October-November), areas of intense convection migrate from northwestern South America to the south (Raia and Cavalcanti, 2008), forming the South Atlantic Convergence Zone (SACZ) during austral summer (Kodama, 1992; Jones and Carvalho, 2002; Vera et al., 2006). Associated with this regime, an upper-tropospheric anticyclone (the Bolivian High) forms over the Altiplano region during the monsoon onset (Lenters and Cook, 1997). The establishment of this upper-level anticyclone has been related to the transition from southerly to northerly winds and the occurrence of strong convective heating over the Amazon (Lenters and Cook, 1997; Wang and Fu, 2002). The SAmErM then retreats during austral autumn/fall (March-April-May) with a northeastward migration of the convection (e.g., Vera et al., 2006).

The SAmErM displays considerable variability on time scales ranging from intraseasonal to decadal (Vera et al., 2006; Marengo et al., 2012; Vuille et al., 2012; Novello et al., 2017). The Madden-Julian Oscillation (MJO, Section AV.1.2.8) influences the SACZ via changes in midlatitude synoptic disturbances (Jones and
Carvalho, 2002; Liebmann et al., 2004). At interannual time scales, ENSO explains most of the SAmerM variability (e.g., Paegle and Mo, 2002; Marengo et al., 2012). Tropical Atlantic temperatures also affect the SAmerM, with reduced atmospheric moisture transport to feed the monsoon under a warmer tropical north Atlantic conditions (e.g., Marengo et al., 2008; Zeng et al., 2008). In addition to SSTs, interannual variability of the SAmerM is linked to changes in land surface processes, cold-air incursions, the latitudinal location of the subtropical jet, and the Southern Annular Mode (Section AVI.2.2) (e.g., Silvestri, 2003; Li and Fu, 2004; Collini et al., 2008; Yin et al., 2014). At interdecadal timescales, the SAmerM is influenced by important modes of climate variability (e.g., Robertson and Mechosso, 2000; Paegle and Mo, 2002; Chiessi et al., 2009; Silvestri and Vera, 2009).

The general large-scale features of the SAmerM are reasonably well simulated by coupled climate models although they do not adequately reproduce maximum precipitation over the core of the monsoon, even when considering simulations under past natural forcings, such as those during the last millennium (Rojas et al., 2016; Diaz and Vera, 2018). However, CMIP5 models featured an improved representation of the SAmerM with respect to CMIP3 (Joetzjer et al., 2013; Jones and Carvalho, 2013; Gulizia and Camilloni, 2015; Diaz and Vera, 2017).

The SAmerM is assessed in Sections 8.3.2.4.5 and 8.4.2.4.5.

**AV.4.6 The Australian-Maritime Continent monsoon**

The Australian-Maritime Continent monsoon (AusMCM) occurs during austral summer (December-January-February), with the large-scale shift of the Inter-Tropical Convergence Zone into the Southern Hemisphere. It covers northern Australia and the Maritime Continent up to 10°N (e.g., McBride, 1987; Suppiah, 1992; Robertson et al., 2011), and it corresponds to the yellow shaded region in Figure AV1. The identification of the Australian monsoon by meteorologists dates back to the early 20th century (see review of Suppiah, 1992), with later studies providing classifications of monsoon circulation regimes (e.g., McBride, 1987) and definitions of monsoon onset (Troup, 1961; Holland, 1986; Hendon and Liebmann, 1990; Drosdowsky, 1996).

The AusMCM is characterized by the seasonal reversal of prevailing easterly winds to westerly winds and the onset of periods of active convection and heavy rainfall (Zhang and Moise, 2016). Over northern Australia, the monsoon season generally lasts from December to March and is associated with west to northwesterly inflow of moist winds, producing convection and heavy precipitation. Over the Maritime Continent, the main rainy season south of the equator is centered on December to February with northwesterly monsoon flow at low levels.

Over Australia, the monsoon is strongly influenced by ENSO on interannual timescales: during El Niño years the monsoon onset tends to be delayed (Nicholls et al., 1982; McBride and Nicholls, 1983; Drosdowsky, 1996). This relationship breaks down after the onset of the wet season, leading to little correlation between ENSO phase and total monsoon rainfall or duration (e.g., Hendon et al., 2012). The Maritime Continent also experiences a delay in monsoon onset during El Niño years and monsoon rainfall is correlated with ENSO during the dry and transition seasons (Robertson et al., 2011). The AusMCM is also influenced by the Indian Ocean Dipole (peaking in September-November) that tends to weaken the following monsoon when in its positive phase (Cai et al., 2005).

The ability of climate models to simulate the Australian monsoon has improved in successive generations of coupled models (i.e., from CMIP3 to CMIP6, Moise et al., 2012; Brown et al., 2016; Narsey et al., 2020), with sensitivity of monsoon rainfall to the magnitude of SST biases in the equatorial Pacific (Brown et al., 2016).
The AusMCM is assessed in Sections 8.3.2.4.6 and 8.4.2.4.6.

Figure AV.1: **Global and regional monsoons domains.** AR6 global monsoon area is represented by the black contour. AR6 regional monsoons are: North American monsoon (shaded magenta), South American monsoon (shaded dark-orange), West African monsoon (shaded grey), South and Southeast Asian monsoon (shaded pink), East Asian monsoon (shaded purple) and Australian-Maritime Continent monsoon (shaded yellow). Areas over Equatorial America and South Africa (dotted red and magenta, respectively) are highlighted but not identified as specific regional monsoons (see explanation in the main text). For each regional monsoon, the seasonal characteristics associated with each domain are specified in the main text.

AVI.1 Introduction

This Annex provides background information on indices used within Chapter 11, Chapter 12, and the Atlas, including technical details of calculation and related references.

In the climate science literature, a number of indices are used to characterize and quantify one or several aspects of climate phenomena occurring due to natural variability or due to long-term changes in the system. There is an extremely large number of examples. One can cite mean global climate indices, such as global mean sea level rise or global surface temperature, which characterize the state of the climate system and act as a shifting baseline for regional changes. One can also examine mean regional trends, for example in mean springtime precipitation, which reflect large-scale patterns and alter the background conditions within which episodic hazards may occur. One can also calculate indices of extremes characterizing episodic events within the tail of the distributions of specific variables within their variability range, for instance the annual maximal temperature at a given location or the 100-year return value of river discharge characterizing extreme floods. Such extreme indices have been the subject of a number of studies and have been used to characterize how climate change modifies extreme values of climate variables and subsequent impacts in the IPCC Special Report on “Managing the risks of Extreme Events and Disasters to Advance Climate Change Adaptation” (IPCC, 2012), as well other recent IPCC reports.

Indices can also characterize aspects of climatic impact-drivers (CIDs) (see Chapter 1 for the definition) that are key to impacts and risks to society and ecosystems. Chapter 12 proposes a definition of “climatic impact-driver indices” as “numerically computable indices using one or a combination of climate variables designed to measure the intensity of the climatic impact-driver, or the probability of exceedance of a threshold. For instance, an index of heat inducing human health stress is the Heat Index (HI) that combines temperature and relative humidity (e.g., (Burkart et al., 2011; Lin et al., 2012; Kent et al., 2014)) and is used among others by the US National Oceanic and Atmospheric Administration (NOAA) for issuing heat warnings”.

Climatic impact-drivers may not be related only to extremes, and therefore require a much broader set of indices. For instance, the rate of coastline recession, due to sea level rise, assessed in Chapter 12, is involved in the risk of damage and losses in coastal settlements and infrastructures. Mean trends and changes themselves are considered throughout the report as CIDs. For instance, beyond the warming trend which has a large number of consequences, changes in other indices such “snow season length” is often used to study economic impacts on winter tourism (Damm et al., 2017). Furthermore, (Mora et al., 2018) used a set of 11 very different key CID indices among which about half are related to extremes to characterize broader threats to society. Section 12.3 in Chapter 12 reviews the CIDs described in the literature to characterize impacts and risks, and reveal the wide variety of indices used to characterize them.

Indices are, in principle, computable from observations, reanalyses or model simulations, although it is important to consider scale in comparing across datasets. For example, an extreme precipitation event has a lower magnitude across a large grid cell than it would at a single station within that grid cell. In many cases, CIDs are simply characterized by the exceedance of a threshold for an Essential Climate Variable (ECV). For instance, the probability of crop failure dramatically increases as temperature rises above certain thresholds, which may differ from one species to another (Hatfield and Prueger, 2015; Grotjahn, 2021). To assess the effect of climate change on threshold-based indices (e.g., the change in the number of days with maximum temperature above 35°C), a bias adjustment of model outputs should be considered where sensible as model simulations can have biases compared to observations and reanalyses (Section 10.3.1.3, Cross Chapter Box 10.2, 12.2).

Indices are used in many chapters of this Report: in Chapter 4 for assessing changes in the global climate, in Chapter 8 for water cycle changes assessment, in Chapter 9 for oceans and the cryosphere, in Chapter 11 for assessing changes in extreme conditions, and in Chapter 12 for assessing CIDs and their changing characteristics due to climate change. The Atlas assesses changes in mean variables/indices (temperature, precipitation and snow). The Interactive Atlas includes indices of mean changes (for temperatures, precipitation, snowfall and wind) and a number of extreme indices and CIDs, allowing for flexible spatial and temporal analysis of the results.
AVI.2  Extreme indices selection

In Chapter 11, extreme weather and climate events (collectively referred to as extremes) are assessed and the main focus is on extreme events over land. Since the analysis of extremes often involves the examination of the tails of the statistical distributions, a parametric or non-parametric approach can be used to define extremes. The non-parametric approach is largely adopted in most of the literature to characterize moderate temperature and precipitation extremes with shorter return periods. The Expert Team on Climate Change Detection and Indices (ETCCDI -https://www.wcrp-climate.org/etccdi) defined 27 indices to characterize different aspects of moderate temperature and precipitation extremes, which are described by (Frich et al., 2002; Alexander et al., 2006; Zhang et al., 2011; Donat et al., 2013; Sillmann et al., 2013), and were also extensively used in previous IPCC reports. In Chapter 11, a subset of these indices is assessed in detail (Section 11.3 and Section 11.4). For events with longer return periods (e.g., events that occur once in 20 years or even rarer), the parametric approach based on Extreme Value Theory (EVT) (Coles, 2001) is used and adopted in the literature (e.g., (Kharin and Zwiers 2000; Brown et al. 2008; Kharin et al. 2013)). These events are also assessed throughout the chapter. Aside from temperature and precipitation, the chapter also assesses indices used to characterize droughts. Table AVI.1 list the indices used.

</table>
[END TABLE AVI.1 HERE]

Some of these indices are included in the Interactive Atlas allowing further analysis (seasons, regions, baselines and future periods – using both time-slices/scenarios and global warming levels): TXx, TNn, Rx1day, Rx5day, FD, CDD, and SPI.

AVI.3 Climatic Impact-Drivers indices selection

In Chapter 12, 33 CID types are identified on the basis of relevance for risks and impacts and available literature. They are classified into 7 categories: heat and cold, wet and dry, wind, snow and ice, coastal, oceanic, and other (see Tables 12.1 and 12.2). It would be impossible to cover all indices that have been developed in the literature. However, in order to illustrate how indices can inform on future regional climate, Chapter 12 and the Atlas use a limited number of indices to illustrate the main CIDs and their evolution with climate change.

The selection of indices, as displayed in Chapter 12 and the Atlas, is based on expert judgement using the following guiding principles. The set of indices should:

(i) describe the evolution of a manageable and illustrative number of indices,
(ii) cover these categories, while giving more weight to those with a higher number of potential impacts as described in the literature,
(iii) be used broadly in the literature,
(iv) allow easy computation from publicly available model outputs and observations, or be accessible from published material through contact with the authors,
(v) be well-evaluated in model simulations, or based on ECVs that are well-evaluated in model simulations, and
(vi) represent CIDs of interest to regional impacts and risk assessments.

The selection results in 16 regional indices that are reported in Table AVI.2. The description of the formulae used for processing is described below.

AVI.3.1 Regional CID indices used in Chapter 12 and the Atlas

Climatic impact-drivers indices

Length of frost-free period (LFFP): Many ecosystems and crops are sensitive to frost conditions, and can only develop over a frost-free period (e.g., Wolfe et al., 2018); the length of frost-free period is calculated in the Atlas as in McCabe et al., (2015) by counting the number of days between the last spring frost and first fall frost using 0°C as a threshold for the daily minimum temperature and adjusting for season between hemispheres (from January to December in the Northern Hemisphere and from July to June in the Southern Hemisphere).

Growing degree-days (GDD): Ecosystems and crop growth is often linked to a widely used index of thermal conditions, the cumulative number of degrees above a threshold (often between 0 and 10 °C, depending on species and farming system) during a given growing period. In Chapter 12 and the Atlas we use 5°C as an indicative threshold, which was also used in Ruosteenoja et al., (2016), and the calculation is taken from this reference. GDD calculations sometimes include a high temperature threshold above which plant development does not occur (e.g., Mu et al., 2017), but no cap was employed for our calculations. The GDD index used here is therefore the accumulated sum of the difference between daily mean temperature and the threshold (when higher than the threshold) over the April-September months that forms the primary growing season for mid-latitude agricultural areas in the northern Hemisphere; and October-March for the
Southern hemisphere.

**Cooling Degree-days (CD):** Energy consumption in hot environments typically depends on the excess of temperature above a given threshold, where cooling is required. In Chapter 12 and the Atlas we used the formulation of Spinoni et al., (2015), which uses the mean (T_M), max (T_X) and min daily (T_N) temperature with the formula taken from this reference:

\[
CDD_i = \begin{cases} 
0 & \text{if } T_X - T_N \leq T_b \\
\frac{T_X - T_N - T_b}{4} & \text{if } T_M \leq T_b < T_X \\
\frac{2 - T_N + T_M - T_B}{4} & \text{if } T_N \leq T_b < T_M \\
& \text{if } T_X \geq T_b 
\end{cases}
\]

With \( T_b = 22^\circ C \), then

\[ CDD = \sum_{i=1}^{365} CDD_i \]

The difference between Chapter 12, Atlas, and the previous reference is that in this report the sum is cumulated over the entire year instead of 6 months, so it applies to all hemispheres.

**Number of days with maximum daily temperature above threshold (TXnn):** The number of days with maximum temperature above a threshold can be critical for human health, infrastructure, ecosystems, and agriculture. Different thresholds are used for different crops, generally varying between 30 degrees and 40 degrees (Hatfield and Prueger, 2015; Grotjahn, 2021). Chapter 12 uses the 35°C threshold globally (Figure 12.4), which was identified as a critical temperature for maize pollination and production (Wolfe et al., 2008; Schlenker and Roberts, 2009; Hatfield et al., 2011, 2014; Lobell and Gourdji, 2012; Gourdji et al., 2013; Lobell et al., 2013; Deryng et al., 2014; Hatfield and Prueger, 2015; Tripathi et al., 2016; Schauberger et al., 2017; Tesfaye et al., 2017) as well as a notable threshold for human health hazards (Kingsley, Eliot, Gold, Vanderslice, & Wellenius, 2016; Petitti et al., 2016). The Interactive Atlas includes both TX35 and TX40 (both raw and bias adjusted; see Atlas 1.4.5).

**NOAA Heat Index (HI):** HI is used by the US National Oceanic and Atmospheric Administration (NOAA) for issuing heat warnings and was applied in several studies that investigated adverse health impacts due to heat stress (e.g., Burkart et al., 2011; Lin et al., 2012; Kent et al., 2014). HI is calculated as multiple linear regression with temperature (T in °F) and relative humidity (RH) as input variables (Steadman, 1979; Rothfusz, 1990):

\[
HI = H_{I_1} + H_{I_1A_1}, \quad \text{if } RH < 13 \% \text{ and } 80 \, ^\circ F < T_F < 112 \, ^\circ F \\
= H_{I_2} + H_{I_2A_2}, \quad \text{if } RH > 85 \% \text{ and } 80 \, ^\circ F < T_F < 87 \, ^\circ F \\
= H_{I_1}, \quad \text{otherwise}
\]

with:

\[
H_{I_1} = c_0 + c_1 \cdot T_F + c_2 \cdot RH + c_3 \cdot T_F \cdot RH + c_4 \cdot T_F^2 + c_5 \cdot RH^2 + c_6 \cdot T_F^2 \cdot RH + c_7 \cdot T_F \cdot RH^2
\]

\[
H_{I_1A} = (13 - RH)/4 \cdot \sqrt{(17 - |T_F - 95^\circ F|)}/17
\]

\[
H_{I_2} = (RH - 85)/10 \cdot (RH^7 - T_F)/5
\]

\[
c_0 = -42.379 \, ^\circ F, c_1 = 2.04901523, c_2 = 10.14333127 \, ^\circ F, c_3 = -0.22475541,
\]

\[
c_4 = -0.00683783 \, ^\circ F^{-1}, c_5 = -0.05481717 \, ^\circ F, c_6 = 0.00122874 \, ^\circ F^{-1}, c_7 = 0.00085282
\]
$c_B = -0.00000199 \, ^\circ F^{-1}$

If $HI < 80 \, ^\circ F$, the following equation is used:

$$HI = 0.5 \cdot (T_F + 61 \, ^\circ F) + 1.2 \cdot (T_P - 68 \, ^\circ F) + 0.094 \, ^\circ F \cdot RH$$

The calculated HI is converted into °C.

HI is calculated for CMIP5, CMIP6 and CORDEX using daily mean near-surface specific humidity, daily mean surface pressure, and daily maximum near-surface air temperature. For CMIP5 and CMIP6, daily mean surface pressure is calculated from daily mean sea level pressure by applying a height adjustment (see Schwingshackl et al., (2021) for details) Additionally, HI is calculated for WFDE5, which is a bias adjusted version of the ERA5 reanalysis (Cucchi et al., 2020). Daily maximum temperature is calculated as maximum, daily mean pressure and humidity as average of the hourly WFDE5 variables near-surface air temperature, near-surface specific humidity, and surface air pressure.

To quantify heat stress, yearly sums of daily HI threshold exceedances are calculated using a threshold of 41°C, which corresponds to conditions that the US National Weather Service classifies into the category of “Danger” (Blazejczyk et al., 2012). Bias adjusted model simulations are used for calculating threshold exceedances of HI, employing the quantile delta mapping (QDM) approach as described by (Cannon et al., 2015). The QDM approach adjusts the model data in the application period to fit the reference data in the reference period (using quantile mapping). Subsequently, the climate change signal is added for each quantile by considering the change between the model’s reference and application periods. QDM is directly applied to the HI data using WFDE5 as reference dataset and 1981-2010 as reference period. WFDE5 HI data are conservatively remapped to each model’s grid before bias adjustment is performed. QDM is applied on each grid point individually and for each month separately. The application periods are the IPCC periods 1995-2014, 2041-2060, and 2081-2100 and 20-year periods for specific warming levels (1.5°C, 2°C, 3°C, and 4°C).

**Heating Degree-days (HD):** symmetrical to the Cooling Degree-Day index, the HD index is used for illustrating energy demand for heating. It has been used in several studies of impacts of climate change on the energy sector. The Atlas follow the formulation proposed by (Spinoni et al., 2015). The calculation follows:

$$HDD_i = \begin{cases} 
\frac{T_b - T_M}{2} \times \frac{T_X - T_b}{4} & \text{if } T_X \leq T_b \\
\frac{T_b - T_N}{2} \times \frac{T_M - T_b}{4} & T_M \leq T_b < T_X \\
\frac{T_N - T_b}{2} \times \frac{T_M - T_b}{4} & T_N \leq T_b < T_M \\
0 & T_X \geq T_b
\end{cases}$$

With $T_b=15.5^\circ C$, then

$$HDD = \sum_{t=1}^{365} 4HDD_i$$

Where $T_M, T_X$ and $T_N$ correspond to daily mean, maximum and minimum temperature respectively.

To account for various geographic zones, however, the HD index is cumulated over the entire year, instead of 6 months, as in the previous reference. This index is included in the Interactive Atlas.

**Number of frost days (FD):** Frost affects crops (Barlow et al., 2015; Crimp et al., 2016; Cradock-Henry, 2017; Mäkinen et al., 2018), and there has been a number of studies investigating changes in the number of
frost days, with various thresholds, mostly between -10°C and 2°C. In Chapter 12 and the Atlas, we use the simple threshold of 0°C for the daily minimum temperature to define frost days as in Table AVI.1. This index is included in the Interactive Atlas.

**River flood index using runoff (FI):** As a flood indicator, the 100-year return value of discharge value (Q) has been used. The computation of the index follows Alfieri et al., (2015):

1. Annual maximum river discharges are selected and an Extreme Value Type I (Gumbel) distribution is fitted on time slices of 30 years and an analytical function is obtained.
2. The analytical function is used to estimate extreme discharge peaks with chosen return period Q(RP), by inverting the formulation of the Gumbel distribution:
   \[ Q(RP) = \xi - \alpha \ln \left( -\ln \left( 1 - \frac{1}{RP} \right) \right) \]
   where \( \alpha \) and \( \xi \) are the scale and location parameters of the analytical Gumbel distribution.
3. The peak discharge corresponding to the 100-year return period, Q(RP=100), is then calculated.

For CORDEX regional models the total runoff of each of the models has been used as an input of the hydrological model CHyM (Coppola et al., 2007, 2018) to produce the river discharge for all the European network. The Q(RP=100) value has been computed for each of the river segment and for each of the 29 CHyM simulations. The results are shown in the regional Figures of 12.4.

**Standardized Precipitation Index (SPI):** The SPI is a statistical index that compares cumulated precipitation for \( n \) months (\( n=6 \) or \( n=12 \)) with the long-term precipitation distribution for the same location and cumulation period. The SPI months have been selected so SPI represent medium-term cumulated value and can be used to measure the medium-term impact on river flow and reservoir storage (McKee et al., 1993).

The index is computed in this way:

1. A monthly precipitation time series is selected (at least 30 years).
2. The running average for the \( n \)-months window is computed.
3. The Gamma distribution is used to fit the data. The fitting can be achieved through the maximum likelihood estimation of the Gamma distribution parameters.
4. The values from this probability distribution are then transformed into a normal distribution, so that the mean SPI for the location and desired period is zero and the standard deviation is 1 (Edwards and McKee, 1997).

Once SPI has been computed, the calculation of the Drought Frequency (DF) follows the method in (Spinoni et al., 2014): a drought event starts in the month when SPI falls below -1 and it ends when SPI returns to positive values, for at least two consecutive months.

It has to be noted that the SPI index has been recognized to be difficult to interpret in high latitudes and in arid areas due to statistical issues linked to inaccuracies in the estimation of the Gamma function (Spinoni et al., 2014). The duration of 6 months is considered in Figure 12.4.

This index is included in the Interactive Atlas, both SPI-6 and SPI-12 versions.

**Soil moisture (SM):**

The soil moisture index is used in Chapter 12 figures. It is simply using the total soil moisture content integrated over the soil depth, normalized by the recent past climatological values at each grid point.

**Snow season length (SWE100):** Several studies use the Snow Water Equivalent (SWE) variable (variable \( \text{snw} \) in model outputs) in order to define a “snow season length” as the number of days with enough snow on the ground. This index is particularly important for the winter tourism sector (Damm et al., 2017; Jacob et al., 2018). Several thresholds are used to define a day with “enough snow on the ground”, with (Wobus et al., 2018). Several thresholds are used to define a day with “enough snow on the ground”, with (Wobus et al., 2018).
Coastal Erosion (CE): Coastal erosion is generally accompanied by shoreline retreat, which can occur as a gradual process (e.g., due to sea level rise) or as an episodic event due to storm surge and/or extreme waves, especially when combined with high tide (Ranasinghe, 2016). The most commonly used shoreline retreat index is the magnitude of shoreline retreat by a pre-determined planning horizon such as 50 or 100 years into the future. Here, the median shoreline retreat, together with the associated 5% - 95% confidence interval, resulting from a fully probabilistic model that incorporates storm surge and waves derived from models forced by an ensemble of 6 GCMs, is used as the index relevant for long-term coastal erosion.

Some of these indices are included in the Interactive Atlas allowing flexible analysis (seasons, regions, baselines and future periods – using both time-slices/scenarios and global warming levels): TX35 and TX40 (both raw and bias adjusted; see Atlas 1.4.5), FD, CD, HD, SPI-6 and SPI-12.

This glossary defines some specific terms as the Lead Authors intend them to be interpreted in the context of this report. Italicized words in definitions indicate that the italicized term is defined in the Glossary. Subterms appear in italics beneath main terms.

Date: August 2021

This document is subject to copy-editing, corrigenda and trickle backs.

This Annex should be cited as:
1.5°C pathway  See Paths.

Ablation (of glaciers, ice sheets, or snow cover)  See Mass balance / budget (of glaciers or ice sheets).

Abrupt change  A change in the system that is substantially faster than the typical rate of the changes in its history.

Abrupt climate change  A large-scale abrupt change in the climate system that takes place over a few decades or less, persists (or is anticipated to persist) for at least a few decades and causes substantial impacts in human and/or natural systems. See also Tipping point and Abrupt change.

Accumulation (of glaciers, ice sheets, or snow cover)  See Mass balance / budget (of glaciers or ice sheets).

Active layer  Layer of ground above permafrost subject to annual thawing and freezing.

Adaptation  In human systems, the process of adjustment to actual or expected climate and its effects, in order to moderate harm or exploit beneficial opportunities. In natural systems, the process of adjustment to actual climate and its effects; human intervention may facilitate adjustment to expected climate and its effects. See also Adaptation options, Adaptive capacity and Maladaptive actions (Maladaptation).

Adaptation options  The array of strategies and measures that are available and appropriate for addressing adaptation. They include a wide range of actions that can be categorised as structural, institutional, ecological or behavioural.

Adaptive capacity  The ability of systems, institutions, humans and other organisms to adjust to potential damage, to take advantage of opportunities, or to respond to consequences (IPCC, 2014; MA, 2005).

Added value  Improvement of the representation of some climatic aspects by one methodology compared to another methodology. For instance, downscaling a coarse resolution global climate model (GCM) may improve the representation of regional climate in complex terrain.

Adjustment time  See Response time or adjustment time.

Advection  Transport of water or air along with its properties (e.g., temperature, chemical tracers) by winds or currents. Regarding the general distinction between advection and convection, the former describes transport by large-scale motions of the atmosphere or ocean, while convection describes the predominantly vertical, locally induced motions.

Aerosol  A suspension of airborne solid or liquid particles, with typical diameters between a few nanometres and a few micrometres and atmospheric lifetimes of up to several days in the troposphere and up to years in the stratosphere. The term aerosol, which includes both the particles and the suspending gas, is often used in this report in its plural form to mean ‘aerosol particles’. Aerosols may be of either natural or anthropogenic origin in the troposphere; stratospheric aerosol mostly stems from volcanic eruptions. Aerosols can cause an effective radiative forcing directly through scattering and absorbing radiation (aerosol-radiation interactions), and indirectly by acting as cloud condensation nuclei or ice nucleating particles which affect the properties of clouds (aerosol-cloud interactions), and upon deposition on snow- or ice-covered surfaces. Atmospheric aerosols may be emitted as primary particulate matter (PM), and form within the atmosphere from gaseous precursors (secondary production). Main classes of aerosol chemical composition are sea salt, organic carbon, black carbon (BC), mineral species (mainly desert dust), sulphate, nitrate, and ammonium. See also Short-lived climate forcers (SLCFs).

Aerosol effective radiative forcing (ERF\text{ari+aci})  See Aerosol-radiation interaction.

Aerosol optical depth (AOD)  Wavelength-dependent aerosol optical depth is a measure of the aerosol
contribution to extinction of top-of-the-atmosphere solar intensity measured at the ground. AOD is unitless.

*Fine-mode aerosol optical depth*  Aerosol optical depth due to aerosol particles smaller than 1 μm in radius.

**Aerosol-cloud interaction**  A process by which a perturbation to aerosol affects the microphysical properties and evolution of clouds through the aerosol role as cloud condensation nuclei or ice nuclei, particularly in ways that affect radiation or precipitation; such processes can also include the effect of clouds and precipitation on aerosol. The aerosol perturbation can be anthropogenic or come from some natural source. The radiative forcing from such interactions has traditionally been attributed to numerous indirect aerosol effects, but in this report, only two levels of radiative forcing (or effect) are distinguished: See also Aerosol-radiation interaction.

*Effective radiative forcing (or effect) due to aerosol-cloud interactions (ERFaci)*  The final radiative forcing (or effect) from the aerosol perturbation including the adjustments to the initial change in droplets or crystal formation rate. These adjustments include changes in the strength of convection, precipitation efficiency, cloud fraction, lifetime or water content of clouds, and the formation or suppression of clouds in remote areas due to altered circulations. See also Aerosol-radiation interaction.

*Instantaneous radiative forcing (or effect) due to aerosol-cloud interactions (IRFaci)*  The radiative forcing (or radiative effect, if the perturbation is internally generated) due to the change in number or size distribution of cloud droplets or ice crystals that is the proximate result of an aerosol perturbation, with other variables (in particular total cloud water content) remaining equal. In liquid clouds, an increase in cloud droplet concentration and surface area would increase the cloud albedo. This effect is also known as the cloud albedo effect, first indirect effect, or Twomey effect. It is a largely theoretical concept that cannot readily be isolated in observations or comprehensive process models due to the ubiquity of adjustments.

**Aerosol-radiation interaction**  An interaction of aerosol directly with radiation produce radiative effects. In this report two levels of radiative forcing (or effect) are distinguished:

* Aerosol effective radiative forcing (ERFari+aci)  The total effective radiative forcing due to both aerosol-cloud and aerosol-radiation interactions is denoted aerosol effective radiative forcing (ERFari+aci).

* Effective radiative forcing (or effect) due to aerosol-radiation interactions (ERFari)  The final radiative forcing (or effect) from the aerosol perturbation including adjustments to the initial change in radiation. These adjustments include changes in cloud caused by the impact of the radiative heating on convective or larger-scale atmospheric circulations, traditionally known as semi-direct aerosol forcing (or effect). See also Aerosol-cloud interaction.

*Instantaneous radiative forcing (or effect) due to aerosol-radiation interactions (IRFari)*  The radiative forcing (or radiative effect, if the perturbation is internally generated) of an aerosol perturbation due directly to aerosol-radiation interactions, with all environmental variables remaining unaffected. Traditionally known in the literature as the direct aerosol forcing (or effect).

**Afforestation**  Conversion to forest of land that historically has not contained forests. [Note: For a discussion of the term forest and related terms such as afforestation, reforestation and deforestation, see the 2006 IPCC Guidelines for National Greenhouse Gas Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019, UNFCCC, 2021a, 2021b).] See also Deforestation, Reducing Emissions from Deforestation and Forest Degradation (REDD+), Reforestation, Anthropogenic removals and Carbon dioxide removal (CDR).

**Agreement**  In this report, the degree of agreement within the scientific body of knowledge on a particular finding is assessed based on multiple lines of evidence (e.g., mechanistic understanding, theory, data, models, expert judgement) and expressed qualitatively (Mastrandrea et al., 2010). See also Confidence, Likelihood, Uncertainty and Evidence.
Agricultural or ecological drought  See Drought.

Air mass  A widespread body of air, the approximately homogeneous properties of which (1) have been established while that air was situated over a particular region of the Earth's surface, and (2) undergo specific modifications while in transit away from the source region (AMS, 2021).

Air pollution  Degradation of air quality with negative effects on human health or the natural or built environment due to the introduction, by natural processes or human activity, into the atmosphere of substances (gases, aerosols) which have a direct (primary pollutants) or indirect (secondary pollutants) harmful effect. See also Short-lived climate forcers (SLCFs).

Airborne fraction  The fraction of total CO₂ emissions (from fossil fuel and land use change) remaining in the atmosphere.

Albedo  The proportion of sunlight (solar radiation) reflected by a surface or object, often expressed as a percentage. Clouds, snow and ice usually have high albedo; soil surfaces cover the albedo range from high to low; vegetation in the dry season and/or in arid zones can have high albedo; whereas photosynthetically active vegetation and the ocean have low albedo. The Earth's planetary albedo changes mainly through changes in cloudiness and of snow, ice, leaf area and land cover.

Alkalinity  See Total alkalinity.

Altimetry  A technique for measuring the height of the Earth's surface with respect to the geocentre of the Earth within a defined terrestrial reference frame (geocentric sea level).

Annular modes  Hemispheric scale patterns of atmospheric variability characterized by opposing and synchronous fluctuations in sea-level pressure between the polar caps and mid-latitudes, with a structure exhibiting a high degree of zonal symmetry, and with no real preferred timescales ranging from days to decades. In each hemisphere, these fluctuations reflect changes in the latitudinal position and strength of the mid-latitude jets and associated storm tracks. Annular modes are defined as the leading mode of variability of extratropical sea-level pressure or geopotential heights and are known as the Northern Annular Mode (NAM) and Southern Annular Mode (SAM) in the two hemispheres, respectively.

Northern Annular Mode (NAM)  A see-saw latitudinal fluctuation in Northern Hemisphere sea-level pressure or geopotential height between the Arctic and the mid-latitudes. The NAM has some links with the stratospheric polar vortex and is related to the fluctuation in strength and latitude of the mean westerlies. Its variance is maximum in winter and its pattern has a strong regional expression in the North Atlantic being strongly correlated with the North Atlantic Oscillation index. The NAM is also known as the Arctic Oscillation (AO). In its positive phase, the NAM is characterized by anomalously low pressure over the Arctic and high pressure over the mid-latitudes/subtropics, with a strengthening of the zonally averaged westerly winds on their polar flank that confines colder air across the Arctic. The negative NAM phase is characterized by a more distorted wind pattern and jet meanders which increases storminess in the midlatitude regions. See Section AIV.2.1 in Annex IV of the AR6 WGI report.

Southern Annular Mode (SAM)  The leading mode of climate variability of Southern Hemisphere sea-level pressure and geopotential height, which is associated with the strength and latitudinal shifts in the mid- to high-latitudes westerly wind belt. The SAM is also known as the Antarctic Oscillation (AAO). A positive SAM phase is defined as lower-than-normal pressures over the polar regions and higher-than-normal pressures in the southern mid-latitudes, with a contraction towards Antarctica and strengthening of the westerly wind belt. The negative SAM phase exhibits positive high latitude pressure anomalies, negative mid-latitude pressure anomalies and a weaker westerly flow expanded towards the equator. See Section AIV.2.2 in Annex IV of the AR6 WGI report. See also Annular modes.

Anomaly  The deviation of a variable from its value averaged over a reference period.
Antarctic amplification  See Polar amplification.

Antarctic ice sheet (AIS)  See Ice sheet.

Antarctic oscillation (AAO)  See Southern Annular Mode (SAM) (under Annular modes).

Anthropocene  A proposed new geological epoch resulting from significant human-driven changes to the structure and functioning of the Earth System, including the climate system. Originally proposed in the Earth System science community in 2000, the proposed new epoch is undergoing a formalization process within the geological community based on the stratigraphic evidence that human activities have changed the Earth System to the extent of forming geological deposits with a signature that is distinct from those of the Holocene, and which will remain in the geological record. Both the stratigraphic and Earth System approaches to defining the Anthropocene consider the mid-20th Century to be the most appropriate starting date (Steffen et al., 2016), although others have been proposed and continue to be discussed. The Anthropocene concept has already been informally adopted by diverse disciplines and the public to denote the substantive influence of humans on the Earth System.

Anthropogenic  Resulting from or produced by human activities.

Anthropogenic emissions  Emissions of greenhouse gases (GHGs), precursors of GHGs and aerosols caused by human activities. These activities include the burning of fossil fuels, deforestation, land use and land use changes (LULUC), livestock production, fertilisation, waste management, and industrial processes. See also Anthropogenic and Anthropogenic removals.

Anthropogenic removals  The withdrawal of greenhouse gases (GHGs) from the atmosphere as a result of deliberate human activities. These include enhancing biological sinks of CO₂ and using chemical engineering to achieve long term removal and storage. Carbon capture and storage (CCS), which alone does not remove CO₂ from the atmosphere, can help reduce atmospheric CO₂ from industrial and energy-related sources if it is combined with bioenergy production (BECCS), or if CO₂ is captured from the air directly and stored (DACCs). [Note: In the 2006 IPCC Guidelines for national GHG Inventories (IPCC, 2006), which are used in reporting of emissions to the UNFCCC, ‘anthropogenic’ land-related GHG fluxes are defined as all those occurring on ‘managed land’, i.e. where human interventions and practices have been applied to perform production, ecological or social functions’. However, some removals (e.g. removals associated with CO₂ fertilisation and N deposition) are not considered as ‘anthropogenic’, or are referred to as ‘indirect’ anthropogenic effects, in some of the scientific literature assessed in this report. As a consequence, the land-related net GHG emission estimates from global models included in this report are not necessarily directly comparable with LULUCF estimates in national GHG Inventories.] See also Carbon dioxide removal (CDR), Afforestation, Biochar, Enhanced weathering, Ocean alkalinisation / Ocean alkalinity enhancement, Reforestation and Soil carbon sequestration (SCS).

Anthropogenic subsidence  Downward motion of the land surface induced by anthropogenic drivers (e.g., loading, extraction of hydrocarbons and/or groundwater, drainage, mining activities) causing sediment compaction or subsidence/deformation of the sedimentary sequence, or oxidation of organic material, thereby leading to relative sea level rise.

Apparent hydrological sensitivity (ηₐ)  The change in global mean precipitation per degree Celsius of global mean temperature change with units of % per °C although can also be calculated as W m⁻² per °C. See also Hydrological sensitivity (η).

Arid amplification  See Polar amplification.

Arid zone  Areas where vegetation growth is severely constrained due to limited water availability. For the most part, the native vegetation of arid zones is sparse. There is high rainfall variability, with annual averages below 300 mm. Crop farming in arid zones requires irrigation.
Aridity  The state of a long-term climatic feature characterised by low average precipitation or available water in a region. Aridity generally arises from widespread persistent atmospheric subsidence or anticyclonic conditions, and from more localised subsidence in the lee side of mountains (adapted from Gbeckor-Kove, 1989; Türkeş, 1999). See also Drought.

Artificial ocean upwelling (AOUpw)  Artificial ocean upwelling (AOUpw) is a potential carbon dioxide removal method that aims to artificially pump up cooler, nutrient-rich waters from deep in the ocean to the surface. The aim is to stimulate phytoplankton activity and thereby increase ocean CO₂ uptake.

Assets  Natural or human-made resources that provide current or future utility, benefit, economic or intrinsic value to natural or human systems.

Atlantic Equatorial Mode  See Atlantic Zonal Mode (AZM) (under Tropical Atlantic Variability (TAV)).

Atlantic Meridional Mode (AMM)  See Tropical Atlantic Variability (TAV).

Atlantic Meridional Overturning Circulation (AMOC)  See Meridional overturning circulation (MOC).

Atlantic Multidecadal Oscillation (AMO)  See Atlantic Multidecadal Variability (AMV).

Atlantic Multidecadal Variability (AMV)  Large-scale fluctuations observed from one decade to the next in a variety of instrumental records and proxy reconstructions over the entire North Atlantic ocean and surrounding continents. Fingerprint of Atlantic Multidecadal Variability (AMV) can be found at the surface ocean, which is characterized by swings in basin-scale sea surface temperature anomalies reflecting the interaction with the atmosphere. The positive phase of the AMV is characterized by anomalous warming over the entire North Atlantic, with the strongest amplitude in the subpolar gyre and along sea-ice margins in the Labrador Sea and Greenland/Barents Sea and in the subtropical North Atlantic basin to a lower extent. In the AR6 WGI report, the term AMV is preferred to Atlantic Multidecadal Oscillation (AMO) used in previous IPCC reports because there is no preferred timescale of decadal variability as the term oscillation would indirectly implied. See Section AIV.2.7 in Annex IV of the AR6 WGI report.

Atlantic Niño  See Atlantic Zonal Mode (AZM) (under Tropical Atlantic Variability (TAV)).

Atlantic Zonal Mode (AZM)  See Tropical Atlantic Variability (TAV).

Atmosphere  The gaseous envelope surrounding the Earth, divided into five layers – the troposphere which contains half of the Earth’s atmosphere, the stratosphere, the mesosphere, the thermosphere, and the exosphere, which is the outer limit of the atmosphere. The dry atmosphere consists almost entirely of nitrogen (78.1% volume mixing ratio) and oxygen (20.9% volume mixing ratio), together with a number of trace gases, such as argon (0.93% volume mixing ratio), helium and radiatively active greenhouse gases (GHGs) such as carbon dioxide (CO₂) (0.04% volume mixing ratio), methane (CH₄), nitrous oxide (N₂O) and ozone (O₃). In addition, the atmosphere contains the GHG water vapour (H₂O), whose concentrations are highly variable (0.5% volume mixing ratio) as the sources (evapotranspiration) and sinks (precipitation) of water vapour show large spatio-temporal variations, and atmospheric temperature exerts a strong constraint on the amount of water vapour an air parcel can hold. The atmosphere also contains clouds and aerosols. See also Hydrological cycle, Stratosphere and Troposphere.

Atmosphere-ocean general circulation model (AOGCM)  See General circulation model (GCM).

Atmospheric boundary layer  The atmospheric layer adjacent to the Earth’s surface that is affected by friction against that boundary surface, and possibly by transport of heat and other variables across that surface (AMS, 2021). The lowest 100 m of the boundary layer (about 10% of the boundary layer thickness), where mechanical generation of turbulence is dominant, is called the surface boundary layer or surface layer.

Atmospheric lifetime  See Lifetime.
Atmospheric rivers (ARs)  Long, narrow (up to a few hundred km wide), shallow (up to a few km deep) and transient corridors of strong horizontal water vapour transport that are typically associated with a low-level jet stream ahead of the cold front of an extratropical cyclone (Ralph et al., 2018).

Attribution  Attribution is defined as the process of evaluating the relative contributions of multiple causal factors to a change or event with an assessment of confidence.

Australian and Maritime Continent monsoon (AusMCM)  See Global monsoon.

Autotrophic respiration  Respiration by photosynthetic (see photosynthesis) organisms (e.g., plants and algae).

Avalanche  A mass of snow, ice, earth or rocks, or a mixture of these, falling down a mountainside.

Barystatic  See Sea level change (sea level rise/sea level fall).

Basal lubrication  Reduction of friction at the base of an ice sheet or glacier due to lubrication by meltwater. This can allow the glacier or ice sheet to slide over its base. Meltwater may be produced by pressure-induced melting, friction or geothermal heat, or surface melt may drain to the base through holes in the ice.

Baseline/reference  The baseline (or reference) is the state against which change is measured. See Baseline scenario (under Scenario) and Baseline/reference (period). See also Baseline period (under Reference period) and Reference period.

Baseline period  See Reference period.

Baseline scenario  See Scenario.

Bifurcation point  See Tipping point.

Biodiversity  Biodiversity or biological diversity means the variability among living organisms from all sources including, among other things, terrestrial, marine and other aquatic ecosystems, and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems (UN, 1992). See also Ecosystem and Ecosystem services.

Bioenergy with carbon dioxide capture and storage (BECCS)  Carbon dioxide capture and storage (CCS) technology applied to a bioenergy facility. Note that depending on the total emissions of the BECCS supply chain, carbon dioxide (CO₂) can be removed from the atmosphere. See also Bioenergy, Carbon dioxide capture and storage (CCS), Anthropogenic removals and Carbon dioxide removal (CDR).

Biogenic volatile organic compounds (BVOCs)  See Volatile organic compounds (VOCs).

Biogeophysical potential  See Mitigation potential.

Biological (carbon) pump  A series of ocean processes through which inorganic carbon (as carbon dioxide, CO₂) is fixed as organic matter by photosynthesis in sunlit surface water and then transported to the ocean interior, and possibly the sediment, resulting in the storage of carbon.

Biomass  Organic material excluding the material that is fossilised or embedded in geological formations. Biomass may refer to the mass of organic matter in a specific area (ISO, 2014). See also Bioenergy and Biofuel.

Biosphere (terrestrial and marine)  The part of the Earth System comprising all ecosystems and living organisms, in the atmosphere, on land (terrestrial biosphere) or in the oceans (marine biosphere), including
derived dead organic matter, such as litter, soil organic matter and oceanic detritus.

**Bipolar seesaw (also interhemispheric seesaw, interhemispheric asymmetry, hemispheric asymmetry)**

A phenomenon in which temperature changes in the northern and southern hemispheres are related but out of phase, generally inferred to represent a change in the magnitude or sign of net heat transport across the equator. Originally called hemispheric asymmetry and linked to changes in thermohaline overturning circulation on multi-millennial scales (Mix et al., 1986), later named bipolar seesaw and applied to millennial scales (Broecker, 1998) with a similar thermohaline mechanism (Stocker and Johnsen, 2003). See also Meridional overturning circulation (MOC) and Deglacial or deglaciation or glacial termination.

**Black carbon (BC)** A relatively pure form of carbon, also known as soot, arising from the incomplete combustion of fossil fuels, biofuel, and biomass. It only stays in the atmosphere for days or weeks. BC is a climate forcing agent with strong warming effect, both in the atmosphere and when deposited on snow or ice. See also Aerosol and Atmosphere.

**Blocking** Associated with persistent, slow-moving high-pressure systems that obstruct the prevailing westerly winds in the middle and high latitudes and the normal eastward progress of extratropical transient storm systems. It is an important component of the intraseasonal climate variability in the extratropics and can cause long-lived weather conditions such as cold spells in winter and summer heat waves.

**Blue carbon** Biologically-driven carbon fluxes and storage in marine systems that are amenable to management. Coastal blue carbon focuses on rooted vegetation in the coastal zone, such as tidal marshes, mangroves and seagrasses. These ecosystems have high carbon burial rates on a per unit area basis and accumulate carbon in their soils and sediments. They provide many non-climatic benefits and can contribute to ecosystem-based adaptation. If degraded or lost, coastal blue carbon ecosystems are likely to release most of their carbon back to the atmosphere. There is current debate regarding the application of the blue carbon concept to other coastal and non-coastal processes and ecosystems, including the open ocean. See also Ecosystem services and Sequestration.

**Brewer-Dobson circulation** The meridional overturning circulation of the stratosphere transporting air upward in the tropics, poleward to the winter hemisphere, and downward at polar and subpolar latitudes. The Brewer-Dobson circulation is driven by the interaction between upward propagating planetary waves and the mean flow.

**Burden** The total mass of a substance of concern in the atmosphere.

**Business as usual (BAU)** The term business as usual scenario has been used to describe a scenario that assumes no additional policies beyond those currently in place and that patterns of socio-economic development are consistent with recent trends. The term is now used less frequently than in the past. See also Reference scenario (under Scenario).

**$^{13}$C** Stable isotope of carbon having an atomic weight of approximately 13. Measurements of the ratio of $^{13}$C/$^{12}$C in carbon dioxide molecules are used to infer the importance of different carbon cycle and climate processes and the size of the terrestrial carbon reservoir.

**$^{14}$C** Unstable isotope of carbon having an atomic weight of approximately 14, and a half-life of about 5700 years. It is often used for dating purposes going back some 40 kyr. Its variation in time is affected by the magnetic fields of the Sun and Earth, which influence its production from cosmic rays (see Cosmogenic radioisotopes).

**Calcification** The process of biologically precipitating calcium carbonate minerals to create organism shells, skeletons, otoliths, or other body structures. The chemical equation describing calcification is $\text{Ca}^{2+} (\text{aq}) + 2\text{HCO}_3^- (\text{aq}) \rightarrow \text{CaCO}_3(s) + \text{CO}_2 + \text{H}_2\text{O}$. Aragonite and calcite are two common crystalline forms of biologically precipitated calcium carbonate minerals that have different solubilities.
Calving (of glaciers or ice sheets) The breaking off of discrete pieces of ice from a glacier, ice sheet or an ice shelf into lake or seawater, producing icebergs. This is a form of mass loss from an ice body.

Canopy temperature The temperature within the canopy of a vegetation structure.

Carbon budget Refers to two concepts in the literature: (1) an assessment of carbon cycle sources and sinks on a global level, through the synthesis of evidence for fossil-fuel and cement emissions, emissions and removals associated with land use and land use change, ocean and natural land sources and sinks of carbon dioxide (CO$_2$), and the resulting change in atmospheric CO$_2$ concentration. This is referred to as the Global Carbon Budget; (2) the maximum amount of cumulative net global anthropogenic CO$_2$ emissions that would result in limiting global warming to a given level with a given probability, taking into account the effect of other anthropogenic climate forcers. This is referred to as the Total Carbon Budget when expressed starting from the pre-industrial period, and as the Remaining Carbon Budget when expressed from a recent specified date.

Note 1: Net anthropogenic CO$_2$ emissions are anthropogenic CO$_2$ emissions minus anthropogenic CO$_2$ removals. See also Carbon Dioxide Removal (CDR).

Note 2: The maximum amount of cumulative net global anthropogenic CO$_2$ emissions is reached at the time that annual net anthropogenic CO$_2$ emissions reach zero.

Note 3: The degree to which anthropogenic climate forcers other than CO$_2$ affect the Total Carbon Budget and Remaining Carbon Budget depends on human choices about the extent to which these forcers are mitigated and their resulting climate effects.

Note 4: The notions of a Total Carbon Budget and Remaining Carbon Budget are also being applied in parts of the scientific literature and by some entities at regional, national, or sub-national level. The distribution of global budgets across individual different entities and emitters depends strongly on considerations of equity and other value judgements.

Carbon cycle The flow of carbon (in various forms, e.g., as carbon dioxide (CO$_2$), carbon in biomass, and carbon dissolved in the ocean as carbonate and bicarbonate) through the atmosphere, hydrosphere, terrestrial and marine biosphere and lithosphere. In this report, the reference unit for the global carbon cycle is GtCO$_2$ or GtC (one Gigatonne = 1 Gt = 10$^{15}$ grams; 1GtC corresponds to 3.667 GtCO$_2$).

Carbon dioxide (CO$_2$) A naturally occurring gas, CO$_2$ is also a by-product of burning fossil fuels (such as oil, gas and coal), of burning biomass, of land use changes (LUC) and of industrial processes (e.g., cement production). It is the principal anthropogenic greenhouse gas (GHG) that affects the Earth's radiative balance. It is the reference gas against which other GHGs are measured and therefore has a Global Warming Potential (GWP) of 1. See also Land use and Land-use change (LUC).

Carbon dioxide (CO$_2$) fertilisation The increase of plant photosynthesis and water-use efficiency in response to increased atmospheric carbon dioxide (CO$_2$) concentration. Whether this increased photosynthesis translates into increased plant growth and carbon storage on land depends on the interacting effects of temperature, moisture and nutrient availability.

Carbon dioxide capture and storage (CCS) A process in which a relatively pure stream of carbon dioxide (CO$_2$) from industrial and energy-related sources is separated (captured), conditioned, compressed and transported to a storage location for long-term isolation from the atmosphere. Sometimes referred to as Carbon Capture and Storage. See also Bioenergy with carbon dioxide capture and storage (BECCS), Carbon dioxide capture and utilisation (CCU), Sequestration, Anthropogenic removals and Carbon dioxide removal (CDR).

Carbon dioxide removal (CDR) Anthropogenic activities removing carbon dioxide (CO$_2$) from the atmosphere and durably storing it in geological, terrestrial, or ocean reservoirs, or in products. It includes
existing and potential anthropogenic enhancement of biological or geochemical CO₂ sinks and direct air capture and storage, but excludes natural CO₂ uptake not directly caused by human activities. See also Anthropogenic removals, Afforestation, Biochar, Enhanced weathering, Ocean alkalisation / Ocean alkalinity enhancement, Reforestation, Soil carbon sequestration (SCS), Bioenergy with carbon dioxide capture and storage (BECCS) and Carbon dioxide capture and storage (CCS).

**Carbon neutrality** Condition in which anthropogenic CO₂ emissions associated with a subject are balanced by anthropogenic CO₂ removals. The subject can be an entity such as a country, an organisation, a district or a commodity, or an activity such as a service and an event. Carbon neutrality is often assessed over the life cycle including indirect ("scope 3") emissions, but can also be limited to the emissions and removals, over a specified period, for which the subject has direct control, as determined by the relevant scheme.

Note 1: Carbon neutrality and net zero CO₂ emissions are overlapping concepts. The concepts can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms carbon neutrality and net zero CO₂ emissions are equivalent. At sub-global scales, net zero CO₂ emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while carbon neutrality generally includes emissions and removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant CO₂ emissions and removals.

Note 2: In some cases achieving carbon neutrality may rely on the supplementary use of offsets to balance emissions that remain after actions by the reporting entity are taken into account.

See also Greenhouse gas neutrality, Land use, land-use change and forestry (LULUCF) and Net zero CO₂ emissions.

**Carbon sequestration** See Sequestration.

**Carbon sink** See Sink.

**Carbon source** See Source.

**Carbon-climate feedback** See Climate-carbon cycle feedback.

**Carbonaceous aerosol** Aerosol consisting predominantly of organic substances and black carbon.

**Carbonate counter pump** See Carbonate pump.

**Carbonate pump** Ocean carbon fixation through the biological formation of carbonates, primarily by plankton that generate bio-mineral particles that sink to the ocean interior, and possibly the sediment. It is also called carbonate counter-pump, since the formation of calcium carbonate (CaCO₃) is accompanied by the release of carbon dioxide (CO₂) to surrounding water and subsequently to the atmosphere.

**Catchment** An area that collects and drains precipitation.

**Cenozoic Era** The third and current geological Era, which began 66.0 Ma. It comprises the Paleogene, Neogene and Quaternary Periods.

**Central Pacific El Niño** See El Niño-Southern Oscillation (ENSO).

**Chaotic** A dynamical system such as the climate system, governed by nonlinear deterministic equations (see Nonlinearity), may exhibit erratic or chaotic behaviour in the sense that very small changes in the initial state of the system in time lead to large and apparently unpredictable changes in its temporal evolution. Such chaotic behaviour limits the predictability of the state of a nonlinear dynamical system at specific future
times, although changes in its statistics may still be predictable given changes in the system parameters or
boundary conditions.

Charcoal  Material resulting from charring of biomass, usually retaining some of the microscopic texture
typical of plant tissues; chemically it consists mainly of carbon with a disturbed graphitic structure, with
lesser amounts of oxygen and hydrogen.

Chlorofluorocarbons (CFCs)  A chlorofluorocarbon is an organic compound that contains chlorine,
carbon, hydrogen, and fluorine and is used for refrigeration, air conditioning, packaging, plastic foam,
insulation, solvents, or aerosol propellants. Because they are not destroyed in the lower atmosphere, CFCs
drift into the upper atmosphere where, given suitable conditions, they break down ozone (O₃). It is one of the
greenhouse gases (GHGs) covered under the 1987 Montreal Protocol as a result of which manufacturing of
these gases has been phased out and they are being replaced by other compounds, including
hydrofluorocarbons (HFCs) which are GHGs covered under the Kyoto Protocol.

Chronology  Arrangement of events according to dates or times of occurrence.

Cirrus cloud thinning (CCT)  See Solar radiation modification (SRM).

Clathrate (methane)  A partly frozen slushy mix of methane gas and ice, usually found in sediments.

Clausius-Clapeyron equation/relationship  The thermodynamic relationship between temperature and the
vapour pressure of a substance in which two phases of the substance are in equilibrium (e.g., liquid water
and water vapour). For gases such as water vapour, this relation gives the increase in equilibrium (or
saturation) vapour pressure per unit change in air temperature.

Climate  Climate in a narrow sense is usually defined as the average weather, or more rigorously, as the
statistical description in terms of the mean and variability of relevant quantities over a period of time ranging
from months to thousands or millions of years. The classical period for averaging these variables is 30 years,
as defined by the World Meteorological Organization (WMO). The relevant quantities are most often surface
variables such as temperature, precipitation and wind. Climate in a wider sense is the state, including a
statistical description, of the climate system.

Climate change  A change in the state of the climate that can be identified (e.g., by using statistical tests)
by changes in the mean and or the variability of its properties and that persists for an extended period,
typically decades or longer. Climate change may be due to natural internal processes or external forcings
such as modulations of the solar cycles, volcanic eruptions and persistent anthropogenic changes in the
composition of the atmosphere or in land use. Note that the United Nations Framework Convention on
Climate Change (UNFCCC), in its Article 1, defines climate change as: ‘a change of climate which is
attributed directly or indirectly to human activity that alters the composition of the global atmosphere and
which is in addition to natural climate variability observed over comparable time periods’. The UNFCCC
thus makes a distinction between climate change attributable to human activities altering the atmospheric
composition and climate variability attributable to natural causes. See also Climate variability, Detection and
attribution, Global warming and Ocean acidification (OA).

Climate change commitment  Climate change commitment is defined as the unavoidable future climate
change resulting from inertia in the geophysical and socio-economic systems. Different types of climate
change commitment are discussed in the literature (see subterms). Climate change commitment is usually
quantified in terms of the further change in temperature, but it includes other future changes, for example in
the hydrological cycle, in extreme weather events, in extreme climate events, and in sea level.

Constant composition commitment  The constant composition commitment is the remaining climate change
that would result if atmospheric composition, and hence radiative forcing, were held fixed at a given value.
It results from the thermal inertia of the ocean and slow processes in the cryosphere and land surface.
Constant emissions commitment The constant emissions commitment is the committed climate change that would result from keeping anthropogenic emissions constant.

Zero emissions commitment The zero emissions commitment is an estimate of the subsequent global warming that would result after anthropogenic emissions are set to zero. It is determined by both inertia in physical climate system components (ocean, cryosphere, land surface) and carbon cycle inertia. In its widest sense it refers to emissions of each climate forcer including greenhouses gases, aerosols and their precursors. The climate response to this can be complex due to the different timescale of response of each climate forcer. A specific sub-category of zero emissions commitment is the Zero CO₂ Emissions Commitment which refers to the climate system response to CO₂ emissions after setting these to net zero. The CO₂-only definition is of specific use in estimating remaining carbon budgets.

Climate extreme (extreme weather or climate event) The occurrence of a value of a weather or climate variable above (or below) a threshold value near the upper (or lower) ends of the range of observed values of the variable. By definition, the characteristics of what is called extreme weather may vary from place to place in an absolute sense. When a pattern of extreme weather persists for some time, such as a season, it may be classified as an extreme climate event, especially if it yields an average or total that is itself extreme (e.g., high temperature, drought, or heavy rainfall over a season). For simplicity, both extreme weather events and extreme climate events are referred to collectively as ‘climate extremes’.

Climate feedback An interaction in which a perturbation in one climate quantity causes a change in a second and the change in the second quantity ultimately leads to an additional change in the first. A negative feedback is one in which the initial perturbation is weakened by the changes it causes; a positive feedback is one in which the initial perturbation is enhanced. The initial perturbation can either be externally forced or arise as part of internal variability. See also Climate-carbon cycle feedback, Cloud feedback and Ice-albedo feedback.

Climate feedback parameter A way to quantify the radiative response of the climate system to a global surface temperature change induced by a radiative forcing. It is quantified as the change in net energy flux at the top of atmosphere for a given change in annual global surface temperature. It has units of W m⁻² °C⁻¹.

Climate forecast See Climate prediction.

Climate index A time series constructed from climate variables that provides an aggregate summary of the state of the climate system. For example, the difference between sea level pressure in Iceland and the Azores provides a simple yet useful historical NAO index. Because of their optimal properties, climate indices are often defined using principal components — linear combinations of climate variables at different locations that have maximum variance subject to certain normalisation constraints (e.g., the NAM and SAM indices which are principal components of Northern Hemisphere and Southern Hemisphere gridded pressure anomalies, respectively). Definitions of observational indices for Modes of variability can be found in the Annex VI.

Climate indicator Measures of the climate system including large-scale variables and climate proxies. See also Global surface temperature indicators and Climate metrics.

Key climate indicators Key indicators constitute a finite set of distinct variables that may collectively point to important overall changes in the climate system of broad societal relevance across the atmospheric, oceanic, cryospheric and biospheric domains, with land as an implicit cross-cutting theme. Taken together, these indicators would be expected to both have changed and continue to change in the future in a coherent and consistent manner. See Cross-Chapter Box 2.2, Table 1 in the AR6 WGI report.

Climate information Information about the past, current state, or future of the climate system that is relevant for mitigation, adaptation and risk management. It may be tailored or “co-produced” for specific contexts, taking into account users’ needs and values.
Climate metrics  Measures of aspects of the overall climate system response to radiative forcing, such as equilibrium climate sensitivity (ECS), transient climate response (TCR), transient climate response to cumulative CO₂ emissions (TCRE) and the airborne fraction of anthropogenic carbon dioxide. See also Greenhouse gas emission metric, Climate indicator and Key climate indicators (under Climate indicator).

Climate model  A qualitative or quantitative representation of the climate system based on the physical, chemical and biological properties of its components, their interactions and feedback processes and accounting for some of its known properties. The climate system can be represented by models of varying complexity; that is, for any one component or combination of components a spectrum or hierarchy of models can be identified, differing in such aspects as the number of spatial dimensions, the extent to which physical, chemical or biological processes are explicitly represented, or the level at which empirical parametrisations are involved. There is an evolution towards more complex models with interactive chemistry and biology. Climate models are applied as a research tool to study and simulate the climate and for operational purposes, including monthly, seasonal and interannual climate predictions. See also Chemistry-climate model, Earth system model (ESM), Earth system model of intermediate complexity (EMIC), Energy balance model (EBM), Simple climate model (SCM), Regional climate model (RCM), Dynamic global vegetation model (DGVM), General circulation model (GCM) and Emulators.

Climate pattern  A set of spatially varying coefficients obtained by “projection” (regression) of climate variables onto a climate index time series. When the climate index is a principal component, the climate pattern is an eigenvector of the covariance matrix, referred to as an Empirical Orthogonal Function (EOF) in climate science.

Climate prediction  A climate prediction or climate forecast is the result of an attempt to produce (starting from a particular state of the climate system) an estimate of the actual evolution of the climate in the future, for example, at seasonal, interannual or decadal time scales. Because the future evolution of the climate system may be highly sensitive to initial conditions, has chaotic elements and is subject to natural variability, such predictions are usually probabilistic in nature.

Climate projection  Simulated response of the climate system to a scenario of future emissions or concentrations of greenhouse gases (GHGs) and aerosols and changes in land use, generally derived using climate models. Climate projections are distinguished from climate predictions by their dependence on the emission/concentration/radiative forcing scenario used, which is in turn based on assumptions concerning, for example, future socio-economic and technological developments that may or may not be realised.

Climate response  A general term for how the climate system responds to a radiative forcing.

Climate scenario  A plausible and often simplified representation of the future climate, based on an internally consistent set of climatological relationships that has been constructed for explicit use in investigating the potential consequences of anthropogenic climate change, often serving as input to impact models. Climate projections often serve as the raw material for constructing climate scenarios, but climate scenarios usually require additional information such as the observed current climate. See also Regional climate scenario.

Climate sensitivity  The change in the surface temperature in response to a change in the atmospheric carbon dioxide (CO₂) concentration or other radiative forcing. See also Climate feedback parameter.

Earth system sensitivity  The equilibrium surface temperature response of the coupled atmosphere-ocean-cryosphere-vegetation-carbon cycle system to a doubling of the atmospheric carbon dioxide (CO₂) concentration is referred to as Earth System sensitivity. Because it allows ice sheets to adjust to the external perturbation, it may differ substantially from the equilibrium climate sensitivity derived from coupled atmosphere-ocean models.

Equilibrium climate sensitivity (ECS)  The equilibrium (steady state) change in the surface temperature following a doubling of the atmospheric carbon dioxide (CO₂) concentration from pre-industrial conditions.
**Transient climate response (TCR)**  The surface temperature response for the hypothetical scenario in which atmospheric carbon dioxide (CO₂) increases at 1% yr⁻¹ from pre-industrial to the time of a doubling of atmospheric CO₂ concentration (year 70).

**Transient climate response to cumulative CO₂ emissions (TCRE)**  The transient surface temperature change per unit cumulative carbon dioxide (CO₂) emissions, usually 1000 GtC. TCRE combines both information on the airborne fraction of cumulative CO₂ emissions (the fraction of the total CO₂ emitted that remains in the atmosphere, which is determined by carbon cycle processes) and on the transient climate response (TCR).

**Climate services**  Climate services involve the provision of climate information in such a way as to assist decision-making. The service includes appropriate engagement from users and providers, is based on scientifically credible information and expertise, has an effective access mechanism, and responds to user needs (Hewitt et al., 2012).

**Climate simulation ensemble**  A group of parallel model simulations characterising historical climate conditions, climate predictions, or climate projections. Variation of the results across the ensemble members may give an estimate of modelling-based uncertainty. Ensembles made with the same model but different initial conditions characterise the uncertainty associated with internal climate variability, whereas multi-model ensembles including simulations by several models also include the effect of model differences. Perturbed parameter ensembles, in which model parameters are varied in a systematic manner, aim to assess the uncertainty resulting from internal model specifications within a single model. Remaining sources of uncertainty unaddressed with model ensembles are related to systematic model errors or biases, which may be assessed from systematic comparisons of model simulations with observations wherever available.

**Climate system**  The global system consisting of five major components: the atmosphere, the hydrosphere, the cryosphere, the lithosphere and the biosphere and the interactions between them. The climate system changes in time under the influence of its own internal dynamics and because of external forcings such as volcanic eruptions, solar variations, orbital forcing, and anthropogenic forcings such as the changing composition of the atmosphere and land-use change.

**Climate threshold**  A limit within the climate system (or its forcing) beyond which the behaviour of the system is qualitatively changed. See also Abrupt climate change and Tipping point.

**Climate variability**  Deviations of climate variables from a given mean state (including the occurrence of extremes, etc.) at all spatial and temporal scales beyond that of individual weather events. Variability may be intrinsic, due to fluctuations of processes internal to the climate system (internal variability), or extrinsic, due to variations in natural or anthropogenic external forcing (forced variability). See also Climate change and Modes of climate variability.

**Decadal variability**  Decadal variability refers to climate variability on decadal time scales. See also Pacific Decadal Variability (PDV), Atlantic Multi-decadal Oscillation/Variability (AMO/AMV) and Pacific Decadal Oscillation (PDO) (under Pacific Decadal Variability (PDV)).

**Internal variability**  Fluctuations of the climate dynamical system when subject to a constant or periodic external forcing (such as the annual cycle). See also Climate variability.

**Natural variability**  Natural variability refers to climatic fluctuations that occur without any human influence, i.e. internal variability combined with the response to external natural factors such as volcanic eruptions, changes in solar activity and, on longer time-scales, orbital effects and plate tectonics. See also Orbital forcing.

**Climate velocity**  The speed at which isolines of a specified climate variable travel across landscapes or seascapes due to changing climate. For example, climate velocity for temperature is the speed at which...

---

isotherms move due to changing climate (km yr⁻¹) and is calculated as the temporal change in temperature (°C yr⁻¹) divided by the current spatial gradient in temperature (°C km⁻¹). It can be calculated using additional climate variables such as precipitation or can be based on the climatic niche of organisms.

**Climate-carbon cycle feedback** A *climate feedback* involving changes in the properties of land and ocean carbon cycle in response to *climate change*. In the ocean, changes in oceanic temperature and circulation could affect the atmosphere-ocean CO₂ flux; on the continents, climate change could affect plant photosynthesis and soil microbial respiration and hence the flux of CO₂ between the atmosphere and the land biosphere.

**Climatic impact-driver (CID)** Climatic impact-drivers (CIDs) are physical *climate system* conditions (e.g., means, events, extremes) that affect an element of society or ecosystems. Depending on system tolerance, CIDs and their changes can be detrimental, beneficial, neutral, or a mixture of each across interacting system elements and regions. See also *Risk, Hazard and Impacts (consequences, outcomes)*.

**Cloud condensation nuclei (CCN)** The subset of *aerosol* particles that serve as an initial site for the condensation of liquid water, which can lead to the formation of cloud droplets, under typical cloud formation conditions. The main factor that determines which *aerosol* particles are CCN at a given supersaturation is their size.

**Cloud feedback** A *climate feedback* involving changes in any of the properties of clouds as a response to a change in the local or *global mean surface temperature*. Understanding cloud feedbacks and determining their magnitude and sign require an understanding of how a change in *climate* may affect the spectrum of cloud types, the cloud fraction and height, the radiative properties of clouds, and finally the Earth's radiation budget. At present, cloud feedbacks remain the largest source of *uncertainty* in *climate sensitivity* estimates.

**Cloud radiative effect** The *radiative effect* of clouds relative to the identical situation without clouds. In previous IPCC reports this was called *cloud radiative forcing*, but that terminology is inconsistent with other uses of the forcing term and is not maintained in this report.

**Cloud-resolving models (CRMs)** Numerical models that are that are of high enough resolution and have the necessary physics to represent the dynamical and physical processes of cloud formation.

**CMIP6** See *Coupled Model Intercomparison Project* (CMIP).

**CO₂ equivalent (CO₂ eq) emission** The amount of *carbon dioxide* (CO₂) emission that would have an equivalent effect on a specified key measure of *climate change*, over a specified time horizon, as an emitted amount of another *greenhouse gas* (GHG) or a mixture of other GHGs. For a mix of GHGs it is obtained by summing the CO₂-equivalent emissions of each gas. There are various ways and time horizons to compute such equivalent emissions (see *greenhouse gas emission metric*). CO₂-equivalent emissions are commonly used to compare emissions of different GHGs, but should not be taken to imply that these emissions have an equivalent effect across all key measures of climate change. [Note: Under the Paris Rulebook [Decision 18/CMA.1, annex, paragraph 37], parties have agreed to use GWP100 values from the IPCC AR5 or GWP100 values from a subsequent IPCC Assessment Report to report aggregate emissions and removals of GHGs. In addition, parties may use other metrics to report supplemental information on aggregate emissions and removals of GHGs.]

**Coast** The land near to the sea. The term ‘coastal’ can refer to that land (e.g., as in ‘coastal communities’), or to that part of the marine environment that is strongly influenced by land-based processes. Thus, coastal seas are generally shallow and near-shore. The landward and seaward limits of the coastal zone are not consistently defined, neither scientifically nor legally. Thus, coastal waters can either be considered as equivalent to territorial waters (extending 12 nautical miles / 22.2 km from mean low water), or to the full Exclusive Economic Zone, or to *shelf seas*, with less than 200 m water depth.

**Cold days/cold nights** Days where maximum temperature, or nights where minimum temperature, falls
below the 10th percentile, where the respective temperature distributions are generally defined with respect to the 1961-1990 reference period. For the corresponding indices, see Box 2.4.

**Common era (CE)**  CE (Common Era) and BCE (Before the Common Era) are alternative names for AD (Anno Domini) and BC (Before Christ) in the Gregorian international standard calendar-year system. CE/BCE are preferred in an international context because they are neutral with respect to religion. The numbering of calendar years is the same under both terminologies. The CE began in year AD 1 and extends to the present day.

**Compatible emissions**  Earth System Models that simulate the land and ocean carbon cycle can calculate CO₂ emissions that are compatible with a given atmospheric CO₂ concentration trajectory. The compatible emissions over a given period of time are equal to the increase of carbon over that same period of time in the sum of the three active reservoirs: the atmosphere, the land and the ocean.

**Compound events**  See Compound weather/climate events.

**Compound weather/climate events**  The combination of multiple drivers and/or hazards that contributes to societal and/or environmental risk (Zscheischler et al., 2018).

**Concentrations scenario**  See Scenario.

**Confidence**  The robustness of a finding based on the type, amount, quality and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and on the degree of agreement across multiple lines of evidence. In this report, confidence is expressed qualitatively (Mastrandrea et al., 2010).

**Constant composition commitment**  See Climate change commitment.

**Constant emissions commitment**  See Climate change commitment.

**Convection**  Vertical motion driven by buoyancy forces arising from static instability, usually caused by near-surface cooling or increases in salinity in the case of the ocean and near-surface warming or cloud-top radiative cooling in the case of the atmosphere. In the atmosphere, convection gives rise to cumulus clouds and precipitation and is effective at both scavenging and vertically transporting chemical species. In the ocean, convection can carry surface waters to deep within the ocean.

**Convection-permitting models**  See Cloud-resolving models (CRMs).

**Coral bleaching**  Loss of coral pigmentation through the loss of intracellular symbiotic algae (known as zooxanthellae) and/or loss of their pigments.

**Coral reef**  An underwater ecosystem characterised by structure-building stony corals. Warm-water coral reefs occur in shallow seas, mostly in the tropics, with the corals (animals) containing algae (plants) that depend on light and relatively stable temperature conditions. Cold-water coral reefs occur throughout the world, mostly at water depths of 50-500 m. In both kinds of reef, living corals frequently grow on older, dead material, predominantly made of calcium carbonate (CaCO₃). Both warm and cold-water coral reefs support high biodiversity of fish and other groups, and are considered to be especially vulnerable to climate change.

**Cosmogenic radioisotopes**  Rare radioactive isotopes that are created by the interaction of a high-energy cosmic ray particles with atoms nuclei. They are often used as indicator of solar activity which modulates the cosmic rays intensity or as tracers of atmospheric transport processes, and are also called cosmogenic radionuclides.

**Coupled Model Intercomparison Project (CMIP)**  A climate modelling activity from the World Climate
Research Programme (WCRP) which coordinates and archives climate model simulations based on shared model inputs by modelling groups from around the world. The CMIP3 multi-model data set includes projections using Special Report on Emissions Scenarios (SRES) scenarios. The CMIP5 data set includes projections using the Representative Concentration Pathways (RCP). The CMIP6 phase involves a suite of common model experiments as well as an ensemble of CMIP-endorsed Model Intercomparison Projects (MIPs).

Cryosphere  The components of the Earth System at and below the land and ocean surface that are frozen, including snow cover, glaciers, ice sheets, ice shelves, icebergs, sea ice, lake ice, river ice, permafrost and seasonally frozen ground.

Cumulative emissions  The total amount of emissions released over a specified period of time. See also Carbon budget and Transient climate response to cumulative CO₂ emissions (TCRE) (under Climate sensitivity).

Dansgaard-Oeschger events (D-O events)  Millennial-scale events first characterized in Greenland ice cores as abrupt warming from a cold stadial state to a warmer interstadial state, followed by a return to a cold stadial state (Dansgaard et al., 1993), and traced in the ocean via deposits of ice-rafted sand grains (Bond and Lotti, 1995). Named after Willi Dansgaard and Hans Oeschger by Bond and Lotti (1995). An example of a D-O event during the most recent deglacial transition is the Bolling-Allerød interstadial. Warm D-O events in Greenland are associated with cooling events in Antarctica (Blunier and Brook, 2001) through ocean thermohaline circulation (Stocker and Johnsen, 2003). See also Bipolar seesaw (also interhemispheric seesaw; interhemispheric asymmetry).

Data assimilation  Mathematical method used to combine different sources of information in order to produce the best possible estimate of the state of a system. This information usually consists of observations of the system and a numerical model of the system evolution. Data assimilation techniques are used to create initial conditions for weather forecast models, and to construct reanalyses describing the trajectory of the climate system over the time period covered by the observations.

Dead zones  Extremely hypoxic (i.e., low-oxygen) areas in oceans and lakes, caused by excessive nutrient input from human activities coupled with other factors that deplete the oxygen required to support many marine organisms in bottom and near-bottom water.

Decadal predictability  Decadal predictability refers to the notion of predictability of the climate system on a decadal time scale. See also Climate prediction, Predictability and Decadal prediction.

Decadal prediction  A decadal prediction is a climate prediction on decadal time scales.

Decadal variability  See Climate variability.

Deep uncertainty  See Uncertainty.

Deforestation  Conversion of forest to non-forest. [Note: For a discussion of the term forest and related terms such as afforestation, reforestation and deforestation, see the 2006 IPCC Guidelines for National Greenhouse Gas Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019, UNFCCC, 2021a, 2021b).]

See also Reducing Emissions from Deforestation and Forest Degradation (REDD+), Afforestation and Reforestation.

Deglacial or deglaciation or glacial termination  The period of transition from glacial conditions at the end of a glacial period to interglacial conditions characterized by a reduction in land ice volume. Gradual changes can be punctuated by abrupt changes linked to stadial / interstadial events and bipolar seesaw aspect. The last deglacial transition occurred between about 18,000 and 11,000 years ago. It encompasses...
rapid events such as *Meltwater Pulse 1A (MWP-1A)* and millennial-scale fluctuations such as the *Younger Dryas*. See also *Glacial-interglacial cycles* and *Ice age*.

**Detection**  Detection of change is defined as the process of demonstrating that climate or a system affected by climate has changed in some defined statistical sense, without providing a reason for that change. An identified change is detected in observations if its likelihood of occurrence by chance due to internal variability alone is determined to be small, for example, <10%.

**Detection and attribution**  See *Detection* and *Attribution*.

**Diatoms**  Silt-sized algae that live in surface waters of lakes, rivers and oceans and form shells of opal. Their species distribution in ocean cores is often related to past *sea surface temperatures*.

**Dimensions of integration**  In IPCC AR6, concepts used to synthesize the knowledge of *climate change* across not just the physical sciences, but also across *impact* and *adaptation*, and *mitigation* research. The concept of ‘dimensions of integration’ includes (i) emission and *concentration scenarios* underlying the climate change *projections* assessed in this report, (ii) levels of projected global mean temperature change and (iii) total amounts of cumulative carbon emissions for projections.

**Direct (aerosol) effect**  See *Aerosol-radiation interaction*.

**Direct air capture (DAC)**  Chemical process by which a pure carbon dioxide (CO₂) stream is produced by capturing CO₂ from the ambient air. See also *Direct air carbon dioxide capture and storage (DACCS)*, *Anthropogenic removals* and *Carbon dioxide removal (CDR)*.

**Direct emissions**  Emissions that physically arise from activities within well-defined boundaries of, for instance, a region, an economic sector, a company, or a process. See also *Indirect emissions*.

**Disaster**  A ‘serious disruption of the functioning of a community or a society at any scale due to hazardous events interacting with conditions of exposure, vulnerability and capacity, leading to one or more of the following: human, material, economic and environmental losses and impacts’ (UNGA, 2016). See also *Exposure, Hazard, Risk* and *Vulnerability*.

**Discharge (of ice)**  See *Mass balance / budget (of glaciers or ice sheets)*.

**Dissolved inorganic carbon**  The combined total of different types of non-organic carbon in (seawater) solution, comprising carbonate (CO₃²⁻), bicarbonate (HCO₃⁻), carbonic acid (H₂CO₃) and *carbon dioxide (CO₂)*.

**Diurnal temperature range (DTR)**  The difference between the maximum and minimum temperature during a 24-hour period.

**Dobson unit (DU)**  A unit to measure the total amount of *ozone* in a vertical column above the Earth's surface (total column ozone). The number of Dobson Units is the thickness in units of 10⁻⁵ m that the ozone column would occupy if compressed into a layer of uniform density at a pressure of 1013 hPa and a temperature of 0°C. One DU corresponds to a column of ozone containing 2.69 × 10³⁰ molecules per square metre. A typical value for the amount of ozone in a column of the Earth's atmosphere, although very variable, is 300 DU.

**Downscaling**  A method that derives local- to regional-scale information from larger-scale models or data analyses. Two main methods exist: dynamical downscaling and empirical/statistical downscaling. The dynamical method uses the output of regional climate models, global models with variable spatial resolution, or high-resolution global models. The empirical/statistical methods are based on observations and develop statistical relationships that link the large-scale atmospheric variables with local/regional climate variables. In all cases, the quality of the driving model remains an important limitation on quality of the downscaled
information. The two methods can be combined, e.g., applying empirical/statistical downscaling to the output of a regional climate model, consisting of a dynamical downscaling of a global climate model.

**Drought** An exceptional period of water shortage for existing *ecosystems* and the human population (due to low rainfall, high temperature, and/or wind). See also *Plant evaporative stress*.

*Agricultural or ecological drought* Agricultural or ecological drought (depending on the affected *biome*): a period with abnormal *soil moisture* deficit, which results from combined shortage of precipitation and excess *evapotranspiration*, and during the growing season impinges on crop production or *ecosystem* function in general.

**Hydrological drought** A period with large *runoff* and water deficits in rivers, lakes and reservoirs.

**Meteorological drought** A period with an abnormal precipitation deficit.

**Dynamic global vegetation model (DGVM)** A model that simulates vegetation development and dynamics through space and time, as driven by climate and other environmental changes.

**Dynamical downscaling** See *Downscaling*.

**Dynamical system** A process or set of processes whose evolution in time is governed by a set of deterministic physical laws. The *climate system* is a dynamical system.

**Early Eocene Climatic Optimum (EECO)** The EECO is a period of geological time that occurred about 53 to 49 million years ago, during the Eocene Epoch. Continental positions at this time were somewhat different to present due to tectonic plate movements. Geological data indicate that the EECO was a period of relatively high atmospheric CO₂ concentrations (about 1150-2500 ppmv) and relative warmth (*global mean surface temperature* was about 10.18 °C above the 1850-1900 reference), and polar *ice sheets* were absent.

**Earth system model (ESM)** A coupled *atmosphere–ocean* general circulation model (AOGCM) in which a representation of the *carbon cycle* is included, allowing for interactive calculation of atmospheric *carbon dioxide* (CO₂) or compatible emissions. Additional components (e.g., atmospheric chemistry, *ice sheets*, dynamic vegetation, nitrogen cycle, but also urban or crop models) may be included. See also *Earth system model of intermediate complexity* (EMIC).

**Earth system model of intermediate complexity (EMIC)** Earth system models of intermediate complexity (EMIC) represent climate processes at a lower resolution or in a simpler, more idealised fashion than an *Earth system model* (ESM).

**Earth's energy budget** For a given time period, Earth's energy budget expresses the balance between total *earth system* heating, the time-integrated *effective radiative forcing* and time-integrated *Earth's radiative response*. Units: Joules. See also Earth's top of *atmosphere energy budget*, Earth's *energy imbalance*, Earth's *surface energy budget*, Earth's radiative response, Earth's *energy flows* and Earth *system heating*.

**Earth's energy flows** The time-mean (or representative) energy exchanges within the *climate system* (including energy energy exchanges at the surface and top-of-atmosphere). This also includes horizontal ocean and atmospheric heat transports. See also Earth's energy budget, Earth's top of *atmosphere energy budget*, Earth's *energy imbalance*, Earth's *surface energy budget*, Earth *system heating* and Earth's radiative response.

**Earth's energy imbalance** The persistent and positive (downward) net top of atmosphere energy flux associated with greenhouse gas *forcing* of the *climate system*. See also Earth's energy budget, Earth's top of *atmosphere energy budget*, Earth's *surface energy budget*, Earth *system heating*, Earth's radiative response and Earth's *energy flows*.
Earth's radiative response The product of global mean surface air temperature (GSAT) change and the net feedback parameter (i.e., sum of all feedbacks), which determines the net top-of-atmosphere radiative flux that opposes a change in radiative forcing. Units: W m\(^{-2}\). See also Earth's energy budget, Earth's top of atmosphere energy budget, Earth's energy imbalance, Earth's surface energy budget, Earth system heating and Earth’s energy flows.

Earth's surface energy budget Earth’s surface energy budget comprises the exchanges of heat at the surface of the Earth associated with both radiative and non-radiative processes. See also Earth's energy budget, Earth's top of atmosphere energy budget, Earth's energy imbalance, Earth system heating, Earth's radiative response and Earth’s energy flows.

Earth system sensitivity See Climate sensitivity.

Earth's top of atmosphere energy budget Earth’s top of atmosphere energy budget comprises the energy fluxes associated with incoming solar radiation, reflected solar radiation and emitted thermal radiation. See also Earth's energy budget, Earth's energy imbalance, Earth's surface energy budget, Earth system heating, Earth's radiative response and Earth’s energy flows.

East Antarctic ice sheet (EAIS) See Ice sheet.

East Asian monsoon (EAsiaM) See Global monsoon.

Eastern boundary upwelling systems (EBUS) Eastern boundary upwelling system (EBUS) are located at the eastern (landward) edges of major ocean basins in both hemispheres, where equatorward winds drive upwelling currents that bring cool, nutrient-rich (and often oxygen-poor) waters from the deep ocean to the surface near the coast.

Economic potential See Mitigation potential.

Ecosystem A functional unit consisting of living organisms, their non-living environment and the interactions within and between them. The components included in a given ecosystem and its spatial boundaries depend on the purpose for which the ecosystem is defined: in some cases they are relatively sharp, while in others they are diffuse. Ecosystem boundaries can change over time. Ecosystems are nested within other ecosystems and their scale can range from very small to the entire biosphere. In the current era, most ecosystems either contain people as key organisms, or are influenced by the effects of human activities in their environment. See also Ecosystem services.

Effective radiative forcing (ERF) See Radiative forcing, Aerosol effective radiative forcing (ERFari+aci) (under Aerosol-radiation interaction), Effective radiative forcing (or effect) due to aerosol-cloud interactions (ERFaci) (under Aerosol-radiation interaction) and Effective radiative forcing (or effect) due to aerosol-radiation interactions (ERFari) (under Aerosol-radiation interaction).

Ekman transport The total transport resulting from a balance between the Coriolis force and the frictional stress due to the action of the wind on the ocean surface.

El Niño-Southern Oscillation (ENSO) The term El Niño was initially used to describe a warm-water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. It has since become identified with warming of the tropical Pacific Ocean east of the dateline. This oceanic event is associated with a fluctuation of a global-scale tropical and subtropical surface pressure pattern called the Southern Oscillation. This coupled atmosphere–ocean phenomenon, with preferred time scales of two to about seven years, is known as the El Niño-Southern Oscillation (ENSO). The warm and cold phases of
ENSO are called El Niño and La Niña, respectively. ENSO is often measured by the surface pressure anomaly difference between Tahiti and Darwin and/or the sea surface temperatures in the central and eastern equatorial Pacific. This phenomenon has a great impact on the wind, sea surface temperature and precipitation patterns in the tropical Pacific. It has climatic effects throughout the Pacific region and in many other parts of the world through global teleconnections. See Section AIV.2.3 in Annex IV of the AR6 WGI report.

Central Pacific El Niño  An El Niño event in which sea surface temperature anomalies are stronger in the central equatorial Pacific than in the east. Also known as a Modoki El Niño event.

Eastern Pacific El Niño  An El Niño event in which sea surface temperature anomalies are largest in the eastern tropical Pacific.

Electromagnetic spectrum  Wavelength, frequency or energy range of all electromagnetic radiation. In terms of solar radiation, the spectral irradiance is the power arriving at the Earth per unit area, per unit wavelength.

Elevation-dependent warming (EDW)  Characteristic of many regions where mountains are located, in which past and/or future surface air temperature changes vary neither uniformly nor linearly with elevation. In many cases, warming is enhanced within or above a certain elevation range.

Emergence (of the climate signal)  Emergence of a climate change signal or trend refers to when a change in climate (the ‘signal’) becomes larger than the amplitude of natural or internal variations (defining the ‘noise’). This concept is often expressed as a ‘signal-to-noise’ ratio and emergence occurs at a defined threshold of this ratio (e.g., S/N > 1 or 2). Emergence can refer to changes relative to a historical or modern baseline (usually at least 20 years long) and can also be expressed in terms of time (time of emergence) or in terms of a global warming level. Emergence is also used to refer to a time when we can expect to see a response of reducing greenhouse gas (GHG) emissions (emergence with respect to mitigation). Emergence can be estimated using observations and/or model simulations. See also Time of emergence (ToE).

Emergent constraint  An attempt to reduce the uncertainty in climate projections, using an ensemble of ESMs to relate a specific feedback or future change to an observation of the past or current climate (typically some trend, variability or change in variability).

Emission factor/Emissions intensity  A coefficient that quantifies the emissions or removals of a gas per unit activity. Emission factors are often based on a sample of measurement data, averaged to develop a representative rate of emission for a given activity level under a given set of operating conditions.

Emissions  See Indirect emissions, Negative CO₂ emissions, Production-based emissions, Scope 1, Scope 2, and Scope 3 emissions, Territorial emissions, Agricultural emissions, Cumulative emissions, Direct emissions, Embodied (embedded) [emissions, water, land], Anthropogenic emissions, Fossil fuel emissions, Non-CO₂ emissions and radiative forcing and Negative greenhouse gas emissions. See also Emissions scenario (under Scenario), Emission pathways and Emission trajectories.

Emulation  Reproducing the behaviour of complex, process-based models (namely, Earth System Models, ESMs) via simpler approaches, using either emulators or simple climate models (SCMs). The computational efficiency of emulating approaches opens new analytical possibilities given that ESMs take a lot of computational resources for each simulation. See also Emulators and Simple climate model (SCM).

Emulators  A broad class of heavily parametrized models (‘one-or-few-line climate models’), statistical methods like neural networks, genetic algorithms or other artificial intelligence approaches, designed to reproduce the responses of more complex, process-based Earth System Models (ESMs). The main application of emulators is to extrapolate insights from ESMs and observational constraints to a larger set of emission scenarios. See also Emulation and Simple climate model (SCM).
Energy balance  The difference between the total incoming and total outgoing energy. If this balance is positive, warming occurs; if it is negative, cooling occurs. Averaged over the globe and over long time periods, this balance must be zero. Because the climate system derives virtually all its energy from the Sun, zero balance implies that, globally, the absorbed solar radiation, that is, incoming solar radiation minus reflected solar radiation at the top of the atmosphere and outgoing longwave radiation emitted by the climate system are equal.

Energy balance model (EBM)  An energy balance model is a simplified model that analyses the energy budget of the Earth to compute changes in the climate. In its simplest form, there is no explicit spatial dimension and the model then provides an estimate of the changes in globally averaged temperature computed from the changes in radiation. This zero-dimensional energy balance model can be extended to a one-dimensional or two-dimensional model if changes to the energy budget with respect to latitude, or both latitude and longitude, are explicitly considered.

Energy budget (of the Earth)  The Earth is a physical system with an energy budget that includes all gains of incoming energy and all losses of outgoing energy. The Earth’s energy budget is determined by measuring how much energy comes into the Earth System from the Sun, how much energy is lost to space, and accounting for the remainder on Earth and its atmosphere. Solar radiation is the dominant source of energy into the Earth System. Incoming solar energy may be scattered and reflected by clouds and aerosols or absorbed in the atmosphere. The transmitted radiation is then either absorbed or reflected at the Earth’s surface. The average albedo of the Earth is about 0.3, which means that 30% of the incident solar energy is reflected into space, while 70% is absorbed by the Earth. Radiant solar or shortwave energy is transformed into sensible heat, latent energy (involving different water states), potential energy, and kinetic energy before being emitted as infrared radiation. With the average surface temperature of the Earth of about 15°C (288 K), the main outgoing energy flux is in the infrared part of the spectrum.

Enhanced weathering  A proposed method to increase the natural rate of removal of carbon dioxide (CO₂) from the atmosphere using silicate and carbonate rocks. The active surface area of these minerals is increased by grinding, before they are actively added to soil, beaches or the open ocean. See also Carbon dioxide removal (CDR) and Anthropogenic removals.

Ensemble  A collection of comparable datasets that reflect variations within the bounds of one or more sources of uncertainty, and that when averaged can provide a more robust estimate of underlying behaviour. Ensemble techniques are used by the observational, reanalysis and modelling communities. See also Climate simulation ensemble.

Equilibrium and transient climate experiment  An equilibrium climate experiment is a climate model experiment in which the model is allowed to fully adjust to a change in radiative forcing. Such experiments provide information on the difference between the initial and final states of the model, but not on the time-dependent response. If the forcing is allowed to evolve gradually according to a prescribed emission scenario, the time-dependent response of a climate model may be analysed. Such an experiment is called a transient climate experiment.

Equilibrium climate sensitivity (ECS)  See Climate sensitivity.

Equilibrium line  The spatially averaged boundary at a given moment, usually chosen as the seasonal mass budget minimum at the end of summer, between the region on a glacier where there is a net annual loss of ice mass (ablation area) and that where there is a net annual gain (accumulation area). The altitude of this boundary is referred to as equilibrium line altitude (ELA).

Equivalent carbon dioxide (CO₂) emission  See CO₂ equivalent (CO₂-eq) emission.

Eutrophication  Over-enrichment of water by nutrients such as nitrogen and phosphorus. It is one of the leading causes of water quality impairment. The two most acute symptoms of eutrophication are hypoxia (or oxygen depletion) and harmful algal blooms.
Evaporation  The physical process by which a liquid (e.g., water) becomes a gas (e.g., water vapour).

Evapotranspiration  The combined processes through which water is transferred to the atmosphere from open water and ice surfaces, bare soil, and vegetation that make up the Earth’s surface.

Potential evapotranspiration  The potential rate of water loss from wet soils and from plant surfaces, without any limits imposed by the water supply.

Evidence  Data and information used in the scientific process to establish findings. In this report, the degree of evidence reflects the amount, quality and consistency of scientific/technical information on which the Lead Authors are basing their findings. See also Agreement, Confidence, Likelihood and Uncertainty.

Exposure  The presence of people; livelihoods; species or ecosystems; environmental functions, services, and resources; infrastructure; or economic, social, or cultural assets in places and settings that could be adversely affected.

Extended concentration pathways (ECPs)  See Representative concentration pathways (RCPs) (under Pathways).

External forcing  External forcing refers to a forcing agent outside the climate system causing a change in the climate system. Volcanic eruptions, solar variations and changes in Earth's orbit, as well as anthropogenic changes in the composition of the atmosphere or in land use are external forcings. See also Orbital forcing.

Extratropical cyclone (ETC)  Any cyclonic-scale storm that is not a tropical cyclone. Usually refers to a middle- or high-latitude migratory storm system formed in regions of large horizontal temperature variations. Sometimes called extratropical storm or extratropical low.

Extratropical jets  Extratropical jets are wind maxima in the upper troposphere marking zones of baroclinic instability. Anomalies in the position of these jets are often associated with storms, blocking, and weather extremes.

Extreme climate event  See Climate extreme (extreme weather or climate event).

Extreme coastal water level (ECWL)  See Extreme sea level (ESL).

Extreme sea level (ESL)  The occurrence of an exceptionally low or high local sea-surface height, arising from (a combination of) short term phenomena (e.g. storm surges, tides and waves). Relative sea-level changes affect extreme sea levels directly by shifting the mean water levels and indirectly by modulating the propagation of tides, waves and/or surges due to increased water depth. In addition, extreme sea levels can be influenced by changes in the frequency, tracks, or strength of weather systems and storms, or due to anthropogenically induced changes such as the modification of coastlines or dredging. In turn, changes in any or all of the contributions to extreme sea levels may lead to long term relative sea-level changes. Alternate expressions for ESL may be used depending on the processes resolved.

Extreme Still Water Level (ESWL) refers to the combined contribution of relative sea-level change, tides and storm surges. Wind-waves also contribute to coastal sea level via three processes: infragravity waves (lower frequency gravity waves generated by the wind waves); wave setup (time-mean sea-level elevation due to wave energy dissipation); and swash (vertical displacement up the shore-face induced by individual waves). Extreme Total Water Level (ETWL) is the ESWL plus wave setup. When considering coastal impacts, swash is also important, and Extreme Coastal Water Level (ECWL) is used. See also Storm surge and Sea level change (sea level rise/sea level fall).

Extreme still water level (ESWL)  See Extreme sea level (ESL).
Extreme total water level (ETWL)  See Extreme sea level (ESL).

Extreme weather event  An event that is rare at a particular place and time of year. Definitions of ‘rare’ vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th percentile of a probability density function estimated from observations. By definition, the characteristics of what is called extreme weather may vary from place to place in an absolute sense. See also Heatwave and Climate extreme event.

Extreme/heavy precipitation event  An extreme/heavy precipitation event is an event that is of very high magnitude with a very rare occurrence at a particular place. Types of extreme precipitation may vary depending on its duration, hourly, daily or multi-days (e.g., 5 days), though all of them qualitatively represent high magnitude. The intensity of such events may be defined with block maxima approach such as annual maxima or with peak over threshold approach, such as rainfall above 95th or 99th percentile at a particular space.

Faculae  Bright patches on the Sun. The area covered by faculae is greater during periods of high solar activity.

Feedback  See Climate feedback.

Fine-mode aerosol optical depth  See Aerosol optical depth (AOD).

Fingerprint  The climate response pattern in space and/or time to a specific forcing is commonly referred to as a fingerprint. The spatial patterns of sea level response to melting of glaciers or ice sheets (or other changes in surface loading) are also referred to as fingerprints. Fingerprints are used to detect the presence of this response in observations and are typically estimated using forced climate model simulations. See also Detection and attribution.

Fire weather  Weather conditions conducive to triggering and sustaining wildfires, usually based on a set of indicators and combinations of indicators including temperature, soil moisture, humidity, and wind. Fire weather does not include the presence or absence of fuel load.

Firn  Snow that has survived at least one ablation season but has not been transformed to glacier ice. Its pore space is at least partially interconnected, allowing air and water to circulate. Firn densities typically are 400–830 kg m$^{-3}$.

Fitness-for-purpose  The suitability of a model (or other resource, such as a dataset or method) for a particular task, such as quantifying the contribution of increased greenhouse gas concentrations to recent changes in global mean surface temperature or projecting changes in drought frequency in a region under a given scenario. Assessment of a model’s fitness-for-purpose can be informed both by how the model represents relevant physical processes and by how it scores on relevant performance metrics.

Flaring  Open air burning of waste gases and volatile liquids, through a chimney, at oil wells or rigs, in refineries or chemical plants, and at landfills.

Flood  The overflowing of the normal confines of a stream or other water body, or the accumulation of water over areas that are not normally submerged. Floods can be caused by unusually heavy rain, for example during storms and cyclones. Floods include river (fluvial) floods, flash floods, urban floods, rain (pluvial) floods, sewer floods, coastal floods, and glacial lake outburst floods (GLOFs).

Flux  A movement (a flow) of matter (e.g., water vapor, particles), heat or energy from one place to another, or from one medium (e.g., land surface) to another (e.g., atmosphere).

Foraminifera  Single-celled, sand-sized marine organisms (protists) that possess a hard test mainly
composed of agglutinated walls (detrital grains glued together with organic cement) or calcium carbonate (predominantly calcite). They are used to reconstruct a range of (paleo)environmental variables such as salinity, temperature, oxygenation, oxygen isotope composition, and organic and nutrient flux.

**Forcing**  See Radiative forcing.

**Forest**  A vegetation type dominated by trees. Many definitions of the term forest are in use throughout the world, reflecting wide differences in biogeophysical conditions, social structure and economics. [Note: For a discussion of the term forest in the context of National GHG inventories, see the 2006 IPCC Guidelines for National GHG Invenories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019, UNFCCC, 2021a, 2021b).] See also Afforestation, Deforestation and Reforestation.

**Fossil fuel emissions**  Emissions of greenhouse gases (in particular carbon dioxide), other trace gases and aerosols resulting from the combustion of fuels from fossil carbon deposits such as oil, gas and coal.

**Fossil fuels**  Carbon-based fuels from fossil hydrocarbon deposits, including coal, oil, and natural gas.

**Free atmosphere**  The atmospheric layer that is negligibly affected by friction against the Earth’s surface, and which is above the atmospheric boundary layer.

**Frozen ground**  Soil or rock in which part or all of the pore water consists of ice. See also Active layer and Permafrost.

**General circulation**  The large-scale motions of the atmosphere and the ocean as a consequence of differential heating on a rotating Earth. General circulation contributes to the energy balance of the system through transport of heat and momentum.

**General circulation model (GCM)**  A numerical representation of the atmosphere-ocean-sea ice system based on the physical, chemical and biological properties of its components, their interactions and feedback processes. General circulation models are used for weather forecasts, seasonal to decadal prediction, and climate projections. They are the basis of the more complex Earth system models (ESMs). See also Climate model.

**Geocentric sea-level change**  See Sea level change (sea level rise/sea level fall).

**Geoid**  The equipotential surface having the same geopotential at each latitude and longitude around the world (geodesists denoting this potential W0) that best approximates the mean sea level. It is the surface of reference for measurement of altitude. In practice, several variations of definitions of the geoid exist depending on the way the permanent tide (the zero-frequency gravitational tide due to the Sun and Moon) is considered in geodetic studies.

**Geostrophic winds or currents**  A wind or current that is in balance with the horizontal pressure gradient and the Coriolis force, and thus is outside of the influence of friction. Thus, the wind or current is directly parallel to isobars and its speed is proportional to the horizontal pressure gradient.

**Glacial isostatic adjustment (GIA)**  The ongoing changes in gravity, rotation and viscoelastic solid Earth deformation (ORD) in response to past changes in the distribution of ice and water on Earth’s surface. On a timescale of decades to tens of millennia following mass redistribution, Earth’s mantle flows viscously as it evolves toward isostatic equilibrium, causing solid Earth movement and geoid changes, which can result in regional to local sea-level variations. See also Sea level change (sea level rise/sea level fall).

**Glacial lake outburst flood (GLOF) / Glacier lake outburst**  A sudden release of water from a glacier lake, including any of the following types – a glacier-dammed lake, a pro-glacial moraine-dammed lake or water that was stored within, under or on the glacier.
Glacial or glaciation  A period characterized by the establishment of expanded ice sheets and glaciers, and associated with global mean sea level (GMSL) substantially lower than present. Generally coincides with even-numbered marine isotope stages. Glacial intervals were interrupted by interglacial intervals. The Last Glacial Maximum (LGM) is a specific interval within the most recent glaciation, when ice sheets were near their global maximum volume (Clark et al., 2009; Gowan et al., 2021) and GMSL was near its most recent lowest stand (Lambeck et al., 2014; Yokoyama et al., 2018). Local or regional glacial maxima may be diachronous, for example ranging from about 29,000 years ago and 16,000 years ago. For purposes of global synthesis, IPCC AR6 adopts a practical chronostratigraphic definition of LGM of 23,000-19,000 years BP (before 1950; chronozone level 1 of Mix et al., 2001). For modeling purposes, LGM is defined by the model time step nearest to the center of this interval, 21,000 years ago (Kageyama et al., 2017). See also Deglacial or deglaciation or glacial termination, Glacial-interglacial cycles, Ice age and Interglacial or interglaciation.

Glacial termination  See Deglacial or deglaciation or glacial termination.

Glacial-interglacial cycles  Phase of the Earth's history marked by large changes in continental ice volume and global sea level. See also Glacial or glaciation, Deglacial or deglaciation or glacial termination, Interglacial or interglaciation and Ice age.

Glaciated  State of a surface that was covered by glacier ice in the past, but not at present. See also Glacierised.

Glacier  A perennial mass of ice, and possibly firn and snow, originating on the land surface by accumulation and compaction of snow and showing evidence of past or present flow. A glacier typically gains mass by accumulation of snow, and loses mass by ablation. Land ice masses of continental size (>50,000 km$^2$) are referred to as ice sheets (Cogley et al., 2011).

Outlet glacier  A glacier, usually between rock walls, that is part of, and drains an ice sheet. See also Ice stream.

Glacierised  A surface that is currently covered by glacier ice. See also Glaciated.

Global carbon budget  See Carbon budget.

Global dimming  Global dimming refers to the observed widespread reduction in the amount of solar radiation received at the Earth’s surface from the 1950s to the 1980s, with an increase in anthropogenic aerosol emissions appearing to have contributed. This was followed by a partial recovery since the 1990s (“brightening”), particularly in industrialized areas, coincident with a reduction in anthropogenic aerosol emissions.

Global mean sea-level (GMSL) change  See Sea level change (sea level rise/sea level fall).

Global mean surface air temperature (GSAT)  Global average of near-surface air temperatures over land, oceans and sea ice. Changes in GSAT are often used as a measure of global temperature change in climate models. See also Global mean surface temperature (GMST).

Global mean surface temperature (GMST)  Estimated global average of near-surface air temperatures over land and sea ice, and sea surface temperature (SST) over ice-free ocean regions, with changes normally expressed as departures from a value over a specified reference period. See also Global mean surface air temperature (GSAT).

Global monsoon  The global monsoon (GM) is a global-scale solstitial mode that dominates the annual variation of tropical and sub-tropical precipitation and circulation. The GM domain is defined as the area where the annual range of precipitation (local summer minus winter mean precipitation rate) is greater than
2.5 mm/day, following on from the definition as in Kitoh et al. (2013). Further details on how the GM is defined, used and related to regional monsoons throughout the report is provided by Annex V.

**Australian and Maritime Continent monsoon (AusMCM)** The Australian-Maritime Continent monsoon (AusMCM) occurs during December-January-February, with the large-scale shift of the Inter-Tropical Convergence Zone into the Southern Hemisphere and covering northern Australia and the Maritime Continent up to 10S. The AusMCM is characterized by the seasonal reversal of prevailing easterly winds to westerly winds and the onset of periods of active convection and heavy rainfall. Over northern Australia, the monsoon season generally lasts from December to March and is associated with west to northwesterly inflow of moist winds, producing convection and heavy precipitation. Over the Maritime Continent, the main rainy season south of the equator is centered on December to February with northwesterly monsoon flow at low levels. Further details on how AusMCM is defined and used throughout the report is provided in the Annex V.

**East Asian monsoon (EAsiaM)** The East Asian monsoon (EAsiaM) is the seasonal reversal in wind and precipitation occurring over East Asia, including eastern China, Japan and the Korean peninsula. Differently from the other monsoons it extends quite far north, out of the tropical belt, and it is largely influenced by subtropical systems and by disturbances from the mid-latitudes. The EAsiaM manifests during boreal summer with warm and wet southerly winds, but also during boreal winter with cold and dry northerly winds. In late April/early May rainfall onsets in central Indochina Peninsula, and in mid-June the rainy season arrives over East Asia with the formation of the Meiyu front along the Yangtze River valley, Changma in Korea and Baiu in Japan. Lately in July, the monsoon advances up to North China, the Korean peninsula and central Japan. During boreal winter, strong north westerlies manifest over north, northeast China, Korea and Japan, while strong north easterlies arrive along the coast of East Asia. Further details on how EAsiaM is defined and used throughout the report is provided in the Annex V.

**North American monsoon (NAmerM)** The North American monsoon (NAmerM) is a regional-scale atmospheric circulation system with increase in summer precipitation over northwestern Mexico and southwest United States. The monsoonal characteristics of the region include a pronounced annual maximum of precipitation in boreal summer (June-July-August) accompanied by a surface low pressure system and an upper-level anticyclone, although seasonal reversal of the surface winds is primarily limited to the northern Gulf of California. Further details on how NAmerM is defined and used throughout the report is provided in the Annex V.

**South American monsoon (SAmerM)** The South American monsoon (SAmerM) is a regional circulation characterized by inflow of low-level winds from the Atlantic to South America, including Brazil, Peru’, Bolivia and northern Argentina, associated with the development of surface pressure gradients (and intense precipitation) during austral summer (December-January-February). During September-October-November areas of intense convection migrate from northwestern South America to the south. Associated to this regime, an upper-tropospheric anticyclone (a.k.a the Bolivian High) forms over the Altiplano region during the monsoon onset. The SAmerM then retreats during March-April-May with a northeastward migration of the convection. Further details on how SAmerM is defined and used throughout the report is provided in the Annex V.

**South and Southeast Asian monsoon (SAasiaM)** The South and Southeast Asian monsoon (SAasiaM) is characterized by pronounced seasonal reversals of wind and precipitation. The SAasiaM region extends across vast geographical areas and several countries including India, Bangladesh, Nepal, Myanmar, Sri Lanka, Pakistan, Thailand, Laos, Cambodia, Vietnam and Philippine. The SAasiaM starts in late May/early June and progresses toward northeast, ending in late September/early October. During the core monsoon season, maxima of SAasiaM precipitation are located over the west coast, northeast and central north India, Myanmar and Bangladesh, whereas minima are located over northwest and southeastern India, western Pakistan, southeastern and northern Sri Lanka. Further details on how SAasiaM is defined and used throughout the report is provided in the Annex V.

**West African monsoon (WAfriM)** The West African monsoon (WAfriM) is a seasonal reversal in wind and precipitation south of the equator, associated with west to northwesterly inflow of moist winds, producing convection and heavy precipitation. The WAfriM starts in late May/early June and progresses toward northeast, ending in late September/early October. During the core monsoon season, maxima of WAfriM precipitation are located over the west coast, northeast and central north Africa, western and central Senegal, Senegal, Gambia, Mauritania, Mali, Burkina Faso, and Niger. Further details on how WAfriM is defined and used throughout the report is provided in the Annex V.
precipitation whose domain includes Benin, Burkina-Faso, northern Cameroon, Cape Verde, northern
Central African Republic, Chad, Gambia, Ghana, Guinea, Guinea Bissau, Ivory, Coast, Liberia, Mali,
Mauritania, Niger, Nigeria, Senegal, Sierra Leone and Togo. The WAfriM is characterized by the northward
progression from May to September of moist low-level south-westerlies from the Gulf of Guinea. In May
and June, rainfall essentially remains along the Guinean coast with a maximum occurring near 5°N, followed
by a sudden decrease of rainfall, marking the “short dry season” in the Guinean coast and the monsoon onset
in the Sahel. Then rainfall continues to progress northward up to about 18-20°N, with a maximum near 12°N
in late August/September, until it retreats starting from October towards the Guinean coast for a second
maximum. Further details on how WAfriM is defined and used throughout the report is provided in the
Annex V.

Global surface temperature  See Global mean surface temperature (GMST) and Global mean surface air
temperature (GSAT). See also Global warming.

Global warming  Global warming refers to the increase in global surface temperature relative to a baseline
reference period, averaging over a period sufficient to remove interannual variations (e.g., 20 or 30 years). A
common choice for the baseline is 1850-1900 (the earliest period of reliable observations with sufficient
geographic coverage), with more modern baselines used depending upon the application. See also Climate
change and Climate variability.

Global warming potential (GWP)  An index measuring the radiative forcing following an emission of a
unit mass of a given substance, accumulated over a chosen time horizon, relative to that of the reference
substance, carbon dioxide (CO2). The GWP thus represents the combined effect of the differing times these
substances remain in the atmosphere and their effectiveness in causing radiative forcing. See also Lifetime
and Greenhouse gas emission metric.

Gravitational, rotational and deformational (GRD) effects  See Sea level change (sea level rise/sea level
fall).

Gravity Recovery And Climate Experiment (GRACE)  A pair of satellites to measure the Earth's gravity
field anomalies from 2002 to 2017. These fields have been used, among other things, to study mass changes
of the polar ice sheets and glaciers.

Greenhouse effect  The infrared radiative effect of all infrared-absorbing constituents in the atmosphere.
Greenhouse gases (GHGs), clouds, and some aerosols absorb terrestrial radiation emitted by the Earth's
surface and elsewhere in the atmosphere. These substances emit infrared radiation in all directions, but,
everything else being equal, the net amount emitted to space is normally less than would have been emitted
in the absence of these absorbers because of the decline of temperature with altitude in the troposphere and
the consequent weakening of emission. An increase in the concentration of GHGs increases the magnitude of
this effect; the difference is sometimes called the enhanced greenhouse effect. The change in a GHG
concentration because of anthropogenic emissions contributes to an instantaneous radiative forcing. Surface
temperature and troposphere warm in response to this forcing, gradually restoring the radiative balance at
the top of the atmosphere.

Greenhouse gas emission metric  A simplified relationship used to quantify the effect of emitting a unit
mass of a given greenhouse gas on a specified key measure of climate change. A relative GHG emission
metric expresses the effect from one gas relative to the effect of emitting a unit mass of a reference GHG on
the same measure of climate change. There are multiple emission metrics and the most appropriate metric
depends on the application. GHG emission metrics may differ with respect to (i) the key measure of climate
change they consider, (ii) whether they consider climate outcomes for a specified point in time or integrated
over a specified time horizon, (iii) the time horizon over which the metric is applied, (iv) whether they apply
to a single emission pulse, emissions sustained over a period of time, or a combination of both, and (v)
whether they consider the climate effect from an emission compared to the absence of that emission, or
compared to a reference emissions level or climate state.
Notes: Most relative GHG emission metrics (such as the Global Warming Potential (GWP), Global Temperature change Potential (GTP), Global Damage Potential, and GWP*), use carbon dioxide as the reference gas. Emissions of non-CO₂ gases, when expressed using such metrics, are often referred to as “carbon dioxide equivalent” emissions. A metric that establishes equivalence regarding one key measure of the climate system response to emissions does not imply equivalence regarding other key measures. The choice of a metric, including its time horizon, should reflect the policy objectives for which the metric is applied.

Greenhouse gas neutrality  Condition in which metric-weighted anthropogenic greenhouse gas (GHG) emissions associated with a subject are balanced by metric-weighted anthropogenic GHG removals. The subject can be an entity such as a country, an organisation, a district or a commodity, or an activity such as a service and an event. GHG neutrality is often assessed over the life cycle including indirect (“scope 3”) emissions, but can also be limited to the emissions and removals, over a specified period, for which the subject has direct control, as determined by the relevant scheme. The quantification of GHG emissions and removals depends on the GHG emission metric chosen to compare emissions and removals of different gases, as well as the time horizon chosen for that metric.

Note 1: GHG neutrality and net zero GHG emissions are overlapping concepts. The concepts can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms greenhouse gas neutrality and net zero greenhouse gas emissions are equivalent. At sub-global scales, net zero greenhouse gas emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while greenhouse gas neutrality generally includes emissions and removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant emissions and removals.

Note 2. Under the Paris Rulebook [Decision 18/CMA.1, annex, paragraph 37], parties have agreed to use GWP100 values from the IPCC AR5 or GWP100 values from a subsequent IPCC Assessment Report to report aggregate emissions and removals of GHGs. In addition, parties may use other metrics to report supplemental information on aggregate emissions and removals of GHGs.

Note 3: In some cases, achieving greenhouse gas neutrality may rely on the supplementary use of offsets to balance emissions that remain after actions by the reporting entity are taken into account.] See also Carbon neutrality, Greenhouse gas emission metric, Land use, land-use change and forestry (LULUCF) and Net zero greenhouse gas emissions.

Greenhouse gases (GHGs)  Gaseous constituents of the atmosphere, both natural and anthropogenic, that absorb and emit radiation at specific wavelengths within the spectrum of radiation emitted by the Earth's surface, by the atmosphere itself, and by clouds. This property causes the greenhouse effect. Water vapour (H₂O), carbon dioxide (CO₂), nitrous oxide (N₂O), methane (CH₄) and ozone (O₃) are the primary GHGs in the Earth's atmosphere. Human-made GHGs include sulphur hexafluoride (SF₆), hydrofluorocarbons (HFCs), chlorofluorocarbons (CFCs) and perfluorocarbons (PFCs); several of these are also O₃-depleting (and are regulated under the Montreal Protocol). See also Well-mixed greenhouse gas.

Greenland ice sheet (GrIS)  See Ice sheet.

Gross Primary Production (GPP)  See Primary production.

Ground-level ozone  Atmospheric ozone (O₃) formed naturally or from human-emitted precursors near Earth's surface, thus affecting human health, agriculture, and ecosystems. Ozone is a greenhouse gas (GHG), but ground-level ozone, unlike stratospheric ozone, also directly affects organisms at the surface. Ground-level ozone is sometimes referred to as tropospheric ozone, although much of the troposphere is well above the surface and thus does not directly expose organisms at the surface.

Grounding line  The junction between a glacier or ice sheet and an ice shelf; the place where ice starts to float. This junction normally occurs over a zone, rather than at a line.
Gyre  Basin-scale ocean horizontal circulation pattern with slow flow circulating around the ocean basin, closed by a strong and narrow (100 to 200 km wide) boundary current on the western side. The subtropical gyres in each ocean are associated with high pressure in the centre of the gyres; the subpolar gyres are associated with low pressure.

Hadley cell  See Hadley circulation.

Hadley circulation  A direct, thermally driven overturning cell in the atmosphere consisting of poleward flow in the upper troposphere, subsiding air into the subtropical anticyclones, return flow as part of the trade winds near the surface, and with rising air near the equator in the so-called Inter-Tropical Convergence Zone.

Halocarbons  A collective term for the group of partially halogenated organic species, which includes the chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs), halons, methyl chloride and methyl bromide. Many of the halocarbons have large global warming potentials. The chlorine and bromine-containing halocarbons are also involved in the depletion of the ozone layer.

Halocline  A layer in the oceanic water column in which salinity changes rapidly with depth. Generally saltier water is denser and lies below less salty water. In some high latitude oceans the surface waters may be colder than the deep waters and the halocline is responsible for maintaining water column stability and isolating the surface waters from the deep waters.

Halosteric  See Sea level change (sea level rise/sea level fall).

Halosteric sea-level change  See Sea level change (sea level rise/sea level fall).

Hazard  The potential occurrence of a natural or human-induced physical event or trend that may cause loss of life, injury, or other health impacts, as well as damage and loss to property, infrastructure, livelihoods, service provision, ecosystems and environmental resources. See also Impacts (consequences, outcomes) and Risk.

Heat index  A measure of how hot the air feels to the human body. The index is mainly based on surface air temperature and relative humidity, thus it reflects the combined effect of high temperature and humidity on human physiology and provides a relative indication of potential health risks.

Heat stress  A range of conditions in, e.g., terrestrial or aquatic organisms when the body absorbs excess heat during overexposure to high air or water temperatures or thermal radiation. In aquatic water breathing animals, hypoxia and acidification can exacerbate vulnerability to heat. Heat stress in mammals (including humans) and birds, both in air, is exacerbated by a detrimental combination of ambient heat, high humidity and low wind-speeds, causing regulation of body temperature to fail.

Heatwave  A period of abnormally hot weather often defined with reference to a relative temperature threshold, lasting from two days to months. Heatwaves and warm spells have various and, in some cases, overlapping definitions. See also Marine heatwave, Warm spell, Blocking, Heat index and Heat stress.

Heavy precipitation event  See Extreme/heavy precipitation event.

Heinrich event  Distinct layers of coarse-grained sediments comprised of ice-rafted debris identified across marine sediment cores in the North Atlantic. These sedimentary layers are closely associated with millennial-scale cooling events in the North Atlantic and a distinct pattern of global temperature and hydrological changes that are largely consistent with evidence for a slowdown, or even near-collapse, of the Atlantic meridional ocean circulation (AMOC) during these times.

Heterotrophic respiration  The conversion of organic matter to carbon dioxide by organisms other than
Hindcast or retrospective forecast  A forecast made for a period in the past using only information available before the beginning of the forecast. A sequence of hindcasts can be used to calibrate the forecast system and/or provide a measure of the average skill that the forecast system has exhibited in the past as a guide to the skill that might be expected in the future.

Holocene  The current interglacial geological epoch, the second of two epochs within the Quaternary Period, the preceding being the Pleistocene. The International Commission on Stratigraphy (ICS) defines the start of the Holocene Epoch at 11,700 years before 2000 (ICS, 2018). It encompasses the mid-Holocene (MH), the 1000-year-long interval centered at 6000 years before 1950; a period of long-standing focus for climate modelling, with enhanced seasonality in the Northern Hemisphere and decreased seasonality in the Southern Hemisphere. The early part of the Holocene is marked by the late stages of deglaciation of Pleistocene land ice, and sea level rise, and the occurrence of warm phases that affected different regions at different times, often referred to as the “Holocene thermal maximum”. In addition, the epoch includes the post-glacial interval, which began approximately 7000 years ago when the fundamental features of the modern climate system were essentially in place, as the influence of remnant Pleistocene ice sheets waned. See also Anthropocene.

Holocene Thermal Maximum (HTM)  See Holocene.

Human influence on the climate system  Human-driven activities that lead to changes in the climate system due to perturbations of the Earth’s energy budget (also called anthropogenic forcing). Human influence results from emissions of greenhouse gases, aerosols, ozone-depleting substances (ODSs), and land-use change. See also Anthropogenic, Anthropogenic emissions and Anthropogenic removals.

Human system  Any system in which human organisations and institutions play a major role. Often, but not always, the term is synonymous with society or social system. Systems such as agricultural systems, urban systems, political systems, technological systems, and economic systems are all human systems in the sense applied in this report.

Hurricane  See Tropical cyclone.

Hydroclimate  Part of the climate pertaining to the hydrology of a region.

Hydrofluorocarbons (HFCs)  One of the seven types of greenhouse gases (GHGs) or groups of GHGs to be mitigated under the Kyoto Protocol. They are produced commercially as a substitute for chlorofluorocarbons (CFCs). HFCs largely are used in refrigeration and semiconductor manufacturing.

Hydrological cycle  The cycle in which water evaporates from the ocean and the land surface, is carried over the Earth in atmospheric circulation as water vapour, condenses to form clouds, precipitates over the ocean and land as rain or snow, which on land can be intercepted by trees and vegetation, potentially accumulating as snow or ice, provides runoff on the land surface, infiltrates into soils, recharges groundwater, discharges into streams, and ultimately, flows into the oceans as rivers, polar glaciers and ice sheets, from which it will eventually evaporate again. The various systems involved in the hydrological cycle are usually referred to as hydrological systems.

Hydrological drought  See Drought.

Hydrological sensitivity ($\eta$)  The change in global-mean precipitation per degree Celsius of global mean temperature change when precipitation changes related to fast atmospheric and land surface adjustments to radiative forcings are removed. Units are % per °C although can also be calculated as W m$^{-2}$ per °C. See also Apparent hydrological sensitivity ($\eta_a$).

Hydrosphere  The component of the climate system comprising liquid surface and subterranean water,
such as in oceans, seas, rivers, freshwater lakes, underground water, wetlands, etc.

**Hypoxic** Conditions of low dissolved oxygen in shallow water ocean and freshwater environments. There is no universal threshold for hypoxia. A value around 60 μmol kg⁻¹ has commonly been used for some estuarine systems, although this does not necessarily directly translate into biological impacts. Anoxic conditions occur where there is no oxygen present at all. See also *Eutrophication*.

**Hypsometry** The distribution of land or ice surface as a function of altitude.

**Ice age** An informal term for a geological period characterised by a long-term reduction in the temperature of the Earth's *climate*, resulting in the presence or expansion of *ice sheets* and glaciers. Among the Earth's ice ages is the current Quaternary Period, characterized by alternating glacial and interglacial intervals. See also Deglacial or deglaciation or glacial termination and Glacial-interglacial cycles.

**Ice core** A cylinder of ice drilled out of a *glacier* or *ice sheet* to determine the physical properties of the ice body, and to gain information on past changes in climate and composition of the atmosphere that are preserved in the ice or in air trapped in the ice.

**Ice sheet** An ice body originating on land that covers an area of continental size, generally defined as covering >50,000 km², and that has formed over thousands of years through accumulation and compaction of snow. An ice sheet flows outward from a high central ice plateau with a small average surface slope. The margins usually slope more steeply, and most ice is discharged through fast-flowing ice streams or outlet glaciers, often into the sea or into *ice shelves* floating on the sea. There are only two ice sheets in the modern world, one on Greenland and one on Antarctica. The latter is divided into the East Antarctic Ice Sheet (EAIS), the West Antarctic Ice Sheet (WAIS) and the Antarctic Peninsula ice sheet. During glacial periods, there were other ice sheets.

**Ice shelf** A floating slab of ice originating from *land* of considerable thickness extending from the *coast* (usually of great horizontal extent with a very gently sloping surface), resulting from the flow of *ice sheets*, initially formed by the accumulation of snow, and often filling embayments in the coastline of an ice sheet. Nearly all ice shelves are in Antarctica, where most of the ice discharged into the *ocean* flows via ice shelves.

**Ice stream** A stream of ice with strongly enhanced flow that is part of an *ice sheet*. It is often separated from surrounding ice by strongly sheared, crevassed margins.

**Ice-albedo feedback** A *climate feedback* involving changes in the Earth's surface albedo. Snow and ice have an albedo much higher (up to ~0.8) than the average planetary albedo (~0.3). With increasing temperatures, it is anticipated that snow and ice extent will decrease, the Earth's overall albedo will decrease and more solar radiation will be absorbed, warming the Earth further.

**Iceberg** Large piece of freshwater ice broken off from a *glacier* or an *ice shelf* during calving and floating in open water (at least five metres height above sea level). Smaller pieces of floating ice known as ‘bergy bits’ (less than 5 metres above sea level) or ‘growlers’ (less than 2 metres above sea level) can originate from glaciers or ice shelves, or from the breaking up of a large iceberg. Icebergs can also be classified by shape, most commonly being either tabular (steep sides and a flat top) or non-tabular (varying shapes, with domes and spires) (NOAA, 2021). In lakes, icebergs can originate by breaking off shelf ice, which forms through freezing of a lake surface.

**Impacts (consequences, outcomes)** The consequences of realised risks on natural and human systems, where risks result from the interactions of climate-related hazards (including extreme weather / climate events), exposure, and vulnerability. Impacts generally refer to effects on lives, livelihoods, health and wellbeing, ecosystems and species, economic, social and cultural assets, services (including ecosystem services), and infrastructure. Impacts may be referred to as consequences or outcomes, and can be adverse or beneficial. See also *Adaptation, Exposure, Hazard, Loss and Damage, and losses and damages*,

Vulnerability and Risk.

Incoming solar radiation  See Insolation.

Indian Ocean Basin (IOB) mode  A mode of interannual variability characterized by a temporal alternation of basin-wide warming and cooling of the Indian Ocean sea surface. It mostly develops in response to El Niño-Southern Oscillation (ENSO), but often persists after ENSO's equatorial eastern Pacific signal has dissipated. The IOB affects atmospheric circulation, temperature, and precipitation in South, Southeast, and East Asia as well as Africa, and modulates tropical cyclone activity in the Northwestern Pacific. See Section AIV.2.4 in Annex IV of the AR6 WGI report. See also Modes of climate variability and Indian Ocean Dipole (IOD).

Indian Ocean Dipole (IOD)  A mode of interannual variability that features an east-west dipole of sea surface temperature anomalies in the tropical Indian Ocean. Its positive phase shows concurrent sea surface cooling off Sumatra and Java and warming off Somalia in the west, combined with anomalous surface easterlies along the equator, while the opposite anomalies are seen in the negative phase. The IOD typically develops in boreal summer and matures in boreal autumn and controls part of the rainfall interannual variability in Australia, South Eastern Asia and Eastern Africa. See Section AIV.2.4 in Annex IV of the AR6 WGI report. See also Indian Ocean Basin (IOB) mode.

Indirect aerosol effect  See Aerosol-cloud interaction.

Indirect land-use change (iLUC)  See Land-use change (LUC).

Industrial revolution  A period of rapid industrial growth with far-reaching social and economic consequences, beginning in Britain during the second half of the 18th century and spreading to Europe and later to other countries including the United States. The invention of the steam engine was an important trigger of this development. The industrial revolution marks the beginning of a strong increase in the use of fossil fuels, initially coal, and hence emission of carbon dioxide (CO₂).

Infrared radiation  See Terrestrial radiation.

Initial condition ensemble (ICE)  See Model ensemble.

Insolation The amount of solar radiation reaching the Earth by latitude and by season measured in W m⁻². Usually insolation refers to the radiation arriving at the top of the atmosphere. Sometimes it is specified as referring to the radiation arriving at the Earth's surface. See also Orbital forcing and Total solar irradiance (TSI).

Instantaneous radiative forcing (or effect) due to aerosol-cloud interactions (IRFaci)  See Aerosol-cloud interaction.

Instantaneous radiative forcing (or effect) due to aerosol-radiation interactions (IRFari)  See Aerosol-radiation interaction.

Integrated assessment model (IAM)  Models that integrate knowledge from two or more domains into a single framework. They are one of the main tools for undertaking integrated assessments. One class of IAM used in respect of climate change mitigation may include representations of: multiple sectors of the economy, such as energy, land use and land use change; interactions between sectors; the economy as a whole; associated greenhouse gas (GHG) emissions and sinks; and reduced representations of the climate system. This class of model is used to assess linkages between economic, social and technological development and the evolution of the climate system. Another class of IAM additionally includes representations of the costs associated with climate change impacts, but includes less detailed representations of economic systems. These can be used to assess impacts and mitigation in a cost-benefit framework and have been used to estimate the social cost of carbon.
Interdecadal Pacific Oscillation (IPO) See Pacific Decadal Variability (PDV).

Inter-Tropical Convergence Zone (ITCZ) The Inter-Tropical Convergence Zone is an equatorial zonal belt of low pressure, strong convection and heavy precipitation near the equator where the northeast trade winds meet the southeast trade winds. This band moves seasonally. See also South Pacific Convergence Zone (SPCZ).

Interglacial or interglaciation A globally warm period lasting thousands of years between glacial periods within an ice age. Generally coincides with odd-numbered marine isotope stages (MIS) when mean sea level was close to present. The Last Interglacial (LIG) occurred between about 129 and 116 ka (thousand years) before present (defined as 1950) although the warm period started in some areas a few thousand years earlier. In terms of marine isotope stages (MIS), interglaciations are defined as the interval between the midpoint of the preceding termination and the onset of the next glaciation. The LIG coincides with MIS 5e. The present interglaciation, the Holocene, started at 11,700 years before 2000 CE, although global mean sea level did not approach its present position until roughly 7000 years ago. See also Deglacial or deglaciation or glacial termination, Glacial-interglacial cycles, Glacial or glaciation and Ice age.

Internal climate variability See Internal variability (under Climate variability).

Irreversibility A perturbed state of a dynamical system is defined as irreversible on a given timescale, if the recovery from this state due to natural processes takes substantially longer than the timescale of interest. See also Tipping point.

Isostatic or Isostasy Isostasy refers to the response of the earth to changes in surface load. It includes the deformational and gravitational response. This response is elastic on short time scales, as in the earth-ocean response to recent changes in mountain glaciation, or viscoelastic on longer time scales, as in the response to the last deglaciation following the Last Glacial Maximum.

Isotopes Atoms of the same chemical element that have the same the number of protons but differ in the number of neutrons. Some proton-neutron configurations are stable (stable isotopes), others are unstable undergoing spontaneous radioactive decay (radioisotopes). Most elements have more than one stable isotope. Isotopes can be used to trace transport processes or to study processes that change the isotopic ratio. Radioisotopes provide in addition time information that can be used for radiometric dating. See also 

\[ ^{14}C \]

Key climate indicators See Climate indicator.

Kriging Kriging is a method of interpolation (normally spatial interpolation when used with atmospheric or oceanographic data), in which the interpolated values are estimated using a Gaussian process governed by prior covariances.

La Niña See El Niño Southern Oscillation (ENSO).

Land The terrestrial portion of the biosphere that comprises the natural resources (soil, near-surface air, vegetation and other biota, and water), the ecological processes, topography, and human settlements and infrastructure that operate within that system (UNCCD, 1994; FAO, 2007).

Land cover The biophysical coverage of land (e.g., bare soil, rocks, forests, buildings and roads or lakes). Land cover is often categorised in broad land-cover classes (e.g., deciduous forest, coniferous forest, mixed forest, grassland, bare ground). [Note: In some literature, land cover and land use are used interchangeably, but the two represent distinct classification systems. For example, the land cover class woodland can be under various land uses such as livestock grazing, recreation, conservation, or wood harvest.]

Land cover change Change from one land cover class to another, due to change in land use or change in
natural conditions (Pongratz et al., 2018). See also Land management change and Land-use change (LUC).

**Land surface air temperature (LSAT)** The near-surface air temperature over land, typically measured at 1.25–2 m above the ground using standard meteorological equipment.

**Land use** The total of arrangements, activities and inputs applied to a parcel of land. The term land use is also used in the sense of the social and economic purposes for which land is managed (e.g., grazing, timber extraction, conservation and city dwelling). In national GHG inventories, land use is classified according to the IPCC land use categories of forest land, cropland, grassland, wetlands, settlements, other lands (see the 2006 IPCC Guidelines for National GHG Inventories and their 2019 Refinement for details (IPCC, 2006, 2019)).

**Land water storage** Land water storage (LWS) includes all surface water, soil moisture, groundwater storage and snow, but excludes water stored in glaciers and ice sheets. Changes in land water storage can be caused either by direct human intervention in the water cycle (e.g., storage of water in reservoirs by building dams in rivers, groundwater extraction from groundwater reservoirs for consumption and irrigation, or deforestation) or by climate variations (e.g., changes in the amount of water in endorheic lakes and wetlands, the canopy, the soil, the permafrost and the snowpack). Land water storage changes caused by climate variations may also be indirectly affected by anthropogenic influences. See also Sea level change (sea level rise/sea level fall).

**Land-use change (LUC)** The change from one land use category to another. Note that in some scientific literature, land-use change encompasses changes in land-use categories as well as changes in land management. See also Afforestation, Agriculture, Forestry and Other Land Use (AFOLU), Deforestation, Land use, land-use change and forestry (LULUCF) and Reforestation.

**Indirect land-use change (iLUC)** Land use change outside the area of focus, that occurs as a consequence of change in use or management of land within the area of focus, such as through market or policy drivers. For example, if agricultural land is diverted to biofuel production, forest clearance may occur elsewhere to replace the former agricultural production. See Land-use change (LUC).

**Lapse rate** The rate of change of an atmospheric variable, usually temperature, with height. The lapse rate is considered positive when the variable decreases with height.

**Large-scale** The climate system involves process interactions from the micro- to the global-scale. Any threshold for defining “large-scale” is arbitrary. Understanding of large-scale climate variability and change requires knowledge of both the response to external forcings and the role of internal variability. Many external forcings have substantial hemispheric or continental scale variations. Modes of climate variability are driven by ocean basin scale processes. Thus we define large-scale to include ocean basin and continental scales as well as hemispheric and global scales.

**Last deglacial transition** See Deglacial or deglaciation or glacial termination and Younger Dryas.

**Last Glacial Maximum (LGM)** See Glacial or glaciation.

**Last Inter-glacial (LIG)** See Inter-glacial or inter-glaciation.

**Last millennium** The interval of the Common Era (CE) between 1001 and 2000 CE. Encompasses the Little Ice Age, a roughly defined period characterized by multiple expansions of mountain glaciers worldwide, the timing of which differs among regions, but generally occurred between 1400 CE and 1900 CE. The last millennium also mostly encompasses the Medieval Warm Period (also called the Medieval Climate Anomaly), a roughly defined period of relatively warm conditions or other climate excursions such as extensive drought, the timing and magnitude of which differ among regions, but generally occurred between 900 and 1400 CE. Transient climate model experiments by the Paleoclimate Modelling Intercomparison Project (PMIP) for the last millennium extend from 850-1849 CE.

Do Not Cite, Quote or Distribute
Latent heat flux  The turbulent flux of heat from the Earth's surface to the atmosphere that is associated with evaporation or condensation of water vapour at the surface; a component of the surface energy budget. See also Atmosphere and Flux.

Lifetime  Lifetime is a general term used for various time scales characterizing the rate of processes affecting the concentration of trace gases. The following lifetimes may be distinguished:

Response time or adjustment time (Ta)  Response time or adjustment time (Ta) is the time scale characterizing the decay of an instantaneous pulse input into the reservoir. The term adjustment time is also used to characterize the adjustment of the mass of a reservoir following a step change in the source strength. Half-life or decay constant is used to quantify a first-order exponential decay process. See Response time or adjustment time for a different definition pertinent to climate variations.

The term lifetime is sometimes used, for simplicity, as a surrogate for adjustment time.

In simple cases, where the global removal of the compound is directly proportional to the total mass of the reservoir, the adjustment time equals the turnover time: T = Ta. An example is CFC-11, which is removed from the atmosphere only by photochemical processes in the stratosphere. In more complicated cases, where several reservoirs are involved or where the removal is not proportional to the total mass, the equality T = Ta no longer holds.

Carbon dioxide (CO2) is an extreme example. Its turnover time is only about 4 years because of the rapid exchange between the atmosphere and the ocean and terrestrial biota. However, a large part of that CO2 is returned to the atmosphere within a few years. The adjustment time of CO2 in the atmosphere is determined from the rates of removal of carbon by a range of processes with timescales from months to hundreds of thousands of years. As a result, 15 to 40% of an emitted CO2 pulse will remain in the atmosphere longer than 1,000 years, 10 to 25% will remain about ten thousand years, and the rest will be removed over several hundred thousand years.

In the case of methane (CH4), the adjustment time is different from the turnover time because the removal is mainly through a chemical reaction with the hydroxyl radical (OH), the concentration of which itself depends on the CH4 concentration. Therefore, the CH4 removal rate S is not proportional to its total mass M.

Turnover time (T)  (also called global atmospheric lifetime) is the ratio of the mass M of a reservoir (e.g., a gaseous compound in the atmosphere) and the total rate of removal S from the reservoir: T = M/S. For each removal process, separate turnover times can be defined. In soil carbon biology, this is referred to as Mean Residence Time.

Light-absorbing particles  Light-absorbing particles (LAP), e.g., black carbon, brown carbon, dust, are particles that absorb solar radiation and convert it into internal energy, thus raising the particle’s temperature and emitting thermal-infrared radiation that is selectively absorbed by the surrounding medium. LAP affect the energy balance of the atmosphere, clouds, and when deposited on snow and ice, they reduce snow/ice albedo, increasing heating and accelerating melting. These particles have a warming effect on climate.

Likelihood  The chance of a specific outcome occurring, where this might be estimated probabilistically. Likelihood is expressed in this report using a standard terminology (Mastrandrea et al., 2010). See also Agreement, Confidence, Evidence and Uncertainty.

Lithosphere  The upper layer of the solid Earth, both continental and oceanic, which comprises all crustal rocks and the cold, mainly elastic part of the uppermost mantle. Volcanic activity, although part of the lithosphere, is not considered as part of the climate system, but acts as an external forcing factor.

Livelihood  The resources used and the activities undertaken in order for people to live. Livelihoods are usually determined by the entitlements and assets to which people have access. Such assets can be...
categorised as human, social, natural, physical, or financial.

Local sea level change  
See Sea level change (sea level rise/sea level fall).

Long-lived climate forcers (LLCFs)  
A set of well-mixed greenhouse gases with long atmospheric lifetimes. This set of compounds includes carbon dioxide (CO₂) and nitrous oxide (N₂O), together with some fluorinated gases. They have a warming effect on climate. These compounds accumulate in the atmosphere at decadal to centennial timescales, and their effect on climate hence persists for decades to centuries after their emission. On timescales of decades to a century already emitted emissions of long-lived climate forcers can only be abated by greenhouse gas removal (GGR).

Longwave radiation  
See Terrestrial radiation.

Low-likelihood, high impact events  
Events whose probability of occurrence is low or not well known (as in the context of deep uncertainty) but whose potential impacts on society and ecosystems could be high. To better inform risk assessment and decision-making, such low-likelihood outcomes are considered if they are associated with very large consequences and may therefore constitute material risks, even though those consequences do not necessarily represent the most likely outcome.

Madden-Julian Oscillation (MJO)  
The largest mode of tropical atmospheric intraseasonal variability with typical periods ranging from 20 to 90 days. The MJO corresponds to planetary-scale disturbances of pressure, wind and deep convection moving predominantly eastward along the equator. As it progresses, the MJO is associated with the temporal alternation of large-scale enhanced and suppressed rainfall, with maximum loading over the Indian and western Pacific oceans, although influences of the MJO can be tracked over the Atlantic/Africa in dynamical fields. See Section AIV.2.8 in Annex IV of the AR6 WGI report.

Maladaptive actions (Maladaptation)  
Actions that may lead to increased risk of adverse climate-related outcomes, including via increased greenhouse gas (GHG) emissions, increased vulnerability to climate change, or diminished welfare, now or in the future. Maladaptation is usually an unintended consequence.

Marine cloud brightening (MCB)  
See Solar radiation modification (SRM).

Marine heatwave  
A period during which water temperature is abnormally warm for the time of the year relative to historical temperatures with that extreme warmth persisting for days to months. The phenomenon can manifest in any place in the ocean and at scales of up to thousands of kilometres. See also Heatwave.

Marine ice cliff instability (MICI)  
A hypothetic mechanism of an ice cliff failure. In case a marine-terminated ice sheet loses its buttressing ice shelf, an ice cliff can be exposed. If the exposed ice cliff is tall enough (about 800 m of the total height, or about 100 m of the above-water part), the stresses at the cliff face exceed the strength of the ice, and the cliff fails structurally in repeated calving events. See also Marine ice shelf instability (MISI).

Marine ice sheet instability (MISI)  
A mechanism of irreversible (on the decadal to centennial time scale) retreat of a grounding line for the marine-terminating glaciers, in case the glacier bed slopes towards the ice sheet interior. See also Marine ice cliff instability (MICI).

Marine isotope stage (MIS)  
Geological periods of alternating glacial and interglacial conditions, each typically lasting tens of thousands of years as inferred from the oxygen isotope composition of microfossils from deep sea sediment cores. MIS numbers increase back in time from the present, which is MIS 1. Even-numbered MISs coincide with glacial periods, and odd-numbered MISs are interglacials.

Marine-based ice sheet  
An ice sheet containing a substantial region that rests on a bed lying below sea level and whose perimeter is in contact with the ocean. The best known example is the West Antarctic ice sheet.
Mass balance / budget (of glaciers or ice sheets)  Difference between the mass input (accumulation) and the mass loss (ablation) of an ice body (e.g., a glacier or ice sheet) over a stated time period, which is often a year or a season. Surface mass balance refers to the difference between surface accumulation and surface ablation.

Ablation (of glaciers, ice sheets, or snow cover)  All processes that reduce the mass of a glacier, ice sheet, or snow cover. The main processes are melting, and for glaciers also calving (or, when the glacier nourishes an ice shelf, discharge of ice across the grounding line), but other processes such as sublimation and loss of wind-blown snow can also contribute to ablation. Ablation also refers to the mass lost by any of these processes.

Accumulation (of glaciers, ice sheets, or snow cover)  All processes that add to the mass of a glacier, an ice sheet, or snow cover. The main process of accumulation is snowfall. Accumulation also includes deposition of hoar, freezing rain, other types of solid precipitation, gain of wind-blown snow, avalanching, and basal accumulation (often beneath floating ice).

Discharge (of ice)  Rate of the flow of ice through a vertical section of a glacier perpendicular to the direction of the flow of ice. Often used to refer to the loss of mass at marine-terminating glacier fronts (mostly calving of icebergs and submarine melt), or to mass flowing across the grounding line of a floating ice shelf.

Mean sea level  The surface level of the ocean at a particular point averaged over an extended period of time such as a month or year. Mean sea level is often used as a national datum to which heights on land are referred.

Medieval Climate Anomaly (MCA)  See Medieval Warm Period (MWP).

Megacity  Urban agglomerations with 10 million inhabitants or more.

Meltwater Pulse 1A (MWP-1A)  A particular interval of rapid global sea level rise between about 14,700 and 14,300 years ago, associated with the end of the last ice age and attributed to freshwater flux to the ocean from accelerated melting of ice sheets and glaciers. First defined based on oxygen isotope data (Duplessy et al., 1981), and later shown to be reflected by high rates of sea-level rise (Fairbanks, 1989). See also Deglacial or deglaciation or glacial termination.

Meridional overturning circulation (MOC)  Meridional (north-south) overturning circulation in the ocean quantified by zonal (east-west) sums of mass transports in depth or density layers. In the North Atlantic, away from the subpolar regions, the MOC (which is in principle an observable quantity) is often identified with the thermohaline circulation (THC), which is a conceptual and incomplete interpretation. The MOC is also driven by wind, and can also include shallower overturning cells such as occur in the upper ocean in the tropics and subtropics, in which warm (light) waters moving poleward are transformed to slightly denser waters and subducted equatorward at deeper levels.

Atlantic Meridional Overturning Circulation (AMOC)  The main current system in the South and North Atlantic Oceans. AMOC transports warm upper-ocean water northwards, and cold, deep water southwards, as part of the global ocean circulation system. Changes in the strength of AMOC can affect other components of the climate system.

Meteorological drought  See Drought.

Methane (CH$_4$)  One of the seven greenhouse gases (GHGs) to be mitigated under the Kyoto Protocol. Methane is the major component of natural gas and associated with all hydrocarbon fuels. Significant anthropogenic emissions also occur as a result of animal husbandry and paddy rice production. Methane is also produced naturally where organic matter decays under anaerobic conditions, such as in wetlands.
future global warming, there is risk of increased methane emissions from thawing permafrost, coastal
wetlands and sub-sea gas hydrates. See also Short-lived climate forcers (SLCFs).

**Microclimate**  Local climate at or near the Earth's surface.

**Microwave sounding unit (MSU)**  A microwave sounder on National Oceanic and Atmospheric
Administration (NOAA) polar orbiter satellites, that estimates the temperature of thick layers of the
atmosphere by measuring the thermal emission of oxygen molecules from a complex of emission lines near
60 GHz. A series of nine MSUs began making this kind of measurement in late 1978. Beginning in mid-
1998, a follow-on series of instruments, the Advanced Microwave Sounding Units (AMSUs), began
operation.

**Mid-Holocene (MH)**  See Holocene.

**Mid-Pliocene Warm Period (MPWP)**  See Pliocene.

**Mineralisation/Remineralisation**  The conversion of an element from its organic form to an inorganic
form as a result of microbial decomposition. In nitrogen mineralisation, organic nitrogen from decaying plant
and animal residues (proteins, nucleic acids, amino sugars and urea) is converted to ammonia (NH$_3$) and
ammonium (NH$_4^+$) by biological activity.

**Mitigation (of climate change)**  A human intervention to reduce emissions or enhance the sinks of
greenhouse gases.

**Mitigation potential**  The quantity of net greenhouse gas emission reductions that can be achieved by a
given mitigation option relative to specified emission baselines. [Note: Net greenhouse gas emission
reductions is the sum of reduced emissions and or enhanced sinks.] See also Sequestration potential.

**Biogeophysical potential**  The mitigation potential constrained by biological, geophysical and geochemical
limits and thermodynamics, without taking into account technical, social, economic, and/or environmental
considerations.

**Economic potential**  The portion of the technical potential for which the social benefits exceed the social
costs, taking into account a social discount rate and the value of externalities

**Technical potential**  The mitigation potential constrained by biogeophysical limits as well as availability of
technologies and practices. Quantification of technical potentials takes into account primarily technical
considerations, but social, economic and/or environmental considerations are occasionally also included, if
these represent strong barriers for the deployment of an option.

**Mitigation scenario**  See Scenario.

**Mixing ratio**  See Mole fraction or mixing ratio.

**Model bias**  See Biases.

**Model drift**  Since model climate differs to some extent from observed climate, climate forecasts will
typically 'drift' from the initial observation-based state towards the model's climate. This drift occurs at
different time scales for different variables, can obscure the initial-condition forecast information and is
usually removed a posteriori by an empirical, usually linear, adjustment.

**Model initialization**  A climate prediction typically proceeds by integrating a climate model forward in
time from an initial state that is intended to reflect the actual state of the climate system. Available
observations of the climate system are 'assimilated' into the model. Initialization is a complex process that is
limited by available observations, observational errors and, depending on the procedure used, may be
affected by uncertainty in the history of climate forcing. The initial conditions will contain errors that grow as the forecast progresses, thereby limiting the time for which the forecast will be useful.

Model spread The range or spread in results from climate models, such as those assembled for Coupled Model Intercomparison Project Phase 6 (CMIP6). Does not necessarily provide an exhaustive and formal estimate of the uncertainty in feedbacks, forcing or projections even when expressed numerically, for example, by computing a standard deviation of the models' responses. In order to quantify uncertainty, information from observations, physical constraints and expert judgement must be combined, using a statistical framework.

Modes of climate variability Recurrent space-time structures of natural variability of the climate system with intrinsic spatial patterns, seasonality and time scales. Modes can arise through the dynamical characteristics of the atmospheric circulation but also through coupling between the ocean and the atmosphere, with some interactions with land surfaces and sea ice. Many modes of variability are driven by internal climate processes and are a critical potential source of climate predictability on sub-seasonal to decadal time scales. See Annex IV of the AR6 WGI report. See also Annular modes, Tropical Atlantic Variability (TAV), Indian Ocean Dipole (IOD), Indian Ocean Basin (IOB) mode, Pacific Decadal Variability (PDV), Pacific Decadal Oscillation (PDO) (under Pacific Decadal Variability (PDV)), El Niño–Southern Oscillation (ENSO), North Atlantic Oscillation (NAO), Northern Annular Mode (NAM) (under Annular modes), Southern Annular Mode (SAM) (under Annular modes), Atlantic Meridional Mode (AMM) (under Tropical Atlantic Variability (TAV)), Atlantic Zonal Mode (AZM) (under Tropical Atlantic Variability (TAV)), Madden-Julian Oscillation (MJO), Atlantic Multidecadal Variability (AMV) and Interdecadal Pacific Oscillation (IPO) (under Pacific Decadal Variability (PDV)).

Mole fraction or mixing ratio Mole fraction, or mixing ratio, is the ratio of the number of moles of a constituent in a given volume to the total number of moles of all constituents in that volume. It is usually reported for dry air. Typical values for well-mixed greenhouse gases are in the order of μmol mol⁻¹ (parts per million: ppm), nmol mol⁻¹ (parts per billion: ppb), and fmol mol⁻¹ (parts per trillion: ppt). Mole fraction differs from volume mixing ratio, often expressed in ppmv etc., by the corrections for non-ideality of gases. This correction is significant relative to measurement precision for many greenhouse gases (Schwartz and Warneck, 1995).

Monsoon See Global monsoon.

Montreal Protocol The Montreal Protocol on Substances that Deplete the Ozone Layer was adopted in Montreal in 1987, and subsequently adjusted and amended in London (1990), Copenhagen (1992), Vienna (1995), Montreal (1997) and Beijing (1999). It controls the consumption and production of chlorine- and bromine-containing chemicals that destroy stratospheric ozone (O₃), such as chlorofluorocarbons (CFCs), methyl chloroform, carbon tetrachloride and many others.

Multi-model ensemble (MME) See Climate simulation ensemble. See also Ensemble.

Narrative See Storyline. See also Pathways.

Natural systems The dynamic physical and biological components of the environment that would operate in the absence of human impacts. Most, if not all, natural systems are also now affected by human activities to some degree.

Natural variability See Climate variability.

Near-surface permafrost See Permafrost.

Negative greenhouse gas emissions Removal of greenhouse gases (GHGs) from the atmosphere by deliberate human activities, i.e., in addition to the removal that would occur via natural carbon cycle or atmospheric chemistry processes. See also Carbon dioxide removal (CDR), Greenhouse gas removal (GGR).
Negative CO₂ emissions, Net negative greenhouse gas emissions, Net zero CO₂ emissions and Net zero greenhouse gas emissions.

**Net negative greenhouse gas emissions** A situation of net negative greenhouse gas emissions is achieved when metric-weighted anthropogenic greenhouse gas (GHG) removals exceed metric-weighted anthropogenic GHG emissions. Where multiple GHG are involved, the quantification of net emissions depends on the metric chosen to compare emissions of different gases (such as global warming potential, global temperature change potential, and others, as well as the chosen time horizon). See also Net zero CO₂ emissions, Net zero greenhouse gas emissions, Negative greenhouse gas emissions, Carbon dioxide removal (CDR), Greenhouse gas removal (GGR) and Greenhouse gas emission metric.

**Net primary production (NPP)** See Primary production.

**Net zero CO₂ emissions** Condition in which anthropogenic carbon dioxide (CO₂) emissions are balanced by anthropogenic CO₂ removals over a specified period. [Note: Carbon neutrality and net zero CO₂ emissions are overlapping concepts. The concept can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms carbon neutrality and net zero CO₂ emissions are equivalent. At sub-global scales, net zero CO₂ emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while carbon neutrality generally includes emissions and removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant CO₂ emissions and removals.] See also Net zero greenhouse gas emissions, Carbon neutrality and Land use, land-use change and forestry (LULUCF).

**Net zero greenhouse gas emissions** Condition in which metric-weighted anthropogenic greenhouse gas (GHG) emissions are balanced by metric-weighted anthropogenic GHG removals over a specified period. The quantification of net zero GHG emissions depends on the GHG emission metric chosen to compare emissions and removals of different gases, as well as the time horizon chosen for that metric.

[Note 1: GHG neutrality and net zero GHG emissions are overlapping concepts. The concept of net zero GHG emissions can be applied at global or sub-global scales (e.g., regional, national and sub-national). At a global scale, the terms GHG neutrality and net zero GHG emissions are equivalent. At sub-global scales, net zero GHG emissions is generally applied to emissions and removals under direct control or territorial responsibility of the reporting entity, while GHG neutrality generally includes anthropogenic emissions and anthropogenic removals within and beyond the direct control or territorial responsibility of the reporting entity. Accounting rules specified by GHG programmes or schemes can have a significant influence on the quantification of relevant emissions and removals.

Note 2. Under the Paris Rulebook [Decision 18/CMA.1, annex, paragraph 37], parties have agreed to use GWP100 values from the IPCC AR5 or GWP100 values from a subsequent IPCC Assessment Report to report aggregate emissions and removals of GHGs. In addition, parties may use other metrics to report supplemental information on aggregate emissions and removals of GHGs.]

See also Net zero CO₂ emissions, Greenhouse gas emission metric, Greenhouse gas neutrality and Land use, land-use change and forestry (LULUCF).

**Nitrogen deposition** Nitrogen deposition is defined as the nitrogen transferred from the atmosphere to the Earth's surface by the processes of wet deposition and dry deposition.

**Nitrous oxide (N₂O)** One of the seven greenhouse gases (GHGs) to be mitigated under the Kyoto Protocol. The main anthropogenic source of N₂O is agriculture (soil and animal manure management), but important contributions also come from sewage treatment, fossil fuel combustion, and chemical industrial processes. N₂O is also produced naturally from a wide variety of biological sources in soil and water, particularly microbial action in wet tropical forests.
Non-CO$_2$ emissions and radiative forcing  Non-CO$_2$ emissions included in this report are all anthropogenic emissions other than CO$_2$ that result in radiative forcing. These include short-lived climate forcers, such as methane (CH$_4$), some fluorinated gases, ozone (O$_3$) precursors, aerosols or aerosol precursors, such as black carbon and sulphur dioxide, respectively, as well as long-lived greenhouse gases, such as nitrous oxide (N$_2$O) or other fluorinated gases. The radiative forcing associated with non-CO$_2$ emissions and changes in surface albedo (e.g., resulting from land-use change) is referred to as non-CO$_2$ radiative forcing.

Non-methane volatile organic compounds (NMVOCs)  See Volatile organic compounds (VOCs).

Nonlinearity  A process is called nonlinear when there is no simple proportional relation between cause and effect. The climate system contains many such nonlinear processes, resulting in a system with potentially very complex behaviour. Such complexity may lead to abrupt climate change.

North American monsoon (NAmerM)  See Global monsoon.

Northern Annular Mode (NAM)  See Annular modes.

North Atlantic Oscillation (NAO)  The leading mode of large-scale atmospheric variability in the North Atlantic basin characterized by alternating (see-saw) variations in sea-level pressure or geopotential height between the Azores High in the subtropics and the Icelandic Low in the mid- to high latitudes with some northward extension deep into the Arctic. It is associated with fluctuations in strength and latitudinal position of the main westerly winds across a vast North Atlantic-Europe domain, and thus with fluctuations in the embedded extratropical cyclones and associated frontal systems leading to strong teleconnection over the entire North Atlantic adjacent continents. The positive and negative phases of the NAO show similar characteristics described for the Northern Annular Mode (NAM). See Section AIV.2.1 in Annex IV of the AR6 WGI report.

Northern polar vortex  See Stratospheric polar vortex.

Ocean  The interconnected body of saline water that covers 71% of the Earth's surface, contains 97% of the Earth's water and provides 99% of the Earth's biologically-habitable space. It includes the Arctic, Atlantic, Indian, Pacific and Southern Oceans, as well as their marginal seas and coastal waters.

Ocean acidification (OA)  A reduction in the pH of the ocean, accompanied by other chemical changes (primarily in the levels of carbonate and bicarbonate ions), over an extended period, typically decades or longer, which is caused primarily by uptake of carbon dioxide (CO$_2$) from the atmosphere, but can also be caused by other chemical additions or subtractions from the ocean. Anthropogenic OA refers to the component of pH reduction that is caused by human activity (IPCC, 2011, p. 37).

Ocean alkalination / Ocean alkalinity enhancement  A proposed carbon dioxide removal method that involves deposition of alkaline minerals or their dissociation products at the ocean surface. This increases surface total alkalinity, and may thus increase ocean CO$_2$ uptake and ameliorate surface ocean acidification. See also Anthropogenic removals and Carbon dioxide removal (CDR).

Ocean carbon cycle  The ocean carbon cycle is the set of processes that exchange carbon between various pools within the ocean, as well as between the atmosphere, Earth's interior, cryosphere, and the seafloor. See also Carbon cycle.

Ocean deoxygenation  The loss of oxygen in the ocean. It results from ocean warming, which reduces oxygen solubility and increases oxygen consumption and stratification, thereby reducing the mixing of oxygen into the ocean interior. Deoxygenation can also be exacerbated by the addition of excess nutrients in the coastal zone.

Ocean dynamic sea level change  See Sea level change (sea level rise/sea level fall).
Ocean fertilisation  A proposed carbon dioxide removal method that relies on the deliberate increase of
nutrient supply to the near-surface ocean with the aim of sequestering additional CO₂ from the atmosphere
through biological production. Methods include direct addition of micro-nutrients or macro-nutrients. To be
successful, the additional carbon needs to reach the deep ocean where it has the potential to be sequestered
on climatically-relevant timescales. See also Anthropogenic removals and Carbon dioxide removal (CDR).

Ocean heat uptake efficiency  This is a measure (W m⁻² °C⁻¹) of the rate at which heat storage by the
global ocean increases as global surface temperature rises. It is a useful parameter for climate change
simulations in which the radiative forcing is changing monotonically, when it can be compared with the
climate feedback parameter to gauge the relative importance of radiative response and ocean heat uptake in
determining the rate of climate change. It can be estimated from such an experiment as the ratio of the rate of
increase of ocean heat content to the surface temperature change.

Ocean stratification  See Stratification.

Orbital forcing  Orbital forcing is the influence of slow, systematic and predictable changes in orbital
parameters (eccentricity, obliquity and precession of the equinox) on incoming solar radiation (insolation),
especially its latitudinal and seasonal distribution. It is an external forcing and a key driver of glacial-
interglacial cycles.

Organic aerosol  Component of the aerosol that consists of organic compounds, mainly carbon, hydrogen,
oxygen and lesser amounts of other elements.

Outgoing longwave radiation  Net outgoing radiation in the infrared part of the spectrum at the top of the
atmosphere.

Outlet glacier  See Glacier.

Oxygen minimum zone (OMZ)  The midwater layer (200–1000 m) in the open ocean in which oxygen
saturation is the lowest in the ocean. The degree of oxygen depletion depends on the largely bacterial
consumption of organic matter and the distribution of the OMZs is influenced by large-scale ocean
circulation. In coastal oceans, OMZs extend to the shelves and may also affect benthic ecosystems.

Ozone (O₃)  The triatomic form of oxygen, and a gaseous atmospheric constituent. In the troposphere, O₃ is
created both naturally and by photochemical reactions involving gases resulting from human activities (e.g.,
smog). Tropospheric O₃ acts as a greenhouse gas (GHG). In the stratosphere, O₃ is created by the interaction
between solar ultraviolet radiation and molecular oxygen (O₂). Stratospheric O₃ plays a dominant role in the
stratospheric radiative balance. Its concentration is highest in the ozone layer. See also Ground-level ozone,
Ozone hole, Ozone layer, Ozone-depleting substances (ODSs), Ozonesonde and Short-lived climate forcers
(SLCFs).

Ozone layer  The ozone layer is a layer of Earth's stratosphere that absorbs most of the Sun's ultraviolet
radiation. It contains high concentrations of ozone (O₃) in relation to other parts of the atmosphere, although
still small in relation to other gases in the stratosphere. The ozone layer contains less than 10 parts per
million of ozone, while the average ozone concentration in Earth's atmosphere as a whole is about 0.3 parts
per million. The ozone layer is mainly found in the lower portion of the stratosphere, from approximately 15
to 35 kilometres (9.3 to 21.7 miles) above Earth, although its thickness varies seasonally and geographically.
See also Ozone hole and Ozone-depleting substances (ODSs).

Ozone-depleting substances (ODSs)  Ozone-depleting substances (ODSs) are man-made gases that
destroy ozone (O₃) once they reach the ozone layer in the stratosphere. Ozone depleting substances include:
chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrobromofluorocarbons (HBFCs),
halons, methyl bromide, carbon tetrachloride and methyl chloroform. They are used as refrigerants in
commercial, home and vehicle air conditioners and refrigerators, foam blowing agents, components in
electrical equipment, industrial solvents, solvents for cleaning (including dry cleaning), aerosol spray propellants and fumigants. See also Ozone layer, Ozone (O₃) and Stratospheric ozone.

Ozonesonde  An ozonesonde is a radiosonde measuring ozone (O₃) concentrations. The radiosonde is usually carried on a weather balloon and transmits measured quantities by radio to a ground-based receiver.

Pacific Decadal Oscillation (PDO)  See Pacific Decadal Variability (PDV).

Pacific Decadal Variability (PDV)  Coupled decadal-to-interdecadal variability of the atmospheric circulation and underlying ocean that is typically observed over the entire Pacific Basin beyond the El Niño-Southern Oscillation (ENSO) timescale. In the AR6 WGI report, PDV encapsulates the Pacific Decadal Oscillation (PDO), the South Pacific Decadal Oscillation (SPDO), tropical Pacific decadal variability (also called decadal ENSO), and the Interdecadal Pacific Oscillation (IPO). Typically, the positive phase of the PDV is characterized by anomalously high sea surface temperatures in the central-eastern tropical Pacific that extend to the extratropical North and South Pacific along the American coasts, encircled to the west by cold sea surface anomalies in the mid-latitude North and South Pacific. The negative phase is accompanied by sea surface temperature anomalies in the opposite sign. Those sea surface temperature anomalies are linked to anomalies in atmospheric and oceanic circulation throughout the whole Pacific Basin. The PDV is associated with decadal modulations in the relative occurrence of El Niño and La Niña. See Section AIV.2.6 in Annex IV of the AR6 WGI report.

Interdecadal Pacific Oscillation (IPO)  An equatorially symmetric pattern of sea surface temperature variability at decadal-to-interdecadal timescales. While the Pacific Decadal Oscillation (PDO) and its South Pacific counterpart, the South Pacific Decadal Oscillation (SPDO), are considered as physically distinct modes, the tropical Pacific decadal-interdecadal variability can drive both the PDO and SPDO, forming the IPO as a synchronized pan-Pacific variability. Its spatial pattern of sea surface temperature anomalies is similar to that of the El Niño-Southern Oscillation (ENSO), but with a broader meridional extent in the tropical signal and more weights in the extratropics compared to the tropics. In the AR6 WGI report, it is encapsulated within the definition and description of the Pacific Decadal Variability (PDO). See also Section AIV.2.6 in Annex IV of the AR6 WGI report.

Pacific Decadal Oscillation (PDO)  The leading mode of variability obtained from decomposition in empirical orthogonal function of sea surface temperature over the North Pacific north of 20°N, and characterized by a strong decadal component. The positive phase of the PDO features a dipole of sea surface temperature anomalies in the North Pacific, with a cold lobe near the center of the basin and extending westward along the Kuroshio, encircled by warmer conditions along the coast of North America and in the subtropics. A positive PDO is accompanied by an intensified Aleutian Low and an associated cyclonic circulation enhancement leading to teleconnections over the continents adjacent to the North Pacific. In AR6 WGI report, the PDO is encapsulated within the definition and description of Pacific Decadal Variability (PDV). See also Section AIV.2.6 in Annex IV of the AR6 WGI report.

Pacific-North American (PNA) pattern  An atmospheric large-scale wave pattern featuring a sequence of tropospheric high and low pressure anomalies stretching from the subtropical west Pacific to the east coast of North America. See also Pacific-South American (PSA) pattern.

Palaeocene-Eocene Thermal Maximum (PETM)  The PETM is a transient event that occurred between 55.9 and 55.7 million years ago. Continental positions at this time were somewhat different to present due to tectonic plate movements. Geological data indicate that the PETM was characterised by a warming (global mean surface temperature rose to about 4-7 °C warmer than the preceding mean state), and an increase in atmospheric CO₂ (from about 900 to about 2000 ppmv). In addition, ocean pH and oxygen content decreased; many deep-sea species went extinct and tropical coral reefs diminished.

Paleoclimate  Climate during periods prior to the development of measuring instruments, including historic and geologic time, for which only proxy climate records are available.
**Parameterisation** In *climate models*, this term refers to the technique of representing processes that cannot be explicitly resolved at the spatial or temporal resolution of the model (sub-grid scale processes) by relationships between model-resolved larger-scale variables and the area- or time-averaged effect of such subgrid scale processes.

**Pathways** The temporal evolution of natural and/or human systems towards a future state. Pathway concepts range from sets of quantitative and qualitative scenarios or narratives of potential futures to solution-oriented decision-making processes to achieve desirable societal goals. Pathway approaches typically focus on biophysical, techno-economic, and/or socio-behavioural trajectories and involve various dynamics, goals, and actors across different scales. See also *Scenario storyline* (under *Storyline*), *Mitigation scenario* (under *Scenario*), *Baseline scenario* (under *Scenario*) and *Stabilisation* (of GHG or CO$_2$-equivalent concentration).

1.5°C pathway A pathway of emissions of greenhouse gases and other climate forcers that provides an approximately one-in-two to two-in-three chance, given current knowledge of the climate response, of global warming either remaining below 1.5°C or returning to 1.5°C by around 2100 following an overshoot.

Representative concentration pathways (RCPs) Scenarios that include time series of emissions and concentrations of the full suite of greenhouse gases (GHGs) and aerosols and chemically active gases, as well as land use/land cover (Moss et al., 2010). The word representative signifies that each RCP provides only one of many possible scenarios that would lead to the specific radiative forcing characteristics. The term pathway emphasises that not only the long-term concentration levels are of interest, but also the trajectory taken over time to reach that outcome (Moss et al., 2010).

RCPs usually refer to the portion of the concentration pathway extending up to 2100, for which *Integrated assessment models* produced corresponding emission scenarios. Extended concentration pathways describe extensions of the RCPs from 2100 to 2300 that were calculated using simple rules generated by stakeholder consultations, and do not represent fully consistent scenarios. Four RCPs produced from Integrated assessment models were selected from the published literature and are used in the Fifth IPCC Assessment and also used in this Assessment for comparison, spanning the range from approximately below 2°C warming to high (>4°C) warming best-estimates by the end of the 21st century: RCP2.6, RCP4.5 and RCP6.0 and RCP8.5.

- RCP2.6: One pathway where radiative forcing peaks at approximately 3 W m$^{-2}$ and then declines to be limited at 2.6 W m$^{-2}$ in 2100 (the corresponding Extended Concentration Pathway, or ECP, has constant emissions after 2100).
- RCP4.5 and RCP6.0: Two intermediate stabilisation pathways in which radiative forcing is limited at approximately 4.5 W m$^{-2}$ and 6.0 W m$^{-2}$ in 2100 (the corresponding ECPs have constant concentrations after 2150).
- RCP8.5: One high pathway which leads to >8.5 W m$^{-2}$ in 2100 (the corresponding ECP has constant emissions after 2100 until 2150 and constant concentrations after 2250).

See also *Coupled Model Intercomparison Project* (CMIP) and *Shared socio-economic pathways* (SSPs) (under *Pathways*).

**Shared socio-economic pathways (SSPs)** Shared socio-economic pathways (SSPs) have been developed to complement the Representative concentration pathways (RCPs). By design, the RCP emission and concentration pathways were stripped of their association with a certain socio-economic development. Different levels of emissions and climate change along the dimension of the RCPs can hence be explored against the backdrop if different socio-economic development pathways (SSPs) on the other dimension in a matrix. This integrative SSP-RCP framework is now widely used in the climate impact and policy analysis literature, where climate projections obtained under the RCP scenarios are analysed against the backstop of various SSPs. As several emission updates were due, a new set of emission scenarios was developed in conjunction with the SSPs. Hence, the abbreviation SSP is now used for two things: On the one hand SSP1, SSP2, ..., SSP5 is used to denote the five socio-economic scenario families. On the other hand, the
abbreviations SSP1-1.9, SSP1-2.6, ..., SSP5-8.5 are used to denote the newly developed emission scenarios that are the result of an SSP implementation within an integrated assessment model. Those SSP scenarios are bare of climate policy assumption, but in combination with so-called shared policy assumptions (SPAs), various approximate radiative forcing levels of 1.9, 2.6, ..., or 8.5 W m$^{-2}$ are reached by the end of the century, respectively.

**Pattern scaling** Techniques used to represent the spatial variations in climate at a given increase in global mean surface air temperature (GSAT) are referred to as ‘pattern scaling’.

**Peat** Soft, porous or compressed, sedimentary deposit of which a substantial portion is partly decomposed plant material with high water content in the natural state (up to about 90%).

**Peatlands** Peatland is a land where soils are dominated by peat.

**Percentile** A partition value in a population distribution that a given percentage of the data values are below or equal to. The 50th percentile corresponds to the median of the population. Percentiles are often used to estimate the extremes of a distribution. For example, the 90th (10th) percentile may be used to refer to the threshold for the upper (lower) extremes.

**Permafrost** Ground (soil or rock, and included ice and organic material) that remains at or below 0°C for at least two consecutive years (Harris et al., 1988). Note that permafrost is defined via temperature rather than ice content and, in some instances, may be ice-free.

**Near-surface permafrost** Permafrost within ~3-4 m of the ground surface. The depth is not precise, but describes what commonly is highly relevant for people and ecosystems. Deeper permafrost is often progressively less ice-rich and responds more slowly to warming than near-surface permafrost. Presence or absence of near-surface permafrost is not the only significant metric of permafrost change, and deeper permafrost may persist when near-surface permafrost is absent.

**Permafrost degradation** Decrease in the thickness and/or areal extent of permafrost.

**Permafrost thaw** Progressive loss of ground ice in permafrost, usually due to input of heat. Thaw can occur over decades to centuries over the entire depth of permafrost ground, with impacts occurring while thaw progresses. During thaw, temperature fluctuations are subdued because energy is transferred by phase change between ice and water. After the transition from permafrost to non-permafrost, ground can be described as thawed.

**Perturbed parameter ensemble** See Model ensemble.

**pH** A dimensionless measure of the acidity of a solution given by its concentration of hydrogen ions (H$^+$). pH is measured on a logarithmic scale where pH = -log$_{10}$(H$^+$). Thus, a pH decrease of 1 unit corresponds to a 10-fold increase in the concentration of H$^+$, or acidity.

**Phenology** The relationship between biological phenomena that recur periodically (e.g., development stages, migration) and climate and seasonal changes.

**Photosynthesis** The production of carbohydrates in plants, algae and some bacteria using the energy of light. Carbon dioxide (CO$_2$) is used as the carbon source.

**Physical climate storyline** See Storyline.

**Piacenzian warm period** See Pliocene.

**Plankton** Microorganisms living in the upper layers of aquatic systems. A distinction is made between phytoplankton, which depend on photosynthesis for their energy supply, and zooplankton, which feed on
phytoplankton.

**Plant evaporative stress**  Plant evaporative stress in both crops and natural vegetation can result from the combination of a high atmospheric evaporative demand and limited available water to supply this demand by means of evapotranspiration, further enhancing *agricultural* or *ecological drought*.

**Pleistocene**  The Pleistocene Epoch is the earlier of two epochs in the *Quaternary* System, extending from 2.59 Ma to the beginning of the *Holocene* at 11.65 ka.

**Pliocene**  The Pliocene Epoch is the more recent of two epochs of the Neogene Period within the *Cenozoic Era*. It extends from 5.33 Ma to the beginning of the *Pleistocene* Epoch at 2.59 Ma. The Neogene Period precedes the current geological period, the *Quaternary Period*, which is one of several ice ages that have occurred during Earth’s geological history. It encompasses the mid-Pliocene warm period (MPWP), also known as the Piacenzian warm period, which occurred approximately 3.3 to 3.0 Ma. The MPWP, in turn, encompasses the interglacial episode, marine isotope stage (MIS) KM5c, which peaked at 3.205 Ma when orbital forcing was similar to modern (Haywood et al., 2016).

**Polar amplification**  Polar amplification describes the phenomenon where surface temperature change at high latitudes exceeds the global average surface temperature change. The terms Arctic Amplification or Antarctic Amplification are used when describing the phenomenon occurring at one of the poles.

**Pollen analysis**  A technique of both relative dating and environmental *reconstruction*, consisting of the identification and counting of pollen types preserved in peat, lake sediments and other deposits.

**Post-glacial period**  See *Holocene*.

**Potential evapotranspiration**  See *Evapotranspiration*.

**Pre-industrial (period)**  The multi-century period prior to the onset of large-scale industrial activity around 1750. The *reference period* 1850–1900 is used to approximate pre-industrial *global mean surface temperature* (GMST). See also *Industrial revolution*.

**Precipitable water**  The total amount of atmospheric water vapour in a vertical column of unit cross-sectional area. It is commonly expressed in terms of the height of the water if completely condensed and collected in a vessel of the same unit cross section.

**Precursors**  Atmospheric compounds that are not *greenhouse gases* (GHGs) or *aerosols*, but that have an effect on GHG or aerosol concentrations by taking part in physical or chemical processes regulating their production or destruction rates.

**Predictability**  The extent to which future states of a system may be predicted based on knowledge of current and past states of the system. Because knowledge of the climate system's past and current states is generally imperfect, as are the models that utilize this knowledge to produce a *climate prediction*, and because the *climate system* is inherently nonlinear and chaotic, predictability of the climate system is inherently limited. Even with arbitrarily accurate models and observations, there may still be limits to the predictability of such a nonlinear system (AMS, 2021).

**Prediction quality/skill**  Measures of the success of a prediction against observationally based information. No single measure can summarize all aspects of forecast quality and a suite of *metrics* is considered. Metrics will differ for forecasts given in deterministic and probabilistic form.

**Primary production**  The synthesis of organic compounds by plants and microbes, on land or in the ocean, primarily by photosynthesis using light and carbon dioxide (CO₂) as sources of energy and carbon respectively. It can also occur through chemosynthesis, using chemical energy, e.g., in deep sea vents.
Gross Primary Production (GPP)  The total amount of carbon fixed by photosynthesis over a specified time period.

Net primary production (NPP)  The amount of carbon fixed by photosynthesis minus the amount lost by respiration over a specified time period.

Probability density function (PDF)  A probability density function is a function that indicates the relative chances of occurrence of different outcomes of a variable. The function integrates to unity over the domain for which it is defined and has the property that the integral over a sub-domain equals the probability that the outcome of the variable lies within that sub-domain. For example, the probability that a temperature anomaly defined in a particular way is greater than zero is obtained from its PDF by integrating the PDF over all possible temperature anomalies greater than zero. Probability density functions that describe two or more variables simultaneously are similarly defined.

Process-based model  Theoretical concepts and computational methods that represent and simulate the behaviour of real-world systems derived from a set of functional components and their interactions with each other and the system environment, through physical and mechanistic processes occurring over time.

Projection  A potential future evolution of a quantity or set of quantities, often computed with the aid of a model. Unlike predictions, projections are conditional on assumptions concerning, for example, future socio-economic and technological developments that may or may not be realised. See also Climate projection, Pathways and Scenario.

Proxy  A proxy climate indicator is any biophysical property of materials formed during the past that is interpreted to represent some combination of climate-related variations back in time. Climate-related data derived in this way are referred to as proxy data and time series of proxy data are proxy records. Examples of proxy types include pollen assemblages, tree ring widths, speleothem and coral geochemistry, and various data derived from marine sediments and glacier ice. Proxy data can be calibrated to provide quantitative climate information.

Proxy records  See Proxy.

Quasi-Biennial Oscillation (QBO)  A near-periodic oscillation of the equatorial zonal wind between easterlies and westerlies in the tropical stratosphere with a mean period of around 28 months. The alternating wind maxima descend from the base of the mesosphere down to the tropopause, and are driven by wave energy that propagates up from the troposphere.

Quaternary  The Quaternary Period is the last of three periods that make up the Cenozoic Era (66 Ma to present), extending from 2.58 Ma to the present, and includes the Pleistocene and Holocene Epochs.

Radiative effect  The impact on a radiation flux or heating rate (most commonly, on the downward flux at the top of atmosphere) caused by the interaction of a particular constituent with either the infrared or solar radiation fields through absorption, scattering and emission, relative to an otherwise identical atmosphere free of that constituent. This quantifies the impact of the constituent on the climate system. Examples include the aerosol-radiation interactions, cloud radiative effect, and greenhouse effect. In this report, the portion of any top-of-atmosphere radiative effect that is due to anthropogenic or other external influences (e.g., volcanic eruptions or changes in the sun) is termed the instantaneous radiative forcing.

Radiative forcing  The change in the net, downward minus upward, radiative flux (expressed in W m$^{-2}$) due to a change in an external driver of climate change, such as a change in the concentration of carbon dioxide (CO$_2$), the concentration of volcanic aerosols or in the output of the Sun. The stratospherically adjusted radiative forcing is computed with all tropospheric properties held fixed at their unperturbed values, and after allowing for stratospheric temperatures, if perturbed, to readjust to radiative-dynamical equilibrium. Radiative forcing is called instantaneous if no change in stratospheric temperature is accounted for. The radiative forcing once both stratospheric and tropospheric adjustments are accounted for is termed
the effective radiative forcing.

**Rapid adjustment**  The response to an agent perturbing the climate system that is driven directly by the agent, independently of any change in the global mean surface temperature. For example, carbon dioxide and aerosols, by altering internal heating and cooling rates within the atmosphere, can each cause changes to cloud cover and other variables thereby producing a radiative effect even in the absence of any surface warming or cooling. Adjustments are rapid in the sense that they begin to occur right away, before climate feedbacks which are driven by warming (although some adjustments may still take significant time to proceed to completion, for example those involving vegetation or ice sheets). It is also called the rapid response or fast adjustment.

**Rapid climate change**  See Abrupt change / abrupt climate change.

**Rapid dynamical change (of glaciers or ice sheets)**  Changes in glacier or ice sheet mass controlled by changes in flow speed and discharge rather than by accumulation or ablation. This can result in a rate of mass change larger than that due to any imbalance between accumulation and ablation. Rapid dynamical change may be initiated by a climatic trigger, such as incursion of warm ocean water beneath an ice shelf, or thinning of a grounded tidewater terminus, which may lead to reactions within the glacier system, that may result in rapid ice loss.

**Reanalysis**  Reanalyses are created by processing past meteorological or oceanographic data using fixed state-of-the-art weather forecasting or ocean circulation models with data assimilation techniques. They are used to provide estimates of variables such as historical atmospheric temperature and wind or oceanic temperature and currents, and other quantities. Using fixed data assimilation avoids effects from the changing analysis system that occur in operational analyses. Although continuity is improved, global reanalyses still suffer from changing coverage and biases in the observing systems.

**Reasons for concern (RFCs)**  Elements of a classification framework, first developed in the IPCC Third Assessment Report, which aims to facilitate judgments about what level of climate change may be dangerous (in the language of Article 2 of the UNFCCC) by aggregating risks from various sectors, considering hazards, exposures, vulnerabilities, capacities to adapt, and the resulting impacts.

**Reconstruction (of climate variable)**  Approach to reconstructing the past temporal and spatial characteristics of a climate variable from predictors. The predictors can be instrumental data if the reconstruction is used to infill missing data or proxy data if it is used to develop paleoclimate reconstructions. Various techniques have been developed for this purpose: linear multivariate regression based methods and nonlinear Bayesian and analogue methods.

**Reference period**  The period relative to which anomalies are computed. See also Baseline/reference (period).

**Baseline period**  The period relative to which anomalies are computed. See also Baseline/reference (period).

**Reference scenario**  See Scenario.

**Reforestation**  Conversion to forest of land that has previously contained forests but that has been converted to some other use. [Note: For a discussion of the term forest and related terms such as afforestation, reforestation and deforestation, see the 2006 IPCC Guidelines for National Greenhouse Gas Inventories and their 2019 Refinement, and information provided by the United Nations Framework Convention on Climate Change (IPCC, 2006, 2019, UNFCCC, 2021a, 2021b).] See also Afforestation, Deforestation, Reducing Emissions from Deforestation and Forest Degradation (REDD+), Anthropogenic removals and Carbon dioxide removal (CDR).

**Region**  Land and/or ocean area characterised by specific geographical and/or climatological features.
climate of a region emerges from a multiscale combination of its own features, remote influences from other regions, and global climate conditions.

Regional climate messages  Regional climate messages translate climate information synthesized from different lines of evidence into the context of a user vulnerable to climate at regional scales taking into account the values of both the producer and user (WGI Section 10.5).

Regional climate model (RCM)  A climate model at higher resolution over a limited area. Such models are used in downscaling global climate results over specific regional domains.

Regional climate scenario  A narrative used to describe how the future might unfold for a region (IPCC-TGICA, 2007). These are often used to guide impact understanding and adaptation efforts. They can include quantitative information based on scaled historical data or derived from GCM-based internally consistent future climates. See also Climate scenario.

Regional sea level change  See Sea level change (sea level rise/sea level fall).

Relative humidity  The relative humidity specifies the ratio of actual water vapour pressure to that at saturation with respect to liquid water or ice at the same temperature. See also Specific humidity.

Relative sea-level (RSL) change  See Sea level change (sea level rise/sea level fall).

Remaining carbon budget  See Carbon budget.

Representative concentration pathways (RCPs)  See Pathways.

Reservoir  A component or components of the climate system where a greenhouse gas (GHG) or a precursor of a greenhouse gas is stored (UNFCCC Article 1.7 (UNFCCC, 1992)).

Resilience  The capacity of interconnected social, economic and ecological systems to cope with a hazardous event, trend or disturbance, responding or reorganising in ways that maintain their essential function, identity and structure. Resilience is a positive attribute when it maintains capacity for adaptation, learning and/or transformation (Arctic Council, 2016). See also Hazard, Risk and Vulnerability.

Resolution  In climate models, this term refers to the physical distance (metres or degrees) between each point on the grid used to compute the equations. Temporal resolution refers to the time step or time elapsed between each model computation of the equations.

Respiration  The process whereby living organisms convert organic matter to carbon dioxide (CO₂), releasing energy and consuming molecular oxygen.

Response time or adjustment time  In the context of climate variations, the response time or adjustment time is the time needed for the climate system or its components to re-equilibrate to a new state, following a forcing resulting from external processes. It is very different for various components of the climate system. The response time of the troposphere is relatively short, from days to weeks, whereas the stratosphere reaches equilibrium on a time scale of typically a few months. Due to their large heat capacity, the oceans have a much longer response time: typically decades, but up to centuries or millennia. The response time of the strongly coupled surface-troposphere system is, therefore, slow compared to that of the stratosphere, and mainly determined by the oceans. The biosphere may respond quickly (e.g., to droughts), but also very slowly to imposed changes.

In the context of lifetimes, response time or adjustment time (Tₐ) is the time scale characterizing the decay of an instantaneous pulse input into the reservoir. See Response time or adjustment time (Tₐ) under Lifetime.

Return period  An estimate of the average time interval between occurrences of an event (e.g., flood or...
extreme rainfall) of (or below/above) a defined size or intensity.

Return value  The highest (or, alternatively, lowest) value of a given variable, on average occurring once in a given period of time (e.g., in 10 years).

Risk  The potential for adverse consequences for human or ecological systems, recognising the diversity of values and objectives associated with such systems. In the context of climate change, risks can arise from potential impacts of climate change as well as human responses to climate change. Relevant adverse consequences include those on lives, livelihoods, health and well-being, economic, social and cultural assets and investments, infrastructure, services (including ecosystem services), ecosystems and species.

In the context of climate change impacts, risks result from dynamic interactions between climate-related hazards with the exposure and vulnerability of the affected human or ecological system to the hazards. Hazards, exposure and vulnerability may each be subject to uncertainty in terms of magnitude and likelihood of occurrence, and each may change over time and space due to socio-economic changes and human decision-making (see also risk management, adaptation and mitigation).

In the context of climate change responses, risks result from the potential for such responses not achieving the intended objective(s), or from potential trade-offs with, or negative side-effects on, other societal objectives, such as the Sustainable Development Goals (SDGs) (see also risk trade-off). Risks can arise for example from uncertainty in implementation, effectiveness or outcomes of climate policy, climate-related investments, technology development or adoption, and system transitions. See also Hazard and Impacts (consequences, outcomes).

Risk assessment  The qualitative and/or quantitative scientific estimation of risks. See also Risk management and Risk perception.

Risk framework  A common framework for describing and assessing risk across all three working groups is adopted to promote clear and consistent communication of risks and to better inform risk assessment and decision making related to climate change.

Risk management  Plans, actions, strategies or policies to reduce the likelihood and/or magnitude of adverse potential consequences, based on assessed or perceived risks. See also Risk assessment, Risk perception and Risk transfer.

Risk perception  The subjective judgement that people make about the characteristics and severity of a risk. See also Risk assessment, Risk management and Risk transfer.

Risk trade-off  The change in the portfolio of risks that occurs when a countervailing risk is generated (knowingly or inadvertently) by an intervention to reduce the target risk (Wiener and Graham, 2009).

River discharge  See Streamflow.

Rock glacier  A debris landform (mass of rock fragments and finer material that contains either an ice core or an ice-cemented matrix) generated by a former or current gravity-driven creep of permafrost in mountain slopes (Harris et al., 1988; Giardino et al., 2011; IPA-RG, 2020). It is detectable in the landscape due to the occurrence of (i) a steep slope delimiting the terminal part; (2) generally well-defined lateral margins in a continuation of the front; (3) transversal or longitudinal ridges and furrows (ridge and furrow topography). These are geomorphological indicators of the occurrence of permafrost conditions. Although it is an ice storage feature, it is not a type of glacier since it is not originated over the surface by the recrystallization of snow.

Runoff  The flow of water over the surface or through the subsurface, which typically originates from the part of liquid precipitation and/or snow/ice melt that does not evaporate, transpire or refreeze, and returns to water bodies.

**Sampling uncertainty**  See *Uncertainty*.

**Scenario**  A plausible description of how the future may develop based on a coherent and internally consistent set of assumptions about key driving forces (e.g., rate of technological change (TC), prices) and relationships. Note that scenarios are neither predictions nor forecasts, but are used to provide a view of the implications of developments and actions. See also *Climate scenario* and *Regional climate scenario*.

**Baseline scenario**  See Reference ScenarioSee *Reference scenario* (under *Scenario*).

**Concentrations scenario**  A plausible representation of the future development of atmospheric concentrations of substances that are radiatively active (e.g., greenhouse gases (GHGs), aerosols, tropospheric ozone), plus human-induced land cover changes that can be radiatively active via albedo changes, and often used as input to a climate model to compute climate projections.

**Emissions scenario**  A plausible representation of the future development of emissions of substances that are radiatively active (e.g., greenhouse gases (GHGs) or aerosols), plus human-induced land cover changes that can be radiatively active via albedo changes, based on a coherent and internally consistent set of assumptions about driving forces (such as demographic and socio-economic development, technological change, energy and land use) and their key relationships. Concentration scenarios, derived from emission scenarios, are often used as input to a climate model to compute climate projections. See also *Representative concentration pathways (RCPs)* (under *Pathways*) and *Shared socio-economic pathways (SSPs)* (under *Pathways*).

**Mitigation scenario**  A plausible description of the future that describes how the (studied) system responds to the implementation of mitigation policies and measures. See also *Pathways*, *Socio-economic scenario* (under *Scenario*) and *Stabilisation* (of GHG or CO₂-equivalent concentration).

**Reference scenario**  Scenario used as starting or reference point for a comparison between two or more scenarios.

[Note 1: In many types of climate change research, reference scenarios reflect specific assumptions about patterns of socio-economic development and may represent futures that assume no climate policies or specified climate policies, for example those in place or planned at the time a study is carried out. Reference scenarios may also represent futures with limited or no climate impacts or adaptation, to serve as a point of comparison for futures with impacts and adaptation. These are also referred to as baseline scenarios in the literature.

Note 2: Reference scenarios can also be climate policy or impact scenarios, which in that case are taken as a point of comparison to explore the implications of other features, e.g., of delay, technological options, policy design and strategy or to explore the effects of additional impacts and adaptation beyond those represented in the reference scenario.

Note 3: The term business as usual scenario has been used to describe a scenario that assumes no additional policies beyond those currently in place and that patterns of socio-economic development are consistent with recent trends. The term is now used less frequently than in the past.

Note 4: In climate change attribution or impact attribution research reference scenarios may refer to counterfactual historical scenarios assuming no anthropogenic greenhouse gas emissions (climate change attribution) or no climate change (impact attribution).

**Socio-economic scenario**  A scenario that describes a plausible future in terms of population, gross domestic product (GDP), and other socio-economic factors relevant to understanding the implications of climate change. See also *Baseline scenario* (under *Scenario*), *Mitigation scenario* (under *Scenario*) and *Pathways*.
Sea ice  Ice found at the sea surface that has originated from the freezing of seawater. Sea ice may be discontinuous pieces (ice floes) moved on the ocean surface by wind and currents (pack ice), or a motionless sheet attached to the coast (land-fast ice). Sea ice concentration is the fraction of the ocean covered by ice.

Sea ice area (SIA)  Sea ice area is the area covered by sea ice. In contrast to sea ice extent, it is a linear measure of sea ice coverage that does not depend on grid resolution.

Sea ice concentration  Sea ice concentration is the fraction of the ocean covered by ice.

Sea ice extent (SIE)  Sea ice extent is calculated for gridded data products as the total area of all grid cells with sea ice concentration above a given threshold, usually 15%. It hence is a grid-dependent, non-linear measure of sea ice coverage.

Sea level change (sea level rise/sea level fall)  Change to the height of sea level, both globally and locally (relative sea level change) at seasonal, annual, or longer time scales due to (1) a change in ocean volume as a result of a change in the mass of water in the ocean (e.g., due to melt of glaciers and ice sheets), (2) changes in ocean volume as a result of changes in ocean water density (e.g., expansion under warmer conditions), (3) changes in the shape of the ocean basins and changes in the Earth’s gravitational and rotational fields, and (4) local subsidence or uplift of the land. Global mean sea level change resulting from change in the mass of the ocean is called barystatic. The amount of barystatic sea level change due to the addition or removal of a mass of water is called its sea level equivalent (SLE). Sea level changes, both globally and locally, resulting from changes in water density are called steric. Density changes induced by temperature changes only are called thermosteric, while density changes induced by salinity changes are called halosteric. Barystatic and steric sea level changes do not include the effect of changes in the shape of ocean basins induced by the change in the ocean mass and its distribution. See also Vertical land motion (VLM), Land water storage, Sea level commitment, Glacial isostatic adjustment (GIA), Extreme sea level (ESL) and Storm surge.

Geocentric sea-level change  The change in local mean sea surface height with respect to the terrestrial reference frame, it is the sea-level change observed with instruments from space. See also Altimetry.

Global mean sea-level (GMSL) change  The increase or decrease in the volume of the ocean divided by the ocean surface area. It is the sum of changes in ocean density through temperature changes (global mean thermosteric sea-level change) and changes in the ocean mass as a result of changes in the cryosphere or land water storage (barystatic sea-level change). See also Terrestrial water storage (TWS).

Gravitational, rotational and deformational (GRD) effects  Changes in Earth Gravity, Earth Rotation and viscoelastic solid Earth Deformation (GRD) result from the redistribution of mass between terrestrial ice and water reservoirs and the ocean. Contemporary terrestrial mass loss leads to elastic solid Earth uplift and a nearby relative sea-level fall (for a single source of terrestrial mass loss this is within ~2000 km, for multiple sources the distance depends on the interaction of the different relative sea-level patterns). Farther away (more than ~7000 km for a single source of terrestrial mass loss), relative sea level rises more than the global average, due to first order, to gravitational effects. Earth deformation associated with adding water to the oceans and a shift of the Earth’s rotation axis towards the source of terrestrial mass loss leads to second-order effects that increase spatial variability of the pattern globally. GRD effects due to the redistribution of ocean water within the ocean itself are referred to as self-attraction and loading effects.

Halosteric sea-level change  Halosteric sea-level change occurs as a result of salinity variations: higher salinity leads to higher density and decreases the volume per unit of mass. Although both processes can be relevant on regional to local scales, only thermosteric changes impact the global mean sea-level change, whereas the global mean halosteric change is negligible (Gregory et al., 2019).
Local sea level change  Change in sea level relative to a datum (such as present-day mean sea level) at spatial scales smaller than 10 km.

Ocean dynamic sea level change  Change in mean sea level relative to the geoid associated with circulation and density-driven changes in the ocean. Ocean dynamic sea-level change is regionally varying but by definition has a zero global mean and conventionally is inverse-barometer corrected (i.e., the effect of the hydrostatic depression of the sea surface by atmospheric pressure changes is removed). Changes in ocean currents occur due to variations in heating and cooling, variability in winds and changes in seasonally- to annually-averaged air temperature and humidity.

Regional sea level change  Change in sea level relative to a datum (such as present-day mean sea level) at spatial scales of about 100 km.

Relative sea-level (RSL) change  The change in local mean sea surface height (SSH) relative to the local solid surface, i.e. the sea floor, as measured by instruments that are fixed to the Earth's surface, such as tide gauges. This reference frame is used when considering coastal impacts, hazards and adaptation needs.

Steric sea level change  Steric sea-level change is caused by changes in the ocean density and is composed of thermosteric sea-level change and halosteric sea-level change.

Thermosteric sea-level change  Thermosteric sea-level change (where thermosteric sea-level rise may also be referred to as thermal expansion) occurs as a result of changes in ocean temperature: increasing temperature reduces ocean density and increases the volume per unit of mass.

Sea level equivalent (SLE)  The SLE of a mass of water, ice, or water vapour is that mass, converted to a volume using a density of 1000 kg m⁻³ and divided by the present-day ocean surface area of 3.625 × 10⁶ m². Thus, 362.5 Gt of water mass added to the ocean correspond to 1 mm of global mean sea level rise. However, more accurate estimates of SLE must account for additional processes affecting mean sea level rise, such as shoreline migration, changes in ocean area, and for vertical land movements.

Sea level rise (SLR)  See Sea level change (sea level rise/sea level fall).

Sea surface temperature (SST)  The subsurface bulk temperature in the top few metres of the ocean, measured by ships, buoys, and drifters. From ships, measurements of water samples in buckets were mostly switched in the 1940s to samples from engine intake water. Satellite measurements of skin temperature (uppermost layer; a fraction of a millimetre thick) in the infrared or the top centimetre or so in the microwave are also used, but must be adjusted to be compatible with the bulk temperature.

Semi-direct (aerosol) effect  See Aerosol-radiation interaction.

Semi-empirical model  Model in which calculations are based on a combination of observed associations between variables and theoretical considerations relating variables through fundamental principles (e.g., conservation of energy). For example, in sea level studies, semi-empirical models refer specifically to transfer functions formulated to project future global mean sea level change, or contributions to it, from future global mean surface temperature change or radiative forcing.

Sensible heat flux  The turbulent or conductive flux of heat from the Earth's surface to the atmosphere that is not associated with phase changes of water; a component of the surface energy budget.

Sequestration  The process of storing carbon in a carbon pool. See also Uptake and Soil carbon sequestration (SCS).

Sequestration potential  The quantity of greenhouse gases that can be removed from the atmosphere by anthropogenic enhancement of sinks and stored in a pool. See Mitigation potential for different subcategories.

Do Not Cite, Quote or Distribute  AVII-54  Total pages: 65
of sequestration potential. See also Pool, carbon and nitrogen, Sequestration and Sink.

**Shared policy assumptions (SPAs)** See Shared socio-economic pathways (SSPs) (under Pathways).

**Shared socio-economic pathways (SSPs)** See Pathways.

**Short-lived climate forcers (SLCFs)** A set of chemically reactive compounds with short (relative to CO₂) atmospheric lifetimes (from hours to decades) but characterised by different physiochemical properties and environmental effects. Their emission or formation has a significant effect on radiative forcing over a period determined by their respective atmospheric lifetimes. Changes in their emissions can also induce long-term climate effects via, in particular, their interactions with some biogeochemical cycles. SLCFs are classified as direct or indirect, with direct SLCFs exerting climate effects through their radiative forcing and indirect SLCFs being the precursors of other direct climate forcers. Direct SLCFs include methane (CH₄), ozone (O₃), primary aerosols and some halogenated species. Indirect SLCFs are precursors of ozone or secondary aerosols. SLCFs can be cooling or warming through interactions with radiation and clouds. They are also referred to as near-term climate forcers (NTCFs). Many SLCFs are also air pollutants. A subset of exclusively warming SLCFs is also referred to as short-lived climate pollutants (SLCPs), including methane, ozone, and black carbon.

**Short-lived climate pollutants (SLCP)** See Short-lived climate forcers (SLCFs).

**Shortwave radiation** See Solar radiation.

**Significant wave height** The average trough-to-crest height of the highest one-third of the wave heights (sea and swell) occurring in a particular time period.

**Simple climate model (SCM)** A broad class of lower-dimensional models of the energy balance, radiative transfer, carbon cycle, or a combination of such physical components. SCMs are also suitable for performing emulations of climate-mean variables of Earth system models (ESMs), given that their structural flexibility can capture both the parametric and structural uncertainties across process-oriented ESM responses. They can also be used to test consistency across multiple lines of evidence with regard to climate sensitivity ranges, transient climate responses (TCRs), transient climate response to cumulative emissions (TCREs) and carbon cycle feedbacks. See also Emulators and Earth system model of intermediate complexity (EMIC).

**Sink** Any process, activity or mechanism which removes a greenhouse gas, an aerosol or a precursor of a greenhouse gas from the atmosphere (UNFCCC Article 1.8 (UNFCCC, 1992)). See also Source and Uptake.

**Small Island Developing States (SIDS)** Small Island Developing States (SIDS), as recognised by the United Nations OHRLLS (Office of the High Representative for the Least Developed Countries, Landlocked Developing Countries and Small Island Developing States), are a distinct group of developing countries facing specific social, economic and environmental vulnerabilities (UN-OHRLLS, 2011). They were recognized as a special case both for their environment and development at the Rio Earth Summit in Brazil in 1992. Fifty-eight countries and territories are presently classified as SIDS by the UN OHRLLS, with 38 being UN member states and 20 being Non-UN Members or Associate Members of the Regional Commissions (UN-OHRLLS, 2018).

**Snow cover** Snow cover refers to all the snow that has accumulated on the ground at a given time (UNESCO/IASH/WMO, 1970).

**Snow cover duration (SCD)** How long snow continuously remains on the land surface, or the period between snow-on and snow-off dates.

**Snow cover extent (SCE)** The areal extent of snow covered ground.

**Snow water equivalent (SWE)** The depth of liquid water that would result if a mass of snow melted.
completely.

**Socio-economic scenario**  See *Scenario*.

**Soil moisture**  Water stored in the soil in liquid or frozen form. Root-zone soil moisture is of most relevance for plant activity.

**Soil temperature**  The temperature of the soil. This can be measured or modelled at multiple levels within the depth of the soil.

**Solar activity**  General term collectively describing a variety of magnetic phenomena on the Sun such as sunspots, *faculae* (bright areas), and flares (emission of high-energy particles). It varies on time scales from minutes to millions of years. The *solar cycle*, with an average duration of 11 years, is an example of a quasi-regular change in solar activity.

**Solar cycle (11-year)**  A quasi-regular modulation of *solar activity* with varying amplitude and a period of between 8 and 14 years.

**Solar radiation**  Electromagnetic radiation emitted by the Sun with a spectrum close to the one of a black body with a temperature of 5770 K. The radiation peaks in visible wavelengths. When compared to the *terrestrial radiation* it is often referred to as shortwave radiation. See also *Insolation* and *Total solar irradiance* (TSI).

**Solar radiation modification (SRM)**  Solar radiation modification (SRM) refers to a range of radiation modification measures not related to greenhouse gas (GHG) mitigation that seek to limit global warming. Most methods involve reducing the amount of incoming solar radiation reaching the surface, but others also act on the longwave radiation budget by reducing optical thickness and cloud lifetime.

**Cirrus cloud thinning (CCT)**  Cirrus cloud thinning is one of several radiation modification approaches to counter the warming caused by greenhouse gases. In the approach, it is proposed to reduce the amount of cirrus clouds by injecting ice nucleating substances in the upper troposphere. The reduction in cirrus clouds is expected to increase the amount of longwave cooling to space resulting in a planetary cooling. Although cirrus cloud thinning primarily affects the longwave radiation budget of our planet, it is often identified as one of the *solar radiation modification (SRM)* approaches in the literature.

**Marine cloud brightening (MCB)**  Marine cloud brightening is one of several solar radiation modification (SRM) approaches to increase the planetary albedo. In the approach, it is proposed to inject sea salt aerosols into the persistent marine lows clouds. This is expected to increase the cloud droplet concentration of these clouds and their reflectivity.

**Stratospheric aerosol injection (SAI)**  Stratospheric aerosol injection is one of several solar radiation modification (SRM) approaches to increase the planetary albedo. In the approach, it is proposed to inject highly reflective aerosols such as sulphates into the lower stratosphere. This is expected to increase the fraction of solar radiation deflected to space resulting in a planetary cooling.

**Solubility pump**  A physicochemical process that transports dissolved inorganic carbon from the ocean’s surface to its interior. The solubility pump is primarily driven by the solubility of *carbon dioxide* (*CO₂*) (with more *CO₂* dissolving in colder water) and the large-scale, thermohaline patterns of ocean circulation.

**Source**  Any process or activity which releases a greenhouse gas, an aerosol or a precursor of a greenhouse gas into the atmosphere (UNFCCC Article 1.9 (UNFCCC, 1992)). See also *Sink*.

**South American monsoon (SAMerM)**  See *Global monsoon*.

**South and Southeast Asian monsoon (SAsiaM)**  See *Global monsoon*.
Southern Annular Mode (SAM)  See Annular modes.

South Pacific Convergence Zone (SPCZ)  A band of low-level convergence, cloudiness and precipitation ranging from the west Pacific warm pool south-eastwards towards French Polynesia, which is one of the most significant features of subtropical Southern Hemisphere climate. It shares some characteristics with the Inter-Tropical Convergence Zone (ITCZ), but is more extratropical in nature, especially east of the Dateline.

Southern Oscillation  See El Niño-Southern Oscillation (ENSO).

Specific humidity  The specific humidity specifies the ratio of the mass of water vapour to the total mass of moist air. See also Relative humidity.

Stadial  A period of North Atlantic cooling during the last glacial period, lasting anywhere from several centuries to millennia, as inferred from oxygen isotopes in Greenland ice cores. These episodes are often referred to as abrupt climate change events, as they are often terminated by abrupt warming. They occur repeatedly during the last glacial period, and are associated with a distinct pattern of global temperature and hydrological variations recorded in paleoclimate records from this interval. See also Younger Dryas.

Statistical downscaling  See Downscaling.

Steric sea level change  See Sea level change (sea level rise/sea level fall).

Storm surge  The temporary increase, at a particular locality, in the height of the sea due to extreme meteorological conditions (low atmospheric pressure and/or strong winds). The storm surge is defined as being the excess above the level expected from the tidal variation alone at that time and place. See also Sea level change (sea level rise/sea level fall) and Extreme sea level (ESL).

Storm tracks  Originally, a term referring to the tracks of individual cyclonic weather systems, but now often generalized to refer to the main regions where the tracks of extratropical disturbances occur as sequences of low (cycloic) and high (anticyclonic) pressure systems.

Storyline  A way of making sense of a situation or a series of events through the construction of a set of explanatory elements. Usually it is built on logical or causal reasoning. In climate research, the term storyline is used both in connection to scenarios as related to a future trajectory of the climate and human systems or to a weather or climate event. In this context, storylines can be used to describe plural, conditional possible futures or explanations of a current situation, in contrast to single, definitive futures or explanations.

Physical climate storyline  A self-consistent and plausible unfolding of a physical trajectory of the climate system, or a weather or climate event, on timescales from hours to multiple decades (Shepherd et al., 2018). Through this, storylines explore, illustrate and communicate uncertainties in the climate system response to forcing and in internal variability.

Scenario storyline  A narrative description of a scenario (or family of scenarios), highlighting the main scenario characteristics, relationships between key driving forces and the dynamics of their evolution.

Stratification  Process of forming of layers of (ocean) water with different properties such as salinity, density and temperature that act as barrier for water mixing. The strengthening of near-surface stratification generally results in warmer surface waters, decreased oxygen levels in deeper water, and intensification of ocean acidification (OA) in the upper ocean.

Stratosphere  The highly stratified region of the atmosphere above the tropopause, extending to about 50 km altitude. See also Troposphere.
Stratospheric aerosol injection (SAI) See Solar radiation modification (SRM).

Stratosphere-troposphere exchange (STE) Stratosphere-troposphere exchange (STE) is understood as the flux of air or trace constituents across the tropopause, including both directions: the stratosphere to troposphere transport (STT) and troposphere to stratosphere transport (TST). STE is one of the key factors controlling the budgets of ozone, water vapour and other substances in both the troposphere and the lower stratosphere.

Stratospheric ozone Stratospheric ozone describes the ozone (O\textsubscript{3}) that resides in the stratosphere, the region of the atmosphere which exists between 10 and 50 kilometres above the surface of the earth. Ninety percent of total-column ozone resides in the stratosphere. See Ozone layer and Ozone (O\textsubscript{3}). See also Ozone-depleting substances (ODSs).

Stratospheric polar vortex A large-scale region of cold air poleward of approximately 60 degrees that is contained by a strong westerly jet from the tropopause (8-10km) to the stratopause (50-60km) and that forms in each hemisphere during the winter half-year. Planetary waves can temporarily disrupt the vortex, producing easterly winds and rapid warming over polar regions in the stratosphere, and leading to substantial weakening or breakdown of the vortex.

Stratospheric sounding unit (SSU) A three-channel infrared sounder on operational NOAA polar-orbiting satellites. The three channels are used to determine profiles of temperature in the stratosphere (AMS, 2020).

Streamflow Water flow within a river channel, for example, expressed in m\textsuperscript{3} s\textsuperscript{-1}. A synonym for river discharge.

Subduction Ocean process in which surface waters enter the ocean interior from the surface mixed layer through Ekman pumping and lateral advection. The latter occurs when surface waters are advected to a region where the local surface layer is less dense and therefore must slide below the surface layer, usually with no change in density.

Sudden stratospheric warming (SSW) A phenomena of rapid warming in the stratosphere at high latitudes (sometimes more than 50°C in 1-2 days) that can cause breakdown of stratospheric polar vortices.

Sulphur hexafluoride (SF\textsubscript{6}) One of the seven types of greenhouse gases (GHGs) to be mitigated under the Kyoto Protocol. SF\textsubscript{6} is largely used in heavy industry to insulate high-voltage equipment and to assist in the manufacturing of cable-cooling systems and semi-conductors.

Sunspots Dark areas on the Sun where strong magnetic fields reduce the convection causing a temperature reduction of about 1500 K compared to the surrounding regions. The number of sunspots is higher during periods of higher solar activity, and varies in particular with the solar cycle.

Surface air temperature See Land surface air temperature (LSAT) and Global mean surface air temperature (GSAT).

Surface mass balance (SMB) See Mass balance / budget (of glaciers or ice sheets).

Surface temperature See Global mean surface air temperature (GSAT), Global mean surface temperature (GMST), Land surface air temperature (LSAT) and Sea surface temperature (SST).

Surprises A class of risk that can be defined as low-likelihood but well-understood events, and events that cannot be predicted with current understanding (see 1.4.4.3 in AR6 WGI Chapter 1). See also Unknown unknowns.
Swash  See Extreme sea level (ESL).

Talik  A layer or body of unfrozen ground in a permafrost area due to a local anomaly in thermal, hydrological, hydrogeological or hydrochemical conditions (IPA, 2005).

Technical potential  See Mitigation potential.

Teleconnection  Association between climate variables at widely separated, geographically fixed locations related to each other through physical processes and oceanic and/or atmospheric dynamical pathways. Teleconnections can be caused by several climate phenomena, such as Rossby wave-trains, mid-latitude jet and storm track displacements, fluctuations of the Atlantic Meridional Overturning Circulation, fluctuations of the Walker circulation, etc. They can be initiated by modes of climate variability thus providing the development of remote climate anomalies at various temporal lags.

Teleconnection pattern  A correlation map obtained by calculating the correlation between variables at different spatial locations and a climate index. It is the special case of a climate pattern obtained for standardized variables and a standardized climate index, that is, the variables and index are each centred and scaled to have zero mean and unit variance. One-point teleconnection maps are made by choosing a variable at one of the locations to be the climate index.

Temperature overshoot  Exceedance of a specified global warming level, followed by a decline to or below that level during a specified period of time (e.g., before 2100). Sometimes the magnitude and likelihood of the overshoot is also characterized. The overshoot duration can vary from one pathway to the next but in most overshoot pathways in the literature and referred to as overshoot pathways in the AR6, the overshoot occurs over a period of at least one and up to several decades. See also Pathways.

Terrestrial radiation  Radiation emitted by the Earth's surface, the atmosphere and the clouds. It is also known as thermal infrared or long-wave radiation, and is to be distinguished from the near-infrared radiation that is part of the solar spectrum. Infrared radiation, in general, has a distinctive range of wavelengths (spectrum) longer than the wavelength of the red light in the visible part of the spectrum. The spectrum of terrestrial radiation is almost entirely distinct from that of shortwave or solar radiation because of the difference in temperature between the Sun and the Earth-atmosphere system.

Thermal expansion  See Steric sea level change (under Sea level change (sea level rise/sea level fall)).

Thermocline  The layer of maximum vertical temperature gradient in the ocean, lying between the surface ocean and the abyssal ocean. In subtropical regions, its source waters are typically surface waters at higher latitudes that have subducted (see Subduction) and moved equatorward. At high latitudes, it is sometimes absent, replaced by a halocline, which is a layer of maximum vertical salinity gradient.

Thermohaline circulation (THC)  See Meridional overturning circulation (MOC).

Thermokarst  Process by which characteristic landforms result from thawing of ice-rich permafrost or melting of massive ice (IPA, 2005).

Thermosteric  See Sea level change (sea level rise/sea level fall).

Tide gauge  A device at a coastal or deep-sea location that continuously measures the level of the sea with respect to the adjacent land. Time averaging of the sea level so recorded gives the observed secular changes of the relative sea level.

Time of emergence (ToE)  Time when a specific anthropogenic signal related to climate change is statistically detected to emerge from the background noise of natural climate variability in a reference period, for a specific region (Hawkins and Sutton, 2012). See also Emergence (of the climate signal).
Tipping element  A component of the Earth System that is susceptible to a tipping point.

Tipping point  A critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly. See also Tipping element, Irreversibility and Abrupt change.

Total alkalinity  Total Alkalinity ($A_7$) is a measurable parameter of the seawater acid-base system which, when expressed in micromoles per kilogram of seawater, is a conservative variable both on mixing, and for changes in temperature and/or pressure. Changes in total alkalinity in the oceans result from a variety of biogeochemical processes that affect the acid-base composition of the seawater itself. However, its value is not affected by the exchange of carbon dioxide gas between seawater and the atmosphere. Measurements of total alkalinity can thus be used to help study these biogeochemical processes, and can also be used to help calculate the state of the seawater acid-base system. Total alkalinity is most commonly measured using an acidimetric titration technique, that determines how much acid is required to titrate a seawater sample to a specified equivalence point.

Total carbon budget  See Carbon budget.

Total solar irradiance (TSI)  The total amount of solar radiation in watts per square metre received outside the Earth's atmosphere on a surface normal to the incident radiation, and at the Earth's mean distance from the Sun. Reliable measurements of solar radiation can only be made from space and the precise record extends back only to 1978. It has recently been estimated to $1360.8 \pm 0.5 \text{ W m}^{-2}$ for the solar minimum of 2008. Variations of a few tenths of a percent are common, usually associated with the passage of sunspots across the solar disk. The solar cycle variation of TSI is of the order of 0.1% (AMS, 2000). See also Insolation.

Total water level  See Extreme sea level (ESL).

Trace gas  A minor constituent of the atmosphere, next to nitrogen and oxygen that together make up 99 % of all volume. The most important trace gases contributing to the greenhouse effect are carbon dioxide (CO$_2$), ozone (O$_3$), methane (CH$_4$), nitrous oxide (N$_2$O), perfluorocarbons (PFCs), chlorofluorocarbons (CFCs), hydrofluorocarbons (HFCs), sulphur hexafluoride (SF$_6$) and water vapour (H$_2$O).

Transient climate response (TCR)  See Climate sensitivity.

Transient climate response to cumulative CO2 emissions (TCRE)  See Climate sensitivity.

Tree rings  Concentric rings of secondary wood evident in a cross section of the stem of a woody plant. The difference between the dense, small-celled late wood of one season and the wide-celled early wood of the following spring enables the age of a tree to be estimated, and the ring widths or density can be related to climate parameters such as temperature and precipitation.

Tropical Atlantic modes  See Tropical Atlantic Variability (TAV).

Tropical Atlantic Variability (TAV)  A generic term to describe the climate variability of the tropical Atlantic which is dominated at interannual to decadal timescale by two main climate modes: the Atlantic Zonal Mode (AZM) and the Atlantic Meridional Mode (AMM). The Atlantic Zonal Mode, also commonly referred to as the Atlantic Niño or Atlantic equatorial mode, is associated with sea surface temperature anomalies near the equator, peaking in the eastern basin, while the Atlantic meridional mode is characterized by an inter-hemispheric gradient of sea surface temperature and wind anomalies. Both modes are associated with significant teleconnections over Africa and South America.

Atlantic Meridional Mode (AMM)  The Atlantic Meridional Mode (AMM) refers to the interannual to decadal variability of the cross-equatorial sea surface temperature gradients and surface wind anomalies in the tropical Atlantic. It modulates the strength and latitudinal shifts of the Inter-tropical Convergence Zone (ITCZ), which impacts regional rainfall over Northeast Brazil and Atlantic hurricane activity. See Section...
AIV.2.5 in Annex IV of the AR6 WGI report.

Atlantic Zonal Mode (AZM) An equatorial coupled mode in the Atlantic similar to El Niño-Southern Oscillation (ENSO) in the Pacific, and therefore sometimes referred to as “Atlantic Niño”. The AZM is associated with sea surface temperature anomalies near the equatorial Atlantic and rainfall disturbances over the African monsoon domain. Its variations are mostly observed in the interannual scale. It is called also Atlantic equatorial mode. See Section AIV.2.5 in Annex IV of the AR6 WGI report.

Tropical cyclone The general term for a strong, cyclonic-scale disturbance that originates over tropical oceans. Distinguished from weaker systems (often named tropical disturbances or depressions) by exceeding a threshold wind speed. A tropical storm is a tropical cyclone with one-minute average surface winds between 18 and 32 m s\(^{-1}\). Beyond 32 m s\(^{-1}\), a tropical cyclone is called a hurricane, typhoon, or cyclone, depending on geographic location.

Tropopause The boundary between the troposphere and the stratosphere. It ranges from 8-9 km at high latitudes to 15-16 km in the tropics.

Troposphere The lowest part of the atmosphere, below the tropopause, where clouds and weather phenomena occur. In the troposphere, temperatures generally decrease with height. See also Stratosphere.

Tropospheric ozone See Ozone (O\(_3\)) and Ground-level ozone.

Tundra A treeless biome characteristic of polar and alpine regions.

Turnover time (T) See Lifetime.

Typhoon See Tropical cyclone.

Typological domains See Typological regions.

Typological regions Regions of the Earth that share one or more specific features (known as 'typologies'), such as geographic location (e.g., coastal), physical processes (e.g., monsoons), and biological (e.g., coral reefs, tropical forests), geological (e.g., mountains) or anthropogenic (e.g., megacities) formation, and for which it is useful to consider the common climate features. Typological regions are smaller than climatic zones (e.g., a mountain region) and can be discontinuous (e.g., a group of megacities affected by the urban heat island effect, or monsoon regions).

Uncertainty A state of incomplete knowledge that can result from a lack of information or from disagreement about what is known or even knowable. It may have many types of sources, from imprecision in the data to ambiguously defined concepts or terminology, incomplete understanding of critical processes, or uncertain projections of human behaviour. Uncertainty can therefore be represented by quantitative measures (e.g., a probability density function) or by qualitative statements (e.g., reflecting the judgment of a team of experts) (see Moss and Schneider, 2000; IPCC, 2004; Mastrandrea et al., 2010). See also Confidence and Likelihood.

Deep uncertainty A situation of deep uncertainty exists when experts or stakeholders do not know or cannot agree on: (1) appropriate conceptual models that describe relationships among key driving forces in a system; (2) the probability distributions used to represent uncertainty about key variables and parameters; and/or (3) how to weigh and value desirable alternative outcomes (Lempert et al., 2003).

Sampling uncertainty Uncertainty arising from incomplete or uneven availability of measurements in either space or time or both.

United Nations Framework Convention on Climate Change (UNFCCC) The UNFCCC was adopted in May 1992 and opened for signature at the 1992 Earth Summit in Rio de Janeiro. It entered into force in
March 1994 and as of September 2020 had 197 Parties (196 States and the European Union). The Convention’s ultimate objective is the ‘stabilisation of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system’. The provisions of the Convention are pursued and implemented by two further treaties: the Kyoto Protocol and the Paris Agreement.

**Uptake**  The transfer of substances (such as carbon) or energy (e.g., heat) from one compartment of a system to another; for example, in the Earth System from the atmosphere to the ocean or to the land. See also Sequestration.

**Upwelling region**  A region of an ocean where cold, typically nutrient-rich waters well up from the deep ocean.

**Urban heat island (UHI)**  The relative warmth of a city compared with surrounding rural areas, associated with changes in runoff, effects on heat retention, and changes in surface albedo.

**Ventilation**  The exchange of ocean properties with the atmospheric surface layer such that property concentrations are brought closer to equilibrium values with the atmosphere (AMS, 2021), and the processes that propagate these properties into the ocean interior.

**Vertical land motion (VLM)**  Vertical land motion (VLM) is the change in height of the land surface or the sea floor and can have several causes in addition to elastic deformation associated with contemporary changes in gravity, rotation and viscoelastic solid Earth deformation (GRD) and viscoelastic deformation associated with glacial isostatic adjustment (GIA). Subsidence (sinking of the land surface or sea floor) can, for instance, occur through compaction of alluvial sediments in deltaic regions, removal of fluids such as gas, oil, and water, or drainage of peatlands. Tectonic deformation of the Earth’s crust can occur as a result of earthquakes and volcanic eruptions. See also Sea level change (sea level rise/sea level fall).

**Very short-lived halogenated substances (VSLSs)**  Very short-lived halogenated substances (VSLSs) are considered to include source gases (very short-lived halogenated substances present in the atmosphere in the form they were emitted from natural and anthropogenic sources), halogenated product gases arising from source gas degradation, and other sources of tropospheric inorganic halogens. VSLSs have tropospheric lifetimes of around 0.5 years or less.

**Volatile organic compounds (VOCs)**  Important class of organic chemical air pollutants that are volatile at ambient air conditions. Other terms used to represent VOCs are hydrocarbons (HCs), reactive organic gases (ROGs) and non-methane volatile organic compounds (NMVOCs). NMVOCs are major contributors – together with nitrogen oxides (NOx), and carbon monoxide (CO) – to the formation of photochemical oxidants such as ozone (O3).

**Biogenic volatile organic compounds (BVOCs)**  Organic gas-phase compounds emitted from terrestrial and aquatic ecosystems that are critical in ecology and plant physiology, from abiotic and biotic stress functions to integrated components of metabolism. BVOCs are important in atmospheric chemistry as precursors for ozone and secondary organic aerosol formation. Other terms used to represent BVOCs are hydrocarbons (HCs), reactive organic gases (ROGs) and non-methane volatile organic compounds (NMVOCs).

**Vulnerability**  The propensity or predisposition to be adversely affected. Vulnerability encompasses a variety of concepts and elements including sensitivity or susceptibility to harm and lack of capacity to cope and adapt. See also Exposure, Hazard and Risk.

**Walker circulation**  Direct thermally driven zonal overturning circulation in the atmosphere over the tropical Pacific Ocean, with rising air in the western and sinking air in the eastern Pacific.

**Warm days/warm nights**  Days where maximum temperature, or nights where minimum temperature, exceeds the 90th percentile, where the respective temperature distributions are generally defined with respect
to the 1961-1990 reference period.

**Warm spell** A period of abnormally warm weather. *Heatwaves* and warm spells have various and, in some cases, overlapping definitions.

**Water cycle** See *Hydrological cycle*.

**Water mass** A body of ocean water with identifiable properties (temperature, salinity, density, chemical tracers) resulting from its unique formation process. Water masses are often identified through a vertical or horizontal extremum of a property such as salinity. North Pacific Intermediate Water (NPIW) and Antarctic Intermediate Water (AAIW) are examples of water masses.

**Water security** ‘The capacity of a population to safeguard sustainable access to adequate quantities of acceptable quality water for sustaining livelihoods, human well-being, and socio-economic development, for ensuring protection against water-borne pollution and water-related disasters, and for preserving ecosystems in a climate of peace and political stability’ (UN-Water, 2013).

**Wave run-up** See *Extreme sea level (ESL)*.

**Wave setup** See *Extreme sea level (ESL)*.

**Weathering** The gradual removal of atmospheric $\text{CO}_2$ through dissolution of silicate and carbonate rocks. Weathering may involve physical processes (mechanical weathering) or chemical activity (chemical weathering).

**Well-mixed greenhouse gas** A greenhouse gas that has an atmospheric *lifetime* long enough (> several years) to be homogeneously mixed in the troposphere, and as such the global average mixing ratio can be determined from a network of surface observations. For many well-mixed greenhouse gases, measurements made in remote regions differ from the global mean by < 15%.

**West African monsoon (WAfriM)** See *Global monsoon*.

**West Antarctic ice sheet (WAIS)** See *Ice sheet*.

**Wetland** Land that is covered or saturated by water for all or part of the year (e.g., *peatland*).

**Younger Dryas** A period 12.85 to 11.65 ka (thousand years before 1950), during the *last deglaciation*, characterized by a temporary return to colder conditions in many locations, especially around the North Atlantic. See also *Stadial* and *Last deglaciation*.

**Zero emissions commitment** See *Climate change commitment*.
