can reduce the mass of waste by 70–80% and the volume of waste by 80–90% (Haraguchi et al. 2019). Incineration technology can reduce water and soil pollution (Gu et al. 2019). However, if not properly handled, dust, and gases such as SO₂, HCL, HF, NO₂, and dioxins in the flue gases can harm the environment (Mutz et al. 2017). Anaerobic digestion technology has a positive environmental impact and the ability to reduce GHG emissions (Ayodele et al. 2018; Cudjoe et al. 2020). The by-product of the anaerobic digestion process could be used as a nutrient-rich fertiliser for enhancing soil richness for agricultural purposes (Wainaina et al. 2020). Due to the potential negative impacts on domestic environment and residents' health, WTE projects such as incineration encounter substantial opposition from the local communities in which they are located (Baxter et al. 2016; Ren et al. 2016). Therefore, for WTE to be deployed more widely, policies would need to be tailored with specific guidelines focused on mitigating emissions, which may have an adverse effect on the environment.

Depending on the origin of the waste used, the integration of WTE and carbon capture and storage (CCS) could enable waste to be a net-zero or even net negative emissions energy source (Kearns 2019; Wienchol et al. 2020). For example, in Europe only, the integration of CCS with WTE facilities has the potential to capture about 60 to 70 million tonnes of carbon dioxide annually (Tota et al. 2021).

Waste-to-energy is an expensive process compared to other energy sources such as fossil fuels and natural gas (Mohammadi and Harjunkoski 2020). However, the environmental and economic benefits make its high financial costs justifiable. In 2019, the global WTE market size was valued at USD31 billion, and it is predicted to experience 7.4% annual growth until 2027 (UNECE 2020).

6.4.3 Energy System Integration

Greenhouse gases are emitted across all economic activities. Therefore, cost-effective decarbonisation requires a 'system of systems' approach that considers the interaction between different energy sectors and systems. Flexibility technologies and advanced control of integrated energy systems (e.g., considering the interaction between electricity, heating/cooling, gas/hydrogen, transport sectors) could reduce energy infrastructure investments substantially in future low-carbon energy systems (Strbac et al. 2015b; Jacobson et al. 2019).

The electricity grid will serve as a backbone of future low-carbon energy systems. Integration of large amounts of VRE generation (Hansen et al. 2019), particularly wind and solar generation (Bistline and Young 2019; Perez et al. 2019), presents economic and technical challenges to electricity system management across different time scales from sub-seconds, hours, days, seasons, to multiple years. Furthermore, electrification of segments of the transport and heat sectors could disproportionately increase peak demand relative to supply (Bistline et al. 2021). Increases in peak demand may require reinforcing network infrastructures and generation in the historical passive system operation paradigm (Strbac et al. 2020).

These challenges to electricity system management can be addressed through system integration and a digitalised control paradigm

involving advanced information and communication technologies. Real-time maintenance of supply-demand balance and sufficient flexibility technologies such as electricity storage, flexible demand, and grid forming converters (Strbac et al. 2015a; López Prol and Schill 2021) would be increasingly valuable for incorporating larger amounts of VRE generation. This flexibility will be particularly important to deal with sudden losses of supply, for example, due to a failure of a large generator or interconnector or a rapid increase in demand (Teng et al. 2017; Chamorro et al. 2020).

The transition to a digitalised-based electricity system control paradigm would facilitate radical changes in the security of supply, moving from the traditional approach of redundancy in assets to a smart control paradigm. Advanced control and communication systems can significantly reduce the electricity system investment and operation costs (Harper et al. 2018; Münster et al. 2020).

6.4.3.1 Importance of Cross-sector Coupling for Cost-effective Energy System Decarbonisation

Integrated whole-system approaches can reduce the costs of low-carbon energy system transitions (*high confidence*). A lack of flexibility in the electricity system may limit the cost-effective integration of technologies as part of broader net-zero energy systems. At the same time, the enormous latent flexibility hidden in heating and cooling, hydrogen, transport, gas systems, and other energy systems provides opportunities to take advantage of synergies and to coordinate operations across systems (Martin et al. 2017; Zhang et al. 2018; Martinez Cesena and Mancarella 2019; Pavičević et al. 2020; Bogdanov et al. 2021) (Figure 6.16).

Sector coupling can significantly increase system flexibility, driven by the application of advanced technologies (Clegg and Mancarella 2016; Heinen et al. 2016; Bogdanov et al. 2019; Solomon et al. 2019; Zhang et al. 2019b; Zhang and Fujimori 2020; Zhao et al. 2021). For example, district heating infrastructure can generate both heat and power. Cooling systems and electrified heating systems in buildings can provide flexibility through preheating and precooling via thermal energy storage (Z. Li et al. 2016; G. Li et al. 2017). System balancing services can be provided by electric vehicles (EVs) based on vehicle-to-grid concepts and deferred charging through smart control of EV batteries without compromising customers' requirements for transport (Aunedi and Strbac 2020).

Hydrogen production processes (power-to-gas and vice versa) and hydrogen storage can support short-term and long-term balancing in the energy systems and enhance resilience (Stephen and Pierluigi 2016; Strbac et al. 2020). However, the economic benefits of flexible power-to-gas plants, energy storage, and other flexibility technological and options will depend on the locations of VRE sources, storage sites, gas, hydrogen, and electricity networks (Jentsch et al. 2014; Heymann and Bessa 2015; Ameli et al. 2020). Coordinated operation of gas and electricity systems can bring significant benefits in supplying heat demands. For example, hybrid heating can eliminate investment in electricity infrastructure reinforcement by switching to heat pumps in off-peak hours and gas boilers in peak hours (Fischer et al. 2017; Dengiz et al. 2019;

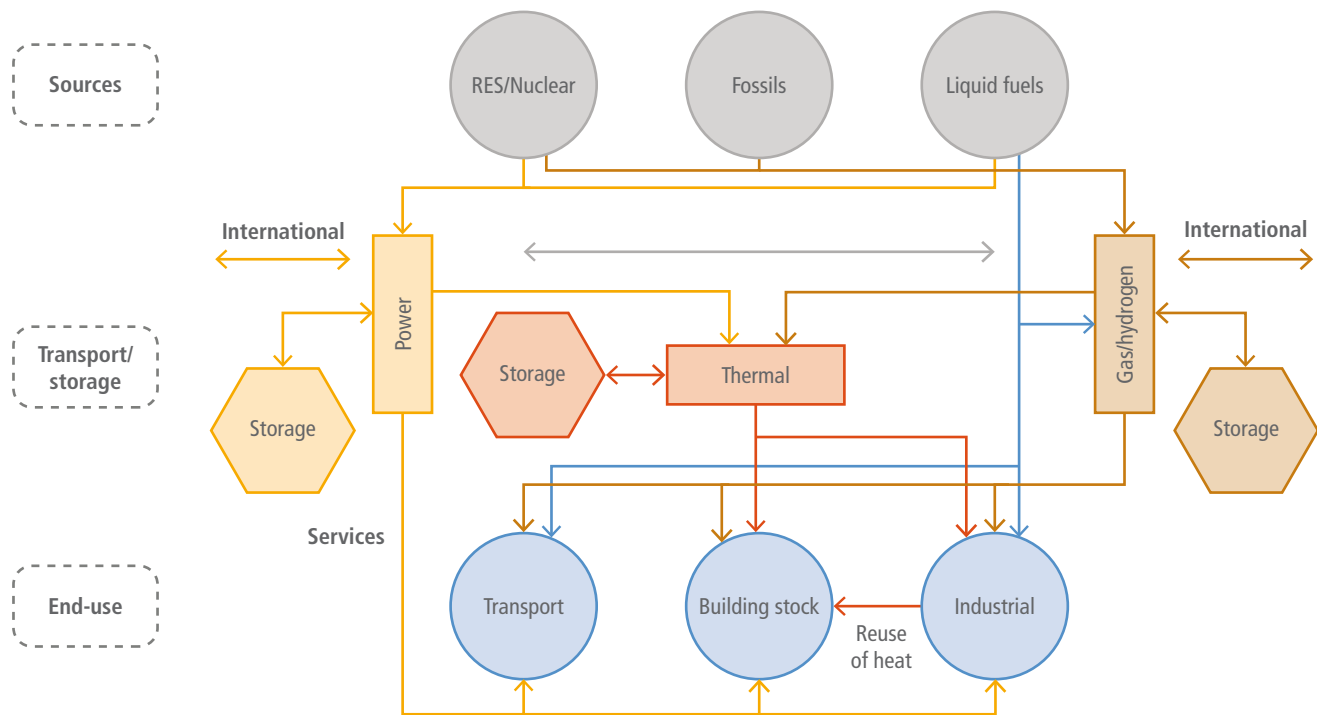

Figure 6.16 | Interaction between different energy sectors. Source: extracted with permission from Münster et al. (2020).

Bistline et al. 2021). The heat required by direct air carbon capture and storage (DACCS) could be effectively supplied by inherent heat energy in nuclear plants, enhancing overall system efficiency (Realmonde et al. 2019).

Rather than incremental planning, strategic energy system planning can help minimise long-term mitigation costs (*high confidence*). With a whole-system perspective, integrated planning can consider both short-term operation and long-term investment decisions, covering infrastructure from local to national and international, while meeting security of supply requirements and incorporating the flexibility provided by different technologies and advanced control strategies (Zhang et al. 2018; O'Malley et al. 2020; Strbac et al. 2020). Management of conflicts and synergies between local district and national level energy system objectives, including strategic investment in local hydrogen and heat infrastructure, can drive significant whole-system cost savings (Zhang et al. 2019b; Fu et al. 2020). For example, long-term planning of the offshore grid infrastructure to support offshore wind development, including interconnection between different countries and regions, can provide significant savings compared to a short-term incremental approach in which every offshore wind farm is individually connected to the onshore grid (E3G 2021).

6.4.3.2 Role of Flexibility Technologies

Flexibility technologies – including energy storage, demand-side response, flexible/dispatchable generation, grid-forming converters, and transmission interconnection – as well as advanced control systems – can facilitate cost-effective and secure low-carbon energy systems (*high confidence*). Flexibility technologies have already

been implemented, but they can be enhanced and deployed more widely. Due to their interdependencies and similarities, there can be both synergies and conflicts for utilising these flexibility options (Bistline et al. 2021). It will therefore be important to coordinate the deployment of the potential flexibility technologies and smart control strategies. Important electricity system flexibility options include the following:

- **Flexible/dispatchable generation.** Advances in generation technologies, for example, gas/hydrogen plants and nuclear plants, can enable them to provide flexibility services. These technologies would start more quickly, operate at lower power output, and make faster output changes, enabling more secure and cost-effective integration of VRE generation and end-use electrification. There are already important developments in increasing nuclear plants flexibility (e.g., in France (Office of Nuclear Energy 2021)) and the development of small modular reactors, which could support system balancing (FTI Consulting 2018).
- **Grid-forming converters (inverters).** The transition from conventional electricity generation, applying mainly synchronous machines to inverter-dominated renewable generation, creates significant operating challenges. These challenges are mainly associated with reduced synchronous inertia, system stability, and 'black start' capability. Grid-forming converters will be a cornerstone for the control of future electricity systems dominated by VRE generation. These converters will address critical stability challenges, including the lack of system inertia, frequency and voltage regulation, and black start services while reducing or eliminating the need to operate conventional generation (Tayyebi et al. 2019).

- **Interconnection.** Electricity interconnections between different regions can facilitate more cost-effective renewable electricity deployment. Interconnection can enable large-scale sharing of energy and provide balancing services. Backup energy carriers beyond electricity, such as ammonia, can be shared through gas/ammonia/hydrogen-based interconnections, strengthening temporal coupling of multiple sectors in different regions (Bhagwat et al. 2017; Brown et al. 2018) (Section 6.4.5).
- **Demand-side response.** Demand-side schemes – including, for example, smart appliances, EVs, and building-based thermal energy storage (Heleno et al. 2014) – can provide flexibility services across multiple time frames and systems. Through differentiation between essential and non-essential needs during emergency conditions, smart control of demands can significantly enhance system resilience (Chaffey 2016).
- **Energy storage.** Energy storage technologies (Section 6.4.4) can act as both demand and generation sources. They can provide services such as system balancing, various ancillary services, and network management. Long-duration energy storage can significantly enhance the utilisation of renewable energy sources and reduce the need for firm low-carbon generation (Sepulveda et al. 2021).

6.4.3.3 Role of Digitalisation and Advanced Control Systems

A digitalised energy system can significantly reduce energy infrastructure investments while enhancing supply security and resilience (*high confidence*) (Andoni et al. 2019; Strbac et al. 2020). Significant progress has been made in the development of technologies essential for the transition to a digitalised energy control paradigm, although the full implementation is still under development. Electrification and the increased integration of the electricity system with other systems will fundamentally transform the operational and planning paradigm of future energy infrastructure. A fully intelligent and sophisticated coordination of the multiple systems through smart control will support this paradigm shift. This shift will provide significant savings through better utilisation of existing infrastructure locally, regionally, nationally, and internationally. Supply system reliability will be enhanced through advanced control of local infrastructure (Strbac et al. 2015a). Furthermore, this paradigm shift offers the potential to increase energy efficiency through a combination of technologies that gather and analyse data and consequently optimise energy use in real-time.

The transition to advanced data-driven control of energy system operations (Cremer et al. 2019; Sun et al. 2019a) will require advanced information and communication technologies and infrastructure, including the internet, wireless networks, computers, software, middleware, smart sensors, internet of things components, and dedicated technological developments (Hossein Motlagh et al. 2020). The transition will raise standardisation and cyber-security issues, given that digitalisation can become a single point of failure for the complete system (Ustun and Hussain 2019; Unsal et al. 2021). Implementing peer-to-peer energy trading based on blockchain is expected to be one of the key elements of next-generation electricity systems (Qiu et al. 2021). This trading will enable consumers to

drive system operation and future design, increasing overall system efficiency and security of supply while reducing emissions without sacrificing users' privacy (Andoni et al. 2019; Ahl et al. 2020). When deployed with smart contracts, this concept will be suitable for energy systems involving many participants, where a prerequisite is digitalisation (e.g., smart meters, end-use demand control systems) (Juhar and Khaled 2018; Teufel et al. 2019).

6.4.3.4 System Benefits of Flexibility Technologies and Advanced Control Systems

New sources of flexibility and advanced control systems provide a significant opportunity to reduce low-carbon energy system costs by enhancing operating efficiency and reducing energy infrastructure and low-carbon generation investments, while continuing to meet security requirements (*high confidence*). In the USA, for example, one study found that flexibility in buildings alone could reduce US CO₂ emissions by 80 Mt yr⁻¹ and save USD18 billion yr⁻¹ in electricity system costs by 2030 (Satchwell et al. 2021). Key means for creating savings are associated with the following:

- **Efficient energy system operation.** Flexibility technologies such as storage, demand-side response, interconnection, and cross-system control will enable more efficient, real-time demand and supply balancing. This balancing has historically been provided by conventional fossil-fuel generation (Nuytten et al. 2013).
- **Savings in investment in low-carbon/renewable generation capacity.** System flexibility sources can absorb or export surplus electricity, thus reducing or avoiding energy curtailment and reducing the need for firm low-carbon capacity such as nuclear and fossil-fuel plants with CCS (Newbery et al. 2013; Solomon et al. 2019). For example, one study found that flexibility technologies and advanced control systems could reduce the need for nuclear power by 14 GW and offshore wind by 20 GW in the UK's low-carbon transition (Strbac et al. 2015b).
- **Reduced need for backup capacity.** System flexibility can reduce energy demand peaks, reducing the required generation capacity to maintain the security of supply, producing significant savings in generation investments (Strbac et al. 2020).
- **Deferral or avoidance of electricity network reinforcement/addition.** Flexibility technologies supported by advanced control systems can provide significant savings in investment in electricity network reinforcement that might emerge from increased demand, for example, driven by electrification of transport and heat sectors. Historical network planning and operation standards are being revised considering alternative flexibility technologies, which would further support cost-effective integration of decarbonised transport and heat sectors (Strbac et al. 2020).

6.4.4 Energy Storage for Low-carbon Grids

Energy storage technologies make low-carbon electricity systems more cost-effective, allowing VRE technologies to replace more expensive firm low-carbon generation technologies (Carbon Trust 2016) and

Table 6.5 | Suitability of low-carbon energy storage technologies, in terms of the grid services they can provide, and overall features such as technology maturity: where Low represents an emerging technology; Med represents a maturing technology; and High a fully mature technology. The opportunity for the cost of a technology to reduce over the next decade is represented by Low, Med and High and the lifetime of installations by: Long, for projects lasting more than 25 years; Med for those lasting 15–25 years; Short, for those lasting less than 15 years.

Suitability factor	PHS	CAES	LAES	TES	FES	LiB	Scap	RFB	PtX	RHFC

reducing investment costs in backup generation, interconnection, transmission, and distribution network upgrades (*high confidence*). Energy system decarbonisation relies on increased electrification (Section 6.6.2.3). Meeting increasing demands with variable renewable sources presents challenges and could lead to costly infrastructure reinforcements. Energy storage enables electricity from variable renewables to be matched against evolving demands across both time and space, using short-, medium- and long-term storage of excess energy for delivery later or at a different location. In 2017, an estimated 4.67 TWh (0.017 EJ) of electricity storage was in operation globally (IRENA 2017b). If the integration of renewables is doubled from 2014 levels by 2030, the total capacity of global electricity storage could triple, reaching 11.89–15.27 TWh (0.043–0.055 EJ) (IRENA 2017b).

Energy storage technologies can provide a range of different grid services (Table 6.5). Energy storage enhances security of supply by providing real-time system regulation services (voltage support, frequency regulation, fast reserve, and short-term reserve). A greater proportion of variable renewable sources reduces system inertia, requiring more urgent responses to changes in system frequency, which rapid response storage technologies can provide (stability requires responses within sub-second time scale for provision of frequency and voltage control services). Energy storage also provides intermittent renewable sources with flexibility, allowing them to contribute a greater proportion of electrical energy and avoiding curtailment (capacity firming). Investment costs in backup generation, interconnection, transmission, and distribution network

upgrades can thus be reduced (upgrade deferral), meaning that less low-carbon generation will need to be built while still reducing emissions. In the event of an outage, energy storage reserves can keep critical services running (islanding) and restart the grid (black start). The ability to store and release energy as required provides a range of market opportunities for buying and selling of energy (arbitrage).

No single, sufficiently mature energy storage technology can provide all the required grid services – a portfolio of complementary technologies working together can provide the optimum solution (*high confidence*). Different energy storage technologies can provide these services and support cost-effective energy system decarbonisation (Carbon Trust 2016). To achieve very low-carbon systems, significant volumes of storage will be required (Strbac et al. 2015a; Section 6.4.3.2). There are few mature global supply chains for many of the less-developed energy storage technologies. This means that, although costs today may be relatively high, there are significant opportunities for future cost reductions, both through technology innovation and through manufacturing scale. Adding significant amounts of storage will reduce the price variation and, therefore, the profitability of additional and existing storage, increasing investment risk.

Energy storage extends beyond electricity storage and includes technologies that can store energy as heat, cold, and both liquid and gaseous fuels. Energy storage is a conversion technology, enabling energy to be converted from one form to another. This diversification improves the overall resilience of energy systems, with each system

being able to cover supply shortfalls in the others. For example, storage can support the electrification of heating or cooling, as well as transport through electric vehicles, powered by batteries or by fuel cells. Storage significantly reduces the need for costly reinforcement of local distribution networks through smart charging schemes and the ability to flow electricity back to the grid (e.g., through vehicle-to-grid). By capturing otherwise wasted energy streams, such as heat or cold, energy storage improves the efficiency of many systems, such as buildings, data centres and industrial processes.

6.4.4.1 Energy Storage Technologies

Pumped hydroelectric storage (PHS). PHS makes use of gravitational potential energy, using water as the medium. Water is pumped into an elevated reservoir using off-peak electricity and stored for later release when electricity is needed. These closed-loop hydropower plants have been in use for decades and account for 97% of worldwide electricity storage capacity (IRENA 2017b; IEA 2018b). PHS is best suited to balancing daily energy needs at a large scale, and advances in the technology now allow rapid response and power regulation in both generating and pumping mode (Valavi and Nysveen 2018; Dong et al. 2019; Kougias et al. 2019). The construction itself can cause disruption to the local community and environment (Hayes et al. 2019), the initial investment is costly, and extended construction periods delay return on investment (Section 6.4.2.3). In addition, locations for large-scale PHS plants are limited.

Advanced pump-turbines are being developed, allowing both reversible and variable-speed operation, supporting frequency control and grid stability with improved round-trip efficiencies (Ardizzon et al. 2014). New possibilities are being explored for small-scale PHS installations and expanding the potential for siting (Kougias et al. 2019). For example, in underwater PHS, the upper reservoir is the sea, and the lower is a hollow deposit at the seabed. Seawater is pumped out of the deposit to store off-peak energy and re-enters

through turbines to recharge it (Kougias et al. 2019). Using a similar concept, underground siting in abandoned mines and caverns could be developed reasonably quickly (IEA 2020h). Storage of energy as gravitational potential can also be implemented using materials other than water, such as rocks and sand. Pumped technology is a mature technology (Rehman et al. 2015; Barbour et al. 2016) and can be important in supporting the transition to future low-carbon electricity grids (IHA 2021).

Batteries. There are many types of batteries, all having unique features and suitability, but their key feature is their rapid response time. A rechargeable battery cell is charged by using electricity to drive ions from one electrode to another, with the reverse occurring on discharge, producing a usable electric current (Crabtree et al. 2015). While lead-acid batteries (LABs) have been widely used for automotive and grid applications for decades (May et al. 2018), LIBs are increasingly being used in grid-scale projects (Crabtree et al. 2015), displacing LABs. The rapid response time of batteries makes them suitable for enhanced frequency regulation and voltage support, enabling the integration of variable renewables into electricity grids (Strbac and Aunedi 2016). Batteries can provide almost all electricity services, except for seasonal storage. LIBs, in particular, can store energy and power in small volumes and with low weight, making them the default choice for EVs (Placke et al. 2017). EV batteries are expected to form a distributed storage resource as this market grows, both impacting and supporting the grid (Staffell and Rustonji 2016).

Drawbacks of batteries include relatively short lifespans and the use of hazardous or costly materials in some variants. While LIB costs are decreasing (Schmidt et al. 2017; Vartiainen et al. 2020), the risk of thermal runaway, which could ignite a fire (Gur 2018; Wang et al. 2019a), concerns about long-term resource availability (Olivetti et al. 2017; Sun et al. 2017), and concerns about global cradle-to-grave impacts (Peters et al. 2017; Kallitsis et al. 2020) need to be addressed.

Table 6.6 | Technical characteristics of a selected range of battery chemistries, categorised as those which precede LIBs (white background), LIBs (yellow background) and post LIBs (blue background).

Battery type	Technology maturity	Lifespan (cycles)	Energy density (Wh L ⁻¹)	Specific energy (Wh kg ⁻¹)	Price (USD kWh ⁻¹) in 2017
Lead acid	High	300–800 ^e	102–106 ^e	38–60 ^e	70–160 ^e
Ni MH	High	600–1200 ^e	220–250 ^e	42–110 ^e	210–365 ^e
Ni Cd	High	1350 ^b	100 ^b	60 ^b	700
High-temperature Na batteries	High	1000 ^e	150–280 ^h	80–120 ^a	315–490 ^h
LIB state of the art	High	1000–6000 ^e	200–680 ^c	110–250 ^c	176 ^f
LIB energy-optimised	Under development		600–850 ^c	300–440 ^c	
Classic Li Metal (CLIM)	Under development		800–1050 ^c	420–530 ^c	
Metal Sulphur (Li S)	Near commercialisation	100–500 ^e	350–680 ^{c, h}	360–560 ^{c, h}	36–130 ^e
Metal Sulphur (Na S)	Under development	5000–10,000 ^h			
Metal Air (Li/air)	Under development	20–100 ^e		470–900 ^d	70–200 ^e
Metal Air (Zn/air)	Under development	150–450 ^e		200–410 ^d	70–160 ^e
Na ion	Under development	500 ^g		600 ^g	
All-solid-state	Under development			278–479 ^c	
Redox	Under development	>12,000–14,000 ^j	15–25 ^j	10–20 ^j	66 ^j

Note: With the exception of the All-solid-state batteries, all use liquid electrolytes. Source: ^a Mahmoudzadeh et al. 2017; ^b Manzetti and Mariasiu 2015; ^c Placke et al. 2017; ^d Nykvist and Nilsson 2015; ^e Cano et al. 2018; ^f Bloomberg Energy Finance, 2019; ^g You and Manthiram 2017; ^h Fotouhi et al. 2017; ⁱ IRENA 2017b; ^j Yang et al. 2020.

The superior characteristics of LIBs will keep them the dominant choice for EV and grid applications in the medium term (*high confidence*). There are, however, several next-generation battery chemistries (Placke et al. 2017), which show promise (*high confidence*). Cost reductions through economies of scale are a key area for development. Extending the life of the battery can bring down overall costs and mitigate the environmental impacts (Peters et al. 2017). Understanding and controlling battery degradation is therefore important. The liquid, air-reactive electrolytes of conventional LIBs are the main source of their safety issues (Janek and Zeier 2016; Gur 2018), so all-solid-state batteries, in which the electrolyte is a solid, stable material, are being developed. They are expected to be safe, be durable, and have higher energy densities (Janek and Zeier 2016). New chemistries and concepts are being explored, such as lithium-sulphur batteries to achieve even higher energy densities (Van Noorden 2014; Blomgren 2017) and sodium chemistries because sodium is more abundant than lithium (Hwang et al. 2017). Cost-effective recycling of batteries will address many sustainability issues and prevent hazardous and wasteful disposal of used batteries (Harper et al. 2019). Post-LIB chemistries include metal sulphur, metal-air, metal ion (besides lithium) and all-solid-state batteries.

Compressed air energy storage (CAES). With CAES, off-peak electricity is used to compress air in a reservoir – either in salt caverns for large-scale or in high-pressure tanks for smaller-scale installations. The air is later released to generate electricity. While conventional CAES has used natural gas to power compression, new low-carbon CAES technologies, such as isothermal or adiabatic CAES, control thermal losses during compression and expansion (Wang et al. 2017c). Fast responses and higher efficiencies occur in small-scale CAES installations, scalable to suit the application as a distributed energy store, offering a flexible, low-maintenance alternative (Luo et al. 2014; Venkataramani et al. 2016).

CAES is a mature technology in use since the 1970s. Although CAES technologies have been developed, there are not many installations at present (Wang et al. 2017b; Blanc et al. 2020). While the opportunities for CAES are significant, with a global geological storage potential of about 6.5 PW (Aghahosseini and Breyer 2018), a significant amount of initial investment is required. Higher efficiencies and energy densities can be achieved by exploiting the hydrostatic pressure of deep water to compress air within submersible reservoirs (Pimm et al. 2014). CAES is best suited to bulk diurnal electricity storage for buffering VRE sources and services, which do not need a very rapid response. In contrast to PHS, CAES has far more siting options and poses few environmental impacts.

Liquid air energy storage (LAES). LAES uses electricity to liquefy air by cooling it to -196°C and storing it in this condensed form (largely liquid nitrogen) in large, insulated tanks. To release electricity, the ‘liquid air’ is evaporated through heating, expanding to drive gas turbines. Low-grade waste heat can be utilised, providing opportunities for integrating with industrial processes to increase system efficiency. There are clear, exploitable synergies with the existing liquid gas infrastructure (Peters and Sievert 2016).

LAES provides bulk daily storage of electricity, with the additional advantage of being able to capture waste heat from industrial processes. This technology is in the early commercial stage (Brandon et al. 2015; Regen 2017). Advances in whole systems integration can be developed to integrate LAES with industrial processes, making use of their waste heat streams. LAES uniquely removes contaminants in the air and could potentially incorporate CO_2 capture (Taylor et al. 2012).

Thermal energy storage (TES). TES refers to a range of technologies exploiting the ability of materials to absorb and store heat or cold, either within the same phase (sensible TES), through phase changes (latent TES), or through reversible chemical reactions (thermochemical TES). Pumped Thermal Energy Storage (PTES), a hybrid form of TES, is an air-driven electricity storage technology storing both heat and cold in gravel beds, using a reversible heat-pump system to maintain the temperature difference between the two beds and gas compression to generate and transfer heat (Regen 2017). TES technologies can store both heat and cold energy for long periods, for example, in underground water reservoirs for balancing between seasons (Dahash et al. 2019; Tian et al. 2019), storing heat and cold to balance daily and seasonal temperatures in buildings and reducing heat build-up in applications generating excessive waste heat, such as data centres and underground operations.

TES can be much cheaper than batteries and has the unique ability to capture and reuse waste heat and cold, enabling the efficiency of many industrial, buildings, and domestic processes to be greatly improved (*high confidence*). Integration of TES into energy systems is particularly important, as the global demand for cooling is expected to grow (Elzinga et al. 2014; Peters and Sievert 2016). Sensible TES is well developed and widely used; latent TES is less developed with few applications. Thermochemical TES is the least developed, with no application yet (Prieto et al. 2016; Clark et al. 2020). The potential for high-density storage of industrial heat for long periods in thermochemical TES (Brandon et al. 2015) is high, with energy densities comparable to that of batteries (Taylor et al. 2012), but material costs are currently prohibitive, ranging from hundreds to thousands of dollars per tonne.

Flywheel energy storage (FES). Flywheels are charged by accelerating a rotor/flywheel. Energy is stored in the spinning rotor's inertia which is only decelerated by friction (minimised by magnetic bearings in a vacuum), or by contact with a mechanical, electric motor. They can reach full charge very rapidly, their state of charge can be easily determined (Amiryar and Pullen 2017), and they operate over a wide range of temperatures. While they are more expensive to install than batteries and supercapacitors, they last a long time and are best suited to stationary grid storage, providing high power for short periods (minutes). Flywheels can be used in vehicles, but not as the primary energy source.

Flywheels are a relatively mature storage technology but not widely used, despite their many advantages over electrochemical storage (Dragoni 2017). Conventional flywheels require costly, high tensile strength materials, but high-energy flywheels, using lightweight rotor materials, are being developed (Hedlund et al. 2015; Amiryar and Pullen 2017).

Supercapacitors – also known as ultracapacitors or double layer capacitors (Scap). Supercapacitors consist of a porous separator sandwiched between two electrodes, immersed in a liquid electrolyte (Gur 2018). When a voltage is applied across the electrodes, ions in the electrolyte form electric double layers at the electrode surfaces, held by electrostatic forces. This structure forms a capacitor, storing electrical charge (Brandon et al. 2015; Lin et al. 2017) and can operate from -40°C to 65°C .

Supercapacitors can supply high peaks of power very rapidly for short periods (seconds up to minutes) and are able to fulfil the grid requirements for frequency regulation, but they would need to be hybridised with batteries for automotive applications. Their commercial status is limited by costly materials and additional power electronics required to stabilise their output (Brandon et al. 2015). Progress in this area includes the development of high-energy supercapacitors, LIB-supercapacitor devices (Gonzalez et al. 2016), and cheaper materials (Wang et al. 2017a), all providing the potential to improve the economic case for supercapacitors, either by reducing manufacturing costs or extending their service portfolio.

Redox flow batteries (RFB). Redox flow batteries use two separate electrolyte solutions, usually liquids, but solid or gaseous forms may also be involved, stored in separate tanks, and pumped over or through electrode stacks during charge and discharge, with an ion-conducting membrane separating the liquids. The larger the tank, the greater the energy storage capacity, whereas more and larger cells in the stack increase the power of the flow battery. This decoupling of energy from power enables RFB installations to be uniquely tailored to suit the requirements of any given application. There are two commercially available types today: vanadium and zinc bromide, and both operate at near ambient temperatures, incurring minimal operational costs.

RFBs respond rapidly and can perform all the same services as LIBs, except for onboard electricity for EVs. Lower cost chemistries are emerging, to enable cost-effective bulk energy storage (Brandon et al. 2015). A new membrane-free design eliminates the need for a separator and also halves the system requirements, as the chemical reactions can coexist in a single electrolyte solution (Navalpotro et al. 2017; Arenas et al. 2018).

Power to fuels (PtX) (see also Section 6.4.3.1). The process of using electricity to generate a gaseous fuel, such as hydrogen or ammonia, is termed power-to-gas (PtG/P2G) (IEA 2020h). When injected into the existing gas infrastructure (Section 6.4.5), it has the added benefit of decarbonising gas (Brandon et al. 2015). Electricity can be used to generate hydrogen, which is then converted back into electricity using combined-cycle gas turbines that have been converted to run on hydrogen. For greater compatibility with existing gas systems and appliances, the hydrogen can be combined with captured carbon dioxide to form methane and other synthetic fuels (Thema et al. 2019), however, methane has high global warming potential and its supply chain emissions have been found to be significant (Balcombe et al. 2013).

PtX can provide all required grid services, depending on how it is integrated. However, a significant amount of PtX is required for

storage to produce electricity again (Bogdanov et al. 2019) due to the low roundtrip efficiency of converting electricity to fuel and back again. However, portable fuels (hydrogen, methane, ammonia, synthetic hydrocarbons) are useful in certain applications, for example, in energy systems lacking the potential for renewables. The high energy density of chemical storage is essential for more demanding applications, such as transporting heavy goods and heating or cooling buildings (IEA 2020h). Research is needed into more efficient and flexible electrolyzers which last longer and cost less (Brandon et al. 2015).

Hydrogen and reversible hydrogen fuel cells (H/RHFC). Hydrogen is a flexible fuel with diverse uses, capable of providing electricity, heat, and long-term energy storage for grids, industry, and transport, and has been widely used industrially for decades (Section 6.4.5.1). Hydrogen can be produced in various ways and stored in significant quantities in geological formations at moderate pressures, often for long periods, providing seasonal storage (Gabrielli et al. 2020). A core and emerging implementation of PtX is hydrogen production through electrolyzers. Hydrogen is a carbon-free fuel holding three times the energy of an equivalent mass of gasoline but occupying a larger volume. An electrolyser uses excess electricity to split water into hydrogen and oxygen through the process of electrolysis. A fuel cell performs the reverse process of recombining hydrogen and oxygen back into water, converting chemical energy into electricity (Elzinga et al. 2014). Reversible hydrogen fuel cells (RHFCs) can perform both functions in a single device, however, they are still in the pre-commercial stage, due to prohibitive production costs.

Hydrogen can play an important role in reducing emissions and has been shown to be the most cost-effective option in some cases, as it builds on existing systems (Staffell et al. 2018). Fuel cell costs need to be reduced and the harmonies between hydrogen and complementary technologies, such as batteries, for specific applications need to be explored further. Hydrogen can provide long-duration storage to deal with prolonged extreme events, such as very low output of wind generation, to support resilience of future low-carbon energy systems. Research in this technology focuses on improving roundtrip efficiencies, which can be as high as 80% with recycled waste heat and in high-pressure electrolyzers, incorporating more efficient compression (Matos et al. 2019). Photo-electrolysis uses solar energy to directly generate hydrogen from water (Amirante et al. 2017).

6.4.4.2 Societal Dimensions of Energy Storage

Public awareness and knowledge about electricity storage technologies, their current state, and their potential role in future energy systems is limited (Jones et al. 2018). For instance, people do not perceive energy system flexibility and storage as a significant issue, or assume storage is already taking place. Public perceptions differ across storage technologies. Hydrogen is considered a modern and clean technology, but people also have safety concerns. Moreover, the public is uncertain about hydrogen storage size and the possibility of storing hydrogen in or near residential areas (Eitan and Fischhendler 2021). Battery storage both on the household and community level was perceived as slightly positive in one study in the UK (Ambrosio-Albala et al. 2020). However, financial costs are seen

as a main barrier. The potential of EV batteries to function as flexible storage is limited by the current numbers of EV owners and concerns that one's car battery might not be fully loaded when needed.

6.4.5 Energy Transport and Transmission

The linkage between energy supply and distribution, on the one hand, and energy use on the other is facilitated by various mechanisms for transporting energy. As the energy system evolves, the way that energy is transported will also evolve.

6.4.5.1 Hydrogen: Low-carbon Energy Fuel

Hydrogen is a promising energy carrier for a decarbonised world (Box 6.9). It can be utilised for electricity, heat, transport, industrial demand, and energy storage (Abdin et al. 2020). In low-carbon energy systems, hydrogen is expected to be utilised in applications that are not as amenable to electrification, such as a fuel for heavy-duty road transport and shipping, or as a chemical feedstock (Schemme et al. 2017; Griffiths et al. 2021). Hydrogen could also provide low-carbon heat for industrial processes or be utilised for direct reduction of iron ore (Vogl et al. 2018). Hydrogen could replace natural gas-based electricity generation (do Sacramento et al. 2013) in certain regions and support the integration of variable renewables into electricity systems by providing a means of long-term electricity storage. Hydrogen-based carriers, such as ammonia and synthetic hydrocarbons, can likewise be used in energy-intensive industries and the transport sector (Schemme et al. 2017; IRENA 2019b) (e.g., synthetic fuels for aviation). These hydrogen-based energy carriers are easier to store than hydrogen. At present hydrogen has limited applications – mainly being produced onsite for the creation of methanol and ammonia (IEA 2019c), as well as in refineries.

Low- or zero-carbon produced hydrogen is not currently competitive for large-scale applications, but it is likely to have a significant role in future energy systems, due to its wide-range of applications (*high confidence*). Key challenges for hydrogen are: (i) cost-effective low/zero carbon production; (ii) delivery infrastructure cost; (iii) land area (i.e., 'footprint') requirements of hydrogen pipelines, compressor stations, and other infrastructure; (iv) challenges in using existing pipeline infrastructure; (v) maintaining hydrogen purity; (vi) minimising hydrogen leakage; and (vii) the cost and performance of end uses. Furthermore, it is necessary to consider the public perception and social acceptance of hydrogen technologies and their related infrastructure requirements (Iribarren et al. 2016; Scott and Powells 2020).

Hydrogen production. Low- or zero-carbon hydrogen can be produced from multiple sources. While there is no consensus on the hydrogen production spectrum, 'blue' hydrogen (Goldmann and Dinkelacker 2018) generally refers to hydrogen produced from natural gas combined with CCS through processes such as steam methane reforming (SMR) (Sanusi and Mokheimer 2019) and advanced gas reforming (Zhou et al. 2020). Low-carbon hydrogen could also be produced from coal coupled with CCS (Hu et al. 2020) (Table 6.7). Current estimates are that adding CCS to produce hydrogen from SMR will add on average 50% on the capital cost, 10% to fuel, and 100% to operating costs. For coal gasification, CCS will add 5% to the capital and fuel costs and 130% to operating costs (Staffell et al. 2018; IEA 2019d). Further, biomass gasification could produce renewable hydrogen, and when joined with CCS could provide negative carbon emissions. 'Green' hydrogen (Jaszczur et al. 2016) is most often referred to as hydrogen produced from zero-carbon electricity sources such as solar power and wind power (Schmidt et al. 2017) (Table 6.8). Nuclear power could also provide clean hydrogen, via electrolysis or thermochemical water splitting (EERE 2020).

Table 6.7 | Key performance and cost characteristics of different non-electric hydrogen production technologies, including carbon capture and storage (CCS).

Technology	LHV efficiency (%)		Carbon intensity (kgCO ₂ (kgH ₂) ⁻¹)	Cost estimates* (USD (kgH ₂) ⁻¹)	
	Current	Long-term		Current	Long-term
Steam methane reforming (SMR)	65 ^e	74 ^{e,f}	1.0–3.6 ^{e,i}	1.0–2.7 ^{a,b,c,d,e}	1.5–2.6 ^e

* USD per GBP exchange rate: 0.72 (August 2021); † The cost of hydrogen production from electrolysis is highly dependent on the technology, source of electricity, and operating hours, and some values provided are based on the assumptions made in the references.

Hydrogen can even be produced by pyrolysis of methane (Sánchez-Bastardo et al. 2020) – sometimes called ‘turquoise’ hydrogen, solar thermochemical water splitting, biological hydrogen production (cyanobacteria) (Velazquez Abad and Dodds 2017) – and microbes that use light to make hydrogen (under research) (EIA 2020).

Hydrogen energy carriers. Hydrogen can be both an energy carrier itself, be converted further into other energy carriers (such as synthetic fuels) and be a means of transporting other sources of energy. For example, hydrogen could be transported in its native gaseous form or liquefied. Hydrogen can also be combined with carbon and transported as a synthetic hydrocarbons (Gumber and Gurumoorthy 2018) (IRENA 2019d) as well as be transported via liquid organic hydrogen carriers (LOHCs) or ammonia (IRENA 2019d). For synthetic hydrocarbons such as methane or methanol to be considered zero carbon, the CO₂ used to produce them would need to come from the atmosphere either directly through DACCS or indirectly through BECCS (IRENA 2019b). LOHCs are organic substances in liquid or semi-solid states, which store hydrogen based on reversible catalytic hydrogenation and de-hydrogenation of carbon double bonds (Niermann et al. 2019; Rao and Yoon 2020). Hydrogen produced from electrolysis could also be seen as an electricity energy carrier. This is an example of the PtX processes (Section 6.4.4), entailing the conversion of electricity to other energy carriers for subsequent use.

Ammonia is a promising cost-effective hydrogen carrier (Creutzig et al. 2019). Onsite generation of hydrogen for the production of ammonia already occurs today, and the ammonia (NH₃) could be subsequently ‘cracked’ (with a 15–25% energy loss) to reproduce hydrogen (Hansgen et al. 2010; Montoya et al. 2015; Bell and Torrente-Murciano 2016). Because the energy density of ammonia is 38% higher than liquid hydrogen (Osman and Sgouridis 2018), it is potentially a suitable energy carrier for long-distance transport and storage (Salmon et al. 2021). Moreover, ammonia is more easily condensable (liquefied at 0.8 MPa, 20°C), which provides economically viable hydrogen storage and supply systems. Ammonia production and transport are also established industrial processes (about 180 MMT yr⁻¹) (Valera-Medina et al. 2017), and hence ammonia is considered to be a scalable and cost-effective hydrogen-based energy carrier. At present, most ammonia is used in fertilisers (about 80%), followed by many industrial processes, such as the manufacturing of mining explosives and petrochemicals (Jiao and Xu 2018). In contrast to hydrogen, ammonia can be used directly as a fuel without any phase change for internal combustion engines, gas turbines, and industrial furnaces (Kobayashi et al. 2019). Ammonia can also be used in low- and high-temperature fuel cells (Lan and Tao 2014), whereby both electricity and hydrogen can be produced without any nitrogen oxide (NO_x) emissions. Furthermore, ammonia provides the flexibility to be dehydrogenated for hydrogen-use purposes. Ammonia is considered a carbon-free sustainable fuel for electricity generation, since in a complete combustion, only water and nitrogen are produced (Valera-Medina et al. 2017). Like hydrogen, ammonia could facilitate management of VRE, due to its cost-effective grid-scale energy storage capabilities. In this regard, production of ammonia via hydrogen from low- or zero-carbon generation technologies along with ammonia energy recovery

technologies (Afif et al. 2016) could play a major role in forming a hydrogen and/or ammonia economy to support decarbonisation. However, there are serious concerns regarding the ability to safely use ammonia for all these purposes, given its toxicity – whereas hydrogen is not considered toxic.

In general, challenges around hydrogen-based energy carriers – including safety issues around flammability, toxicity, storage, and consumption – require new devices and techniques to facilitate their large-scale use. Relatively high capital costs and large electricity requirements are also challenges for technologies that produce hydrogen energy carriers. Yet, these energy carriers could become economically viable through the availability of low-cost electricity generation and excess of renewable energy production (Daiyan et al. 2020). A key challenge in use of ammonia is related to the significant amount of NO_x emissions, which is released from nitrogen and oxygen combustion, and unburned ammonia. Both have substantial air pollution risks, which can result in lung and other injuries, and can reduce visibility (EPA 2001). Due to the low flammability of hydrogen energy carriers such as liquefied hydrogen (Nilsson et al. 2016) and ammonia (Li et al. 2018), a stable combustion (Lamas and Rodriguez 2019; Zengel et al. 2020) in the existing gas turbines is not currently feasible. In recent developments, however, the proportion of hydrogen in gas turbines has been successfully increased, and further development of gas turbines may enable them to operate on 100% hydrogen by 2030 (Pflug et al. 2019).

Long-distance hydrogen transport. Hydrogen can allow regional integration and better utilisation of low- or zero-carbon energy sources (Boxes 6.9 and 6.10). Hydrogen produced from renewables or other low-carbon sources in one location could be transported for use elsewhere (Philibert 2017; Ameli et al. 2020). Depending on the distance to the user and specific energy carrier utilised (e.g., gaseous hydrogen or LOHC), various hydrogen transport infrastructures, distribution systems, and storage facilities would be required (Hansen 2020; Schönauer and Glanz 2021) (Figure 6.17).

Hydrogen can be liquefied and transported at volume over the ocean without pressurisation. This requires a temperature of –253°C and is therefore energy-intensive and costly (Niermann et al. 2021). Once it reaches its destination, the hydrogen needs to be re-gasified, adding further cost. A demonstration project is under development exporting liquid hydrogen from Australia to Japan (Yamashita et al. 2019). Hydrogen could also be transported as ammonia by ocean in liquid form. Ammonia is advantageous because it is easier to store than hydrogen (Zamfirescu and Dincer 2008; Soloveichik 2016; Nam et al. 2018). Liquid ammonia requires temperatures below –33°C and is therefore more straightforward and less costly to transport than liquefied hydrogen and even liquefied natural gas (Singh and Sahu 2018). A project exporting ammonia from Saudi Arabia to Japan is under consideration (Nagashima 2018). LOHCs could also be used to transport hydrogen at ambient temperature and pressure. This advantageous property of LOHCs makes them similar to oil products, meaning they can be transported in existing oil infrastructure including oil tankers and tanks (IEA 2019; Niermann et al. 2019). A project is under development to export hydrogen from Brunei to Japan using LOHCs (Kurosaki 2018).

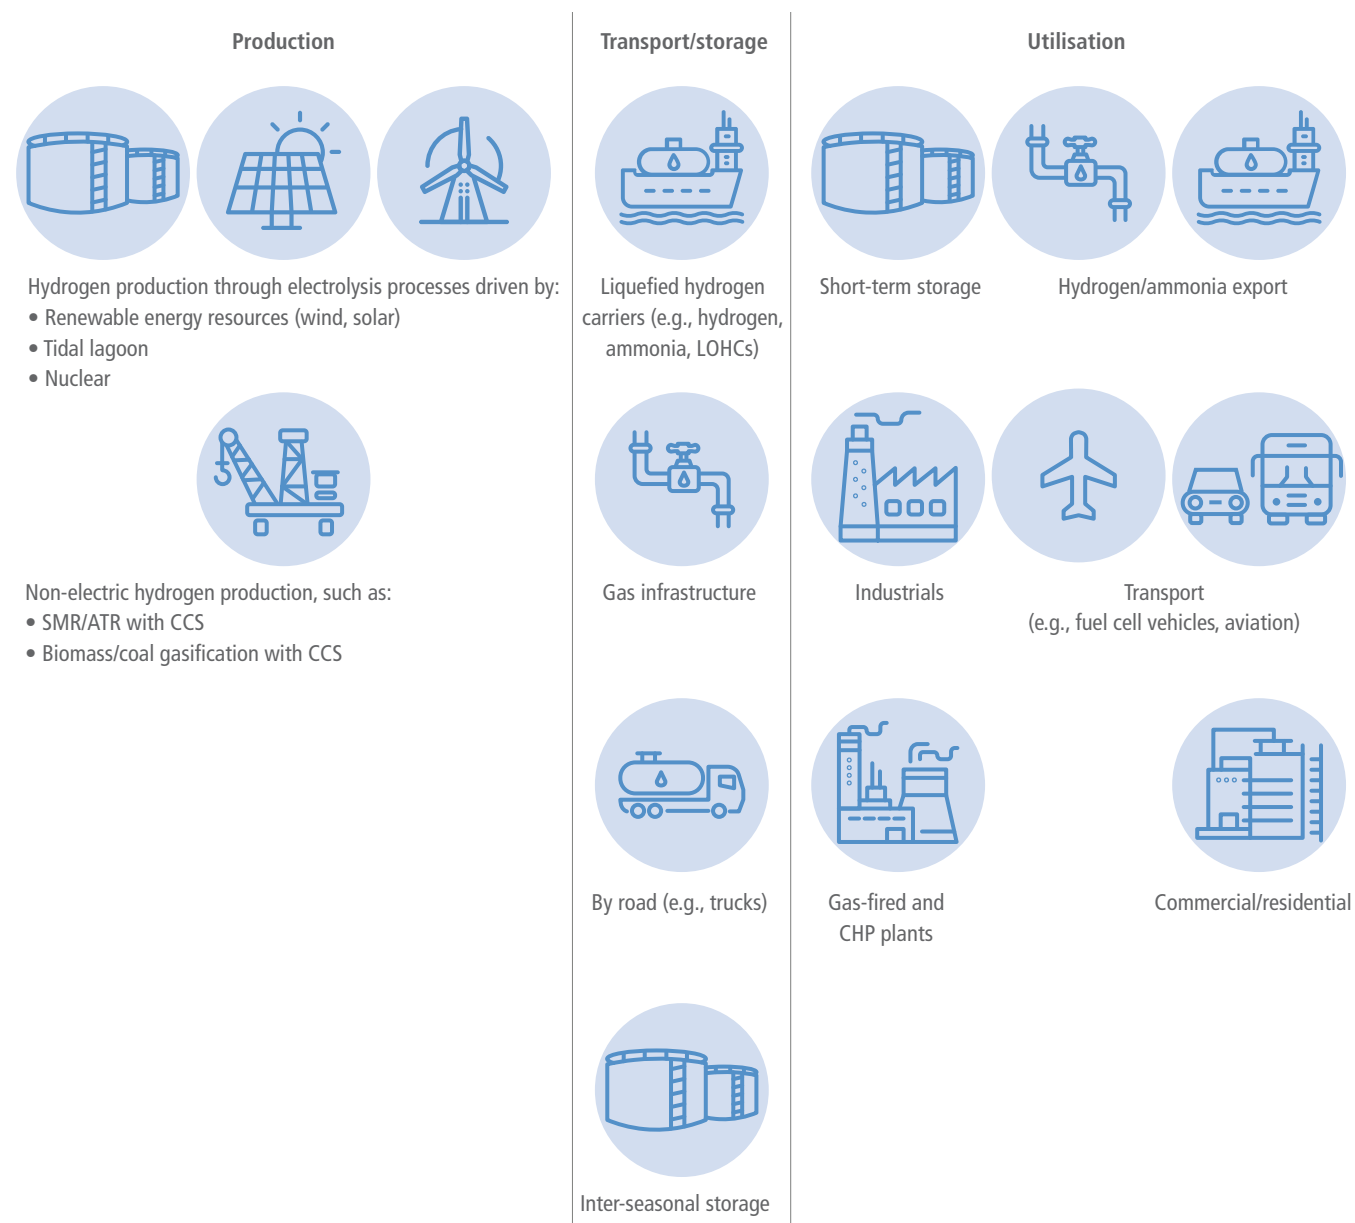

Figure 6.17 | Hydrogen value chain. Hydrogen can be produced by various means and input and fuel sources. These processes have different emissions implications. Hydrogen can be transported by various means and in various forms, and it can be stored in bulk for longer-term use. It also has multiple potential end uses. CHP: Combined heat and power.

Intra-regional hydrogen transportation. Within a country or region, hydrogen would likely be pressurised and delivered as compressed gas. About three times as much compressed hydrogen by volume is required to supply the same amount of energy as natural gas. Security of supply is therefore more challenging in hydrogen networks than in natural gas networks. Storing hydrogen in pipelines (linepack) would be important to maintaining security of supply (Ameli et al. 2017, 2019). Due to the physics of hydrogen, in most cases exiting gas infrastructure would need to be upgraded to transport hydrogen. Transporting hydrogen in medium- or high-pressure networks most often would require reinforcements in compressor stations and pipeline construction routes (Dohi et al. 2016). There are several recent examples of efforts to transport hydrogen by pipeline. For example, in the Iron Mains Replacement Programme in the UK, the existing

low-pressure gas distribution pipes are being converted from iron to plastic (Committee on Climate Change 2018). In the Netherlands, an existing low-pressure 12 km natural gas pipeline has been used for transporting hydrogen (Dohi et al. 2016).

To bypass gas infrastructure in transporting hydrogen, methane can be transported using the existing gas infrastructure, while hydrogen can be produced close to the demand centres. This approach will only make sense if the methane is produced in a manner that captures carbon from the atmosphere and/or if CCS is used when the methane is used to produce hydrogen.

Bulk hydrogen storage. Currently, hydrogen is stored in bulk in chemical processes such as metal and chemical hydrides as well as

in geologic caverns (Andersson and Grönkvist 2019; Caglayan et al. 2019) (e.g., salt caverns operate in Sweden) (Elberry et al. 2021). There are still many challenges, however, due to salt or hard rock geologies, large size, and minimum pressure requirements of the sites (IEA 2019c). Consequently, alternative carbon-free energy carriers, which store hydrogen, may become more attractive (Lan et al. 2012; Kobayashi et al. 2019).

6.4.5.2 Electricity Transmission

Given the significant geographical variations in the efficiency of renewable resources across different regions and continents, electricity transmission could facilitate cost-effective deployment of renewable generation, enhance resilience and security of supply, and increase operational efficiency (*high confidence*). The diurnal and seasonal characteristics of different renewable energy sources such as wind, solar, and hydropower can vary significantly by location. Through enhanced electricity transmission infrastructure, more wind turbines can be deployed in areas with high wind potential and more solar panels in areas with larger solar irradiation. Increases in electricity transmission and trade can also enhance operational efficiency and reduce or defer the need for investment in peaking plants, storage, or other load management techniques needed to meet security of supply requirements associated with localised use of VRE sources. Increased interconnectivity of large-scale grids also allows the aggregation of 'smart grid' solutions such as flexible heating and cooling devices for flexible demand in industrial, commercial, and domestic sectors (Hakimi et al. 2020) and EVs (Muratori and Mai 2020; Li et al. 2021). In general, interconnection is more cost-optimal for countries that are geographically close to each other and can benefit from the diversity of their energy mixes and usage (Schlachtberger et al. 2017). Such developments are not without price, however, and among other concerns, raise issues surrounding land use, public acceptance, and resource acquisition for materials necessary for renewable developments (Capellán-Pérez et al. 2017; Vakulchuk et al. 2020).

A number of studies have demonstrated the cost benefits of interconnected grids in a range of geographical settings, including across the USA (Bloom et al. 2020), Europe (Newbery et al. 2013; Cluet et al. 2020), between Australia and parts of Asia (Halawa et al. 2018), and broader global regions, for example between the Middle East and Europe or North Africa and Europe (Tsoutsos et al. 2015). While there is growing interest in interconnection among different regions or continents, a broad range of geopolitical and socio-techno-economic challenges would need to be overcome to support this level of international cooperation and large-scale network expansion (Bertsch et al. 2017; Palle 2021).

Status of electricity transmission technology. Long-distance electricity transmission technologies are already available. High voltage alternating current (HVAC), high-voltage direct current (HVDC), and ultra HVDC (UHVDC) technologies are well-established and widely used for bulk electricity transmission (Alassi et al. 2019). HVDC is used with underground cables or long-distance overhead lines (typically voltages between 100–800 kV) (Alassi et al. 2019) where HVAC is infeasible or not economic. A project development agreement, worth approximately USD17 billion, was signed in January

2021 that would connect 10 GW of PVs in the north of Australia via a 4500 km 3 GW HVDC cable to Singapore, suggesting that this would be cost effective (Sun Cable 2021). In September 2019, the Changji-Guquan $\pm 1,100$ kV UHVDC transmission project built by State Grid Corporation of China was officially completed and put into operation. The transmission line is able to transmit up to 12 GW over 3341 km (Pei et al. 2020). This is the UHVDC transmission project with the highest voltage level, the largest transmission capacity, and the longest transmission distance in the world (Liu 2015).

Other technologies that could expand the size of transmission corridors and/or improve the operational characteristics include low-frequency AC transmission (LFAC) (Y. Tang et al. 2021; Xiang et al. 2021) and half-wave AC transmission (HWACT) (Song et al. 2018; Xu et al. 2019). LFAC is technically feasible, but the circumstances in which it is the best economic choice compared to HVDC or HVAC still needs to be established (Xiang et al. 2016). HWACT is restricted to very long distances, and it has not been demonstrated in practice, so its feasibility is unproven. There are still a number of technological challenges for long-distance transmission networks such as protection systems for DC or hybrid AC-DC networks (Chaffey 2016; Franck C. et al. 2017), improvement in cabling technology, and including the use of superconductors and nanocomposites (Ballarino et al. 2016; Doukas 2019), which require advanced solutions.

Challenges, barriers, and recommendations. The main challenge to inter-regional transmission is the absence of appropriate market designs and regulatory and policy frameworks. In addition, there are commercial barriers for further enhancement of cross-border transmission. The differing impacts of cross-border interconnections on costs and revenues for generation companies in different regions could delay the development of these interconnectors. It is not yet clear how the investment cost of interconnections should be allocated and recovered, although there is growing support for allocating costs in accordance with the benefits delivered to the market participants. Increased cross-border interconnection may also require new business models which provide incentives for investment and efficient operation, manage risks and uncertainties, and facilitate coordinated planning and governance (Poudineh and Rubino 2017).

Optimising the design and operation of the interconnected transmission system, both onshore and offshore grids, also requires more integrated economic and reliability approaches (Moreno et al. 2012) to ensure the optimal balance between the economics and the provision of system security while maximising the benefits of smart network technologies.

A wide range of factors, including generation profiles, demand profiles circuit losses, reliability characteristics, and maintenance, as well as the uncertainties around them will need to be considered in designing and operating long-distance transmission systems if they are to be widely deployed (Djapic et al. 2008; Du 2009; De Sa and Al Zubaidy 2011; E3G 2021). Public support for extending transmission systems will also be crucial, and studies indicate that such support is frequently low (Vince 2010; Perlaviciute et al. 2018).

6.4.6 Demand-side Mitigation Options from an Energy Systems Perspective

Demand-side measures are fundamental to an integrated approach to low-carbon energy systems (*high confidence*). Mitigation options, such as wind parks, CCS, and nuclear power plants, may not be implemented when actors oppose these options. Further, end users, including consumers, governments, businesses and industry, would need to adopt the relevant options, and then use these as intended; user adoption can be a key driver to scale up markets for low-carbon technologies. This section discusses which factors shape the likelihood that end users engage in relevant mitigation actions, focusing on consumers; strategies to promote mitigation actions are discussed in Section 6.7.6.1.

A wide range of actions of end users would reduce carbon emissions in energy systems (Abrahamse et al. 2007; Dietz 2013; Hackmann et al. 2014; Creutzig et al. 2018; Grubler et al. 2018), including:

- use of low-carbon energy sources and carriers. Actors can produce and use their own renewable energy (e.g., install solar PV, solar water heaters, heat pumps), buy shares in a renewable energy project (e.g., wind shares), or select a renewable energy provider.
- adoption of technologies that support flexibility in energy use and sector coupling, thereby providing flexibility services by balancing demand and renewable energy supply. This would reduce the need to use fossil fuels to meet demand when renewable energy production is low and put less pressure on deployment of low-emission energy supply systems. Examples are technologies to store energy (e.g., batteries and EVs) or that automatically shift appliances on or off (e.g., fridges, washing machines).
- adoption of energy-efficient appliances and systems and increase of resource efficiency of end uses so that less energy is required to provide the same service. Examples are insulating buildings, and passive or energy-positive buildings.
- change behaviour to reduce overall energy demand or to match energy demand to available energy supplies. Examples include adjusting indoor temperature settings, reducing showering time, reducing car use or flying, and operating appliances when renewable energy production is high.
- purchase and use products and services that are associated with low GHG emissions during their production (e.g., reduce dairy and meat consumption) or for transporting products (e.g., local products). Also, end users can engage in behaviour supporting a circular economy, by reducing waste (e.g., of food), sharing products (e.g., cars, equipment), and refurbishing products (e.g., repair rather than buying new products) so that fewer new products are used.

Various factors shape whether such mitigation actions are feasible and considered by end users, including contextual factors, individual abilities, and motivational factors. Mitigation actions can be facilitated and encouraged by targeting relevant barriers and enablers (Section 6.7.6.1).

Contextual factors, such as physical and climate conditions, infrastructure, available technology, regulations, institutions, culture, and financial conditions define the costs and benefits of mitigation

options that enable or inhibit their adoption (*high confidence*). Geographic location and climate factors may make some technologies, such as solar PV or solar water heaters, impractical (Chang et al. 2009). Culture can inhibit efficient use of home heating or PV (Sovacool and Griffiths 2020), low-carbon diets (Dubois et al. 2019), and advanced fuel choices (Van Der Kroon et al. 2013). Also, favourable financial conditions promote the uptake of PV (Wolske and Stern 2018), good facilities increase recycling (Geiger et al. 2019), and vegetarian meal sales increase when more vegetarian options are offered.

Mitigation actions are more likely when individuals feel capable to adopt them (Pisano and Lubell 2017; Geiger et al. 2019), which may depend on income and knowledge. Low-income groups may lack resources to invest in refurbishments and energy-efficient technology with high upfront costs (Chang et al. 2009; Andrews-Speed and Ma 2016; Wolske and Stern 2018). Yet, higher-income groups can afford more carbon-intensive lifestyles (Golley and Meng 2012; Frederiks et al. 2015; Wiedenhofer et al. 2017; Namazkhan et al. 2019; Santillán Vera and de la Vega Navarro 2019; Mi et al. 2020). Knowledge of the causes and consequences of climate change and of ways to reduce GHG emissions is not always accurate, but lack of knowledge is not a main barrier to mitigation actions (Boudet 2019).

Motivation to engage in mitigation action, reflecting individuals' reasons for actions, depends on general goals that people strive for in their life (i.e., values). People who strongly value protecting the environment and other people are more likely to consider climate impacts and to engage in a wide range of mitigation actions than those who strongly value individual consequences of actions, such as pleasure and money (Taylor et al. 2014; Steg 2016). Values affect which types of costs and benefits people consider and prioritise when making choices, including individual, affective, social, and environmental costs and benefits (Gowdy 2008; Steg 2016).

First, people are more likely to engage in mitigation behaviour (i.e., energy savings, energy efficiency, resource efficiency in buildings, low-carbon energy generation) when they believe such behaviour has more individual benefits than costs (Harland et al. 1999; Steg and Vlek 2009; Kastner and Stern 2015; Korcaj et al. 2015; Kardooni et al. 2016; Kastner and Matthies 2016; Wolske et al. 2017), including financial benefits, convenience, comfort, autonomy, and independence in energy supply (Wolske and Stern 2018). Yet, financial consequences seem less important for decisions to invest in energy-efficiency and renewable energy production than people indicate (Zhao et al. 2012).

Second, people are less likely to engage in mitigation behaviours that are unpleasurable or inconvenient (Steg 2016), and more likely to do so when they expect to derive positive feelings from such actions (Smith et al. 1994; Pelletier et al. 1998; Steg 2005; Carrus et al. 2008; Brosch et al. 2014; Taufik et al. 2016). Positive feelings may be elicited when behaviour is pleasurable, but also when it is perceived as meaningful (Bolderdijk et al. 2013; Taufik et al. 2015).

Third, social costs and benefits can affect climate action (Farrow et al. 2017), although people do not always recognise this (Nolan et al. 2008; Noppers et al. 2014). People engage more in mitigation actions when they think others expect them to do so and when others act as well

(Harland et al. 1999; Nolan et al. 2008; Rai et al. 2016). Being part of a group that advocates mitigation encourages such actions (Biddau et al. 2016; Fielding and Hornsey 2016; Jans et al. 2018). Talking with peers can reduce uncertainties and confirm benefits about adoption of renewable energy technology (Palm 2017), and peers can provide social support (Wolske et al. 2017). People may engage in mitigation actions when they think this would signal something positive about them (Milinski et al. 2006; Griskevicius et al. 2010; Noppers et al. 2014; Kastner and Stern 2015). Social influence can also originate from political and business leaders (Bouman and Steg 2019); GHG emissions are lower when legislators have strong environmental records (Jensen and Spoon 2011; Dietz et al. 2015).

Fourth, mitigation actions, including saving energy and hot water, limiting meat consumption, and investing in energy efficiency, resource efficiency in buildings, and renewable energy generation are more likely when people care more strongly about others and the environment (Steg et al. 2015; Van Der Werff and Steg 2015; Wolske et al. 2017). People across the world generally strongly value the environment (Steg 2016; Bouman and Steg 2019), suggesting that they are motivated to mitigate climate change. The more individuals are aware of the climate impact of their behaviour, the more they think their actions can help reduce such impacts, which strengthens

their moral norms to act accordingly, and promotes mitigation actions (Steg and de Groot 2010; Jakovcevic and Steg 2013; Chen 2015; Wolske et al. 2017).

Initial mitigation actions can encourage engagement in other mitigation actions when people experience that such actions are easy and effective (Lauren et al. 2016), and when initial actions make them realise they are a pro-environmental person, motivating them to engage in more mitigation actions so as to be consistent (van der Werff et al. 2014; Lacasse 2015, 2016; Peters et al. 2018). This implies it would be important to create conditions that make it likely that initial mitigation actions motivate further actions.

6.4.7 Summary of Mitigation Options

Designing feasible, desirable, and cost-effective energy sector mitigation strategies requires comparison between the different mitigation options. One such metric is the cost of delivering one unit of energy, for example, the levelised cost, or USD MWh⁻¹, of electricity produced from different sources. Levelised costs of electricity (LCOE) are useful because they normalise the costs per unit of service provided. While useful in characterising options in broad strokes,

Figure 6.18 | Range of LCOE (in USD kWh⁻¹) from recent studies for different electricity-generating technologies circa 2020 and in the future between 2020–2040. LCOEs are primarily taken from recent studies, because the costs of some technologies are changing rapidly. To make the figure more tractable across the studies, we highlight the data from IEA WEO 2020 STEPS scenario in yellow (IEA 2020), the EIA AEO 2021 in light blue (EIA 2021), NREL ATB 2021 in brown, (NREL 2021), and IRENA's 2020 Renewable Power Generation Costs in dark blue (IRENA 2021). All other studies are shown in light grey markers. Marker shapes identify the regions included in the studies. Studies that included several regions are labelled as global. Only sources that provided LCOEs are included. Ranges for studies frequently reflect variations among regional estimates. Studies that are shown as a mid-point and a solid line represent studies that reported either a median or an average, and that had either a confidence interval or a minimum and a maximum reported. Dashed lines with markers at the end represent the range of values reported in studies that had several point estimates for either different regions or used different assumptions. All estimates were converted to USD2020. The publication year was used if no USD year was provided. Some studies included transmissions costs, and some of the CCS studies included storage and sequestration costs, while others did not. Vertical axis is capped at USD2020 0.30 kWh⁻¹, but some estimates for hydro, geothermal, natural gas and bioelectricity were higher than 0.30. The grey horizontal band denotes the range of fossil fuel electricity LCOEs circa 2020.

Table 6.9 | Examples of cost of mitigation for selected electricity options. Results represent variations in mitigation options and displaced fossil generation. LCOEs are illustrative, but consistent with recent estimates. Negative values mean that the mitigation option is cheaper than the displaced option, irrespective of emissions benefits. NGCC: natural gas combined cycle.

		Baseline			
		New coal	Existing coal	New NGCC	Existing NGCC
	Baseline emissions rate (tCO ₂ MWh ⁻¹)	0.8	0.9	0.34	0.42
	LCOEs (USD2020 kWh ⁻¹)	0.065	0.041	0.044	0.028
Utility scale solar PV (poor resource site)	0.100	USD44 tCO ₂ -eq ⁻¹	USD66 tCO ₂ -eq ⁻¹	USD165 tCO ₂ -eq ⁻¹	USD171 tCO ₂ -eq ⁻¹
Utility scale solar PV (good resource site)	0.035	-38 USD tCO ₂ -eq ⁻¹	-7 USD tCO ₂ -eq ⁻¹	-26 USD tCO ₂ -eq ⁻¹	USD17 tCO ₂ -eq ⁻¹

it is important to acknowledge and understand several caveats associated with these metrics, particularly when applied globally. They may be constructed with different discount rates; they require information on energy input costs for options that require energy inputs (e.g., fossil electricity generation, biofuels); they depend on local resource availability, for example, solar insolation for solar power, wind classes for wind power, and rainfall and streamflow for hydropower; and actual implementation costs may include additional elements, for example, the costs of managing electricity grids heavily dependent on VRE electricity sources. These complicating factors vary across regions, some depend strongly on the policy environment in which mitigation options are deployed, and some depend on how technologies are constructed and operated.

The literature provides multiple LCOE estimates for mitigation options today and in the future (see Table 6.9 for electricity generation options). LCOE ranges for low- and zero-carbon electricity technologies overlap with LCOE's of fossil generation without CCS. For example, LCOEs for utility solar and wind today and in the future overlap with those of new coal and gas without CCS (IEA WEO 2020; Lazard, 2020; NREL 2021) (Figure 6.18). Some of the overlap stems from differences in assumptions or regional conditions that apply to all technologies (e.g., variations in assumed discount rates), but the overlap also reflects the fact that low- and zero-carbon electricity generation options are, and will be, less expensive than emitting options in many regions. Future cost projections also illustrate that several technologies are anticipated to experience further cost declines over the coming decades, reinforcing the increasingly competitiveness of low- and zero-carbon electricity. For example, IEA's LCOEs estimates for offshore wind halve between 2020 and 2040 in several regions (IEA WEO 2020).

A more direct metric of mitigation options is the cost to reduce one tonne of CO₂ or equivalent GHGs, or USD tCO₂-eq⁻¹ avoided. In addition to the comparison challenges noted above, this metric must account for the costs and emissions of the emitting options that are being displaced by the low-carbon option. Assumptions about the displaced option can lead to very different mitigation cost estimates (Table 6.9). Despite these challenges, these metrics are useful for identifying broad trends and making broad comparisons, even from the global perspective in this assessment. But local information will always be critical to determine which options are most cost-effective in any specific applications.

The feasibility and desirability of mitigation options extends well beyond the market economic costs of installation and operation (Section 6.4.1). Figure 6.19 summarises the barriers and enablers for implementing different mitigation options in energy systems. The feasibility of different options can be enhanced by removing barriers and/or strengthening enablers of the implementation of the options. The feasibility of options may differ across context (e.g., region), time (e.g., 2030 versus 2050), scale (e.g., small versus large) and the long-term warming goal (e.g., 1.5°C versus 2°C).

6.5 Climate Change Impacts on the Energy System

6.5.1 Climate Impacts on the Energy System

Many components of the energy system are affected by individual weather events and climate conditions (Table 6.10). In addition, a range of compounding effects can be anticipated, as the complex, interconnected climate and energy systems are influenced by multiple weather and climate conditions. This raises the question of whether the energy system transformation needed to limit warming will be impacted by climate change.

The impacts of *climate change* on the energy system can be divided into three areas: impacts on the energy supply; impacts on energy consumption; and impacts on energy infrastructure. The rest of this section focuses on how the *future changes* in climate drivers might affect the ability of the energy system transformation needed to mitigate climate change. The discussion of energy infrastructure in this section is limited to electricity system vulnerability.

Figure 6.19 | Summary of the extent to which different factors would enable or inhibit the deployment of mitigation options in energy systems. Blue bars indicate the extent to which the indicator enables the implementation of the option (E) and orange bars indicate the extent to which an indicator is a barrier (B) to the deployment of the option, relative to the maximum possible barriers and enablers assessed. An X signifies that the indicator is not applicable or does not affect the feasibility of the option, while a forward slash indicates that there is no or limited evidence whether the indicator affects the feasibility of the option. The shading indicates the level of confidence, with darker shading signifying higher levels of confidence. Appendix II provides an overview of the factors affecting the feasibility of options and how they differ across context (e.g., region), time (e.g., 2030 versus 2050), and scale (e.g., small versus large), and includes a line of sight on which the assessment is based. The assessment method is explained in Annex II.11.

6.5.2 Impacts on Energy Supply

The increased weather dependency of future low-carbon electricity systems amplifies the possible impacts of climate change (Staffell and Pfenninger 2018). However, *globally* climate change impacts on electricity generation – including hydro, wind and solar power potentials – should not compromise climate mitigation strategies (*high confidence*). Many of the changes in the climate system will be geographically complex at the regional and local levels. Thus, *regionally* climate change impacts on electricity generation could be significant. Climate change impacts on bioenergy potentials are more uncertain because of uncertainties associated with the crop response to climate change, future water availability and crop deployment. Climate change can reduce the efficiency of thermal power generation and increase the risk of power plant shutdowns during droughts. The potential additional cooling water needs of CCS can increase these risks.

6.5.2.1 Hydropower

The impacts of climate change on hydropower will vary by region. High latitudes in the northern hemisphere are anticipated to experience increased runoff and hydropower potential. For other regions, studies find both increasing and decreasing runoff and hydropower potential. Areas with decreased runoff are anticipated to experience reduced hydropower production and increased water conflict among different economic activities (*high confidence*).

Hydropower production is directly related to the availability of water. Changes in runoff and its seasonality and changes in temperature and precipitation intensity will influence hydroelectricity production

(IHA 2019). In general, increased precipitation will increase water availability and hydropower production. Increased precipitation intensity, however, may impact on the integrity of dam structures and affect power production by increasing debris accumulation and vegetation growth. Additionally, increased precipitation intensity results in the silting of the reservoirs or increases the amount of water spilt, resulting in erosion (Schaeffer et al. 2012; IHA 2019). Climate change will likely lead to higher air temperatures, resulting in more surface evaporation, less water storage, and loss of equipment efficiency (Ebinger and Vergara 2011; Mukheibir 2013; Fluixà-Sanmartín et al. 2018; Hock et al. 2019). Climate change may alter the demands for water use by other sectors that often rely on stored water in multi-purpose reservoirs, and may therefore generate conflicts over water use. The increased need for water for irrigation and/or industry can affect the availability of water for hydropower generation (Spalding-Fecher et al. 2016; Solaun and Cerdá 2017). Higher temperatures increase glacier melt, increasing water availability for hydropower while the glaciers exist. Changes in the timing of snow and ice melt may require upgrading in storage capacity and adaptation of the hydropower plant management for fully exploiting the increase in water availability.

The conclusions regarding climate change impacts on hydropower vary due to differences in modelling assumptions and methodology, such as choice of the climate and hydrological models, choice of metrics (e.g., projected production vs hydropower potential), level of modelling details between local and global studies, reservoir operation assumptions. Also important is how hydropower production matches up with other reservoir purposes, accounting for other water and energy users, and how the competing uses are impacted by climate change (van Vliet et al. 2016b; Turner et al. 2017). Nonetheless,

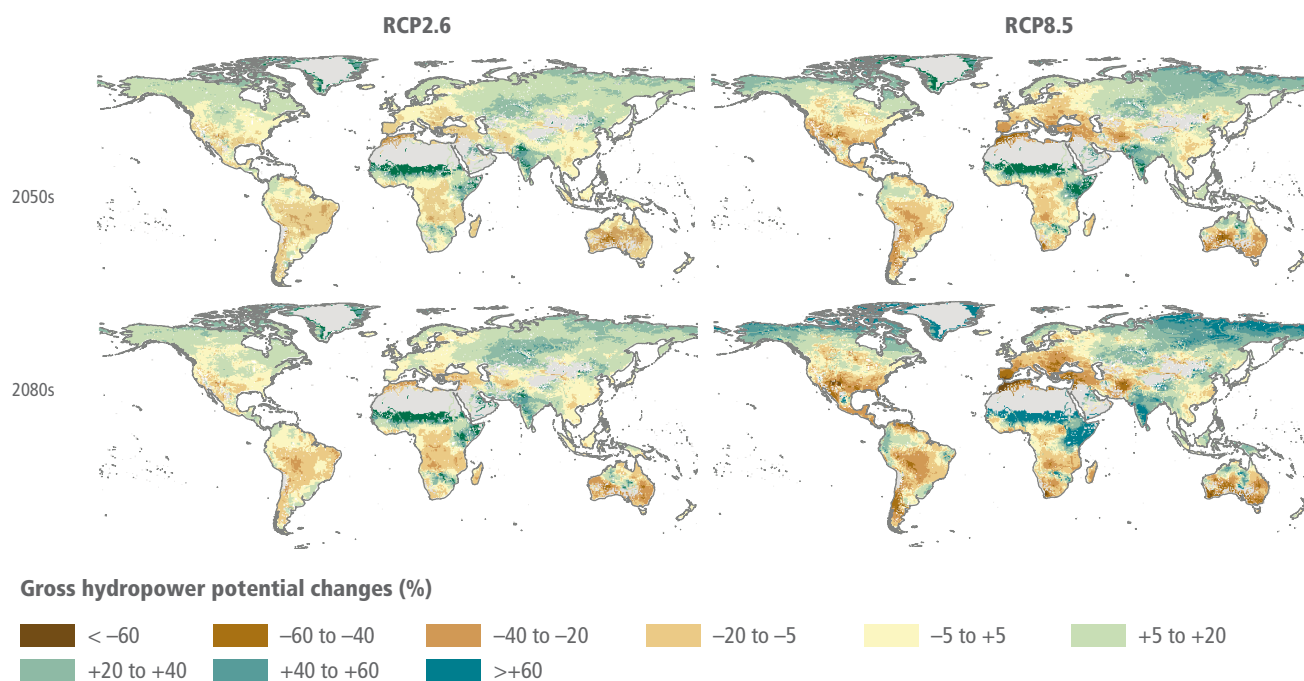

Figure 6.20 | Global spatial patterns of changes in gross hydropower potential based on climate forcing from five climate models. Changes are shown for the 2050s (upper) and the 2080s (lower) for the low-emission scenario (RCP2.6; left) and highest emission scenario (RCP8.5; right) scenarios relative to the control period (1971–2000). Source: data from van Vliet et al. (2016b).

analyses consistently demonstrate that the global impact of climate change on hydropower will be small, but the regional impacts will be larger, and will be both positive and negative (Figure 6.20). Gross global hydropower potential in the 2050s has been estimated to slightly decrease (Hamududu and Killingtveit 2012) between 0.4% (for the low-emission scenario) and 6.1% (for the highest-emission scenario) for the 2080s compared to 1971–2000 (van Vliet et al. 2016a).

Regional changes in hydropower are estimated from 5–20% increases for most areas in high latitudes (van Vliet et al. 2016b; Turner et al. 2017) to decreases of 5–20% in areas with increased drought conditions (Cronin et al. 2018). Models show a consistent increase in streamflow and hydropower production by 2080 in high latitudes of the northern hemisphere and parts of the tropics (Figure 6.20) (e.g., central Africa and southern Asia) while decreasing in the USA, southern and central Europe, Southeast Asia and southern South America, Africa and Australia (van Vliet et al. 2016c,a). Decreases in hydropower production are indicated for parts of North America, central and southern Europe, the Middle East, central Asia and Southern South America. Studies disagree on the changes in hydropower production in China, central South America, and partially in southern Africa (Hamududu and Killingtveit 2012; van Vliet et al. 2016b; Solaun and Cerdá 2019; Fan et al. 2020).

6.5.2.2 Wind Energy

Climate change will not substantially impact future wind resources and will not compromise the ability of wind energy to support low-carbon transitions (*high confidence*). Changing wind variability may have a small-to-modest impact on backup energy and storage needs (*low confidence*); however, current evidence is largely from studies focused on Europe.

Long-term global wind energy resources are not expected to substantially change in future climate scenarios (Karnauskas et al. 2018; Pryor et al. 2020; Yalew et al. 2020). However, recent research has indicated consistent shifts in the geographic position of atmospheric jets in the high-emission scenarios (Harvey et al. 2014), which would decrease wind power potentials across the Northern Hemisphere mid-latitudes and increase wind potentials across the tropics and the Southern Hemisphere. However, the climate models used to make these assessments differ in how well they can reproduce the historical wind resources and wind extremes, which raises questions about the robustness of their predictions of future wind resources (Pryor et al. 2020).

There are many regional studies on changes in wind resources from climate change. For Europe, there is medium evidence and moderate agreement that wind resources are already increasing and will continue to increase in Northern Europe and decrease in Southern Europe (Carvalho et al. 2017; Devis et al. 2018; Moemken et al. 2018). For North America, the various studies have low agreement for the changes in future wind resources in part because the year-to-year variations in wind resources are often larger than the future change due to climate change (Johnson and Erhardt 2016; Chen 2020; Costoya et al. 2020; Wang et al. 2020b). Studies show increases in future wind resources in windy areas in South America (Ruffato-

Ferreira et al. 2017; de Jong et al. 2019). No robust future changes in wind resources have been identified in China (Xiong et al. 2019). However, none of the global or regional studies of the effects of climate change on wind resources considers the fine-scale dependence of wind resources on the topography and wind direction (Sanz Rodrigo et al. 2016; Dörenkämper et al. 2020) or the effect of expanding wind energy exploitation (Volker et al. 2017; Lundquist et al. 2019). There is limited evidence that extreme wind speeds, which can damage wind turbines, will increase due to climate change (Pes et al. 2017; Pryor et al. 2020). Nevertheless, projected changes in Europe and North America – regions where the most extensive analysis has been undertaken – are expected to be within the estimates embedded in the design standards of wind turbines (Pryor and Barthelmie 2013).

Future wind generation in Europe could decrease in summer and autumn, increasing in winter in northern-central Europe but decreasing in southernmost Europe (Carvalho et al. 2017). Towards 2100, intra-annual variations increase in most of Europe, except around the Mediterranean area (Reyers et al. 2016), but this may reflect natural multi-decadal variability (Wohland et al. 2019b). Wind speeds may become more homogeneous over large geographical regions in Europe due to climate change, increasing the likelihood of large areas experiencing high or low wind speeds simultaneously (Wohland et al. 2017). These changes could result in fewer benefits in the transmission of wind generation between countries and increased system integration costs. Europe could require a modest increase (up to 7%) in backup energy towards the end of the 21st century due to more homogeneous wind conditions over Europe (Wohland et al. 2017; Weber et al. 2018). However, other studies report that the impact of climate change is substantially smaller than interannual variability, with no significant impact on the occurrence of extreme low wind production events in Europe (Van Der Wiel et al. 2019). If European electricity systems are designed to manage the effects of existing weather variability on wind power, they can likely also cope with climate change impacts on wind power (Ravestein et al. 2018). Changes in wind-generation variability caused by climate change are also reported for North America (Haupt et al. 2016; Losada Carreño et al. 2018), with modest impacts on electricity system operation (Craig et al. 2019).

6.5.2.3 Solar Energy

Climate change is not expected to substantially impact global solar insolation and will not compromise the ability of solar energy to support low-carbon transitions (*high confidence*). Models show dimming and brightening in certain regions, driven by cloud, aerosol and water vapour trends (Chapter 12 of IPCC AR6 WGI). The increase in surface temperature, which affects all regions, decreases solar power output by reducing the PV panel efficiency. In some models and climate scenarios, the increases in solar insolation are counterbalanced by reducing efficiency due to rising surface air temperatures, which increase significantly in all models and scenarios (Jerez et al. 2015; Bartók et al. 2017; Emodi et al. 2019). Increases in aerosols would reduce the solar resource available and add to maintenance costs (Chapter 12 of IPCC AR6 WGI).

In many emission scenarios, the effect on solar PV from temperature-induced efficiency losses is smaller than the effect expected from

changes on solar insolation due to variations in water vapour and clouds in most regions. Also, future PV technologies will likely have higher efficiency, which would offset temperature-related declines (Müller et al. 2019). Cloud cover is projected to decrease in the subtropics (around -0.05% per year), including parts of North America, vast parts of Europe and China, South America, South Africa and Australia (*medium agreement, medium evidence*). Thus, models project modest ($<3\%$) increases in solar PV by the end of the century for southern Europe, northern and southern Africa, Central America, and the Caribbean (Emodi et al. 2019). There are several studies projecting decreasing solar production, but these are generally influenced by other factors, for example, increasing air pollution (Ruosteenoja et al. 2019). The multi-model means for solar insolation in regional models decrease 0.60 W m^{-2} per decade from 2006 to 2100 over most of Europe (Bartók et al. 2017), with the most significant decreases in the Northern countries (Jerez et al. 2015).

6.5.2.4 Bioenergy

Climate change can affect biomass resource potential directly, via changes in the suitable range (i.e., the area where bioenergy crops can grow) and/or changes in yield, and indirectly, through changes in land availability. Increases in CO_2 concentration increase biomass yield; climate changes (e.g., temperature, precipitation, and so on) can either increase or decrease the yield and suitable range.

Climate change will shift the suitable range for bioenergy towards higher latitudes, but the net change in the total suitable area is uncertain (*high confidence*). Several studies show northward shifts in the suitable range for bioenergy in the northern hemisphere (Tuck et al. 2006; Barney and DiTomaso 2010; Bellarby et al. 2010; Hager et al. 2014; Wang et al. 2014a; Preston et al. 2016; Conant et al. 2018; Cronin et al. 2018), but the net effect of climate change on total suitable area varies by region, species, and climate model (Barney and DiTomaso 2010; Hager et al. 2014; Wang et al. 2014a).

The effect of climate change on bioenergy crop yields will vary across region and feedstock (*high confidence*); however, in general, yields will decline in low latitudes (*medium confidence*) and increase in high latitudes (*low confidence*) (Haberl et al. 2010; Cosentino et al. 2012; Preston et al. 2016; Cronin et al. 2018; Mbow et al. 2019). However, the average change in yield varies significantly across studies, depending on the feedstock, region, and other factors (Beringer et al. 2011; Kyle et al. 2014; Mbow et al. 2019; Dolan et al. 2020). Only a few studies extend the modelling of climate change impacts on bioenergy to quantify the effect on bioenergy deployment or its implications on the energy system (Calvin et al. 2013, 2019; Kyle et al. 2014; Thornton et al. 2017). These studies find that changes in deployment are of the same sign as changes in yield; that is, if yields increase, then deployment increases.

Some of the uncertainty in the sign and magnitude of the impacts of climate change on bioenergy potential is due to uncertainties in CO_2 fertilisation (the increase in photosynthesis due to increases in atmospheric CO_2 concentration) (Haberl et al. 2011; Bonjean Stanton et al. 2016; Cronin et al. 2018; Solaun and Cerdá 2019; Yalaw et al. 2020). For example, earlier studies found that, without CO_2 fertilisation,

climate change will reduce global bioenergy potential by about 16%; with CO_2 fertilisation, however, climate change increases this potential by 45% (Haberl et al. 2011). However, newer studies in the USA find little effect of CO_2 fertilisation on switchgrass yield (Dolan et al. 2020). There is also a considerable uncertainty across climate and crop models in estimating bioenergy potential (Hager et al. 2014).

6.5.2.5 Thermal Power Plants

The operation of thermal power plants will be affected by climate change, deriving from changes in the ambient conditions like temperature, humidity and water availability (Schaeffer et al. 2012) (*high confidence*). Changes in ambient temperature have relatively small impacts on coal-fired and nuclear power plants (Rankine cycle); however, gas-fired power plants (Brayton or combined-cycle) may have their thermal efficiency and power output significantly decreased (De Sa and Al Zubaidy 2011; Schaeffer et al. 2012). Droughts decrease potential cooling water for thermal power plants and increase the probability of water outlet temperatures exceeding regulatory limits, leading to lower production or shutdowns. Thermal power utilisation has been reported to be, on average, 3.8% lower during drought years globally (van Vliet et al. 2016c), and further significant decreases in available thermal power plant capacity due to climate change are projected (Koch et al. 2014; van Vliet et al. 2016b; Yalaw et al. 2020). An increase in climate-related nuclear power disruptions has been reported in the past decades globally (Ahmad 2021).

Carbon capture may increase cooling water usage significantly, especially in retrofits, with up to 50% increase in water usage for coal-fired power plants globally, depending on the CCS technology (Rosa et al. 2020) (Section 6.4). In Asia, planned coal capacity is expected to be vulnerable to droughts, sea level rise, and rising air temperatures, and this may be exacerbated by incorporating carbon capture (Wang et al. 2019c). Recently, however, studies have proposed designs of CCS with a minimal increase in water requirements (Magneschi et al. 2017; Mikunda et al. 2021).

Older thermal power plants can be retrofitted to mitigate climate impacts by altering and redesigning the cooling systems (Westlén 2018), although the costs for these solutions may be high. For example, dry cooling may be used instead of once-through cooling; however, it lowers thermal efficiency and would leave plants vulnerable to ambient temperature increase (Ahmad 2021). Closed-circuit cooling is much less sensitive to water temperature than once-through cooling (Bonjean Stanton et al. 2016). Modifying policies and regulation of water and heat emissions from power plants may also be used to mitigate plant reliability problems induced by climate change (Eisenack 2016; Mu et al. 2020), albeit with potential impacts for other water users and ecology. Improvements in water use and thermal efficiencies and the use of transmission capabilities over large geographical regions to mitigate risks on individual plants are also possible mitigation options (Miara et al. 2017).

6.5.3 Impacts on Energy Consumption

Heating demand will decrease, and cooling demand will increase in response to climate change. Peak load may increase more than energy consumption, and the changing spatial and temporal load patterns can impact transmission and needs for storage, demand-side management, and peak-generating capacity (*high confidence*).

Climate change will decrease heating demands, especially in cold regions, and it will increase cooling demands, especially in warm regions (Yalew et al. 2020). Recent studies report significant net impacts, with the commercial and industrial sectors and substantial air condition penetration driving an increase in energy demand (Davis and Gertler 2015; Levesque et al. 2018; De Cian and Sue Wing 2019; van Ruijven et al. 2019; Yalew et al. 2020). For example, globally, De Cian and Sue Wing (2019) found a 7–17% increase in energy consumption due to climate change in 2050, with the range depending on the climate change scenario. The overall effects of climate change on building energy consumption are regionally dependent. For example, Zhang et al. (2019) find that reduced heating will outweigh increased cooling in the residential buildings in Europe, but the reverse will be true in China.

While many studies have focused on energy consumption, climate extremes are expected to alter peak energy demands, with the potential for blackouts, brownouts, and other short-term energy system impacts (Yalew et al. 2020). For example, peak energy demand during heatwaves can coincide with reduced transmission and distribution capacity at higher temperatures. In large cities, extreme heat events increase cooling degree days significantly, with the urban heat island effect compounding the impact (Morakinyo et al. 2019). One study found that total electricity consumption at the end of the century in the USA could increase on average by 20% during summer months and decrease on average by 6% in the winter (Ralston Fonseca et al. 2019). While the average increase in consumption is modest, climate change is projected to have severe impacts on the frequency and intensity of peak electricity loads (Auffhammer et al. 2017). Bartos et al. (2016) find that peak per-capita summertime load in the USA may rise by 4.2–15% by mid-century. Efficient cooling technologies and other demand-side measures can limit cooling energy loads during periods of particularly high demand (IEA 2018; Dreyfus et al. 2020).

Box 6.6 | Energy Resilience

In February 2021, the state of Texas was hit by three major storms and suffered significant scale power outages. More than 4.5 million homes and businesses on the Texas electric grid were left without electricity for days, limiting the ability to heat homes during dangerously low temperatures and leading to food and clean water shortages (Busby et al. 2021). The Texas and other events – for example, Typhoon Haiyan in Southeast Asia in 2013; the Australian bush fires in 2019–2020; forest fires in 2018 in California; water shortages in Cape Town, South Africa in 2018 and the western USA during 2021 – raise the question of whether future low-carbon energy systems will be more or less resilient than those of today.

Some characteristics of low-carbon energy systems will make them less resilient. Droughts reduce hydroelectric electricity generation (Gleick 2016; van Vliet et al. 2016c); wind farms do not produce electricity in calm conditions or shut down in very strong winds (Petersen and Troen 2012); solar PV generation is reduced by clouds and is less efficient under extreme heat, dust storms, and wildfires (Perry and Troccoli 2015; Jackson and Gunda 2021). In addition, the electrification of heating will increase the weather dependence of electricity consumption (Staffell and Pfenninger 2018; Gea-Bermúdez et al. 2021). Non-renewable generation, for example, from nuclear and fossil power plants, are also vulnerable to high temperatures and droughts as they depend on water for cooling (Cronin et al. 2018; Ahmad 2021).

But some aspects of low-carbon energy systems will make them more resilient. Wind and solar farms are often spread geographically, which reduces the chances of being affected by the same extreme weather event (Perera et al. 2020). The diversification of energy sources, in which each component has different vulnerabilities, increases resilience. Less reliance on thermal electricity generation technologies will reduce the risks of curtailment or efficiency losses from droughts and heat waves (Lohrmann et al. 2019). More generally, increased electricity system integration and flexibility (Section 6.4.3) and weatherisation of generators increases electricity system resilience (Busby et al. 2021; Heffron et al. 2021). Likewise, local district micro-grids with appropriate enabling technologies (e.g., distributed generation, energy storage, greater demand-side participation, electric vehicles) may ensure access to electricity during major long-duration power outage events and radically enhance the resilience of supply of essential demand (Stout et al. 2019).

6.5.4 Impacts on Electricity System Vulnerability

While long-term trends are important for electricity system planning, short-term effects associated with loss of power can be disruptive and lead to significant economic losses along with cascading impacts on health and safety. Extreme weather and storms threaten the electricity system in different ways, affecting system resilience, reliability, and adequacy (Moreno-Mateos et al. 2020). The implications of climate change for electricity system vulnerability will depend on the degree to which climate change alters the frequency and intensity of extreme weather events. The complex compounding effects of simultaneous events (e.g., high winds and lightning occurring at the same time) are not well understood.

High wind speeds can shear lines through mechanical failure or cause lines to collide, causing transient events (Panteli and Mancarella 2015; Yalew et al. 2020). Hurricane conditions can damage electricity system infrastructures, including utility-scale wind and solar PV plants. Electricity systems may experience high demand when lines are particularly at risk from mechanical failure from wind and storm-related effects. However, except for medium evidence of increases in heavy precipitation associated with tropical cyclones, there is limited evidence that extreme wind events will increase in frequency or intensity in the future (Kumar et al. 2015; Pryor et al. 2020).

Wildfires pose a significant threat to electricity systems in dry conditions and arid regions (Dian et al. 2019). With climate change, wildfires will probably become more frequent (Flannigan et al. 2013) and more difficult to address, given that they frequently coincide with dry air and can be exacerbated by high winds (Mitchell 2013).

Lightning can cause wildfires or common-mode faults on electricity systems associated with vegetation falling on power substations or overhead lines but is more generally associated with flashovers and overloads (Baliyepalli et al. 2005). Climate change may change the probability of lightning-related events (Romps et al. 2014).

Snow and icing can impact overhead power lines by weighing them down beyond their mechanical limits, leading to collapse and cascading outages (Feng et al. 2015). Snow can also lead to flashovers on lines due to wet snow accumulation on insulators (Yaji et al. 2014; Croce et al. 2018) and snow and ice can impact wind turbines (Davis et al. 2016). Climate change will lower the risk of snow and ice conditions (McColl et al. 2012), but there is still an underlying risk of sporadic acute cold conditions such as those associated with the winter storms in Texas in 2021 (Box 6.6).

Flooding poses a threat to the transmission and distribution systems by inundating low-lying substations and underground cables. Coastal flooding also poses a threat to electricity system infrastructure. Rising sea levels from climate change and associated storm surge may also pose a significant risk for coastal electricity systems (Enriken and Lordan 2012).

Temperature increases influence electricity load profiles and electricity generation, as well as potentially impact supporting information and communication infrastructure. Heat can pose direct impacts to electricity system equipment such as transformers. Referred to as ‘solar heat faults’, they occur under high temperatures and low wind speeds and can be exacerbated by the urban heat island effect (McColl et al. 2012). Increasing temperatures affect system adequacy by reducing electric transmission capacity, simultaneously increasing peak load due to increased air conditioning needs (Bartos et al. 2016).

Box 6.7 | Impacts of Renewable Energy Production on Climate

While climate change will affect energy systems (Section 6.5), the reverse is potentially also true: increasing the use of renewable energy sources could affect local climate. Large solar PV arrays and hydroelectric dams darken the land surface, and wind turbines extract the wind’s kinetic energy near the Earth’s surface. Their environmental impacts of renewable energy production are mostly confined to areas close to the production sources and have been shown to be trivial compared to the mitigation benefits of renewable energy (*high confidence*).

Solar energy. Observations and model simulations have addressed whether large-scale solar PV power plants can alter the local and regional climate. In rural areas at the local scale, large-scale solar PV farms change the surface characteristics and affect air temperatures (Taha 2013). Measurements in rural Arizona, USA show local night-time temperatures 3°C–4°C warmer at the PV farm than surroundings (Barron-Gafford et al. 2016). In contrast, measurements in urban settings show that solar PV panels on roofs provide a cooling effect (Taha 2013; Ma et al. 2017). On the regional scale, modelling studies suggest cooling in urban areas (0.11–0.53°C) and warming in rural areas (up to 0.27°C) (Millstein and Menon 2011). Global climate model simulations show that solar panels induce regional cooling by converting part of the incoming solar energy to electricity (Hu et al. 2016). However, converting the generated electricity to heat in urban areas increases regional and local temperatures, compensating for the cooling effect.

Wind energy. Surface temperature changes in the vicinity of wind farms have been detected (Smith et al. 2013; Lee and Lundquist 2017; Takle et al. 2019; Xia et al. 2019) in the form of night-time warming. Data from field campaigns suggest that a ‘suppression of cooling’ can explain the observed warming (Takle et al. 2019). Regional and climate models have been used to describe the interactions between turbines and the atmosphere and find minor impacts (Vautard et al. 2014). More sophisticated models confirm the local warming effect of wind farms but report that the impact on the regional area is slight and occasional (Wang et al. 2019d). Wind turbines alter the transport and dissipation of momentum near the surface but do not directly impact the Earth’s energy balance

Box 6.7 (continued)

(Fischereit et al. 2021). However, the secondary modifications to the energy and water exchanges have added implications for the climate system (Jacobson and Archer 2012).

Hydropower. The potential climate impacts of hydropower concentrate on the GHG emissions from organic matter decomposition when the carbon cycle is altered by the flooding of the hydroelectric power plant reservoir (Ocko and Hamburg 2019), but emissions from organic matter decomposition decrease over time. The darker surface of the reservoir, compared to the lighter surrounding land may counterbalance part of the reduced GHG emissions by hydropower production (Wohlfahrt et al. 2021). However, these impacts vary significantly among facilities due to the surrounding land properties and the area inundated by the reservoir.

6.6 Key Characteristics of Net-zero Energy Systems

6.6.1 What is a Net-zero Energy System?

Limiting warming to well below 2°C requires that CO₂ emissions from the energy sector be reduced to near zero or even below zero (Section 6.7; Chapter 3). Policies, technologies, behaviours, investments, and other factors will determine the speed at which countries transition to net-zero energy systems – those that emit very little or no emissions. An understanding of these future energy systems can help to chart a course toward them over the coming decades.

This section synthesises current understanding of net-zero energy systems. Discussions surrounding efforts to limit warming are frequently communicated in terms of the point in time at which net anthropogenic CO₂ emissions reach zero, accompanied by substantial reductions in non-CO₂ emissions (IPCC 2018, Chapter 3). Net-zero GHG goals are also common, and they require net-negative CO₂ emissions to compensate for residual non-CO₂ emissions. Economy-wide CO₂ and GHG goals appear in many government and corporate decarbonisation strategies, and they are used in a variety of ways. Most existing carbon-neutrality commitments from countries and sub-national jurisdictions aim for economies with very low emissions rather than zero emissions. Offsets, carbon dioxide removal (CDR) methods, and/or land sink assumptions are used to achieve net-zero goals (Kelly Levin et al. 2020).

Figure 6.21 | Residual emissions and carbon dioxide removal (CDR) when global energy and industrial CO₂ emissions reach net-zero. Residual emissions and CDR in net-zero scenarios from the AR6 Scenarios Database show global differences across warming levels (light blue = scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot and scenarios that return warming to 1.5°C (>50%) after a high overshoot; yellow = scenarios that limit warming to 2°C (>67%) and scenarios that limit warming to 2°C (>50%); dark blue = scenarios that limit warming to 2.5°C (>50%), scenarios that limit warming to 3°C (>50%), scenarios that limit warming to 4°C (>50%), and scenarios that exceed warming of 4°C (≥50%)). In each case, the boxes show the 25th to 75th percentile ranges, and whiskers show the 5th and 95th percentiles. Lines and circles within the boxes denote the median and mean values, respectively.

Precisely describing a net-zero energy system is complicated by the fact that different scenarios attribute different future CO₂ emissions to the energy system, even under scenarios where economy-wide CO₂ emissions reach net zero. It is also complicated by the dependence of energy system configurations on unknown future conditions such as population and economic growth, and technological change. The energy system is not the only source or sink of CO₂ emissions. Terrestrial systems may store or emit carbon, and CDR options like BECCS or DACCS can be used to store CO₂, relieving pressure on the energy system (Chapter 3). The location of such CDR options is ambiguous, as it might be deployed within or outside of the energy sector (Figure 6.21), and many CDR options, such as DACCS, would be important energy consumers (Bistline and Blanford 2021a) (Section 6.6.2). If CDR methods are deployed outside of the energy system (e.g., net negative agriculture, forestry, and land-use CO₂ emissions), it is possible for the energy system to still emit CO₂ but have economy-wide emissions of zero or below. When global energy and industrial CO₂ emissions reach net zero, the space remaining for fossil energy emissions is determined by deployment of CDR options (Figure 6.21).

This section focuses on energy systems that produce very little or no CO₂ emissions, referred to in this chapter as 'net-zero energy systems'. While energy systems may not reach net zero concurrently with economy-wide CO₂ or GHG emissions, they are a useful benchmark for planning a path to net zero. Note that the focus here is on energy systems with net-zero CO₂ emissions from fossil fuel combustion and industrial processes, but the lessons will be broadly applicable to net-zero GHG energy systems as well. Net-zero GHG energy systems would incorporate the major efforts made to reduce non-CO₂ emissions (e.g., CH₄ from oil, gas and coal as discussed in Section 6.4) and would also need to incorporate more CDR to compensate for remaining non-CO₂ GHG emissions. Energy sector emissions in many countries may not reach net zero at the same time as global energy system emissions (Figure 6.25 and Cross-Chapter Box 3 in Chapter 3).

6.6.2 Configurations of Net-zero Energy Systems

Net-zero energy systems entail trade-offs across economic, environmental, and social dimensions (Davis et al. 2018). Many socio-economic, policy, and market uncertainties will also influence the configuration of net-zero energy systems (Smith et al. 2015; van Vuuren et al. 2018; Bistline et al. 2019; Krey et al. 2019; Azevedo et al. 2021; Pye et al. 2021). There are reasons that countries might focus on one system configuration versus another, including cost, resource endowments, related industrial bases, existing infrastructure, geography, governance, public acceptance, and other policy priorities (Section 6.6.4 and Chapter 18 of WGII).

Explorations of net-zero energy systems have been emerging in the detailed systems modelling literature (Azevedo et al. 2021; Bistline 2021b). Reports associated with net-zero economy-wide targets for countries and sub-national entities typically do not provide detailed roadmaps or modelling but discuss high-level guiding principles, though more detailed studies are emerging at national levels (Capros et al. 2019; Wei et al. 2020; Duan et al. 2021; Williams et al. 2021a). Most analysis has focused on identifying potential decarbonisation technologies and

pathways for different sectors, enumerating opportunities and barriers for each, their costs, highlighting robust insights, and characterising key uncertainties (Davis et al. 2018; Hepburn et al. 2019).

The literature on the configuration of net-zero energy systems is limited in a few respects. On the one hand, there is a robust integrated assessment literature that provides characterisations of these systems in broad strokes (the AR6 database), offering internally consistent global scenarios to link global warming targets to regional/national goals. All integrated assessment scenarios that discuss net-zero energy system CO₂ emissions provide high-level characterisations of net-zero systems. Because these characterisations have less temporal, spatial, technological, regulatory, and societal detail, however, they may not consider the complexities that could ultimately influence regional, national, or local pathways. High-fidelity models and analyses are needed to assess the economic and environmental characteristics and the feasibility of many aspects of net-zero or net-negative emissions energy systems (*high confidence*) (Blanford et al. 2018; Bistline and Blanford 2020). For example, evaluating the competitiveness of electricity sector technologies requires temporal, spatial, and technological detail to accurately represent system investments and operations (Collins et al. 2017; Santen et al. 2017; Helistoe et al. 2019; Bistline 2021c; Victoria et al. 2021).

Configurations of net-zero energy systems will vary by region but are likely to share several common characteristics (*high confidence*) (Figure 6.22). We focus on seven of those common characteristics in the remainder of this subsection.

6.6.2.1 Limited and/or Targeted Use of Fossil Fuels

Net-zero energy systems will use far less fossil fuel than today (*high confidence*). The precise quantity of fossil fuels will largely depend on the relative costs of such fuels, electrification, alternative fuels, and CDR (Section 6.6.2.4) in the energy system (*high confidence*). All of these are affected by regional differences in resources (McGlade and Ekins 2015), existing energy infrastructure (Tong et al. 2019), demand for energy services, and climate and energy policies. Fossil fuel use may persist, for example, if and where the costs of such fuels and the compensating carbon management (e.g., CDR, CCS) are less than non-fossil energy. For most applications, however, it is likely that electrification (McCollum et al. 2014; Madeddu et al. 2020; Zhang and Fujimori 2020) or use of non-fossil alternative fuels (Zeman and Keith 2008; Graves et al. 2011; Hänggi et al. 2019; Ueckerdt et al. 2021) will prove to be the cheapest options. Most residual demand for fossil fuels is likely to predominantly be petroleum and natural gas given their high energy density (Davis et al. 2018), while demand for coal in net-zero energy systems is likely to be very low (Luderer et al. 2018; Jakob et al. 2020, Section 6.7.4) (*high confidence*).

There is considerable flexibility regarding the overall quantity of liquid and gaseous fuels that will be required in net-zero energy systems (*high confidence*) (Figure 6.22 and Section 6.7.4). This will be determined by the relative value of such fuels as compared to systems which rely more or less heavily on zero-emissions electricity. In turn, the share of any fuels that are fossil or fossil-derived is uncertain and will depend on the feasibility of CCS and CDR technologies and

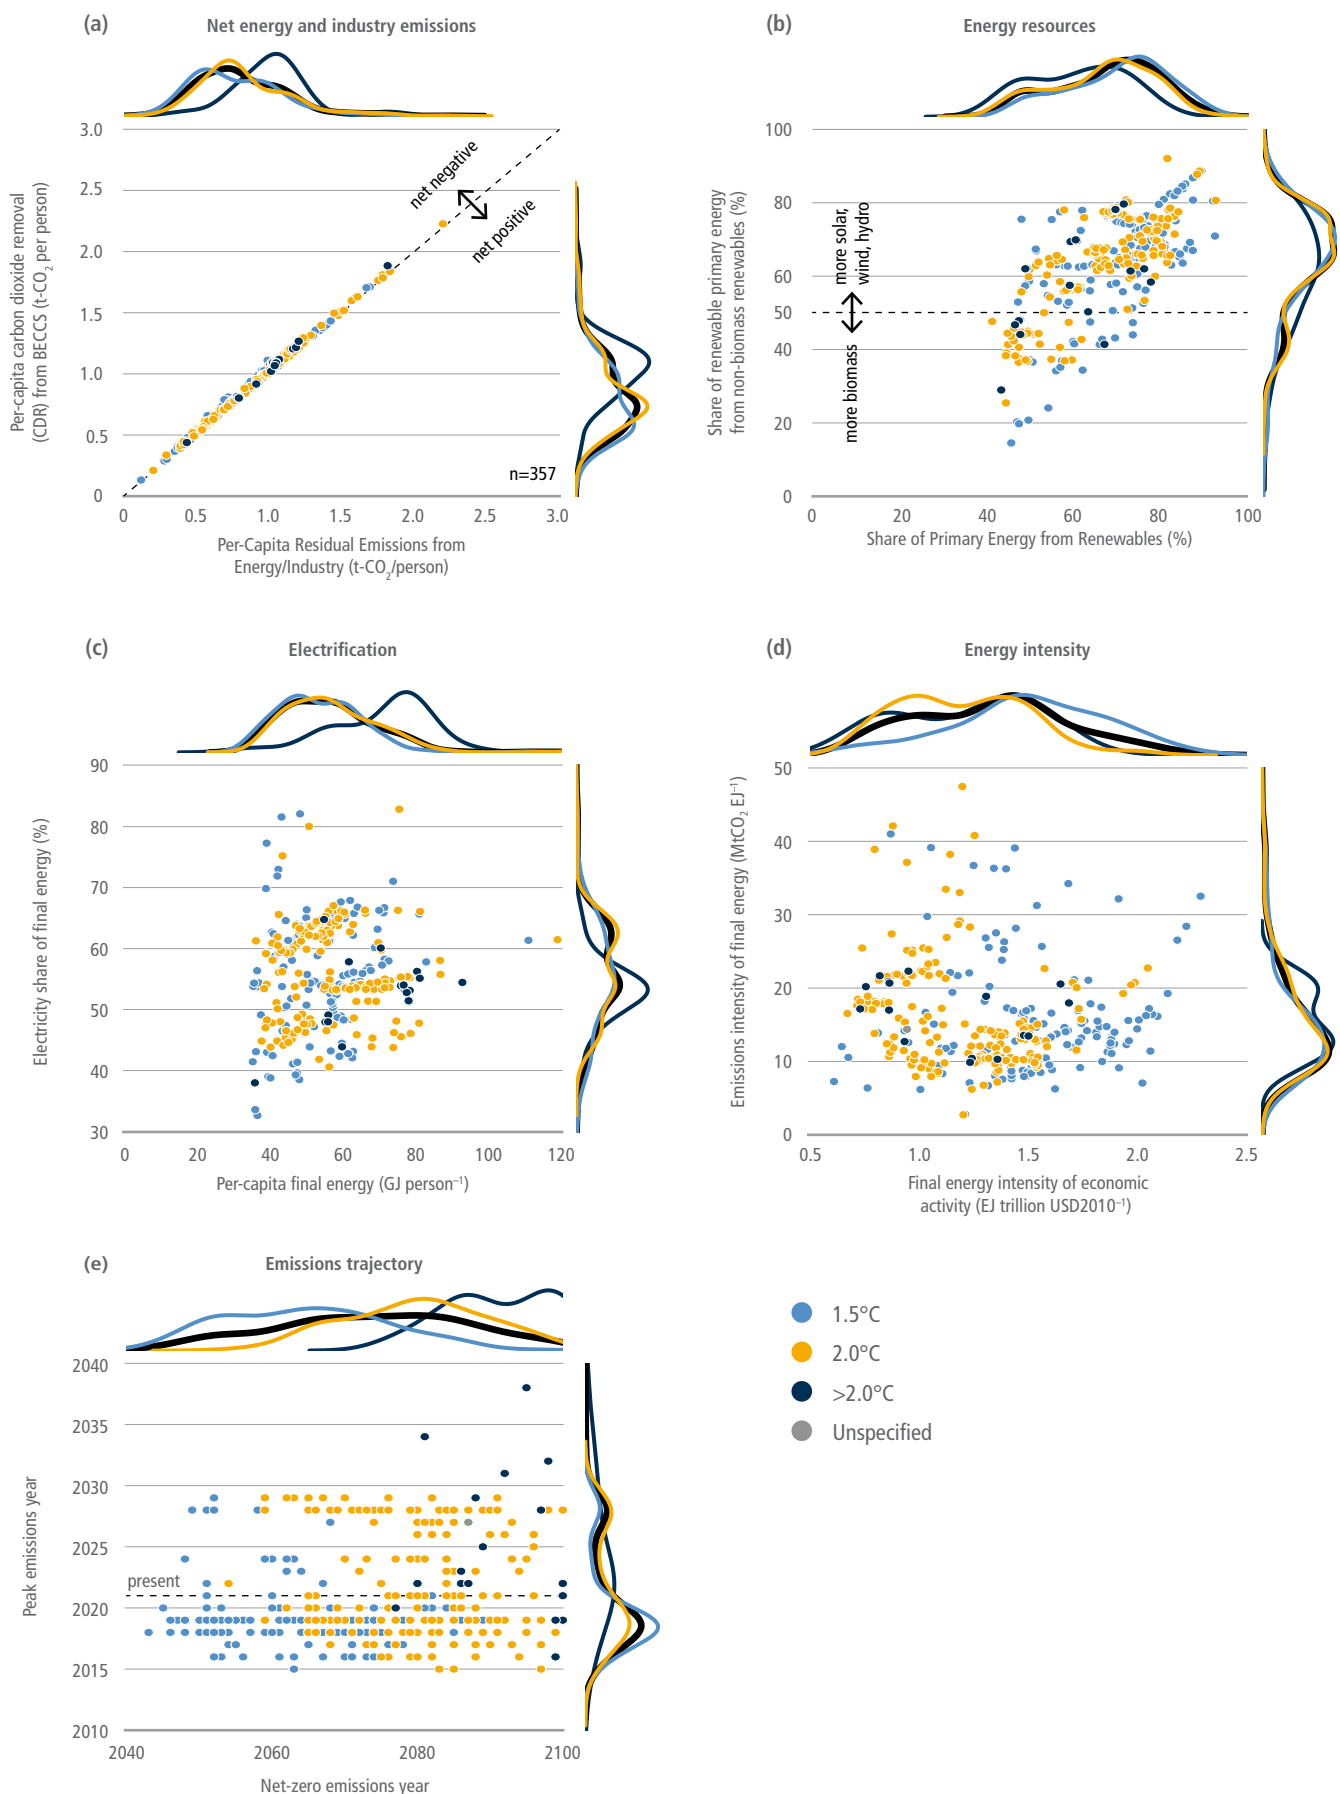

Figure 6.22 | Characteristics of global net-zero energy systems when global energy and industrial CO₂ emissions reach net-zero.

Figure 6.22 (continued): Characteristics of global net-zero energy systems when global energy and industrial CO₂ emissions reach net-zero. Scenarios reaching net-zero emissions show differences in residual emissions and carbon removal (a), energy resources (b), electrification (c), energy intensity (as measured here by energy GDP⁻¹) (d), and emissions trajectory (e), particularly with respect to warming levels (light blue = scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot and scenarios that return warming to 1.5°C (>50%) after a high overshoot; yellow = scenarios that limit warming to 2°C (>67%) and scenarios that limit warming to 2°C (>50%); dark blue = scenarios that limit warming to 2.5°C (>50%), scenarios that limit warming to 3°C (>50%), scenarios that limit warming to 4°C (>50%), and scenarios that exceed warming of 4°C (≥50%); grey = unspecified warming). Points represent individual scenarios from the AR6 Scenarios Database, with probability density distributions shown along each axis for each warming level (colours corresponding to warming levels) and for all scenarios (black).

long-term sequestration as compared to alternative, carbon-neutral fuels. Moreover, to the extent that physical, biological, and/or socio-political factors limit the availability of CDR (Smith et al. 2015; Field and Mach 2017), carbon management efforts may prioritise residual emissions related to land use and other non-energy sources.

6.6.2.2 Zero or Negative CO₂ Emissions from Electricity

Net-zero energy systems will rely on decarbonised or net-negative CO₂ emissions electricity systems, due to the many lower-cost options for producing zero-carbon electricity and the important role of end-use electrification in decarbonising other sectors (*high confidence*).

There are many possible configurations and technologies for zero- or net-negative-emissions electricity systems (*high confidence*). These systems could entail a mix of variable renewables, dispatchable renewables (e.g., biomass, hydropower), other firm, dispatchable ('on-demand') low-carbon generation (e.g., nuclear, CCS-equipped capacity), energy storage, transmission, carbon removal options (e.g., BECCS, DACCS), and demand management (Luderer et al. 2017; Bistline et al. 2018; Jenkins et al. 2018b; Bistline and Blanford 2021b). The marginal cost of deploying electricity sector mitigation options increases as electricity emissions approach zero; in addition, the most cost-effective mix of system resources changes as emissions approach zero and, therefore, so do the implications of electricity sector mitigation for sustainability and other societal goals (Mileva et al. 2016; Bistline et al. 2018; Sepulveda et al. 2018; Jayadev et al. 2020; Cole et al. 2021). Key factors influencing the electricity mix include relative costs and system benefits, local resource bases, infrastructure availability, regional integration and trade, co-benefits, societal preferences and other policy priorities, all of which vary by country and region (Section 6.6.4). Many of these factors depend on when the net-zero point is reached (Figure 6.22).

Based on their increasing economic competitiveness, VRE technologies, especially wind and solar power, will likely comprise large shares of many regional generation mixes (*high confidence*) (Figure 6.22). While wind and solar will likely be prominent electricity resources, this does not imply that 100% renewable energy systems will be pursued under all circumstances, since economic and operational challenges increase nonlinearly as shares approach 100% (Box 6.8) (Frew et al. 2016; Imelda et al. 2018b; Shaner et al. 2018; Bistline and Blanford 2021a; Cole et al. 2021). Real-world experience planning and operating regional electricity systems with high instantaneous and annual shares of renewable generation is accumulating, but debates continue about how much wind and solar should be included in different systems, and the cost-effectiveness of mechanisms for managing variability (Box 6.8). Either firm, dispatchable generation (including nuclear, CCS-equipped capacity, dispatchable renewables such as geothermal, and fossil units run with low capacity factors and CDR to balance emissions) or seasonal energy storage (alongside

other balancing resources discussed in Box 6.8) will be needed to ensure reliability and resource adequacy with high percentages of wind and solar (Jenkins et al. 2018b; Dowling et al. 2020; Denholm et al. 2021) though each option involves uncertainty about costs, timing, and public acceptance (Albertus et al. 2020).

Electricity systems require a range of different functional roles – for example, providing energy, capacity, or ancillary services. As a result, a range of different types of generation, energy storage, and transmission resources may be deployed in these systems (Baik et al. 2021). There are many options for each of these roles, each with their strengths and weaknesses (Sections 6.4.3 and 6.4.4), and deployment of these options will be influenced by the evolution of technological costs, system benefits, and local resources (Fell and Linn 2013; Hirth 2015; Bistline et al. 2018; Mai et al. 2018; Veers et al. 2019).

System management is critical for zero- or negative-emissions electricity systems. Maintaining reliability will increasingly entail system planning and operations that account for characteristics of supply- and demand-side resources (Hu et al. 2018). Coordinated planning and operations will likely become more prevalent across portions of the electricity system (e.g., integrated generation, transmission, and distribution planning), across sectors, and across geographies (EPRI 2017; Konstantelos et al. 2017; Chan et al. 2018; Bistline and Young 2019) (Section 6.4.3).

Energy storage will be increasingly important in net-zero energy systems, especially in systems with shares of VRE (*high confidence*). Deployment of energy storage will vary based on the system benefits and values of different options (Arbabzadeh et al. 2019; Denholm and Mai 2019). Diurnal storage options like lithium-ion batteries have different value than storing and discharging electricity over longer periods through long-duration energy storage with less frequent cycling, which require different technologies, supporting policies, and business models (Gallo et al. 2016; Blanco and Faaij 2017; Albertus et al. 2020; Dowling et al. 2020; Sepulveda et al. 2021) (Section 6.4.4). The value of energy storage varies with the level of deployment and on the competitiveness of economic complements such as VRE options (Mileva et al. 2016; Bistline and Young 2020) and substitutes such as flexible demand (Brown et al. 2018; Merrick et al. 2018), transmission (Schlachtberger et al. 2017; Brown et al. 2018; Merrick et al. 2018; Bistline and Young 2019), trade (Bistline et al. 2020b), dispatchable generators (Hittinger and Lueken 2015; Gils et al. 2017; Arbabzadeh et al. 2019), direct air capture (DAC) (Daggash et al. 2019), and efficiencies in system operations (Tuohy et al. 2015).

The approach to other sectors could impact on electricity sector planning, and the role of some technologies (e.g., hydrogen, batteries, CCS) could depend on deployment in other sectors. CCS offers opportunities for CO₂ removal when fuelled with syngas or biomass containing carbon captured from the atmosphere (Hepburn et al. 2019); however,

concerns about lifecycle environmental impacts, uncertain costs, and public acceptance are potential barriers to widespread deployment (Section 6.4.2). It is unclear whether CDR options like BECCS will be included in the electricity mix to offset continued emissions in other parts of the energy system or beyond (MacDowell et al. 2017; Bauer et al. 2018a; Luderer et al. 2018). Some applications may also rely on

power to fuels (PtX) electricity conversion to create low-emissions synthetic fuels (Sections 6.6.2.6, 6.4.4, and 6.4.5), which could impact on electricity system planning and operations. Additionally, if DAC technologies are used, electricity and heat requirements to operate DAC could impact electricity system investments and operations (Realmonde et al. 2019; Bistline and Blanford 2021a).

Box 6.8 | 100% Renewables in Net-zero Energy Systems

The decreasing cost and increasing performance of renewable energy has generated interest in the feasibility of providing nearly all energy services with renewables. Renewable energy includes wind power, solar power, hydroelectric power, bioenergy, geothermal energy, tidal power, and ocean power. There are two primary frames around which 100% renewable energy systems are discussed: 100% renewable electricity systems and 100% renewable energy systems, considering not only electricity but all aspects of the energy system.

It is technically feasible to use very high renewable shares (e.g., above 75% of annual regional generation) to meet hourly electricity demand under a range of conditions, especially when VRE options, notably wind and solar, are complemented by other resources (*high confidence*). There are currently many grids with high renewable shares and large anticipated roles for VRE sources, in particular wind and solar (Section 6.4), in future low-carbon electricity systems. An increasingly large set of studies examines the feasibility of high renewable penetration and economic drivers under different policy, technology, and market scenarios (Cochran et al. 2014; Deason 2018; Jenkins et al. 2018b; Bistline et al. 2019; Hansen et al. 2019; Dowling et al. 2020; Blanford et al. 2021; Denholm et al. 2021). High wind and solar penetration involves technical and economic challenges due to their unique characteristics such as spatial and temporal variability, short- and long-term uncertainty, and non-synchronous generation (Cole et al. 2017). These challenges become increasingly important as renewable shares approach 100% (Sections 6.6.2.2 and 6.4.3).

There are many balancing options in systems with very high renewables (Milligan et al. 2015; Jenkins et al. 2018b; Mai et al. 2018; Bistline 2021a; Denholm et al. 2021).

- **Energy storage.** Energy storage technologies like batteries, pumped hydro, and hydrogen can provide a range of system services (Balducci et al. 2018; Bistline et al. 2020a) (Section 6.4.4). Lithium-ion batteries have received attention as costs fall and installations increase, but very high renewable shares typically entail either dispatchable generation or long-duration storage in addition to short-duration options (Jenkins et al. 2018b; Arbabzadeh et al. 2019; Schill 2020). Energy storage technologies are part of a broad set of options (including synchronous condensers, demand-side measures, and even inverter-based technologies themselves) for providing grid services (Castillo and Gayme 2014; EPRI 2019a).
- **Transmission and trade.** To balance differences in resource availability, high renewable systems will very likely entail investments in transmission capacity (Mai et al. 2014; Macdonald et al. 2016; Pleßmann and Blechinger 2017; Zappa et al. 2019) (Section 6.4.5) and changes in trade (Abrell and Rausch 2016; Bistline et al. 2019). These increases will likely be accompanied by expanded balancing regions to take advantage of geographical smoothing.
- **Dispatchable ('on-demand') generation.** Dispatchable generation could include flexible fossil units or low-carbon fuels such as hydrogen with lower minimum load levels (Denholm et al. 2018; Bistline 2019), renewables like hydropower, geothermal, or biomass (Hirth 2016; Hansen et al. 2019), or flexible nuclear (Jenkins et al. 2018a). The composition depends on costs and other policy goals, though in all cases, capacity factors are low for these resources (Mills et al. 2020).
- **Demand management:** Many low-emitting and high-renewables systems also utilise increased load flexibility in the forms of energy efficiency, demand response, and demand flexibility, utilising newly electrified end uses such as electric vehicles to shape demand profiles to better match supply (Ameli et al. 2017; Hale 2017; Brown et al. 2018; Imelda et al. 2018a; Bistline 2021a).
- **Sector coupling:** Sector coupling includes increased end-use electrification and PtX electricity conversion pathways, which may entail using electricity to create synthetic fuels such as hydrogen (Davis et al. 2018; Ueckerdt et al. 2021) (Sections 6.4.3, 6.4., 6.4.5, 6.6.4.3, and 6.6.4.6).

Deployment of integration options depends on their relative costs and value, regulations, and electricity market design. There is considerable uncertainty about future technology costs, performance, availability, scalability, and public acceptance (Kondziella and Bruckner 2016; Bistline et al. 2019). Deploying balanced resources likely requires operational, market design, and other institutional changes, as well as technological changes in some cases (Denholm et al. 2021; Cochran et al. 2014). Mixes will differ based on resources, system size, flexibility, and whether grids are isolated or interconnected.

Box 6.8 (continued)

Although there are no technical upper bounds on renewable electricity penetration, the economic value of additional wind and solar capacity typically decreases as their penetration rises, creating economic challenges at higher deployment levels (Hirth 2013; Gowrisankaran et al. 2016; Cole et al. 2021; Denholm et al. 2021; Millstein et al. 2021). The integration options above, as well as changes to market design, can mitigate these challenges but likely will not solve them, especially since these options can exhibit declining value themselves (De Sisternes et al. 2016; Bistline 2017; Denholm and Mai 2019) and may be complements or substitutes to each other.

Energy systems that are 100% renewable (including all parts of the energy sector, and not only electricity generation) raise a range of technological, regulatory, market, and operational challenges that make their competitiveness uncertain (*high confidence*). These systems require decarbonising all electricity, using this zero-carbon electricity broadly, and then utilising zero-carbon energy carriers for all end uses not served by electricity, for example, air travel, long-distance transport, and high-temperature process heat. Broader questions emerge regarding the attractiveness of supplying all energy, and not just electricity, with renewables (Figure 6.22). Integrated assessment and energy systems research suggest large roles for renewables, but energy and electricity shares are far from 100%, even with stringent emissions reductions targets and optimistic assumptions about future cost reductions (Bauer et al. 2018; Bistline et al. 2018; Jenkins et al. 2018b; Huntington et al. 2020) (Section 6.7.1). Scenarios with 100% renewable energy systems are an emerging subset in the decarbonisation literature, especially at regional levels (Hansen et al. 2019; Denholm et al. 2021). Many 100% renewables studies focus more heavily on electrification for decarbonising end uses, and include less biofuels and hydrogen than the broader literature on deep decarbonisation (Bauer et al. 2018a). These studies typically assume a constrained set of available technologies to demonstrate the technical feasibility of very high renewable systems and do not optimise to find least-cost, technology-neutral decarbonisation pathways, and many 100% renewables studies focus on the electricity sector or a limited number of sectors (Jenkins et al. 2018a; Hansen et al. 2019). In addition to renewables, studies broadly agree that including additional low-carbon options – including not only low-carbon electricity but also targeted use of fossil fuels with and without CCS (Section 6.6.2.1) and alternative fuels for sectors that are difficult to electrify (Section 6.6.2.4) – can lower the cost of decarbonisation, even with very high shares of renewables (Figure 6.22). However, there is disagreement about the magnitude of cost savings from larger portfolios, which depend on context- and scenario-specific assumptions about technologies, markets, and policies.

6.6.2.3 Widespread Electrification of End Uses

Net-zero energy systems will rely more heavily on increased use of electricity (electrification) in end uses (*high confidence*). The literature on net-zero energy systems almost universally calls for increased electrification (Sugiyama 2012; Williams et al. 2012; Kriegler et al. 2014a; Williams et al. 2014; Rogelj et al. 2015a; Sachs et al. 2016; Luderer et al. 2018; Sven et al. 2018; Schreyer et al. 2020). At least 30% of the global final energy needs are expected to be served by electricity, with some estimates suggesting upwards of 80% of total energy use being electrified (Figure 6.22, panel c). Increased electrification is especially valuable in net-zero energy systems in tandem with decarbonised electricity generation or net-negative emissions electricity generation (Section 6.5.4.2). Flexible electric loads (electric vehicles, smart appliances) can in turn facilitate incorporation of VRE electricity options, increase system flexibility, and reduce needs for grid storage (Section 6.4.3) (Mathiesen et al. 2015; Lund et al. 2018).

Several end uses, such as passenger transportation (light-duty electric vehicles, two and three wheelers, buses, rail) as well as building energy uses (lighting, cooling) are likely to be electrified in net-zero energy systems (*high confidence*). Variations in projections of electrification largely result from differences in expectations about the ability and cost-competitiveness of electricity to serve other end uses such as non-rail freight transport, aviation, and heavy industry (McCollum et al. 2014; Bataille et al. 2016; EPRI 2018; Breyer et al. 2019)

(Section 6.5.4.4), especially relative to biofuels and hydrogen ('low-carbon fuels') (McCollum et al. 2014; Sachs et al. 2016; Rockström et al. 2017), the prospects for which are still quite uncertain (Section 6.4). The emergence of CDR technologies and the extent to which they allow for residual emissions as an alternative to electrification will also affect the overall share of energy served by electricity (Section 6.6.2.7).

Regions endowed with cheap and plentiful low-carbon electricity resources (wind, solar, hydropower) are likely to emphasise electrification, while those with substantial bioenergy resources or availability of other liquid fuels might put less emphasis on electrification, particularly in hard-to-electrify end uses (*medium confidence*). For example, among a group of Latin American countries, relative assumptions about liquid fuels and electricity result in an electrification range of 28–82% for achieving a net-zero energy system (Bataille et al. 2020). Similarly, the level of penetration of biofuels that can substitute for electrification will depend on regional circumstances such as land-use constraints, competition with food, and sustainability of biomass production (Section 6.6.2.4).

Electrification of most buildings services, with the possible exception of space heating in extreme climates, is expected in net-zero energy systems (*high confidence*) (Chapter 9). Space cooling and water heating are expected to be largely electrified. Building electrification is expected to rely substantially on heat pumps, which will help lower emissions both through reduced thermal requirements and higher efficiencies

(Mathiesen et al. 2015; Sven et al. 2018; Rissman et al. 2020). The level of electrification for heating will depend on the trade-offs between building or household level heat pumps versus more centralised district heating network options (Mathiesen et al. 2015; Brown et al. 2018), as well as the cost and performance of heat pumps in more extreme climates and regional grid infrastructure (EPRI 2018; Waite and Modi 2020).

A significant share of transportation, especially road transportation, is expected to be electrified in net-zero energy systems (*high confidence*). In road transportation, two- and three-wheelers, light-duty vehicles (LDVs), and buses, are especially amenable to electrification, with more than half of passenger LDVs expected to be electrified globally in net-zero energy systems (*medium confidence*) (Fulton et al. 2015; Sven et al. 2018; Khalili et al. 2019; Bataille et al. 2020). Long-haul trucks, large ships, and aircraft are expected to be harder to electrify without technological breakthroughs (Fulton et al. 2015; Mathiesen et al. 2015), although continued improvements in battery technology may enable electrification of long-haul trucks (Nykqvist and Olsson 2021) (Chapter 10). Due to the relative ease of rail electrification, near complete electrification of rail and a shift of air and truck freight to rail is expected in net-zero energy systems (Fulton et al. 2015; Rockström et al. 2017; Sven et al. 2018; Khalili et al. 2019). The degree of modal shifts and electrification will depend on local factors such as infrastructure availability and location accessibility. Due to the challenges associated with electrification of some transport modes, net-zero energy systems may include some residual emissions associated with the freight sector that are offset through CDR technologies (Muratori et al. 2017b), or reliance on low and zero-carbon fuels instead of electrification.

A non-trivial number of industry applications could be electrified as a part of a net-zero energy system, but direct electrification of heavy industry applications such as cement, primary steel manufacturing, and chemical feedstocks is expected to be challenging (*medium confidence*) (Davis et al. 2018; Philibert 2019; Madeddu et al. 2020; van Sluisveld et al. 2021). Process and boiler heating in industrial facilities are anticipated to be electrified in net-zero energy systems. Emissions intensity reductions for cement and concrete production can be achieved through the use of electrified cement kilns, while emissions associated with steel production can be reduced through the use of an electric arc furnace (EAF) powered by decarbonised electricity (Rissman et al. 2020). Electricity can also be used to replace thermal heat such as resistive heating, EAFs, and laser sintering (Madeddu et al. 2020; Rissman et al. 2020). One study found that as much as 60% of the energy end-use in European industry could be met with direct electrification using existing and emerging technologies (Madeddu et al. 2020). Industry electrification for different regions will depend on the economics and availability of alternative emissions mitigation strategies such as carbon neutral fuels and CCS (Davis et al. 2018; Madeddu et al. 2020).

6.6.2.4 Alternative Fuels in Sectors not Amenable to Electrification

Net-zero energy systems will need to rely on alternative fuels – notably hydrogen or biofuels – in several sectors that are not amenable to electricity and otherwise hard to decarbonise (*medium confidence*).

Useful carbon-based fuels (e.g., methane, petroleum, methanol), hydrogen, ammonia, or alcohols can be produced with net-zero CO₂ emissions and without fossil fuel inputs (Sections 6.4.4 and 6.4.5). For example, liquid hydrocarbons can be synthesised via hydrogenation of non-fossil carbon by processes such as Fischer-Tropsch (MacDowell et al. 2017) or by conversion of biomass (Tilman et al. 2009). The resulting energy-dense fuels can serve applications that are difficult to electrify, but it is not clear if and when the combined costs of obtaining necessary feedstocks and producing these fuels without fossil inputs will be less than continuing to use fossil fuels and managing the related carbon through, for example, CCS or CDR (Ueckerdt et al. 2021).

CO₂ emissions from some energy services are expected to be particularly difficult to cost-effectively avoid, among them: aviation; long-distance freight by ships; process emissions from cement and steel production; high-temperature heat (e.g., >1000°C); and electricity reliability in systems with high penetration of variable renewable energy sources (NAS) (Davis et al. 2018; Luderer et al. 2018; Sepulveda et al. 2018; Chiaramonti 2019; Bataille 2020; Madeddu et al. 2020; Rissman et al. 2020; Thiel and Stark 2021). The literature focused on these services and sectors is growing, but remains limited, and provides minimal guidance on the most promising or attractive technological options and systems for avoiding these sectors' emissions. Technological solutions do exist, but those mentioned in the literature are prohibitively expensive, exist only at an early stage, and/or are subject to much broader concerns about sustainability (e.g., biofuels) (Davis et al. 2018).

Liquid biofuels today supply about 4% of transportation energy worldwide, mostly as ethanol from grain and sugar cane and biodiesel from oil seeds and waste oils (Davis et al. 2018). These biofuels could conceivably be targeted to difficult-to-electrify sectors, but face substantial challenges related to their lifecycle carbon emissions, cost, and further scalability (Tilman et al. 2009; Staples et al. 2018), (Section 6.4.2). The extent to which biomass will supply liquid fuels or high temperature heat for industry in a future net-zero energy system will thus depend on advances in conversion technology that enable use of feedstocks such as woody crops, agricultural residues, algae, and wastes, as well as competing demands for bioenergy and land, the feasibility of other sources of carbon-neutral fuels, and integration of bioenergy production with other objectives, including CDR, economic development, food security, ecological conservation, and air quality (Fargione 2010; Williams and Laurens 2010; Creutzig et al. 2015; Chatziaras et al. 2016; Laurens 2017; Lynd 2017; Bauer et al. 2018a, b; Streffler et al. 2018; Muratori et al. 2020b; Fennell et al. 2021) (Section 6.4.2.6).

Costs are the main barrier to synthesis of net-zero emissions fuels (*high confidence*), particularly costs of hydrogen (a constituent of hydrocarbons, ammonia, and alcohols) (Section 6.4.5). Today, most hydrogen is supplied by steam reformation of fossil methane (CH₄ into CO₂ and H₂) at a cost of 1.30–USD1.50 kg⁻¹ (Sherwin 2021). Non-fossil hydrogen can be obtained by electrolysis of water, at current costs of USD5–7 kgH₂⁻¹ (assuming relatively low electricity costs and high utilisation rates) (Graves et al. 2011; DOE 2020a; Newborough and Cooley 2020; Peterson et al. 2020). At these costs for electrolytic hydrogen, synthesised net-zero emissions fuels would cost at least USD1.6 per litre of diesel equivalent (or USD6 gallon⁻¹ and USD46 GJ⁻¹, assuming non-fossil carbon feedstock costs

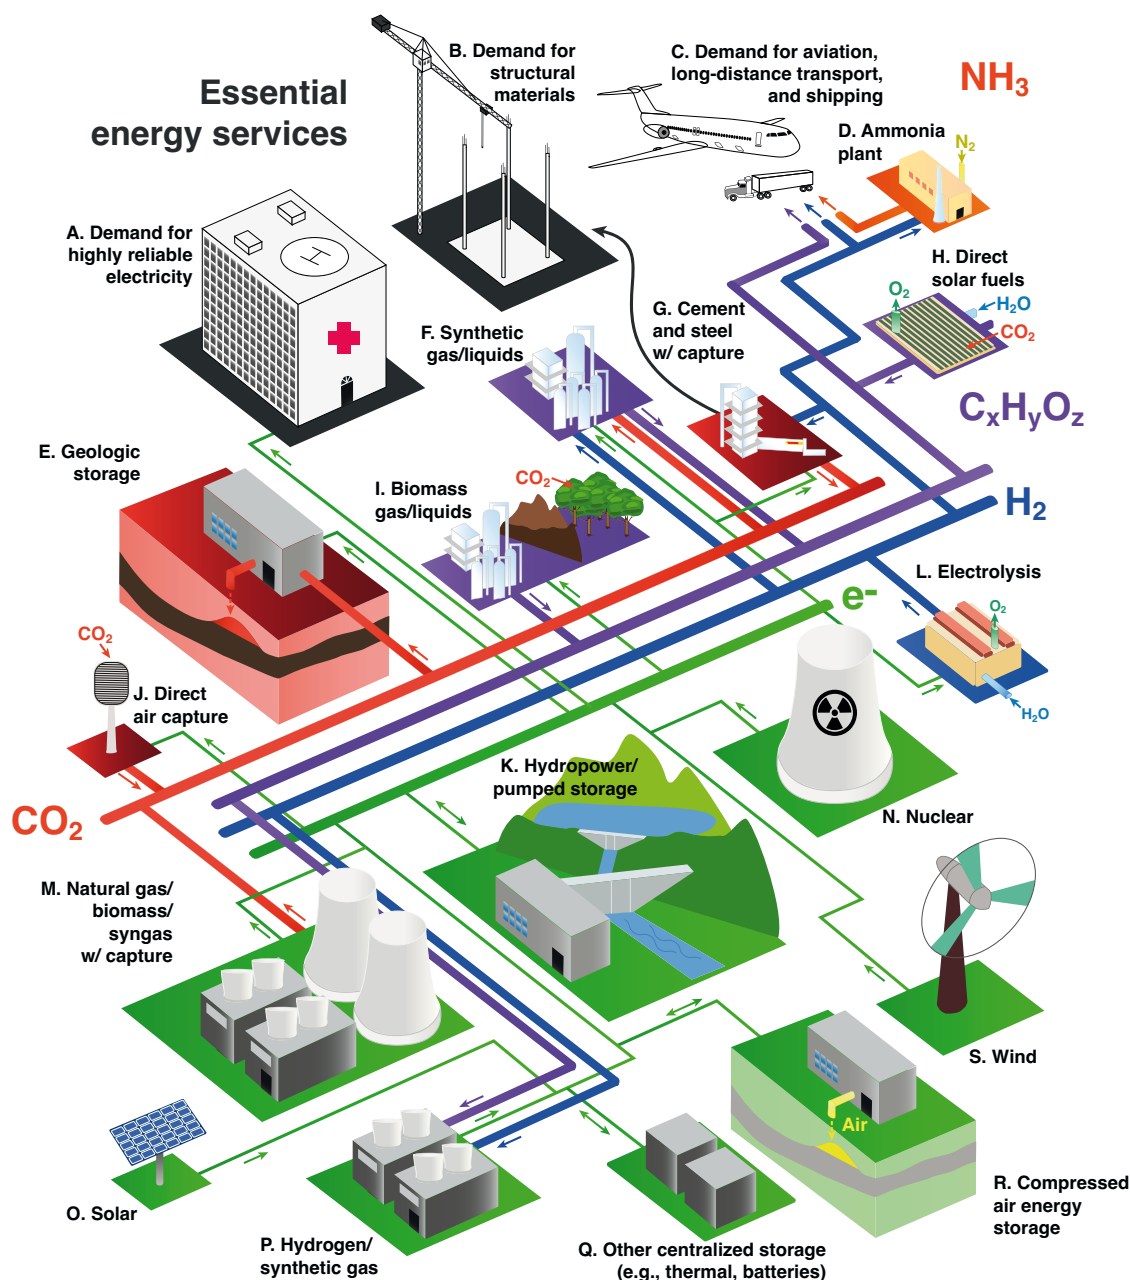

Figure 6.23 | Schematic of net-zero emissions energy system, including methods to address difficult-to-electrify sectors. Source: with permission from Davis et al. (2018).

of USD100 per tonne of CO_2 and low process costs of USD0.05 litre⁻¹ or USD1.5 GJ⁻¹). Similar calculations suggest that synthetic hydrocarbon fuels could currently avoid CO_2 emissions at a cost of USD936–1404 tonne⁻¹ (Ueckerdt et al. 2021). However, economies of scale are expected to bring these costs down substantially in the future (IRENA 2020c; Ueckerdt et al. 2021), and R&D efforts are targeting 60–80% reductions in costs (to less than USD2 kg⁻¹ (H_2)⁻¹) possibly by use of less mature but promising technologies such as high-temperature electrolysis and thermochemical water splitting (Kuckshinrichs et al. 2017; Pes et al. 2017; Schmidt et al. 2017; Saba et al. 2018; DOE, 2018, 2020b). Technologies capable of producing hydrogen directly from water and sunlight (photoelectrochemical cells or photocatalysts) are also under development, but are at

an early stage (Nielander et al. 2015; DOE 2020a). High hydrogen production efficiencies have been demonstrated, but costs, capacity factors, and lifetimes need to be improved in order to make such technologies feasible for net-zero emissions fuel production at scale (McKone et al. 2014; DOE 2020a; Newborough and Cooley 2020).

The carbon contained in net-zero emissions hydrocarbons must have been removed from the atmosphere either through DAC, or, in the case of biofuels, by photosynthesis (which could include CO_2 captured from the exhaust of biomass or biogas combustion) (Zeman and Keith 2008; Graves et al. 2011). A number of different groups are now developing DAC technologies, targeting costs of USD100 per tonne of CO_2 or less (Darton and Yang 2018; Keith et al. 2018; Fasihi et al. 2019).

Box 6.9 | The Hydrogen Economy

The phrase ‘hydrogen economy’ is often used to describe future energy systems in which hydrogen plays a prominent role. These future energy systems would not use hydrogen for all end uses; they would use hydrogen to complement other energy carriers, mainly electricity, where hydrogen might have advantages. Hydrogen could provide long-term electricity storage to support high-penetration of intermittent renewables and could enable trading and storage of electricity between different regions to overcome seasonal or production capability differences (Dowling et al. 2020; Sepulveda et al. 2021). It could also be used in lieu of natural gas for peaking generation, provide process heat for industrial needs, or be used in the metal sector via direct reduction of iron ore (Chapter 11). Clean hydrogen could be used as a feedstock in the production of various chemicals and synthetic hydrocarbons. Finally, hydrogen-based fuel cells could power vehicles. Recent advances in battery storage make electric vehicles the most attractive alternative for light-duty transport. However, fuel cell technology could complement electric vehicles in supporting the decarbonisation of heavy-duty transport segments (e.g., trucks, buses, ships, and trains) (Chapter 10).

Hydrogen production costs have historically been prohibitive, but recent technological developments are bringing costs down. These developments include improvements in hydrogen production technologies in terms of efficiency and capital costs (e.g., steam methane reforming) (Alrashed and Zahid 2021; Boretti and Banik 2021) and the emergence of alternative production technologies such as electrolyzers (Dawood et al. 2020). These technological changes, along with decreasing costs of renewable power, are increasing the viability of hydrogen. Other improvements in hydrogen-based technologies are also emerging quickly. Gas turbines now run on blended fuels containing 5–95% hydrogen by volume (GE 2020) and could operate entirely on hydrogen by 2030 (Pflug et al. 2019). Fuel cell costs have decreased by 80–95% since the early 2000s, while power density and durability have improved (Jouin et al. 2016; IEA 2019e; Kurtz et al. 2019).

For hydrogen to support decarbonisation, it will need to be produced from zero-carbon or extremely low-carbon energy sources. One such production category is ‘green hydrogen’. While there is no unified definition for green hydrogen, it can be produced by the electrolysis of water using electricity generated without carbon emissions (such as renewables). Hydrogen can also be produced through biomass gasification with carbon capture and storage (BECCS), leading to negative carbon emissions (Arnaiz del Pozo et al. 2021). Additionally, ‘blue hydrogen’ can be produced from natural gas through the process of auto-thermal reforming (ATR) or steam methane reforming, combined with CCS technology that would absorb most of the resulting CO₂ (80–90%).

However, the potential role of hydrogen in future energy systems depends on more than just production methods and costs. For some applications, the competitiveness of hydrogen also depends on the availability of the infrastructure needed to transport and deliver it at relevant scales (Lee et al. 2021). Transporting hydrogen through existing gas pipelines is generally not feasible without changes to the infrastructure itself (Gumber and Gurumoorthy 2018; Muratori et al. 2018). Existing physical barriers, such as steel embrittlement and degradation of seals, reinforcements in compressor stations, and valves, require retrofitting during the conversion to H₂ distribution or new dedicated pipelines to be constructed (Dohi et al. 2016). The capacity to leverage and convert existing gas infrastructure to transport hydrogen will vary regionally, but in many cases could be the most economically viable pathway (Cerniauskas et al. 2020; Brändle et al. 2021; Brooks 2021; Wettengel 2021). Hydrogen could also be transported as liquid gas or as liquid organic hydrogen carriers such as ammonia, for which industry knowledge exists (Demir et al. 2018; Wulf et al. 2018; Hong et al. 2021). Additionally, improvements in fuel cell technologies are needed to make hydrogen-based transport economically viable. There are also safety concerns associated with the flammability (Nilsson et al. 2017) and storage (Andersson and Grönkvist 2019; Caglayan et al. 2019) of hydrogen which will need to be considered.

6.6.2.5 Using Less Energy and Using It More Efficiently

Demand-side or demand reduction strategies include technology efficiency improvements, strategies that reduce energy consumption or demand for energy services (such as reducing the use of personal transportation, often called ‘conservation’) (Creutzig et al. 2018), and strategies such as load curtailment.

Net-zero energy systems will use energy more efficiently than those of today (*high confidence*). Energy efficiency and energy use reduction strategies are generally identified as being flexible

and cost-effective, with the potential for large-scale deployment (Chapters 5, 9, 10, and 11). For this reason, existing studies find that energy efficiency and demand reduction strategies will be important contributors to net-zero energy systems (Creutzig et al. 2018; Davis et al. 2018; DeAngelo et al. 2021). Lower demand reduces the need for low-carbon energy or alternative fuel sources.

Characterising efficiency of net-zero energy systems is problematic due to measurement challenges (*high confidence*). Efficiency itself is difficult to define and measure across full economies (Saunders et al. 2021). There is no single definition of energy efficiency and the

definition understandably depends on the context used (Patterson 1996), which ranges from device-level efficiency all the way to the efficient use of energy throughout an economy. Broadly, energy-efficient strategies allow for the same level of services or output while using less energy. At the level of the entire economy, measures such as primary or final energy per capita or per GDP are often used as a proxy for energy efficiency; these measures reflect not only efficiency, but also many other factors such as industrial structure, endowed natural resources, consumer preferences, policies, and regulations. Energy efficiency and other demand-side strategies represent such a large set of technologies, strategies, policies, market and consumers' responses and policies that aggregate measures can be difficult to define (Saunders et al. 2021).

Measurement issues notwithstanding, virtually all studies that address net-zero energy systems assume improved energy intensity in the future (*high confidence*). The overall efficiency outcomes and the access to such improvements across different nations, however, are not clear. Energy consumption will increase over time – despite energy efficiency improvements – due to population growth and development (DeAngelo et al. 2021).

A study (DeAngelo et al. 2021) reviewed 153 integrated asset management scenarios that attain net-zero energy sector CO₂ emissions and found that, under a scenario with net-zero emissions: global final energy per capita lies between 21–109 GJ per person (median: 57), in comparison to 2018 global final energy use of 55 GJ per person; many countries use far more energy per capita than today as their incomes increase; global final energy use per unit of economic output ranges from 0.7–2.2 EJ per trillion USD (median: 1.5), in comparison to 5 EJ per trillion USD in 2018; and the median final energy consumption is 529 EJ. By comparison, final energy consumption would be 550 EJ if current energy consumption per capita continued under a future population of 10 billion people. Across all scenarios, total final energy consumption is higher today than in the year in which net-zero emissions are attained, and regionally, only the OECD+EU and Eurasia have lower median total final energy than in 2010.

Net-zero energy systems will be characterised by greater efficiency and more efficient use of energy across all sectors (*high confidence*). Road transportation efficiency improvements will require a shift from liquid fuels (Chapters 5 and 10). Emissions reductions will come from a transition to electricity, hydrogen, or synthetic fuels produced with low-carbon energy sources or processes. Vehicle automation, ride-hailing services, online shopping with door delivery services, and new solutions like last mile delivery with drones may result in increased service share. Lighter vehicles, a shift to public transit, and incorporation of two- and three-wheelers will be features of a net-zero energy system (Chapter 10). Teleworking and automation of work may provide reductions in driving needs. Other sectors, such as air travel and marine transportation may rely on alternative fuels such as biofuels, synthetic fuels, ammonia, produced with zero carbon energy source (Section 6.6.2.4).

Under net-zero energy systems, buildings would be characterised by improved construction materials, an increase in multi-family

dwelling, early retirement of inefficient buildings, smaller floor areas, and smart controls to optimise energy use in the building, namely for heating, cooling, LED lighting, and water heating (Chapter 9). End uses would utilise electricity, or potentially hydrogen, produced from zero-carbon sources. The use of electricity for heating and cooking may often be a less efficient process at converting primary energy to energy services than using natural gas, but using natural gas would require CDR in order to be considered net-zero emissions. Changes in behaviour may modestly lower demand. Most economies would have buildings with more efficient technologies powered by zero-carbon electricity, and developing economies would shift from biomass to electricity, raising their energy consumption as population and wealth increase under net-zero energy systems.

Industry has seen major efficiency improvements in the past, but many processes are now close to their thermodynamic limits. Electrification and breakthrough processes (such as producing steel with electricity and hydrogen), using recycled materials, using heat more efficiently by improving thermal insulation, and using waste heat for heat pumps, as well as using advanced sensors, monitoring, and visualisation and communication technologies may provide further efficiency improvements (Chapter 11).

6.6.2.6 Greater Reliance on Integrated Energy System Approaches

Energy systems integration refers to connected planning and operations across energy carriers, including electricity, fuels, and thermal resources. Coordinated planning could be important in lowering system costs, increasing reliability, minimising environmental impacts, and ensuring that costs of R&D and infrastructure account for not just current needs but also for those of future energy systems (Section 6.4.3). Integration includes not only the physical energy systems themselves but also simultaneous societal objectives (e.g., sustainable development goals), innovation processes (e.g., coordinating R&D to increase the likelihood of beneficial technological spillovers), and other institutional and infrastructural transformations (Sachs et al. 2019). Given system variability and differences in regional resources, there are economic and technical advantages to greater coordination of investments and policies across jurisdictions, sectors, and levels of government (Schmalensee and Stavins 2017). Coordinated planning and operations can improve system economics by sharing resources, increasing the utilisation of capital-intensive assets, enhancing the geographical diversity of resource bases, and smoothing demand. But integration could require regulatory and market frameworks to facilitate and appropriate price signals to align incentives and to coordinate investments and operations.

Carbon-neutral energy systems are likely to be more interconnected than those of today (*high confidence*). The many possible feedstocks, energy carriers, and interconversion processes imply a greater need for the integration of production, transport, storage, and consumption of different fuels (Davis et al. 2018). For instance, electrification is expected to play an important role in decarbonising light-duty vehicles (Chapter 10, Section 6.4.3), yet the electricity and transport sectors have few direct interactions today. Systems integration and

sectoral coupling are increasingly relevant to ensure that net-zero energy systems are reliable, resilient, and affordable (EPRI 2017; Martin et al. 2017; Buttler and Spliethoff 2018; O'Malley et al. 2020). Deep decarbonisation offers new opportunities and challenges for integrating different sectors as well as supply- and demand-side options. For instance, increasing electrification will change daily and seasonal load shapes, and end-use flexibilities and constraints could impact the desirability of different supply-side technologies (Brown et al. 2018; EPRI 2019b). The feasibility of net-zero energy system configurations could depend on demonstrating cross-sector benefits like balancing VRE sources in the electricity sector, and on offering the flexibility to produce multiple products. For instance, low-emissions synthetic fuels could help to bridge stationary and mobile applications, since fuel markets have more flexibility than instantaneously balanced electricity markets due to the comparative ease and cost of large-scale, long-term storage of chemical fuels (Davis et al. 2018).

There are few detailed archetypes of integrated energy systems that provide services with zero- or net-negative CO₂ emissions (such as Jacobson et al. 2019), so there is considerable uncertainty about integration and interactions across parts of the system. Although alternate configurations, trade-offs, and pathways are still being identified, common elements include fuels and processes like zero- or negative-CO₂ electricity generation and transmission, hydrogen production and transport, synthetic hydrocarbon production and transport, ammonia production and transport, and carbon management, where linkages across pathways could include the use of electricity to produce hydrogen via electrolysis (Smith et al. 2016; Moore 2017; Davis et al. 2018; Jenkins et al. 2018b; Shih et al. 2018; van Vuuren et al. 2018). Linked analytical frameworks are increasing being used to understand the potential role for system coupling with greater temporal resolution, spatial resolution, and heterogeneity of consumer and firm decisions (Bohringer and Rutherford 2008; Bistline and de la Chesnaye 2017; Collins et al. 2017; Gerboni et al. 2017; Santen et al. 2017; Pye et al. 2021).

Challenges associated with integrating net-zero energy systems include rapid technological change, the importance of behavioural dimensions in domains with limited experience and data, policy changes and interactions, and path dependence. Technological cost and public acceptance will influence the degree of integration. Sectoral pathways will likely be adaptive and adjust based on the resolution of uncertainties over time, and the relative competitiveness will evolve as the technological frontier evolves, which is a complex and path-dependent function of deployment, R&D, and inter-industry spillovers. Supply-side options interact with demand-side measures in increasingly integrated energy systems (Sorrell 2015; van Vuuren et al. 2018).

6.6.2.7 Carbon Dioxide Removal

While CDR is likely necessary for net-zero energy systems, the scale and mix of strategies is unclear –nonetheless some combination of BECCS and DACCS are likely to be part of net-zero energy systems (*high confidence*). Studies indicate that energy-sector CDR may potentially remove 5–12 GtCO₂ annually globally in net-zero energy systems (Fuss et al. 2018) (Figure 6.22; Section 6.7; Chapter 12). CDR

is not intended as a replacement for emissions reduction, but rather as a complementary effort to offset residual emissions from sectors that are not decarbonised and from other low-carbon technologies such as fossil CCS (McLaren et al. 2019; Gaffney et al. 2020; Iyer et al. 2021).

CDR covers a broad set of methods and implementation options (Chapters 7 and 12). The two CDR methods most relevant to the energy sector are BECCS, which is used to produce energy carriers, and DACCS which is an energy user (Smith et al. 2016; Singh and Colosi 2021). BECCS has value as an electricity generation technology, providing firm, dispatchable power to support electricity grids with large amounts of VRE sources, and reducing the reliance on other means to manage these grids, including electricity storage (Mac Dowell et al. 2017; Bistline and Blanford 2021a). BECCS may also be used to produce liquid fuels or gaseous fuels, including hydrogen (Section 6.4.2.6) (Muratori et al. 2020b). For instance, CO₂ from bio-refineries could be captured at <USD45 tCO₂⁻¹ (Sanchez et al. 2018). Similarly, while CO₂ capture is expensive in the electricity sector, its integration with hydrogen via biomass gasification can be achieved at an incremental capital cost of 3–35% (Muratori et al. 2020b) (Section 6.4). As with all uses of bioenergy, linkages to broad sustainability concerns may limit the viable development, as will the presence of high-quality geologic sinks in close proximity (Melara et al. 2020).

DACCS offers a modular approach to CDR (Creutzig et al. 2019), but it could be a significant consumer of energy. DAC could also interact with other elements of the energy systems as the captured CO₂ could be reused to produce low-carbon methanol and other fuels (Hoppe et al. 2018; Realmonte et al. 2019; Zhang and Fujimori 2020). DACCS might also offer an alternative for use of excess electricity produced by variable renewables (Wohland et al. 2018), though there are uncertainties about the economic performance of this integrated approach.

6.6.3 The Institutional and Societal Characteristics of Net-zero Energy Systems

The transition to net-zero energy systems is not just technological; it requires shifts in institutions, organisations, and society more generally. As such, it involves institutional changes alongside changes in supply, technology, or markets (Andrews-Speed 2016; Pai et al. 2021). Institutional relationships between governments and energy sector actors (e.g., consumers, electricity companies) affect the nature of net-zero systems, as these entities may collaborate on or dispute net-zero goals and measures to achieve them. For example, following the Fukushima disaster, Japan placed emphasis on government-utility-public cooperation on use of nuclear power as a means of reducing carbon emissions (Sklarew 2018). Institutions are instrumental in shaping net-zero energy systems in multiple ways, complemented by and interacting with the behaviours of actors and policy regimes in these systems (Figure 6.24).

One level of institutional interactions reflects embedded institutions, norms, beliefs, and ideas that would need to change to support net-zero energy systems. This applies, for example, to the objectives of modern economies and the potentially contradictory dynamics embedded in

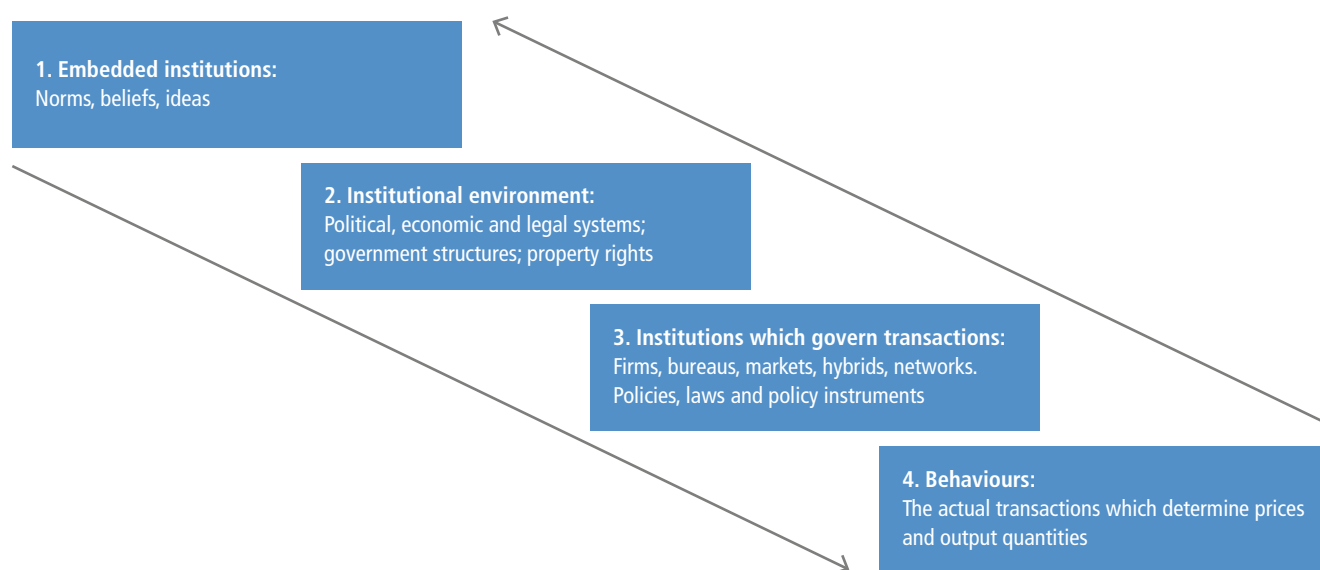

Figure 6.24 | A four-level framework for institutional change. The diagram depicts three levels of institutions (1–3) which collectively govern actor behaviours (4). Source: with permission from Andrews-Speed (2016).

the concept of ‘green growth’ (Stegemann and Ossewaarde 2018; Stoknes and Rockström 2018). The institutional environment – the political and legal systems that govern exchanges and protect property rights – would also need to be different in net-zero energy systems. In this setting, changing regulations or subsidies that continue to favour carbon-intensive systems over the technologies of a net-zero energy system might prove difficult (Sovacool 2017). More generally, net-zero energy systems will need new regulatory frameworks to undertake new challenges, from managing a more interconnected grid to adequately governing underground storage of CO₂. Institutions may also govern specific transactions, such as firms or networks that supply energy fuels or services. Current actors are typically resistant to disruptions, even if such disruptions may broadly benefit society (Kungl 2015; Schmid et al. 2017; Mori 2018).

For example, one energy system characterised by differentiated institutional interactions is the USA, where delivery of liquid fuels is lightly regulated, while electricity delivery is closely regulated (Dworkin et al. 2013). Reforming this two-pronged system for decarbonisation would require four types of institutional change: (i) changes to the control systems that coordinate generation and transmission through a pyramidal architecture for the operational control, dispatch, and delivery of electricity with a primary emphasis on reliability; (ii) changes to the financing of central-station power plants through long-term bonds, as valued by Wall Street ratings analysts; (iii) changes to the structure of investor-owned utilities that attract private investors who expected decades of technological stability to yield long-term, low-risk revenues; and (iv) changes to regulations to restructure and limit excessive returns and easy entry of new retail competitors, all recognising local and national concerns through state and federal regulatory agencies. The example shows how decision-making and the infrastructures involved are layered, and can create ‘nested hierarchies’ where institutions fulfil multiple roles for energy governance or regulation simultaneously

(Stern et al. 2016b). Internationally and across different parts of the energy system, institutional challenges such as these could become even more stark and complex (Van de Graaf 2013).

6.6.4 Regional Circumstances and Net-zero Energy Systems

Countries have flexibility to pursue options that make the most sense for their national circumstances (Figure 6.25). They may emphasise supply transformation over demand reduction; deploy different resources; engage at different levels in international energy trade; support different energy industries; focus on different energy carriers (e.g., electricity, hydrogen); or focus more on distributed or integrated systems, among others. Many factors may influence the long-term net-zero energy systems that are appropriate for any country’s national circumstances, including the following.

Future technology. Technological transitions have often been driven by the relative merits of different technology options. Recent trends in the use of PV cells, wind power, and in batteries, for example, have been spurred by their increasing economic competitiveness (Section 6.3). Yet future technology cannot be fully predicted, so it provides only a partial guide today for charting a path toward future systems.

Indigenous energy resources. Countries may emphasise approaches that take advantage of indigenous energy resources such as solar power, wind, hydroelectric resources, land for bioenergy crops, CO₂ storage capability, or fossil resources to be used with CCS. Countries with less abundant resources may put greater emphasis on demand reductions and regional integration. Countries with resource bases that are easily tradeable, like low-carbon electricity or bioenergy, may choose to trade those resources rather than use them domestically (Box 6.10, Section 6.4.3, 6.4.5).

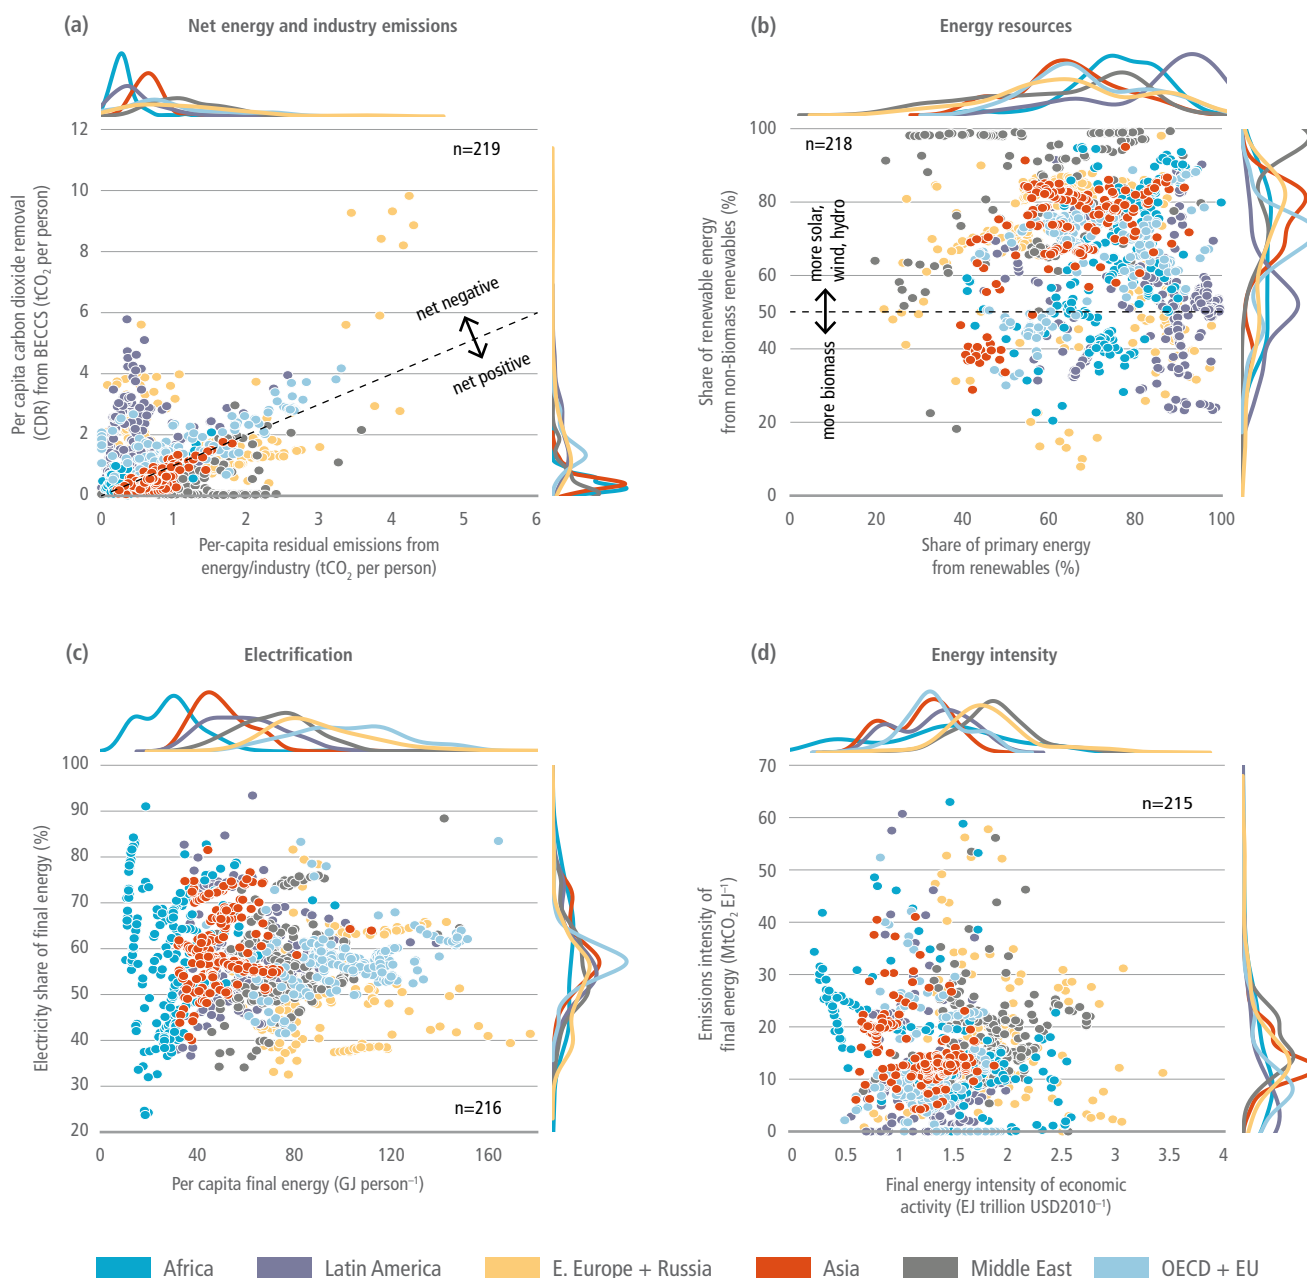

Figure 6.25 | Characteristics of regional energy systems and emissions when global energy and industrial CO₂ emissions reach net-zero. Regional differences are shown for: (a) residual emissions and carbon removal; (b) energy resources; (c) electrification; and (d) energy intensity. Distributions of scenarios are shown along each axis for each region. Colour scheme is shown in (a). Points represent individual scenarios from the AR6 Scenarios Database (R6 regions dataset).

Regional climate. Climate influences heating and cooling demand, both of which influence countries' energy demands and energy infrastructure to meet those demands (Section 6.5). In addition to daily demand profiles, heating and cooling are seasonal, influencing which energy sources may serve these loads and the seasonal storage they require. Cooling is almost entirely served by electricity today, and heating has commonly been served by non-electric fuels. In low-carbon energy systems, heating may be increasingly served by electricity (Section 6.6.4), meaning that the influence of regional climate may be strongest on countries' electricity systems.

Current energy system configuration. Future sectoral energy demands and the potential for demand-side transformation are partially determined by existing infrastructure (e.g., building stocks, transport infrastructure). Countries with less developed or growing energy systems will have more flexibility to create the systems that best match their long-term goals, but there may be substantial challenges in transitioning directly to the most advanced low-carbon technology options, and countries may have different capacities to absorb technology from other countries.

Regional integration. Regional integration will allow countries to bridge energy gaps using external linkages, including regional electricity integration and trade in hydrogen, biomass, and other fuels. Countries with greater integration can rely more heavily on imports and may therefore rely less on indigenous resources (Box 6.10).

Societal preferences. Citizens in every country have preferences for certain technological options or mitigation approaches over others that will influence energy system choices. The public generally prefers a future energy system based largely on renewables. Preferences for non-renewable energy differ across regions and groups. For example, studies have found that people in the UK, Germany, the Netherlands, and Switzerland prefer renewable energy and personal energy efficiency and savings to nuclear, fossil fuels and CCS (Jones et al. 2012; Scheer et al. 2013; Demski et al. 2017; Bessette and Arvai 2018; Steg 2018; Volken et al. 2018). Studies have found that people with higher education levels, higher incomes, females, and liberals prefer renewables to fossil fuels and nuclear (Van Rijnsoever et al. 2015; Bertsch et al. 2016; Blumer et al. 2018; Jobin et al. 2019). The willingness to pay for renewable electricity differs by source (Ma et al. 2015; Sundt and Rehdanz 2015).

Technological leadership, economic opportunities, and growth. Countries may emphasise technologies in which they intend to have technological leadership and a competitive advantage. These could emerge over time or be based on current areas of opportunity or leadership. Industrial policy will influence future energy system as technological choices can benefit or hamper incumbents or new market actors.

Energy security. Countries emphasising import security will tend to rely more heavily on indigenous resources (Section 6.3). Some indigenous resources may raise security of supply issues that will influence energy system configurations. Bioenergy and hydropower, for example, can be subject to import climate risks (Section 6.5), and significant integration of VRE technologies will influence electricity system infrastructure and management (Section 6.6.2, Box 6.8).

Other factors. Countries will consider a wide range of other factors in building toward low-carbon energy systems. Population density, for example, will influence building and transportation energy demands; economic transitions will influence industrial energy demands. Societal priorities beyond climate, notably SDGs may influence technology choices and types of energy systems (Sections 6.3 and 6.7.7).

Box 6.10 | Regional Integration of Energy Systems

Energy systems are linked across countries in many ways: countries transport crude oil across the ocean in supertankers, pipelines carry oil and natural gas across country boundaries, electric power lines cross country boundaries, and countries trade industrial commodities that carry embodied energy or that are essential inputs to mitigation technologies. Future systems will generate electricity using different mixes of technologies, produce and transport different carriers (e.g., hydrogen or biofuels), and use far less fossil fuel, among other major changes. Important examples include electricity, hydrogen, and biomass.

Electricity system integration. Net-zero energy systems will rely more heavily on electricity generated from low-emissions technologies. Given the significant variations in the location of low-carbon electricity resources and the temporal variability of some renewable electricity sources, notably solar and wind power, regional electricity grids could reduce overall costs of net-zero energy systems (Section 6.4.5). Furthermore, electricity transmission interconnections could significantly reduce local energy balancing costs and investment in peaking plants needed to meet security of supply requirements, and it could increase system resilience, especially in the case of extreme events such as heat waves or cold spells (Fasihi and Bogdanov 2016). Important challenges to regional electricity integration include geopolitical concerns from cross-border trade and societal and technological challenges associated with building new transmission lines.

Hydrogen trade. Hydrogen may play an important role in future net-zero energy systems, particularly in applications where electricity is not economically advantageous (Box 6.9). Hydrogen can be used to decarbonise regions in which it is produced, and it can also be transported long distances to facilitate decarbonisation of sectors distant from sources of low-cost supply. Methods of long-distance, high-volume hydrogen transport could include liquid storage, chemical carriers, and gaseous delivery via pipelines (Section 6.4.5). In net-zero systems with substantial wind and solar power generation, hydrogen can be generated through electrolysis and then shipped to other locations. Important challenges to hydrogen trade include cost-effective low-carbon production, cost of delivery infrastructure, storage, and end-use technology costs and safety.

Trade in biomass. Biomass may also play an important role in net-zero energy systems (Section 6.6.4, Chapter 3). Large-scale bioenergy production and consumption is likely to trigger global biomass trade. Global bioenergy trade volumes presently exceed 1 EJ yr⁻¹, of which 60% is directly traded for energy purposes (Proskurina et al. 2019a). Established trade mechanisms include wood pellet transport, ethanol, and biodiesel (Proskurina et al. 2019b). In a net-zero global energy system, bioenergy trade could be greater than current trade of coal or natural gas, but less than that of petroleum (Sharmina et al. 2017; Mandley et al. 2020). Some studies indicate

Box 6.10 (continued)

that Latin America and Africa could become key exporting regions, with the EU, the USA, and East Asia emerging as key importers (Alsaleh and Abdul-Rahim 2018; Rentizelas et al. 2019). Studies have found that net bioenergy exports could be as high as 10% of GDP for some Latin American countries, while other regions like the EU may be faced with burgeoning import reliance (Daioğlu et al. 2020b; Mahlknecht et al. 2020). In addition to challenges associated with bioenergy production (Section 6.4 and Chapter 7), important challenges to biomass trade include differences in sustainability criteria and land/biomass definitions in different jurisdictions, and difficulties in establishing consistent monitoring and auditing systems (Lamers et al. 2016).

6.7 Low-carbon Energy System Transitions in the Near and Medium Term

6.7.1 Low-carbon Energy System Transition Pathways

6.7.1.1 Energy System Emissions

Without additional efforts to reduce emissions, it is very unlikely that energy system CO₂ emissions will decrease sufficiently to limit warming to well below 2°C (*high confidence*). Scenarios assuming improvements in technology but no additional climate policies beyond those in place today provide a benchmark for comparison against energy-related CO₂ emissions in mitigation scenarios (Figure 6.26). Emissions in these reference scenarios increase through 2050 but span a broad range (Riahi et al. 2017; Wei et al. 2018) (Chapter 3, Figure 3.16). The highest emission levels are about four times current emissions; the lowest are modestly below today's emissions. Emissions in these scenarios increase in most regions, but they diverge significantly across regions (Bauer et al. 2017). Asia and the Middle East and Africa account for the majority of increased emissions across these scenarios (Figure 6.27). While it is unlikely that there will be no new climate policies in the future, these scenarios

nonetheless support the conclusion that the energy sector will not be decarbonised without explicit policy actions to reduce emissions.

Warming cannot be limited to well below 2°C without rapid and deep reductions in energy system GHG emissions (*high confidence*). Energy sector CO₂ emissions fall by 87–97% (interquartile range) by 2050 in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot and 60–79% in scenarios limiting warming to 2°C (>67%) with action starting in 2020 (Figure 6.26). Energy sector GHG emissions fall by 85–95% (interquartile range) in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot, and 62–78% in scenarios limiting warming to 2°C (>67%) with action starting in 2020 (Figure 6.26). In 2030, in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot, net CO₂ and GHG emissions fall by 35–51% and 38–52% respectively. Key characteristics of emissions pathways – the year of peak emissions, the year when net emissions reach zero, and the pace of emissions reductions – vary widely across countries and regions. These differences arise from differences in economic development, demographics, resource endowments, land use, and potential carbon sinks (Schaeffer, et al. 2020; Schreyer, et al. 2020; van Soest, Heleen et al. 2021) (Figure 6.27, Figure 6.28, Box 6.11). If countries do not move quickly

Figure 6.26 | Projected energy sector GHG emissions for the 1.5°C scenarios (without and with overshoot), and likely below 2°C scenarios (without and with delayed policy action) during 2020–2050 (Source: AR6 Scenarios Database). Boxes indicate 25th and 75th percentiles, while whiskers indicate 5th and 95th percentiles. GHG emissions are inclusive of energy sector CO₂, CH₄, N₂O emissions and 80% of global HFC emissions. Number of model-scenario combinations in AR6 Scenarios Database: limit warming to 1.5°C (>50%) with no or limited overshoot: 77; return warming to 1.5°C (>50%) after a high overshoot: 110; limit warming to 2°C (>67%) with action starting in 2020: 164; limit warming to 2°C (>67%) with NDCs until 2030: 97.

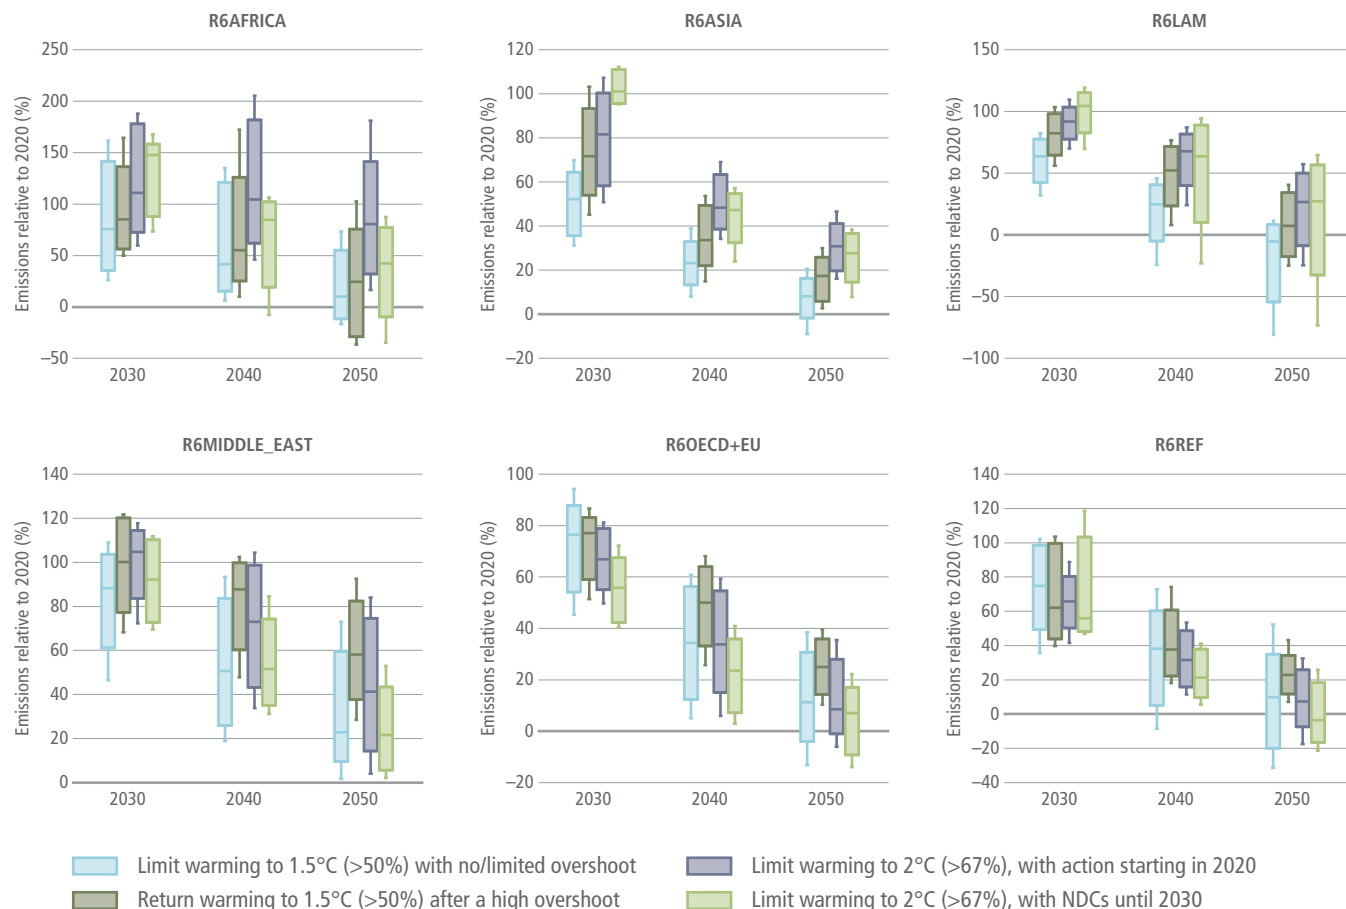

Figure 6.27 | Net regional (R6) CO₂ emissions from energy across scenarios that limit/return warming to 1.5°C (>50%) with no or limited/after a high overshoot, and scenarios that limit warming to 2°C (>67%) with action starting in 2020 or with NDCs until 2030, during 2020–2050 (Source: AR6 Scenarios Database). Boxes indicate 25th and 75th percentiles, while whiskers indicate 5th and 95th percentiles. Most mitigation scenarios are based on a cost-minimising framework that does not consider historical responsibility or other equity approaches.

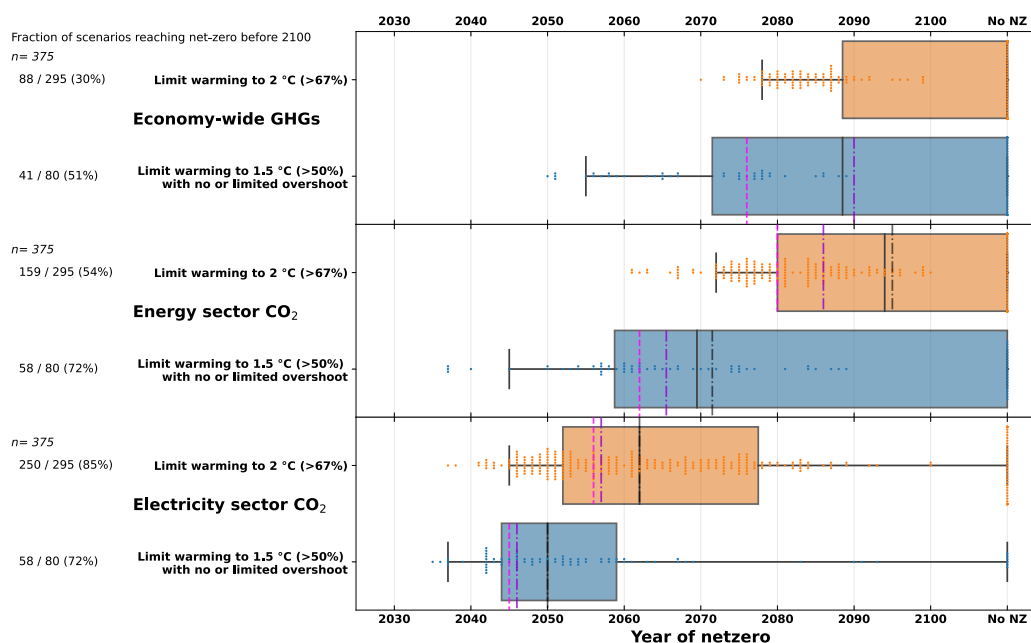

Figure 6.28 | The timing of net-zero emissions for full economy greenhouse gases (GHGs), energy sector CO₂, and electricity sector CO₂. Boxes indicate 25th and 75th percentiles, centre black line is the median, while whiskers indicate 1.5x the inter-quartile range. The vertical dashed lines represent the median point at which emissions in the scenarios have dropped by 95% (pink) and 97.5% (purple), respectively. Dots represent individual scenarios. The fraction indicates the number of scenarios reaching net-zero by 2100 out of the total sample. Source: AR6 Scenario Database.

to reduce emissions – if reductions are delayed – a more rapid energy transition will subsequently be required to limit warming to 2°C or lower (Rogelj et al. 2015a, 2018a; IPCC 2018).

The timing of net-zero energy system emissions varies substantially across scenarios. In scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot (2°C (>67%)), the energy system reaches net-zero CO₂ emissions (interquartile range) from 2060 onwards (2080–). (Figure 6.28). However, net emissions reach near-zero more quickly. For example, in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot (2°C (>67%)) net energy system CO₂ emissions drop by 95% between 2056 and 2075 (2073 and 2093). Net full economy GHG emissions reach zero more slowly than net CO₂ emissions. In some scenarios, net energy system CO₂ and total GHG emissions do not reach zero this century, offset by CDR in other sectors.

The timing of emissions reductions will vary across the different parts of the energy sector (Figure 6.28). To decarbonise most cost-effectively, global net CO₂ emissions from electricity generation will likely reach zero before the rest of the energy sector (*medium confidence*). In scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot (2°C (>67%)), net electricity sector CO₂ emissions

(interquartile range) reach zero globally between 2044 and 2055 (2052 and 2078) (Figure 6.28). It is likely to be less costly to reduce net CO₂ emissions close to or below zero in the electricity sector than in other sectors, because there are relatively more low-emissions options in electricity. Sectors such as long-distance transport, air transport, and process heat are anticipated to face greater challenges to decarbonisation than the electricity sector (Clark and Herzog 2014; Rogelj et al. 2015b, 2018b; IPCC 2018; Luderer et al. 2018).

In addition, there are potential options to remove CO₂ from the atmosphere in the electricity sector, notably BECCS, which would allow electricity sector emissions to drop below zero. Without CDR options, electricity sector emissions may not fall all the way to zero. If CDR is accomplished in other sectors and not in electricity, some fossil fuel plants may still lead to positive net electricity sector CO₂ emissions, even in net-zero economies (Bistline and Blanford 2021b; Williams et al. 2021a).

We lack sufficient understanding to pin down precise dates at which energy system CO₂ emissions in individual countries, regions, or sectors will reach net zero. Net-zero timing is based on many factors that are not known today or are bound up in development of key technologies, such as energy storage, bioenergy, or hydrogen. Some

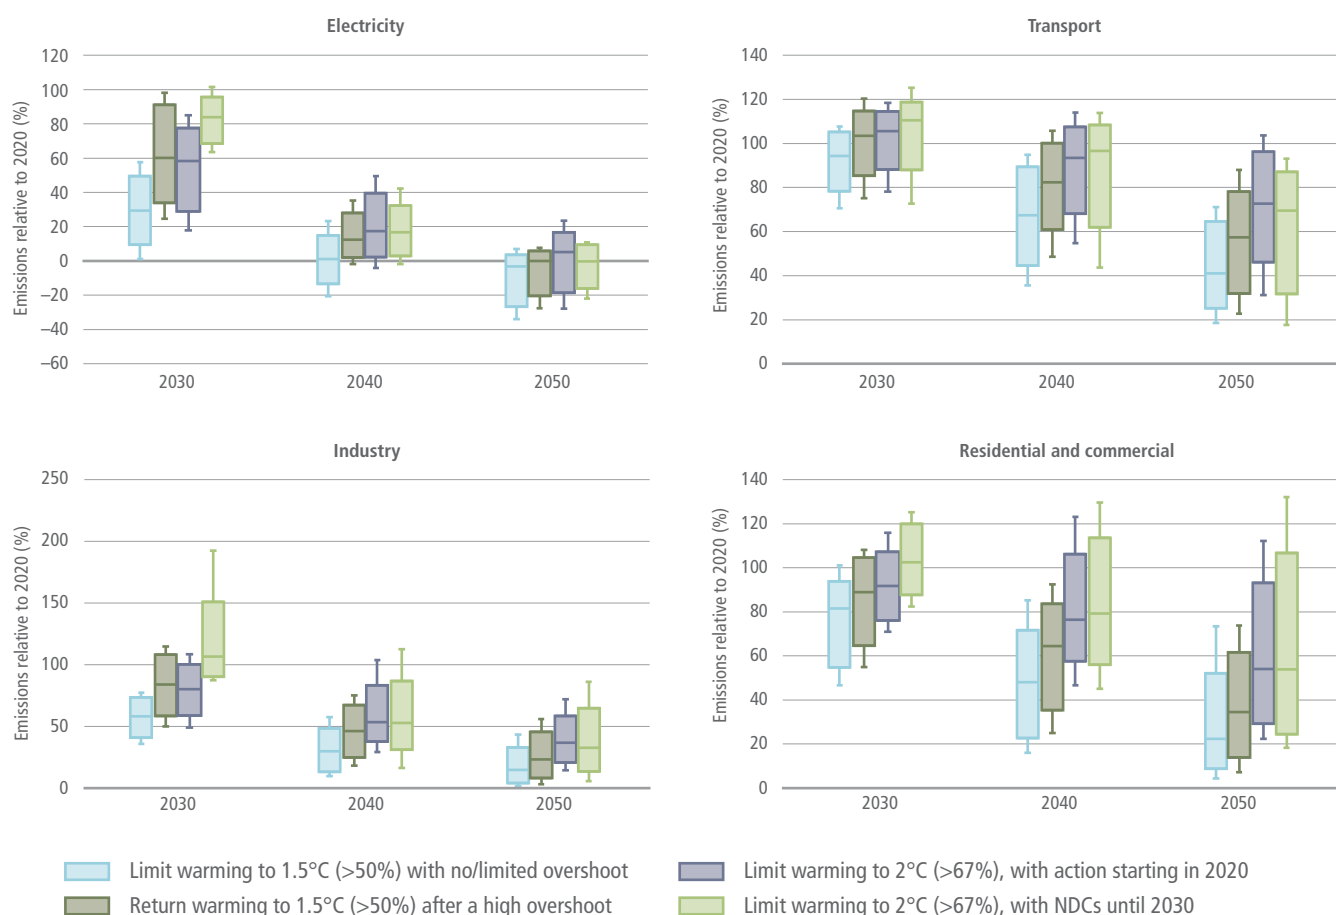

Figure 6.29 | Reductions in CO₂ emissions relative to 2020 levels for scenarios that limit/return warming to 1.5°C (>50%) with no or limited/after a high, overshoot, and scenarios that limit warming to 2°C (>67%), with action starting in 2020 or NDCs until 2030, during 2030–2050. Boxes indicate 25th and 75th percentiles while whiskers indicate 5th and 95th percentiles. Source: AR6 Scenarios Database.

countries have low-carbon resource bases that could support deep emissions reductions, while others do not. Timing is also affected by the availability of CDR options, whether these options are in the energy sector or elsewhere, and the discount rate used to assess strategies (Bednar et al. 2019; Emmerling et al. 2019). Moreover, while many scenarios are designed to minimise global mitigation costs, many other frameworks exist for allocating mitigation effort across countries (van den Berg et al. 2019) (Chapter 4).

6.7.1.2 Low-carbon Energy Transition Strategies

There are multiple technological routes to reduce energy system emissions (Section 6.6). Here we discuss three of these: (i) decarbonising primary energy and electricity generation; (ii) switching to electricity, bioenergy, hydrogen, and other fuels produced from low-carbon sources; and (iii) limiting energy use through improvement of efficiency and conservation. CDR is discussed in Section 6.7.1.3 Fossil fuel transitions are discussed in Section 6.7.4.

Decarbonising primary energy and electricity generation. Limiting warming to well below 2°C requires a rapid and dramatic increase in energy produced from low- or zero-carbon sources (*high*

confidence). Low- and zero-carbon technologies produce 74–82% (interquartile range) of primary energy in 2050 in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot and 55–68% in scenarios limiting warming to 2°C (>67%) (Figure 6.29). The share of low-carbon technologies in global primary energy supply today is below 20% (Chapter 3, Section 6.3, and Figure 6.29). The percentage of low- and zero-carbon energy will depend in part on the evolution of energy demand – the more that energy demand grows, the more energy from low- and zero-carbon sources will be needed, and the higher the percentage of total primary energy these sources will represent.

Low- and zero-carbon sources produce 97–99% of global electricity in 2050 in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot and 93–97% in scenarios limiting warming to 2°C (>67%) (Figure 6.29) (*medium confidence*). Decarbonising electricity generation, in tandem with increasing use of electricity (see below), is an essential near-term strategy for limiting warming. The increase in low- and zero-carbon electricity will occur while electricity demand grows substantially. Studies have projected that global electricity demand will roughly double by 2050 and quadruple to quintuple by 2100 irrespective of efforts to reduce emissions (Bauer et al. 2017; Luderer et al. 2017; IEA 2019a).

Figure 6.30 | Shares of low-carbon energy (all sources except unabated fossil fuels) and bioenergy (including both traditional and commercial biomass) in total primary energy, and solar+wind, CCS and nuclear in electricity for scenarios that limit/return warming to 1.5°C (>50%) with no or limited/after a high, overshoot, and scenarios that limit warming to 2°C (>67%), with action starting in 2020 or NDCs until 2030, during 2030–2050 (Source: AR6 Scenarios Database). Boxes indicate 25th and 75th percentiles while whiskers indicate 5th and 95th percentiles.

Renewable energy, especially generation from solar and wind, is likely to have an important role in many low-carbon electricity systems. The contributions of wind and solar electricity will depend on their levelised costs relative to other options, integration costs, system value, and the ability to integrate variable resources into the grid (Section 6.6). Electric sector technology mixes will vary by region but will typically include additional resources such as hydropower, nuclear power, fossil generation with CCS, energy storage resources, and geothermal energy, among others. Contributions of different options vary widely across scenarios based on different assumptions about these factors (Figure 6.30).

Nonetheless, it is likely that wind and solar will dominate low-carbon generation and capacity growth over the next couple of decades due to supporting policies in many countries, and due to their significant roles in early electric sector decarbonisation, alongside reductions in coal generation (Bistline and Blanford 2021b; Pan et al. 2021). Clean firm technologies play important roles in providing flexibility and on-demand generation for longer durations, though deployment of these technologies is typically associated with deeper decarbonisation levels (e.g., beyond 70–80% reductions), which are likely to be more important after 2030 in many regions, and with more limited CDR deployment (Baik et al. 2021; Bistline and Blanford 2021a; Williams et al. 2021a).

Box 6.11 | Illustrative Low-carbon Energy System Transitions

There are multiple possible strategies to transform the energy system to reach net-zero CO₂ emissions and to limit warming to 2°C (>67%) or lower. All pathways rely on the strategies for net-zero CO₂ energy systems highlighted in Section 6.6.2, but they vary in the emphasis that they put on different aspects of these strategies and the pace at which they approach net-zero emissions. The pathway that any country or region might follow will depend on a wide variety of factors (Section 6.6.4), including, for example, resource endowments, trade and integration with other countries and regions, carbon sequestration potential, public acceptability of various technologies, climate, the nature of domestic industries, the degree of urbanisation, and the relationship with other societal priorities such as energy access, energy security, air pollution, and economic competitiveness. The Illustrative Mitigation Pathways presented in this box demonstrate four distinct strategies for energy system transformations and how each plays out for a different region, aligned with global strategies that would limit warming to 2.0°C (>67%) or to 1.5°C (>50%). Each pathway represents a very different vision of a net-zero energy system. Yet, all these pathways share the common characteristic of a dramatic system-wide transformation over the coming decades.

Box 6.11, Figure 1 | Illustrative Mitigation Pathway 2.0-Neg: Latin America & Caribbean (LAM) in a scenario that limits warming to 2°C (>67%) (LAM net-zero economy 2040–2045, net-zero energy system 2045–2050). Supply-side focus with growing dependency on carbon dioxide removal and agriculture, forestry and other land-use (AFOLU), thus achieves net-zero CO₂ relatively early.

Box 6.11 (continued)

Box 6.11, Figure 2 | Illustrative Mitigation Pathway 1.5-Renewables: Africa (AF) in a scenario that limits warming to 1.5°C (>50%) (AF net-zero economy, 2055–2060, AF net-zero energy system 2055–2060). Rapid expansion of non-biomass renewables, high electrification, and a fossil fuel phase-out.

Box 6.11, Figure 3 | Illustrative Mitigation Pathway 1.5-Low Demand: Developed Countries (DEV) in a scenario that limits warming to 1.5°C (>50%) (DEV net-zero economy, 2055–2060, net-zero energy system 2075–2080). Major reduction of energy demand, high electrification, and gradual fossil fuel phase-out.

Box 6.11 (continued)

Box 6.11, Figure 4 | Illustrative Mitigation Pathway 1.5-Shifting Pathways: Asia and Pacific (APC) in a scenario that limits warming to 1.5°C (>50%) (APC net-zero economy, 2075–2080, net-zero energy system 2090–2095). Renewables, high electrification, fossil fuel phase-out and low agriculture, forestry and other land-use (AFOLU) emissions. Reaches net-zero CO₂ relatively late.

Box 6.11, Table 1 | Summary of selected Illustrative Mitigation Pathways energy system characteristics in 2050 for the chosen regions.

		Energy sector CO ₂ Reduction 2020–2050	Energy intensity		Variable renewable electricity generation		Low-carbon electricity capacity additions		CO ₂ removal BECCS, AFOLU, Total	GDP per capita		Year net-zero CO ₂ emissions		
		%	MJ/PPP USD2010		EJ yr ⁻¹ (%)		GW yr ⁻¹		GtCO ₂ yr ⁻¹	PPP USD2010 per person		Full economy	Energy sector	Electricity
	Region	2050	2020	2050	2020	2050	2020	2050	2050	2020	2050

Switching to low-carbon energy carriers. Switching to energy carriers produced from low-carbon sources will be an important strategy for energy sector decarbonisation. Accelerated electrification of end uses such as light duty transport, space heating, and cooking is a critical near-term mitigation strategy (Sugiyama 2012; Zou et al. 2015; Rockström et al. 2017; IEA 2019f; Waisman et al. 2019; B. Tang et al. 2021). Electricity supplies 48–58% (interquartile range) of the global final energy demand by 2050 in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot and 36–47% in scenarios limiting warming to 2°C (>67%) (Figure 6.29). Globally, the current level of electrification is about 20%.

Indirect electrification encompasses the use of electricity to produce hydrogen and synthetic fuels (efuels or power fuels). The extent of indirect electrification of final energy will depend on resource endowments and other regionally specific circumstances. Although indirect electrification is less efficient compared to direct electrification, it allows low-carbon fuels to be imported from regions with abundant low-carbon electricity generation resources (Fasihi and Bogdanov 2016; Lehtveer et al. 2019; Fasihi and Breyer 2020) (Box 6.10 on regional integration).

Figure 6.31 | Shares of electricity and hydrogen in final energy in scenarios that limit/return warming to 1.5°C (>50%) with no or limited/after a high overshoot, and scenarios that limit warming to 2°C (>67%), with action starting in 2020 or NDCs until 2030, during 2030–2050 (Source: AR6 Scenarios Database). Boxes indicate 25th and 75th percentiles while whiskers indicate 5th and 95th percentiles.

While electrifying end uses is a key decarbonisation strategy, some end uses such as long-distance transport (freight, aviation, and shipping) and energy-intensive industries will be harder to electrify. For these sectors, alternative fuels or energy carriers such as biofuels, hydrogen, ammonia or synthetic methane, may be needed (Section 6.6 and Box 6.9). Most scenarios find that hydrogen consumption will grow gradually, becoming more valuable when the energy system has become predominantly low-carbon (Figure 6.31).

Reducing energy demand. Energy service demand is expected to continue to increase with growth of the economy, but there is great uncertainty about how much it will increase (Bauer et al. 2017; Riahi et al. 2017; Yu et al. 2018). Given the need to produce low-carbon energy, the scale of energy demand is a critical determinant of the mitigation challenge (Riahi et al. 2012). Higher energy demand calls for more low-carbon energy and increases the challenge; lower energy demand reduces the need for low-carbon sources and therefore can ease a low-carbon transition. Recent studies have shown that tempering the growth of energy demand, while ensuring services and needs are still satisfied, can materially affect the need for technological CDR (Section 6.7.1.3) (Grubler et al. 2018; van Vuuren et al. 2018). Two of the Illustrative Mitigation Pathways (IMP-SP, IMP-LD) feature substantially lower final energy demand

across buildings, transport, and industry than most other pathways in the literature. In some cases, energy demand levels are lower in 2050 (and later) than in 2019. These lower demands result in less reliance on bioenergy and a more limited role for CDR (Figure 3.18).

6.7.1.3 Technology Options to Offset Residual Emissions

CDR technologies can offset emissions from sectors that are difficult to decarbonise (Section 6.6), altering the timeline and character of energy sector transitions. A number of studies suggest that CDR is no longer a choice, but rather a necessity to limit warming to 1.5°C (Rogelj et al. 2015a; Detz et al. 2018; Luderer et al. 2018; Streffer et al. 2018; van Vuuren et al. 2018). The reliance on CDR varies across scenarios and is tightly linked to future energy demand and the rate of emission reductions in the next two decades: deeper near-term emissions reductions will reduce the need to rely on CDR to constrain cumulative CO₂ emissions. Some studies have argued that only with a transition to lower energy demands will it be possible to largely eliminate the need for engineered CDR options (Grubler et al. 2018; van Vuuren et al. 2018). Overall, the amount of CDR will depend on CO₂ capture costs, lifestyle changes, reduction in non-CO₂ GHGs, and utilisation of zero-emission end-use fuels (Murator et al. 2017; van Vuuren et al. 2018).

There is substantial uncertainty about the amount of CDR that might ultimately be deployed. In most scenarios that limit warming to 1.5°C, CDR deployment is fairly limited through 2030 at less than 1 GtCO₂ yr⁻¹. The key projected increase in CDR deployment (BECCS and DAC only) occurs between 2030 and 2050, with annual CDR in 2050 projected at 2.5–7.5 GtCO₂ yr⁻¹ in 2050 (interquartile range) in scenarios limiting warming to 1.5°C (>50%) with limited or no overshoot, and 0.7–1.4 GtCO₂ yr⁻¹ in 2050 in scenarios limiting warming to 2°C (>67%) with action starting in 2020. This characteristic of scenarios largely reflects substantial capacity addition of BECCS power plants. BECCS is also deployed in multiple ways across sectors. For instance, the contribution (interquartile range) of BECCS to electricity is 1–5% in 2050 in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot, and 0–5% in scenarios that limit warming to 2°C (>67%) with action starting in 2020. The contribution (interquartile range) of BECCS to liquid fuels is 9–21% in 2050 in scenarios limiting

warming to 1.5°C (>50%) with no or limited overshoot and 2–11% in scenarios that limit warming to 2°C (>67%) with action starting in 2020. Large-scale deployment of CDR allows flexibility in timing of emissions reduction in hard-to-decarbonise sectors.

CDR will influence the potential fossil-related stranded assets (Box 6.13). Availability of low-cost CDR can help reduce premature retirement for some fossil fuel infrastructure. CDR can allow countries to reach net-zero emissions without phasing out all fossil fuels. Specific infrastructure could also be extended if it is used to burn biomass or other non-emitting sources. For example, existing coal-fired power plants, particularly those with CCS, could be co-fired with biomass (Woolf et al. 2016; Lu et al. 2019; Pradhan et al. 2021). In many scenarios, energy sector CDR is deployed to such an extent that energy sector CO₂ emissions become negative in the second half of the century (Chapter 3).

Box 6.12 | Taking Stock of the Energy System Transition

The Global Stocktake is a regularly occurring process under the UN Framework Convention on Climate Change (UNFCCC) in which efforts will be made to understand progress on, among other things, global mitigation. Collective progress of countries towards the Paris Agreement goal will be assessed and its outcome will inform Parties in updating and enhancing their Nationally Determined Contributions (NDCs). This box explores potential indicators to understand energy system mitigation progress.

CO₂ emissions from fuel combustion are the bottom line on energy system progress. Beyond CO₂ emissions, primary energy demand by energy sources, final energy consumption by sectors, and total electricity demand provide a first order assessment of energy system transitions. The year at which CO₂ emissions peak is also important. The Kaya Identity can be used to decompose energy system CO₂ emissions into carbon intensity of the energy system (CO₂ emissions from fossil-fuel combustion and industry divided by energy use), energy intensity (energy use divided by economic output), and economic output. The impacts of energy and climate policy are reflected in the changes of carbon intensity and energy intensity. Carbon intensity captures decarbonisation of energy supply systems, for example, through fuel switching from fossil fuels to non-fossil fuels, upscaling of low-carbon energy sources, and deploying carbon dioxide removal technologies. The carbon intensity of electricity is specifically important, given the role of the electricity sector in near-term mitigation. Economy-wide energy intensity represents efforts of demand-side energy, such as energy conservation, increase of energy performance of technologies, structural change of economy, and development of efficient urban infrastructure.

Beyond these aggregate indicators, a second order assessment would capture more details, such as the electrification rate, share of renewables, nuclear, CCS or other low-carbon technologies in electricity generation, land area used for energy production, and the number of EVs or PHEVs. Consumption of coal, oil and gas captures the underlying factors of CO₂ emissions. The emphasis of these indicators could differ across countries in the context of national specific circumstances. Technology- or project-based statistics are also useful to check the progress of the low-carbon transition, for example, the number of CCS facilities.

A critical challenge in the assessment of energy sector progress is how to measure societal, institutional, and political progress. These factors are difficult to quantify, yet they are fundamental determinants of the ability to reduce emissions. Public opinion, special interest politics, implications of mitigation for employment, energy subsidies, and energy policies are all critical indicators of progress. In addition, while much of the literature focuses on national-level action, mitigation is increasingly being led by cities, states, provinces, businesses, and other sub-national or non-national actors. Understanding the progress of these actors will be critical to assess energy system mitigation progress. New research is needed to better assess these ‘societal’ indicators and the role of non-national actors.

6.7.2 Investments in Technology and Infrastructure

Total global energy investment was roughly USD1940 billion yr⁻¹ in 2019 (IEA 2021f). This total can be broken down into the following main categories: fossil-related energy supply, including

oil, gas, and coal extraction and fossil electricity generation (USD990 billion yr⁻¹); renewable electricity, primarily solar and wind (USD340 billion yr⁻¹); nuclear energy (USD40 billion yr⁻¹); electricity networks (USD270 billion yr⁻¹); and end-use energy efficiency (USD270 billion yr⁻¹).

Figure 6.32 | Global average annual investments from 2023 to 2052 (undiscounted, in USD billion yr⁻¹) for electricity supply sub-sectors and for extraction of fossil fuels in scenarios that limit warming to 2°C (>67%) or lower (C1-C3) (Source: AR6 Scenarios Database and Chapter 3). Historical investments are also shown for comparison (Source: IEA 2021; approximations are made for hydro and geothermal based on available data; solar and wind values are for 2020). T&D: transmission and distribution of electricity. Bars show median values across models-scenarios, and whiskers the interquartile ranges. See Chapters 3 and 15 for additional information on investments and finance.

Energy investment needs are projected to rise, according to investment-focused scenario studies found in the literature (McCollum et al. 2018a; Zhou et al. 2019; Bertram et al. 2021). While these increases are projected to occur in emissions-intensive pathways as well as low-carbon pathways, they are projected to be largest in low-carbon pathways. Average annual global energy investments over the 2016–2050 period range (across six models) from USD2100 to 4100 billion yr⁻¹ in pathways limiting warming to 2°C (>67%) and from USD2400 to 4700 billion yr⁻¹ in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (McCollum et al. 2018). Whatever the scenario, a significant and growing share of investments between now and 2050 will be channelled toward infrastructure build-out in emerging economies, particularly in Asia (Zhou et al. 2019).

More widespread electrification of buildings, transport, and industry means particularly substantial investment in the electricity system. According to C1–C3 pathways in the IPCC's *Sixth Assessment Report* (AR6 Scenarios Database), such investments could be at the following average annual levels (inter-quartile range, USD2015)

over the 2023–2052 timeframe: USD1670 to 3070 billion yr⁻¹ (C1), USD1600 to 2780 billion yr⁻¹ (C2), and USD1330 to 2680 billion yr⁻¹ (C3) (see also Section 3.6.1.3).

Beyond these sector-wide numbers, a key feature of stringent mitigation pathways is a pronounced reallocation of investment flows across sub-sectors, namely from unabated fossil fuels (extraction, conversion, and electricity generation) and toward renewables, nuclear power, CCS, electricity networks and storage, and end-use energy efficiency (McCollum et al. 2018a; Bertram et al. 2021; IEA 2021f) (Figure 6.32). Investments in solar, wind, and electricity transmission, distribution, and storage increase the most in mitigation scenarios. Up to 2050, the bulk of these investments are made in OECD and Asian countries (Figure 6.33). While fossil fuel extraction investments exhibit a marked downscaling across all regions, compared to reference scenarios, the declines are especially strong in the Middle East, Reforming Economies of Eastern Europe and the Former Soviet Union (REF), and OECD.

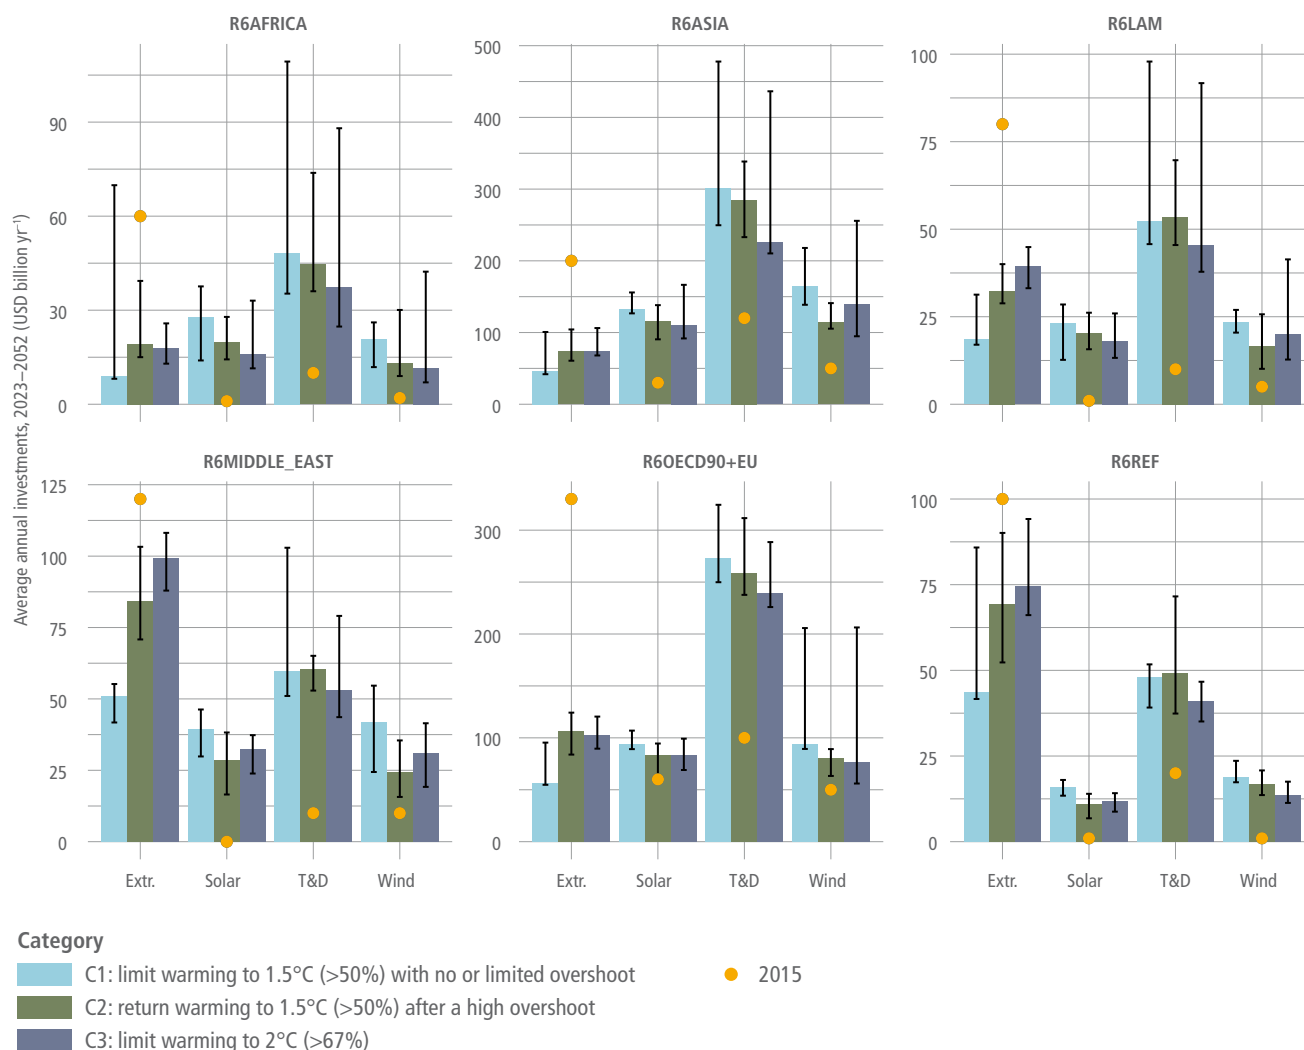

Figure 6.33 | Regional average annual investments from 2023 to 2052 (undiscounted, in USD billion yr^{-1}) for four of the largest sub-sectors of the energy system in scenarios that limit warming to 2°C (>67%) or lower (C1–C3) (Source: AR6 Scenarios Database and Chapter 3). Historical investments are also shown for comparison (Source: IEA, 2016). T&D: transmission and distribution of electricity. Extr.: extraction of fossil fuels. Bars show median values across models-scenarios, and whiskers the inter-quartile ranges. See Chapters 3 and 15 for additional information on investments and finance.

Investments into end-use energy efficiency are projected to also be substantial in mitigation pathways, potentially upwards of several hundred USD billion yr^{-1} on average to 2050, compared to USD270 billion yr^{-1} in 2019 (McCollum et al. 2018a; IEA 2021f). However, the literature is inconsistent in how demand-side investments are calculated, as boundary conditions are less clear than for energy supply investments. Taking a broader definition can result in estimates that are an order-of-magnitude higher, meaning as large or larger than supply-side investments (Grubler et al. 2012; IEA 2021f).

Increasing low-carbon investment primarily requires shifting existing capital investment through regulation and incentives as well as removing existing investment barriers (McCollum et al. 2018; Hafner et al. 2020; Ameli, N. et al. 2021). While there is a considerable amount of capital in the world, it is not always available to those wishing to invest in certain projects. Total annual global investment in fixed

capital was USD22.4 trillion in 2021, over an order-of-magnitude larger than energy sector investment (World Bank 2021).

Future investment patterns will vary by region, as they do now, due to differences in risk profiles, resource endowments and economic and governance structures (Fizaine et al. 2016; Zhou et al. 2019; Ameli, N. et al. 2021). In rapidly growing countries, investments to support a low-carbon energy system transition will be integrated with those needed to meet rapidly increasing energy demands, irrespective of whether efforts are made to reduce emissions. In less rapidly growing countries (Sun et al. 2019), investments will focus on transitioning current energy systems to low-carbon configurations. Most current energy investments are concentrated in high- and upper-middle-income countries (IEA 2021f), but this will change as investment needs continue to grow in today's lower-middle- and low-income countries (McCollum et al. 2018a; Zhou et al. 2019; Bertram et al. 2021; IEA 2021f).

6.7.3 Energy System Lock-in and Path Dependence

Path dependence refers to resistance to change due to favourable socio-economic conditions with existing systems; decisions made in the past unduly shape future trajectories. Carbon lock-in is a specific type of path dependence (Seto et al. 2016). Given that energy system

mitigation will require a major course change from recent history, lock-in is an important issue for emission reductions in the energy sector. While lock-in is typically expressed in terms of physical infrastructure that would need to be retired early to reach mitigation goals, it involves a much broader set of issues that go beyond physical systems and into societal and institutional systems (Table 6.11).

6.7.3.1 Societal and Institutional Inertia

A combination of factors – user, business, cultural, regulatory, and transnational – will hinder low-carbon energy transitions. Strong path dependencies, even in early formative stages, can have lasting impacts on energy systems, producing inertia that cuts across technological, economic, institutional and political dimensions (*high confidence*) (Rickards et al. 2014; Vadén et al. 2019) (Chapter 5).

Energy systems exemplify the ways in which massive volumes of labour, capital, and effort become sunk into particular institutional configurations (Bridge et al. 2013, 2018). Several embedded factors affect large-scale transformation of these systems and make technological diffusion a complex process:

- **User environments** affect purchase activities and can involve the integration of new technologies into user practices and the development of new preferences, routines, habits and even values (Kanger et al. 2019).
- **Business environments** can shape the development of industries, business models, supply and distribution chains, instrument constituencies and repair facilities (Béland and Howlett 2016).
- **Culture** can encompass the articulation of positive discourses, narratives, and visions that enhance cultural legitimacy and societal acceptance of new technologies. Regulatory embedding can capture the variety of policies that shape production, markets and use of new technologies.
- **Transnational community** can reflect a shared understanding in a community of global experts related to new technologies that transcends the borders of a single place, often a country.

While low-carbon innovation involves systemic change (Geels et al. 2018), these are typically less popular than energy supply

innovations among policymakers and the wider public. Managing low-carbon transitions is therefore not only a techno-managerial challenge (based on targets, policies, and expert knowledge), but also a broader political project that involves the building of support coalitions that include businesses and civil society (*moderate evidence, high agreement*).

Low-carbon transitions involve cultural changes extending beyond purely technical developments to include changes in consumer practices, business models, and organisational arrangements. The development and adoption of low-carbon innovations will therefore require sustained and effective policies to create appropriate incentives and support. The implementation of such policies entails political struggles because actors have different understandings and interests, giving rise to disagreements and conflicts.

Such innovation also involves pervasive uncertainty around technical potential, cost, consumer demand, and social acceptance. Such uncertainty carries governance challenges. Policy approaches facing deep uncertainty must protect against and/or prepare for unforeseeable developments, whether it is through resistance (planning for the worst possible case or future situation), resilience (making sure you can recover quickly), or adaptation (changes to policy under changing conditions). Such uncertainty can be hedged in part by learning by firms, consumers, and policymakers. Social interactions and network building (e.g., supply and distribution chains, intermediary actors) and the articulation of positive visions, such as in long-term, low-emission development strategies, all play a crucial role. This uncertainty extends to the impacts of low-carbon innovations on energy demand and other variables, where unanticipated and unintended outcomes are the norm. For instance, rapid investments in public transport networks could restrict car ownership from becoming common in developing countries (Du and Lin 2017).

6.7.3.2 Physical Energy System Lock-In

Current investments in fossil infrastructure have committed 500–700 GtCO₂ of emissions, creating significant risks for limiting warming to 1.5°C (Callaghan 2020) (*high confidence*). These current investments combined with emissions from proposed fossil infrastructure exceed the emissions required to limit warming to 1.5°C (*medium confidence*). Existing coal- and gas-fired electricity generation accounts for 200–300 GtCO₂ of committed emissions. Emissions from coal generation are larger than for gas plants (Smith et al. 2019; Tong et al. 2019). The lifetime of coal-fired power plants is 25–50 years, creating long-lasting risks to climate goals (Erickson and Tempest 2015). Gas-fired power plants are younger on average than coal-fired power plants. Industry sector lock-in amounts for more than 100 GtCO₂, while buildings and transport sector together contribute another 50–100 GtCO₂ (Erickson and Tempest 2015).

Lock-in is also relevant to fossil resources. Both coal and gas exploration continue, and new permits are being issued, which may cause economic (Erickson et al. 2018) as well as non-economic issues (Boettcher et al. 2019).

The nature of lock-in varies across the energy system. For example, lock-in in urban and transport sectors is different from the electricity sector. Broadly, urban environments involve infrastructural, institutional, and behavioural lock-in (Ürge-Vorsatz et al. 2018). Addressing lock-in in these sectors requires action by multiple stakeholders and is unlikely with just technological evolution (Table 6.11).

Committed carbon emissions are unevenly distributed. The disproportionate high share of committed emissions in emerging economies is the result of rapid growth in recent years, which has led to a comparably young fossil infrastructure with substantial remaining life (Shearer et al. 2017). Mature industrialised countries tend to have older infrastructures, part of which will be up for retirement in the near

future (Tong et al. 2019). Coal-fired power plants currently planned or under construction are associated with 150–300 GtCO₂, of which about 75% and about 10% are located in Asia and the OECD respectively (Edenhofer et al. 2018; Pfeiffer et al. 2018). If implemented, these new fleets will further shorten all coal plants' lifetimes by another 10 years for meeting climate goals (Cui et al. 2019).

Despite the imperative to reduce use of fossil fuels and the multiple health and other benefits from closing coal-based infrastructure (Portugal-Pereira et al. 2018; Liu et al. 2019a; Karlsson et al. 2020; Rauner et al. 2020; Cui et al. 2021), coal power plants have continued to be commissioned globally (Jewell et al. 2019; Jakob et al. 2020), most notably in Asian countries. Gas power plants also continue to be built. In many regions, new fossil electricity generation exceeds needed capacity (Shearer et al. 2017).

Existing policies and the NDCs are insufficient to prevent an increase in fossil infrastructure and associated carbon lock-in (*high confidence*) (Bertram et al. 2015; Johnson et al. 2015). Current investment decisions are critical because there is limited room within the carbon budget required to limit warming to well below 2°C (Kalkuhl et al. 2019; Rosenbloom 2019). Delays in mitigation will increase carbon lock-in and could result in large-scale stranded assets if stringency is subsequently increased to limit warming (Box 6.11). Near-term implementation of stringent GHG mitigation policies are likely to be most effective in reducing carbon lock-in (Haelg et al. 2018). Near-term mitigation policies will also need to consider different energy transition strategies as a result of different resources and carbon budgets between countries (Lucas 2016; Bos and Gupta 2018).

Near-term policy choices are particularly consequential for fast-growing economies. For example, Malik et al. (2020) found that 133 to 227 GW of coal capacity would be stranded after 2030 if India were to delay ambitious mitigation through 2030 and then pursue an ambitious, post-2030 climate strategy. Cui et al. (2021) identified 18% of old, small, inefficient coal plants for rapid near-term retirement in China to help achieve air quality, health, water, and other societal goals and a feasible coal phase-out under climate goals. Comparable magnitudes of stranded assets may also be created in Latin America when adding all announced, authorised, and procured power plants up to 2060 (González-Mahecha et al. 2019). Options to reduce carbon lock-in include reducing fossil fuels subsidies (Box 6.3), building CCS-ready facilities, or ensuring that facilities are appropriately designed for fuel switching (Budinis et al. 2018). Substantial lock-in may necessitate considerable deployment of CDR to compensate for high cumulative emissions.

Past and present energy sector investments have created technological, institutional, and behavioural path dependencies aligned towards coal, oil, and natural gas (*high confidence*). In several emerging economies, large projects are planned that address poverty reduction and economic development. Coal infrastructure may be the default choice for these investments without policies to invest in low-carbon infrastructure instead (Joshua and Alola 2020; Steckel et al. 2020). Path dependencies frequently have sustainability implications beyond carbon emissions. (Box 6.2 and Section 6.7.7).

Figure 6.34 | Annual emissions from existing, proposed, and future energy system infrastructure. Source: with permission from Tong et al. 2019.

There are several SDG co-benefits associated with decarbonisation of energy systems (Section 6.7.7) (Sörgel et al. 2021). For example, coal

mining communities frequently experience significant health and economic burdens from resource extraction.

Box 6.13 | Stranded Assets

Limiting warming to 2°C (>67%) or lower will result in stranded assets (*high confidence*). Stranded assets can be broadly defined as assets that ‘suffer from unanticipated or premature write-offs, downward revaluations or [conversion] to liabilities’. Stranded assets may create risks for financial market stability and macro-economic stability (Battiston et al. 2017; Mercure et al. 2018; Sen and von Schickfus 2020), and they will result in a rapid loss of wealth for the owners of affected assets (Vogt-Schilb and Hallegatte 2017; Ploeg and Rezaei 2020).

There are two types of stranded assets: fossil-fuel resources that cannot be burned; and premature retirement of fossil infrastructure (e.g., power plants). About 30% of oil, 50% of gas, and 80% of coal reserves will remain unburnable if warming is limited to 2°C (Meinshausen et al. 2009; Leaton 2011; Leaton Ranger 2013; McGlade and Ekins 2015; Bauer et al. 2016; IRENA 2017b; Pye et al. 2020) (*high confidence*). Significantly more reserves are expected to remain unburned if warming is limited to 1.5°C. Countries with large oil, gas, and coal reserves are most at risk (Caldecott et al. 2017; Ansari and Holz 2020).

About 200 GW of fossil fuel electricity generation per year will likely need to be retired prematurely after 2030 to limit warming to 2°C, even if countries achieve their Nationally Determined Contributions (NDCs) (*medium confidence*) (Iyer et al. 2015; Johnson et al. 2015; Fofrich et al. 2020). Limiting warming to 1.5°C will require significantly more rapid premature retirement of electricity generation capacity (Binsted et al. 2020). Coal- and gas-fired power plants will likely need to retire about 25 years earlier than in the past to limit warming to 2°C, and 30 years earlier to limit warming to 1.5°C (Cui et al. 2019; Fofrich et al. 2020). Coal-fired power plants are at significantly greater risk of stranding compared with gas-fired and oil-fired plants (Iyer et al. 2015; Johnson et al. 2015; Fofrich et al. 2020). The risks of stranded power plants are greatest in countries with newer fossil infrastructure.

If warming is limited to 2°C, the discounted economic impacts of stranded assets, including unburned fossil reserves, could be as high as USD1–4 trillion from 2015 through 2050 (USD10–20 trillion in undiscounted terms) (*medium confidence*) (IRENA, 2017c; Mercure et al. 2018). About 40% of these impacts correspond to unburned fossil reserves (IRENA 2017b). If warming is limited to 1.5°C, the economic impacts of stranded assets are expected to be significantly higher (Binsted et al. 2020).

Stronger near-term mitigation will reduce premature retirements of fossil infrastructure, because more rapid mitigation will decrease new builds of fossil infrastructure that might later be stranded (Johnson et al. 2015; Bertram et al. 2018) (*high confidence*). For example, if warming is limited to 2°C, strengthening the NDC pledges beyond their 2015 levels could decrease stranded electricity sector assets by more than 50% (Iyer et al. 2015). By contrast, if countries fail to meet their NDCs and continue to build fossil infrastructure, mitigation will need to be accelerated beyond 2030, resulting up to double the amount of stranded electricity generation capacity (Iyer et al. 2015). This corresponds to a total undiscounted cost of about USD2 trillion from electricity infrastructure alone, from the period 2015 to 2050 (IRENA 2017). CCS (6.4) could potentially help reduce hundreds of gigawatts stranded power plant capacity along with other fossil-based capital (Clark and Herzog 2014; Iyer et al. 2017; Fan et al. 2018).

6.7.4 Fossil Fuels in a Low-carbon Transition

Global fossil fuel use will need to decline substantially by 2050 to limit warming to 2°C (>67%), and it must decline substantially by 2030 to limit warming to 1.5°C (>50%) with no or limited overshoot (*high confidence*). Failing to reduce global fossil fuel use below today’s levels by 2030 will make it more challenging to limit warming to below 2°C (>67%). (*high confidence*). Fossil fuel use declines by 260–330 EJ (52–73% from 2020 levels, interquartile range) through 2050 in scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot, and 124–231 EJ (24–51% reduction compared to 2020 levels) in scenarios that limit warming to 2°C (>67%) with action starting in 2020. This will require a significant reduction in coal, oil and gas investments. Fossil fuels account for about 80% of primary energy today. In scenarios limiting warming to 1.5°C (>50%) with

limited or no overshoot, fossil energy provides 59–69% (interquartile range) of primary energy in 2030 and 25–40% primary energy in 2050 (AR6 Scenarios Database). In scenarios limiting warming to 2°C (>67%) with action starting in 2020, fossil energy provides 71–75% (interquartile range) primary energy in 2030 and 41–57% primary energy in 2050 (AR6 Scenarios Database). The timeline for reducing production and usage varies across coal, oil, and gas due to their differing carbon intensities and uses.

Global coal consumption without CCS needs to be largely eliminated by 2040–2050 to limit warming to 1.5°C (>50%), and 2050–2060 to limit warming to 2°C (>67%) (*high confidence*). New investments in coal-fired electricity without CCS are inconsistent with limiting warming to 2°C (>67%) or lower (*high confidence*) (Edenhofer et al. 2018; Pfeiffer et al. 2018; Spencer et al. 2018; Cui et al. 2019). Coal

consumption declines 130 EJ yr⁻¹ to 140 EJ yr⁻¹ in 2050 (78–99% compared to 2020 levels, interquartile range) in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot and 118 EJ yr⁻¹ to 139 EJ yr⁻¹ (65% to 98% compared to 2020 levels) in scenarios limiting warming to 2°C (>67%) with action starting in 2020. Coal consumption without CCS falls by 67% to 82% (interquartile range) in 2030 in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot. Studies indicate that coal use may decline substantially in the USA and Europe over the coming decade, based on the increasing competitiveness of low-carbon sources and near-term policy actions (Grubert and Brandt 2019; Oei et al. 2020). In several developing economies, the relative youth of the coal-fired electricity fleet will make a complete phase-out before 2050 difficult (Garg and Shukla 2009; Jewell et al. 2016). There are considerable differences in projected coal phase-out timelines in major Asian economies. Some studies suggest that coal may continue to be a part of the Chinese energy mix composing around one-third of the total primary energy consumption by 2050, even if emissions are reduced by 50% by 2030 (He et al. 2020). Others indicate that a strategic transition would decrease the risk of stranded assets and enable a near-complete phase-out by 2050 (Wang et al. 2020a; Cui et al. 2021). This would entail prioritising

earlier retirements of plants based on technical (efficiency), economic (profitability, local employment) and environmental considerations (e.g., water scarcity for cooling).

Natural gas may remain part of energy systems through mid-century, both for electricity generation and use in industry and buildings, and particularly in developed economies, even if warming is limited to 2°C (>67%) or lower (*medium confidence*). The decline in natural gas use from 2020 to 2050 is 38 EJ yr⁻¹ to 78 EJ yr⁻¹ (21–62% decline from 2020 levels, interquartile range) in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot and –22 EJ yr⁻¹ to 46 EJ yr⁻¹ (–14% to 36% decline from 2020 levels, interquartile range) in scenarios limiting warming to 2°C (>67%) with action starting in 2020. Scenarios indicate that gas use in electricity will likely peak around 2035 and 2050 if warming is limited to 1.5°C (>50%) with limited or no overshoot or to 2°C (>67%) with action starting in 2020, respectively. There is variability in the role gas would play in future scenarios based on national climate commitments and availability of cheap renewables (Malik et al. 2020; Vishwanathan and Garg 2020; Vrontisi et al. 2020). Note that these differences are not only present in the electricity sector but also in other end uses.

Figure 6.35 | Global fossil fuel pathways for scenarios that limit/return warming to 1.5°C (>50%) with no or limited/after a high, overshoot, and scenarios that limit warming to 2°C (>67%), with action starting in 2020 or NDCs until 2030, during 2030–2050. Boxes indicate 25th and 75th percentiles while whiskers indicate 5th and 95th percentiles. Results for total consumption are expressed as a percentage relative to 2020 consumption. Results for fossil energy with CCS are expressed in total energy consumption. Oil use with CCS is not shown here as it remains below 5% of total use. Source: AR6 Scenarios Database.

While oil use is anticipated to decline substantially, due to changes in the transport sector, its use will likely continue through the mid-century, even if warming is limited to 2°C (>67%) or lower (*medium confidence*). Oil use declines by 73 EJ yr⁻¹ to 145 EJ yr⁻¹ (30–78% from 2020 levels, interquartile range) in scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot and 26 EJ yr⁻¹ to 86 EJ yr⁻¹ (14–45% from 2020 levels) by 2050 in scenarios that limit warming to 2°C (>67%) with action starting in 2020. While oil use is anticipated to decline immediately in scenarios limiting warming to 1.5°C (>50%), it is likely to continue to be used through 2050. Oil use continues to be a significant source of transport fuels in most scenarios limiting warming to 2°C (Welsby et al. 2021). Oil use may drop to about half of current levels as a transport fuel by 2050 if warming is limited to 2°C, because of the availability of other options (biofuels, green hydrogen) and rapid deployment of EVs (Feijoo et al. 2020). In the absence of rapid transport electrification, the decline is slower with some studies projecting peak oil use around 2035 (Delgado et al. 2020; Pan et al. 2020).

There is a lack of consensus about how CCS might alter fossil fuel transitions for limiting warming to 2°C (>67%) or lower. CCS deployment will increase the shares of fossil fuels associated with limiting warming, and it can ease the economic transition to a low-carbon energy system (Muratori et al. 2016; Marcucci et al. 2019). While some studies find a significant role for fossil fuels with CCS by 2050 (Koelbl et al. 2014; Eom et al. 2015; Vishwanathan and Garg 2020), others find that retirement of unabated coal far outpaces the deployment of coal with CCS (Budinis et al. 2018; Xie et al. 2020; McJeon et al. 2021). Moreover, several studies also project that, with availability of CO₂ capture technology, BECCS might become significantly more appealing than fossil CCS, even before 2050 (Muratori et al. 2017; Luderer et al. 2018b).

6.7.5 Policy and Governance

Policy and governance frameworks are essential for shaping near- and medium-term low-emissions energy system transitions (*high confidence*). While policy interventions are necessary to achieve low-carbon energy system transitions, appropriate governance frameworks are crucial to ensure policy implementation (*high confidence*). The policy environment in energy transition pathways relate to climate policy goals, the characteristics of the policy regimes and measures to reach the policy goals including implementation limits and obstacles, and the timing of the climate instrument (Kriegler et al. 2014b).

The literature discusses a broad set of policy approaches. Environmental economics focuses mainly on market-based approaches as the least-cost policy to achieve emission reductions (Kube et al. 2018). Many countries, however, have implemented policy mixes with a diverse set of complementary policies to achieve energy and climate policy targets. One example is the German *Energiewende*, which includes substantial support for renewables, an action plan for energy efficiency, and phase-out processes for nuclear- and coal-based power generation next to carbon pricing (Löschel et al. 2019). The halving of CO₂ emissions in UK power generation reflects multiple

policies, particularly within the UK's Climate Change Act 2008 (Grubb and Newbery 2018). More generally, the implementation of the NDCs under the Paris Agreement are all characterised by diverse climate policy mixes.

These policy mixes (or policy packages) are shaped by different factors, including policy goals and objectives (including political, social and technological influences), multiple market, governance or behavioural failures or previous policy choices of earlier policy eras (Rogge 2017). When pursuing multiple policy goals or targeting some type of imperfection, well designed policy mixes can, in principle, reduce mitigation costs (Corradini et al. 2018) or address distributional concerns, especially vulnerable populations. For example, the interaction between carbon pricing and the support for clean energy technologies in the EU clean low-carbon strategy for 2050 can reduce mitigation costs and allow for the early adoption of more stringent climate targets (Vandyck et al. 2016). Policy efforts to promote adoption of low-carbon technologies are more successful if they focus not only on economic incentives but include behavioural interventions that target relevant cognitive and motivational factors (Mundaca et al. 2019; Khanna et al. 2021) (Section 6.7.6). Overlapping nudges might not necessarily lead to lower effectiveness (Brandon et al. 2019).

Well-designed policy mixes can support the pursuit of multiple policy goals, target effectively different types of imperfections and framework conditions and take into account the technological, economical, and societal situation (*high confidence*). Accounting for the different development stages of new technologies will enhance low-emissions transitions (Graaf and Sovacool 2020). For prototype technologies and technologies in the demonstration phase, research subsidies and demonstration projects are most important. For technologies experiencing early adoption, infrastructure development and strengthening of markets are increasingly important, while retiring or repurposing of existing assets is important for mature technologies (IEA 2020h). Effective policy mixes will address different market frictions and deal with various uncertainties, for example, those pertaining to technological, climate, and socio-economic developments (Aldy 2020), but also with respect to outcomes of individual policies (e.g., Borenstein et al. 2019). Therefore, policy mixes may balance the trade-off between stability and the flexibility to change individual policies (Gawel and Lehmann 2019) and the policy mix over time (Rayner et al. 2017). Some policy instruments may become feasible over time, for example, as technological advancements reduce the transaction costs of comprehensive market-based approaches (Andoni et al. 2019; Di Silvestre et al. 2020), or as weakened barriers to stringency enable policy sequencing (Pahle et al. 2018). Energy system policy mixes often include sector-specific regulation. Compared to economy-wide approaches, sectoral policies may be able to directly target specific sectors or mitigation options. However, uncoordinated implementation or limited coordination across sectors may lead to efficiency losses (e.g. Rosendahl et al. 2017). These losses also depend on other policies, such as pre-existing taxes (Goulder et al. 2016; Marten et al. 2018) or research and development policies (Acemoglu et al. 2016). Moreover, unilateral policies – those taken by individual countries in the absence of coordination with other countries – could raise carbon leakage risks, while balancing

potential issues of (industrial) competitiveness (Martin et al. 2014; Rosendahl et al. 2017). Energy leakage may become more important during low-carbon energy systems. Numerous studies have identified pathways for carbon leakage in electricity markets with incomplete emission markets (Caron et al. 2015; Murray and Maniloff 2015; Thurber et al. 2015; Duan et al. 2017; Fell and Maniloff 2017; Qian et al. 2018). Well-designed policy mixes will need to target the whole lifecycle or value chains, for example, through policies on limiting fossil fuel extraction (Asheim et al. 2019), or they will need to include measures to limit carbon leakage (e.g. Cosbey et al. 2019).

Interactions between policy measures including their scope, stringency, and timing, influence the costs of reducing emissions (Corradini et al. 2018). In particular, some policy instruments may lead to lock-in effects (Section 6.7.3), compete with other regulations (Graaf and Sovacool 2020), or trigger negative policy interactions (Perino 2015; Jarke-Neuert and Perino 2020). Existing policy mixes often reflect different political economy constraints, and sometimes not well coordinated goals. The resulting policy mixes are often economically inefficient. However, comprehensive evaluation of policy mixes requires a broader set of criteria that reflect different considerations, such as broader goals (e.g., SDGs) and the feasibility of policies (*high confidence*).

Policy mixes might rather emerge piece-by-piece over time out of individual policy interventions rather than be designed as a whole from the outset (Howlett 2014; Rogge 2017) and may reflect differences across jurisdictions and sectors (Howlett 2014). For example, taking into account country-specific objectives, failures, and limitations, carbon prices may be only one part of a broader policy mix, and thereby may not be uniform across countries (Bataille 2020). This lack of consistency makes it more difficult to assess economic outcomes since costs of complementary policies are often less visible and are often targeted at high-cost mitigation options (Borenstein et al. 2019).

Effective assessment of policy mixes requires comprehensive, validated international data, methodologies, and indicators. Existing policy mixes are difficult to evaluate because they target multiple objectives, and the evaluation must consider various criteria (Chapter 13 and Section 6.7.7), such as environmental and economic effectiveness, distributional effects, transformative potential, institutional requirements, and feasibility. Economic outcomes depend on policy goals and implementation. Existing studies on policy mixes suggest the benefits of a comprehensive approach (Rosenow et al. 2017), while also highlighting that an 'excessive' number of instruments may reduce overall effectiveness (Costantini et al. 2017). Combining environmental regulation and innovation policies may be of particular importance to tackle both emissions and innovation market failures (Fabrizi et al. 2018). The consistency and credibility of policy mixes is positively associated with green innovation (Rogge and Schleich 2018).

Potential future policies are difficult to evaluate due to methodological challenges (*high confidence*). Recent model-based analyses of future policy mixes based on 'current policy scenarios' try to implement existing policies besides explicit or implicit carbon prices (den Elzen et al. 2016; Rogelj et al. 2016; van Soest et al. 2017; Roelfsema et al. 2020). Many assessments of future low-carbon energy transitions are

still based on cost-optimal evaluation frameworks and include only limited analysis of interactions between policy measures. Hence they are often not describing real-world energy transitions properly, but rather differences in implied carbon prices, constraints in technology deployment, and timing of policies (Trutnevyte 2016).

6.7.6 Behaviour and Societal Integration

Members of societies, including individuals, civil society, and businesses, will all need to engage with, and be affected by, low-carbon energy system transitions (*high confidence*). This raises questions about the extent to which different strategies and policy would effectively promote mitigation behaviours and the factors that increase the social acceptability of mitigation options, policies, and system changes.

6.7.6.1 Strategies to Encourage Climate Mitigation Actions

Climate policy will be particularly effective if it targets key factors inhibiting, enabling, and motivating mitigation behaviours. As barriers differ across mitigation options, regions, and groups, tailored approaches are more effective (Grubb et al. 2017). When people face important barriers to change (e.g., high costs, legal barriers), policy would be needed make low-carbon actions more attractive, or to make high-carbon actions less attractive. As people generally face multiple barriers for change, combinations of policies would be more effective (Rosenow et al. 2017).

Financial incentives can motivate mitigation actions (Santos 2008; Thøgersen 2009; Bolderdijk et al. 2011; Eliasson 2014; Maki et al. 2016), particularly when actions are costly (Mundaca 2007). In many countries, more residential solar PV were installed after the introduction of favourable financial schemes such as feed-in-tariffs, federal income tax credits, and net metering (Wolske and Stern 2018). Similarly, many programs have promoted the installation of lower-carbon household options such as heat pumps, district heating, or solar water heaters across Europe, the Asia-Pacific and Africa (Hu et al. 2012; Sovacool and Martiskainen 2020; Ahmed et al. 2021). Yet, financial incentives may underperform expectations when other factors are overlooked. For example, people may not respond to financial incentives when they do not trust the organisation sponsoring the programme, or when it takes too much effort to receive the incentive (Mundaca 2007; Stern et al. 2016a). Financial incentives are more effective if combined with strategies addressing non-financial barriers.

Communicating financial consequences of behaviour seems less effective than emphasising social rewards (Handgraaf et al. 2013) or benefits of actions for people (e.g., public health, comfort) and the environment (Bolderdijk et al. 2013; Asensio and Delmas 2015, 2016; Schwartz et al. 2015; Ossokina 2020). Financial appeals may have limited effects because they reduce people's focus on environmental consequences, weaken intrinsic motivation to engage in mitigation actions, provide a licence to pollute (Agrawal et al. 2015; Bolderdijk and Steg 2015; Schwartz et al. 2015), and because pursuing small

financial gains is perceived not worth the effort (Bolderdijk et al. 2013; Dogan et al. 2014).

Providing information on the causes and consequences of climate change or on effective mitigation actions increases people's knowledge and awareness, but generally does not promote mitigation actions by individuals (Abrahamse et al. 2005) or organisations (Anderson and Newell 2004). Fear-inducing representations of climate change may inhibit action when they make people feel helpless (O'Neill and Nicholson-Cole 2009). Energy-related advice and feedback can promote energy savings, load shifting in electricity use and sustainable travel, particularly when framed in terms of losses rather than gains (Gonzales et al. 1988; Wolak 2011; Bradley et al. 2016; Bager and Mundaca 2017). Also, credible and targeted information at the point of decision can promote action (Stern et al. 2016a). Information is more effective when delivered by a trusted source, such as peers (Palm 2017), advocacy groups (Schelly 2014), and community organisations (Noll et al. 2014), and when tailored to actors' personal situations and core values (Daamen et al. 2001; Abrahamse et al. 2007; Bolderdijk et al. 2013; Boomsma and Steg 2014; Wolsko et al. 2016; van den Broek et al. 2017). This explains why home energy audits promoted energy savings (Delmas et al. 2013; Alberini and Towe 2015), and investments in resource efficiency and renewable energy generation (Kastner and Stern 2015).

Energy use feedback can promote energy saving behaviour within households (Fischer 2008; Grønhøj and Thøgersen 2011; Delmas et al. 2013; Karlin et al. 2015; Zangheri et al. 2019) and at work (Young et al. 2015), particularly when provided in real time or immediately after the action so that people learn the impact of different actions (Abrahamse et al. 2005; Faruqui et al. 2009; Delmas et al. 2013; Yu et al. 2015; Stern et al. 2016a; Tiefenbeck et al. 2016). Energy labels (Banerjee and Solomon 2003; Stadelmann 2017), visualisation techniques (Pahl et al. 2016), and ambient persuasive technology (Midden and Ham 2012) can encourage energy savings as they immediately make sense and hardly require users' conscious attention. Feedback can make people aware of their previous mitigation behaviours, which can strengthen their environmental self-identity, and motivate them to engage in other mitigation actions, to act in line with their self-image (Van der Werff et al. 2014).

Social influence approaches that communicate what other people do or think can encourage mitigation actions (Clayton et al. 2015), as can social models of desired actions (Osbaldeston and Schott 2012; Abrahamse and Steg 2013; Sussman and Gifford 2013; Wolsko et al. 2020). Feedback on one's own energy use relative to others can be effective (Nolan et al. 2008; Allcott 2011; Schultz et al. 2015), although not always, and effect sizes are small (Abrahamse and Steg 2013) compared to other types of feedback (Karlin et al. 2015).

Interventions that capitalise on people's motivation to be consistent can promote mitigation actions (Steg 2016). Examples are commitment strategies where people pledge to act (Abrahamse and Steg 2013; Lokhorst et al. 2013), implementation intentions where they additionally explicate how and when they will perform the relevant action and how they would cope with possible barriers (Bamberg 2000, 2002; Rees et al. 2018), and hypocrisy-related strategies that make people aware

of inconsistencies between their attitudes and behaviour (Osbaldeston and Schott 2012).

Bottom-up approaches can promote mitigation action (Abrahamse and Steg 2013). Indeed, community energy initiatives can encourage members' low-carbon behaviour (Middlemiss 2011; Seyfang and Haxeltine 2012; Abrahamse and Steg 2013; Sloot et al. 2018). Organisations can promote mitigation behaviour among their employees and customers by communicating their mission and strategies to mitigate climate change (Ruepert et al. 2017; van der Werff et al. 2021).

Default options, where a preset choice is implemented if users do not select another option, can promote mitigation actions such as energy savings, green electricity uptake, and meat-free options (Pichert and Katsikopoulos 2008; Bessette et al. 2014; Campbell-Arvai et al. 2014; Kunreuther and Weber 2014; Ölander and Thøgersen 2014; Ebeling and Lotz 2015; Liebe et al. 2018; Liebe et al. 2021).

6.7.6.2 Acceptability of Policy, Mitigation Options and System Changes

Public acceptability reflects the extent to which the public evaluates climate policy, mitigation options, and system changes (un)favourably, which can shape, enable, or prevent low-carbon energy system transitions. Public acceptability of policy and mitigation options is higher when people expect these have more positive and less negative consequences for self, others, and the environment (Perlaviciute and Steg 2014; Demski et al. 2015; Drews and Van den Bergh 2016). Public opposition may result when a culturally valued landscape is affected by renewable energy development (Warren et al. 2005; Devine-Wright and Howes 2010), particularly when place-based identities are threatened (Devine-Wright 2009, 2013; Boudet 2019). Acceptability can increase after a policy or change has been implemented and the consequences appear to be more positive than expected (Schuitema et al. 2010; Eliasson 2014; Weber 2015; Carattini et al. 2018); effective policy trials can thus build public support.

Next, climate policy and low-carbon options are evaluated as more fair and acceptable when costs and benefits are distributed equally, and when nature, the environment and future generations are protected (Schuitema et al. 2011; Drews and Van den Bergh 2016). Compensating affected groups for losses due to policy or systems changes enhanced public acceptability in some cases (Perlaviciute and Steg 2014), but people may disagree on which compensation would be worthwhile (Aitken 2010b; Cass et al. 2010), on the distribution of compensation (Devine-Wright and Sherry-Brennan 2019; Leer Jørgensen et al. 2020), or feel they are being bribed (Cass et al. 2010; Perlaviciute and Steg 2014). Pricing policies are more acceptable when revenues are earmarked for environmental purposes (Steg et al. 2006; Sælen and Kallbekken 2011) or redistributed towards those affected (Schuitema and Steg 2008).

Climate policy and mitigation options, such as renewable energy projects, are also perceived as more fair and acceptable when the public (Dietz 2013; Bidwell 2014; Bernauer et al. 2016b) or public society organisations (Terwel et al. 2010; Bernauer et al. 2016b) could participate in the decision-making (Arvai 2003; Devine-Wright 2005;

Terwel et al. 2012; Walker and Baxter 2017; Perlaviciute and Squintani 2020). People are more motivated to participate in decision-making on local projects than on national or general policy goals (Perlaviciute and Squintani 2020). Public acceptability is also higher when people can influence major rather than only minor decisions, particularly when trust in responsible parties is low (Liu et al. 2019a). Public participation can enhance the quality and legitimacy of decisions by including local knowledge and views that may otherwise be missed (Dietz 2013; Bidwell 2016).

Public support is higher when people trust responsible parties (Perlaviciute and Steg 2014; Drews and Van den Bergh 2016; Michaels and Parag 2016; Jiang et al. 2018; Liu et al. 2019a). Public support for unilateral climate policy is rather strong and robust (Bernauer et al. 2016a), even in the absence of reciprocal commitments by other states (Bernauer and Gampfer 2015).

Public acceptability of climate policy and low-carbon options differs across individuals. Climate policy and low-carbon options are more acceptable when people strongly value protecting other people and the environment, and support egalitarian worldviews, left-wing or green political ideologies, while acceptability is lower when people strongly endorse self-centred values, and support individualistic worldviews (Dietz et al. 2007; Perlaviciute and Steg 2014; Drews and Van den Bergh 2016). Similarly, public decision-makers support climate policy more when they endorse environmental values (Nilsson et al. 2016). Climate and energy policy is more acceptable when people are more concerned about climate change (Hornsey et al. 2016), when they believe their actions would help mitigate climate change, and feel responsible to mitigate climate change (Steg 2005; Eriksson et al. 2006; Jakovcovic and Steg 2013; Drews and Van den Bergh 2016; Kim and Shin 2017; Ünal et al. 2019).

6.7.7 The Costs and Benefits of Low-carbon Energy System Transitions in the Context of Sustainable Development

The attractiveness of energy sector mitigation ultimately depends on the way that it provides benefits and reduces the costs for the many different priorities that societies value (Yang et al. 2018a; Wei et al. 2018, 2020). While costs and benefits of climate mitigation are often considered in the context of pure economic outcomes – for example, GDP effects or changes in value of consumption – costs and benefits should be viewed with a broader lens that accounts for the many ways that the energy system interacts with societal priorities (Karlsson et al. 2020). Climate mitigation is not separate from countries' broader growth and development strategies, but rather as a key element of those strategies.

Cost reductions in key technologies, particularly in electricity and light-duty transport, have increased the economic attractiveness of near-term low-carbon energy system transitions (*high confidence*). The near-term, economic outcomes of low-carbon energy system transitions in some sectors and regions may be on par with or superior to those of an emissions-intensive future (*high confidence*). Even in cases when system costs are higher for low-carbon transitions, these

transitions may still be economically favourable when accounting for health impacts and other co-benefits (Gielen et al. 2019). Past assessments have quantified the aggregate economic costs for climate change mitigation using different metrics, for example, carbon prices, GDP losses, investments in energy infrastructure, and energy system costs. Assessments of mitigation costs from integrated assessment and energy system models vary widely. For example, scenarios include carbon prices in 2030 of less than USD20 tCO₂⁻¹, but also more than USD400 tCO₂⁻¹ depending on the region, sector boundary, and methodology (e.g., Bauer et al. 2016; Brouwer et al. 2016; Oshiro et al. 2017; Vaillancourt et al. 2017; Chen et al. 2019). Those arise both from different methodologies (Guivarch and Rogelj 2017) and assumptions about uncertainties in key factors that drive costs (Meyer et al. 2021).

Recent developments, however, raise the prospect that economic outcomes could be substantially superior to prior estimates, particularly if key technologies continue to improve rapidly. In some regions and circumstances, particularly in the electricity sector, near-term mitigation may lead to superior economic outcomes than continuing to invest in and utilise emissions-intensive infrastructure (e.g. Brown et al. 2017; Kumar et al. 2020). Given the importance of electricity decarbonisation in near-term mitigation strategies (Section 6.7.1), decreasing costs of solar PV, wind power, and batteries to support their integration, have an outsized influence on near-term economic outcomes from mitigation. At the same time, economic outcomes may vary across regions depending, among other things, on the characteristics of the current energy systems, energy resources, and needs for integrating VRE technologies.

The long-term economic characteristics of low-emissions energy system transitions are not well understood, and they depend on policy design and implementation along with future costs and availability of technologies in key sectors (e.g., process heat, long-distance transport), and the ease of electrification in end-use sectors (*high confidence*). The long-term aggregate economic outcomes from a low-emissions future are not likely to be substantially worse than in an emissions-intensive future and may prove superior (Child et al. 2019; Farmer et al. 2020; Bogdanov et al. 2021) (*medium confidence*). For the whole economy, the interquartile range of estimated mitigation costs is between 140 USD2015 and 340 USD2015 tCO₂⁻¹ in 2050 in scenarios limiting warming to 2°C (>67%) and between 430 USD2015 and 990 USD2015 tCO₂⁻¹ in scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot (Chapter 3). For energy sectors in various regions and globally, different scenarios show a wide range of implied carbon prices in 2050 to limit warming to 1.5°C, from below USD50 tCO₂⁻¹ to more than USD900 tCO₂⁻¹ (Brouwer et al. 2016; Rogelj et al. 2018a). Mitigation costs for scenarios limiting warming to 2°C (>67%) were 3–11% in consumption losses in AR5, but the median in newer studies is about 3% in GDP losses (Su et al. 2018; Gambhir et al. 2019).

Estimates of long-run mitigation costs are highly uncertain and depend on various factors. Both faster technological developments and international cooperation are consistently found to improve economic outcomes (Paroussos et al. 2019). Long-term mitigation is likely to be more challenging than near-term mitigation because low-

cost opportunities get utilised first and later efforts would require mitigation in more challenging sectors (Section 6.6). Advances in low-carbon energy resources and carriers such as next-generation biofuels, hydrogen produced from electrolysis, synthetic fuels, and carbon-neutral ammonia would substantially improve the economics of net-zero energy systems (*high confidence*). Current estimates of cumulative mitigation costs are comparably high for developing countries, amounting to up to 2–3% of GDP, indicating difficulties for mitigation without adequate support from developed countries (Dorband et al. 2019; Fujimori et al. 2020). In scenarios involving large amounts of stranded assets, the overall costs of low-carbon transitions also include the additional costs of early retirements (Box 6.11).

Focusing only on aggregate economic outcomes neglects distributional impacts, impacts on broader SDGs, and other outcomes of broad societal importance. Strategies to increase energy efficiency and energy conservation are, in most instances, mutually reinforcing with strategies to support sustainable development. Improving efficiency and energy conservation will promote sustainable consumption and production of energy and associated materials (SDG 12) (*high confidence*). Contrastingly, successful implementation of demand-side options requires sustainable partnerships (SDG 17) between different actors in energy systems, for example, governments, utilities, distributors, and consumers. Many authors have argued that energy efficiency has a large untapped potential in both supply and demand (Lovins 2018; Méjean et al. 2019). For example, improved fossil power plant efficiency has been estimated to lower the costs of CCS from USD80–100 tCO₂⁻¹ for a subcritical plant to <USD40 tCO₂⁻¹ for a high-efficiency plant (Hu and Zhai 2017; Singh et al. 2017). This could enhance energy access and affordability. Eliminating electricity

transmission losses has been estimated to mitigate 500 MtCO₂ per year globally (Surana and Jordaan 2019). For several other options, such as methane mitigation from the natural gas sector, the costs of infrastructure refurbishing could be offset with the value of the recovered natural gas (Kang et al. 2019).

Efficient end-use technologies are likely to be particularly cost-effective in developing countries where new infrastructure is rapidly getting built and there is an opportunity to create positive path dependencies (Section 6.7.3). Aside from reducing energy consumption, efficient end-use technologies reduce resource extraction, for example, fossil fuel extraction or mining for materials used in wind turbines or solar PV cells (Luderer et al. 2019). Reduced resource extraction is an important precursor to SDG 12 on sustainable consumption and production of minerals. End-use efficiency strategies also reduce the need for, and therefore SDG trade-offs associated with, CDR towards the end of the century and avoid temperature overshoot (van Vuuren et al. 2018). But fully leveraging the demand-side efficiency would entail behavioural changes and thus rely on strong partnerships with communities (SDG 17). For instance, approaches that inform households of the economic value of conservation strategies at home could be particularly useful (Niamir et al. 2018). Improved energy efficiency is interlinked with higher economic growth in Africa (Lin and Abudu 2020; Ohene-Asare et al. 2020). An important distinction here between SDGs focusing on infrastructural and behavioural interventions is the temporal context. Improving building heat systems or the electricity grid with reduced T&D losses would provide climate mitigation with one-time investments and minor maintenance over decades. On the other hand, behavioural changes would be an ongoing process involving sustained, long-term societal interactions.

Figure 6.36 | The relationship between total per capita energy use, rate of electrification and human development index (HDI). Improved efficiency has lowered the energy demand required for meeting a threshold HDI during 2012–2017.

Figure 6.37 | Nature of the interactions between SDG 7 (Energy) and the non-energy SDGs. Source: McCollum et al. 2018c, reproduced under Creative Commons 3.0 Licence.

Increasing electrification will support and reduce the costs of key elements of human development, such as education, health, and employment (*high confidence*). Greater access to electricity might offer greater access to irrigation opportunities for agricultural communities (Peters and Sievert 2016) which could have the potential for increasing farmer incomes in support of SDG 1. Coordinated electrification policies also improve enrolment for all forms of education (Kumar and Rauniyar 2018; López-González et al. 2020). Empirical evidence from India suggests that electrification reduced the time for biomass collection, and thus increased the time children have available for schooling (SDGs 4 and 5) (Khandker et al. 2014). Reduced kerosene use in developing countries has improved indoor air quality (SDG 3) (Barron and Torero 2017; Lewis and Severnini 2020). These positive linkages between climate change mitigation and other goals have improved perceptions of solar PV among the public and policymakers. ‘Goodwill’ towards solar PV is the highest among all the major mitigation options considered in this chapter (Section 6.4.2).

Past trends have also indicated that, in some Asian countries, electrification has been obtained at lower income levels as compared to developed countries (Rao and Pachauri 2017), with corresponding impacts for development goals. For example, a human development index (HDI) greater than 0.7 (Figure 6.36) which signifies high development is now possible at close to 30 GJ yr⁻¹ per person. This was attainable only at the energy consumption of 50 GJ yr⁻¹ per person in preceding decades.

Electrification also improves energy efficiency, with corresponding implications for development goals. For example, the availability of electric cooking may reduce the cooking primary energy requirement considerably compared to traditional stoves (Yang and Yang 2018; Batchelor et al. 2019; Khan and Alam 2020) while also promoting improved indoor air quality (SDG 3). Similarly, PV-powered irrigation and water pumping reduces pumping energy demands, which has

the added advantage of promoting SDG 6 on clean water (Rathore et al. 2018; Elkadeem et al. 2019).

Phasing out fossil fuels in favour of low-carbon sources is likely to have considerable SDG benefits, particularly if trade-offs such as unemployment to fossil fuel workers are minimised (*high confidence*). A phase-out of coal (Box 6.2) will support SDGs 3, 7 and 14, but it is also anticipated to create large job losses if not properly managed. At the same time, there are large potential employment opportunities that may be created in alternative sectors such as renewables and bioenergy for both skilled and unskilled workers. ‘Sustainable transition’ pathways have indicated a complete fossil phase-out which could entail numerous other co-benefits. For instance, fossil fuels are estimated to generate only 2.65 jobs per million USD as compared to projected 7.49 from renewables (Garrett-Peltier 2017). Similar synergies may also emerge for nuclear power in the long term, though the high costs create trade-offs in developing country contexts (Agyekum et al. 2020; Castor et al. 2020). While bioenergy production may create jobs, it may also be problematic for SDG 2 on zero hunger by affecting the supplies and prices of food. Phasing out of fossil fuels will also improve air quality (SDG 3) and premature deaths by reducing PM2.5 emissions, (He et al. 2020; Li et al. 2020c). Energy transitions from fossil fuels to renewables, as well as within fossil fuels (coal to gas switching), are already occurring in some regions, spurred by climate concerns, health concerns, market dynamics, or consumer choice (e.g., in the transport sector).

CDR and CCS can create significant land and water trade-offs (*high confidence*). For large-scale CDR and CCS deployment to not conflict with development goals requires efforts to reduce implications on water and food systems. The water impacts of carbon capture are large, but these impacts can be strategically managed (Magneschi et al. 2017; Liu et al. 2019a; Realmonte et al. 2019; Giannaris et al. 2020c). In addition, high-salinity brines are produced from geologic carbon storage, which may be a synergy or trade-off depending on

the energy intensity of the treatment process and the reusability of the treated waters (Klapperich et al. 2014; Arena et al. 2017); if the produced brine from geologic formations can be treated via desalination technologies, there is an opportunity to keep the water intensity of electricity as constant (Section 6.4.2.5). Both implications of CCS and CDR are related to SDG 6 on clean water. CDR discussions in the context of energy systems frequently pertains to BECCS which could affect food prices based on land management approaches (Daioglou et al. 2020a). Several CDR processes also require considerable infrastructure refurbishment and electrification to reduce upstream CO₂ emissions (Singh and Colosi 2021). Large-scale CDR could also open the potential for low-carbon transport and urban energy (by offsetting emissions in these sectors) use that would create synergies with SDG 11 (sustainable cities and communities). Effective siting of CDR infrastructure therefore requires consideration of trade-offs with other priorities. At the same time, several SDG synergies have also been reported to accompany CCS projects, such as with reduced air pollution (SDG 3) (Mikunda et al. 2021).

Greater energy system integration (Sections 6.4.3 and 6.6.2) would enhance energy-SDG synergies while eliminating trade-offs associated with deploying mitigation options (*high confidence*). Energy system integration strategies focus on codependence of individual technologies in ways that optimise system performance. Accordingly, they can improve economic outcomes and reduce negative implications for SDGs. For example, VRE electricity options raise intermittency concerns and hydrogen can be expensive due to the costs of electricity. Both are relevant to SDG 7 on affordable and reliable energy access. Routing excess solar generation during daytime for hydrogen production will improve grid stability as lower hydrogen costs (Tarroja et al. 2015). Due to the varying patterns of solar and wind energy, these two energy sources could be operated in tandem, thus reducing the material needs for their construction and for storage, thus promoting SDG 12 on sustainable production (Weitemeyer et al. 2015; Wang et al. 2019d). For CCS facilities, co-firing of fossil fuels and biomass could enable a more gradual, near-term low-carbon transition (Lu et al. 2019). This could enable early retirements (associated with SDG 1) while also providing air pollution reductions (associated with SDG 3).

Overall, the scope for positive interactions between low-carbon energy systems and SDGs is considerably larger than the trade-offs (Figure 6.37) (McCollum et al. 2018b). Some critical trade-offs include impact to biodiversity due to large-scale mineral mining needed for renewable infrastructure (Sonter et al. 2020).

Frequently Asked Questions

FAQ 6.1 | Will energy systems that emit little or no CO₂ be different than those of today?

Low-carbon energy systems will be similar to those of today in that they will provide many of the same services as today – for example, heating and cooling homes, travelling to work or on vacation, transporting goods and services, and powering manufacturing. But future energy systems may be different in that people may also demand new services that aren't foreseen today, just as people now use energy for many information technology uses that were not anticipated 50 years ago. More importantly, low-carbon energy systems will be different in the way that energy is produced, transformed, and used to provide these services. In the future, almost all electricity will be produced from sources that emit little or no CO₂, such as solar power, wind power, nuclear power, bioenergy, hydropower, geothermal power, or fossil energy in which the CO₂ is captured and stored. Electricity, hydrogen, and bioenergy will be used in many situations where fossil fuels are used today, for example, in cars or heating homes. And energy is likely to be used more efficiently than today, for example, through more efficient cars, trucks, and appliances, buildings that use very little energy, and greater use of public transportation. All of these changes may require new policies, institutions, and even new ways for people to live their lives. And fundamental to all of these changes is that low-carbon energy systems will use far less fossil fuel than today.

FAQ 6.2 | Can renewable sources provide all the energy needed for energy systems that emit little or no CO₂?

Renewable energy technologies harness energy from natural sources that are continually replenished, for example, from the sun (solar energy), the wind (wind energy), plants (bioenergy), rainfall (hydropower), or even the ocean. The energy from these sources exceeds the world's current and future energy needs many times. But that does not mean that renewable sources will provide all energy in future low-carbon energy systems. Some countries have a lot of renewable energy, whereas others do not, and other energy sources, such as nuclear power or fossil energy in which CO₂ emissions are captured and stored (carbon dioxide capture and storage, or CCS) can also contribute to low-carbon energy systems. The energy from sources such as solar energy, wind energy, and hydropower can vary throughout the day or over seasons or years. All low-carbon energy sources have other implications for people and countries, some of which are desirable, for example, reducing air pollution or making it easy to provide electricity in remote locations, and some of which are undesirable, for example decreasing biodiversity or mining of minerals to produce low-emissions technologies. For all of these reasons, it is unlikely that all low-carbon energy systems around the world will rely entirely on renewable energy sources.

FAQ 6.3 | What are the most important steps to decarbonise the energy system?

To create a low-carbon energy system, emissions must be reduced across all parts of the system, and not just one or two. This means, for example, reducing the emissions from producing electricity, driving cars, hauling freight, heating and cooling buildings, powering data centres, and manufacturing goods. There are more opportunities to reduce emissions over the next decade in some sectors compared to others. For example, it is possible to substantially reduce electricity emissions over the next decade by investing in low-carbon electricity sources, while at the same time halting the construction of new coal-fired power plants, retiring existing coal-fired power plants or retrofitting them with carbon capture and storage (CCS), and limiting the construction of new gas-fired power plants. There are also opportunities to increase the number of electric cars, trucks, and other vehicles on the road, or to use electricity rather than natural gas or coal to heat homes. And across the whole energy system, emissions can be reduced by using more efficient technologies. While these and other actions will be critical over the coming decade, it is also important to remember that the low-carbon energy transition needs to extend for many decades into the future to limit warming. This means that it is important now to improve and test options that could be useful later on, for example, producing hydrogen from low-carbon sources or producing bioenergy from crops that require less land than today.

Skea, R. Slade, A. Al Khourdajie, R. van Diemen, D. McCollum, M. Pathak, S. Some, P. Vyas, R. Fradera, M. Belkacemi, A. Hasija, G. Lisboa, S. Luz, J. Malley, (eds.)]. Available from <https://www.ipcc.ch/report/ar6/wg3/>.

Overview of the factors affecting the feasibility of mitigation options in energy systems and how they differ across context (e.g., region), time (e.g., 2030 versus 2050), and scale (e.g., small versus large), and the line of sight on which the feasibility assessment shown in Figure 6.9 is based. The feasibility assessment method is explained in Annex II.11 and Box TS.7.

	Geophysical		
	Physical potential	Geophysical resources	Land use
Solar energy	+	+	±
<i>Role of context</i>	Limited in higher latitudes	Not limited by materials	Limited in urban areas

Notes:

- The indicator has a negative impact on the feasibility of the option
- ± The indicator has mixed positive and negative impacts on the feasibility of the option
- +
- 0 The indicator does not affect the feasibility of the option

NA The indicator is not applicable for the option

NE no evidence available to assess the impact of the indicator on the feasibility of the option

LE limited evidence available to assess the impact of the indicator on the feasibility of the option

	Geophysical		
	Physical potential	Geophysical resources	Land use
Nuclear	±	+	+
<i>Role of context</i>	Physical potential is not an issue. Existing sites could be reused, new sites can be identified and only a few countries might face space limitations.	Sufficient resources for deployment at meaningful scales	Has low footprint for land. Some reference to the longevity of permanent storage for high-level radioactive waste, which has a long span in utilisation but still very low footprint in land use
<i>Line of sight</i>	Damoom, M.M., S. Hashim, M.S. Aljohani, M.A. Saleh, and N. Xoubi, 2019: Potential areas for nuclear power plants siting in Saudi Arabia: GIS-based multi-criteria decision making analysis. <i>Prog. Nucl. Carbon dioxide (CO₂) capture, utilisation and storage	±	±	+
<i>Role of context</i>	Limited in some sectors – including CO ₂ utilisation, bioenergy with carbon capture and storage (CCS), etc.	Limited in some sectors – including CO ₂ utilisation, bioenergy with CCS, etc.	Less than several other mitigation options (not considering bioenergy)
<i>Line of sight</i>	Budinis, S., S. Krevor, N. Mac Dowell, N. Brandon, and A. Hawkes, 2018: An assessment of CCS costs, barriers and potential. <i>Energy Strateg. Rev.</i> , 22 , 61–81, doi:10.1016/j.esr.2018.08.003. Selosse, S. and O. Ricci, 2017: Carbon capture and storage: Lessons from a storage potential and localization analysis. <i>Appl. Energy</i> , 188 , 32–44, doi:10.1016/j.apenergy.2016.11.117.		
Bioenergy	+	NA	–
<i>Role of context</i>	Very large physical potential. Wastes and residues (e.g., from agricultural, forestry, animal manure processing) or biomass grown on degraded, surplus, and marginal land can provide opportunities for cost-effective and sustainable bioenergy at significant but limited scale. A major scale-up of bioenergy production will require dedicated production of advanced biofuels. Assessing the potential for a major scale-up of purpose-grown bioenergy is challenging due to its far-reaching linkages to issues beyond the energy sector, including competition with land for food production and forestry, water use, impacts on ecosystems, and land-use change). These factors, rather than geophysical characteristics, largely define the potential for bioenergy.	Not limited by materials	Potentially large land-use implications but depends on scale and bioenergy feedstocks

	Environmental-ecological			
	Air pollution	Toxic waste, ecotoxicity eutrophication	Water quantity and quality	Biodiversity
Nuclear	+	±	±	±
<i>Role of context</i>	Has low nitrogen oxides (NO _x), sulphur dioxide (SO ₂), particulate matter (PM), and non-methane volatile organic compound (NMVOC) emissions on a life-cycle basis.	Low impacts to ecosystems, acidification, eutrophication, ecotoxicity, ozone depletion, and photochemical ozone creation potential (POCP). Long-term solutions for high-level radioactive waste are under development.	Water withdrawal rates depend a lot on the type of cooling system. Once-through cooling systems need a lot of water, but most of it is returned to freshwater bodies. Withdrawal rates from closed-loop cooling systems are significantly lower as compared to once-through systems.	Low impacts to biodiversity but high impact in case of an accident.

	Environmental-ecological			
	Air pollution	Toxic waste, ecotoxicity eutrophication	Water quantity and quality	Biodiversity
Bioenergy	±	NE	±	±
<i>Role of context</i>	Direct use of bioenergy without carbon capture and storage (CCS) leads to air pollutant emissions. For bioenergy, the life cycle assessment of criteria pollutants is considerably different than that for greenhouse gases (GHGs). The impact of bioenergy use on air pollutants needs to be examined on smaller spatial scales and might be more or less significant compared to fossil fuels. Bioenergy with CCS for hydrogen or electricity production offers an opportunity to mitigate pollutants emissions, while bioenergy with carbon capture and storage (BECCS) for liquid fossil fuels doesn't solve the problem of end-use pollutants emissions at the final point of use.	Can use wastes as a feedstock for bioenergy but the overall impact of bioenergy on toxic waste, ecotoxicity, and eutrophication remains to be assessed.	Depends on scale, feedstock, prior land use, and management practice. If bioenergy is irrigated and produced at a large scale, water use and water scarcity could increase. If fertilised, bioenergy could have implications for water quality. However, if perennial grasses with low nitrogen input are planted on previously cropped land, bioenergy could improve water quality.	The impact of bioenergy on biodiversity depends on the initial land use condition, the type of bioenergy production system, and the landscape configuration. The impacts of second-generation bioenergy crops tend to be less negative than first generation ones, and are in some cases positive.

	Environmental-ecological			
	Air pollution	Toxic waste, ecotoxicity eutrophication	Water quantity and quality	Biodiversity
Energy storage for low-carbon grids	+	–	–	±
Role of context	<p>The storage techniques and devices can also affect the environment positively. The positive impacts may be the decreased impact on global warming and a lesser effect emerging from the use of fossil fuels. Some materials and manufacturing processes do emit greenhouse gases (GHGs), either directly, or due to the source of the power they use.</p>	<p>Disposal of devices' material may also emerge as a constraint to the environment if not deployed and managed appropriately. Some devices use critical resources and materials which are eco-toxic or polluting, particularly during extraction and manufacturing.</p>	<p>The extraction of materials and manufacturing processes for some devices uses a considerable amount of fresh water. The wastewater generated during different processes (e.g., manufacturing, treatment, recycling) can be dangerous. If wastewater penetrates into the ground and flows into surface waters, it can create many problems for human health, so capture and treatment of contaminated wastewater is very important and vital.</p>	<p>Direct impacts on ecosystems largely come from material extraction; some devices require more impactful materials than others. Some technologies would directly encroach on ecosystems due to their land use.</p>

	Environmental-ecological			
	Air pollution	Toxic waste, ecotoxicity eutrophication	Water quantity and quality	Biodiversity
System integration	+	+	+	NE
<i>Role of context</i>	By using the synergies within and between sectors, Energy System Integration (ESI) aims to increase flexibility in the energy system, maximise the integration of renewable energy and distributed generation, and reduce environmental impact.	Potential of reducing nitrogen oxides (NO _x) by optimal use of ammonia.	ESI aims to increase flexibility in the energy system such as the link between electricity-water nexus, which can optimise the quantity of water.

Bioenergy	–	±	±
<i>Role of context</i>	Logistically challenging requiring widespread infrastructural coordination	While traditional biomass and first-generation biofuels are widely used today, their scalability is limited by resource constraints. Scale-up of bioenergy use for other feedstocks will require advanced technologies such as gasification, Fischer-Tropsch processing, hydrothermal liquefaction (HTL), and pyrolysis. And scaling up these processes will require robust business strategies and optimised use of co-products. Several technological and institutional barriers exist for large-scale bioenergy with carbon capture and storage (BECCS) implementation.	Electricity generated from biomass contributes about 3% of global generation. Tens of billions of gallons of first-generation biofuels are produced per year. Advanced bioenergy pathways could deliver several final energy carriers, starting from multiple feedstocks, and many of these pathways can potentially provide CDR. However, while potentially cost-competitive in the future, these are mostly not cost-competitive yet.

	Socio-cultural		
	Public acceptance	Effects on health and well-being	Distributional effects
Hydroelectric power	±	±	–
Role of context	New large hydropower is controversial in some areas if local residents and ecosystems are endangered and trust in government or companies is low, but the technology is generally well-accepted in many regions.	Both positive (reduce climate change) and negative (can have negative health impacts)	Large hydropower could have negative impacts on livelihoods, and so affecting distributional and equity aspects.

	Socio-cultural		
	Public acceptance	Effects on health and well-being	Distributional effects
Nuclear	±	±	±
Role of context	In some countries public acceptance is low, in others it is higher, depending on perceived risks and benefits for economy, climate change mitigation and energy security.	The overall impacts on human health from the normal operation of nuclear power plants are low. Yet, there are serious health impacts in case of nuclear accidents.	The need to isolate high-level radioactive waste from the biosphere for millennia might raise concerns about intergenerational equity.

	Socio-cultural		
	Public acceptance	Effects on health and well-being	Distributional effects
Carbon dioxide (CO₂) capture, utilisation and storage	–	±	±
<i>Role of context</i>	Many people are unfamiliar with carbon capture and storage (CCS), so have not formed firm opinions. Some firmly reject CCS; some are concerned that CCS may avoid making greenhouse gas (GHG) emission reductions.	Positive impacts on health due to reductions in climate change, but also negative impacts due to increase or no change in air pollution due to fossil energy use.	Protects future generation against negative impacts of climate change, but a lot of uncertainty about the technology for future generations.
<i>Line of sight</i>	<p>Brown, D.A., 2011: Comparative ethical issues entailed in the geological disposal of radioactive waste and carbon dioxide in the light of climate change. In: <i>Geological disposal of carbon dioxide and radioactive waste: A comparative assessment</i> [Toth, F.L., (ed.)], Springer, Dordrecht, Netherlands, pp. 317–337.</p> <p>Science for Environment Policy: European Commission DG Environment News Alert Service, edited by SCU, The University of the West of England, Bristol, UK.</p> <p>Jacobson, M.Z., 2019: The health and climate impacts of carbon capture and direct air capture. <i>Energy Environ. Sci.</i>, 12(12), 3567–3574, doi:10.1039/C9EE02709B.</p>		
Bioenergy	–	±	±
<i>Role of context</i>	Acceptability of bioenergy is relatively low compared to other renewable energy sources like solar and wind. Usually bioenergy from waste products (e.g., food waste) is seen more favourably than from purposely-grown energy crops, which are more controversial.	Bioenergy use (without CCS at the final point of use) impacts air quality, and large-scale adoption raises a broad set of sustainability concerns.	Labour conditions could determine impacts on poverty and equity. Bioenergy offers an opportunity to replace displaced fossil fuel jobs and impact on global trade. Costs and benefits of bioenergy could be unevenly distributed.

Energy storage for low-carbon grids	±	+	±
<i>Role of context</i>	Awareness of storage technologies is low, and limited evidence varies across technologies; hydrogen is perceived to have advantages (clean, offers energy storage) and disadvantages (safety concerns). Batteries are evaluated slightly positively, but are believed to be expensive, somewhat unsafe, and people are concerned about recycling options; for electric vehicle (EV) batteries, people are concerned about cars not being fully loaded when needed ('range anxiety'). Very important to address safety concerns now, as just a few high-profile accidents can damage the technology's reputation.	In addition to emission reductions, energy storage is also vital for essential service providers such as the healthcare sector which rely mainly on energy storage. Safety issues for workers in material extraction, processing and component manufacture for some technologies. No issues at point of use, under normal operation, as long as hydrogen and battery safety is controlled.	High upfront costs deter adoption in developing countries, despite low costs. Distribution of costs and benefits change as a function of design choices. There are global supply chain issues with some materials, which could be solved through local recycling.

	Socio-cultural		
	Public acceptance	Effects on health and well-being	Distributional effects
Demand-side mitigation	±	+	+
<i>Role of context</i>	Acceptance is higher for options that do not require significant changes in lifestyles. Acceptance will be higher when financial, legal and infrastructural barriers for demand-side mitigation are removed.		Energy savings save money, improve equity and reduce poverty, but some options are associated with high costs that can increase inequality. Access to modern energy can reduce poverty.

System integration	±	+	LE
<i>Role of context</i>	Most evidence is on the different aspects of system integration, not the system as a whole. Public acceptance will be higher when investment costs are removed and privacy issues are addressed. Extending transmission lines is generally evaluated negatively. Energy independence and being self-sufficient are positively evaluated.	Reducing air pollution prevents some diseases.

Energy storage for low-carbon grids	+	±	±
<i>Role of context</i>	General political acceptance and active promotion in the US, UK and Europe.	Given the concerns expressed about the competency of some communities and local authorities, there may well be a space for community, local government and private sector organisations to develop partnerships to deliver energy services in new, more flexible ways. It is not clear how such hybrid relationships may co-evolve with storage and other flexibility technologies over the longer term. Work is required on the markets.	The UK and Europe are exploring how to overcome these barriers and have been largely successful.
<i>Line of sight</i>	Imperial College London, Poyry (2017): ROADMAP FOR FLEXIBILITY SERVICES TO 2030 A report to the Committee on Climate Change Strachinescu, A. The Role Of The Storage In The Future European Energy System (2017); http://www.europeanenergyinnovation.eu/Articles/Spring-2017/The-role-of-the-storage-in-the-future-European-energy-system	Thomas, G., Demski, C., & Pidgeon, N. (2019). Deliberating the social acceptability of energy storage in the UK. <i>Energy Policy</i> , 133, 110908.	Strachinescu, A. Executive Summary

The Agriculture, Forestry and Other Land Use¹ (AFOLU) sector encompasses managed ecosystems and offers significant mitigation opportunities while delivering food, wood and other renewable resources as well as biodiversity conservation, provided the sector adapts to climate change. Land-based mitigation measures represent some of the most important options currently available. They can both deliver carbon dioxide removal (CDR) and substitute for fossil fuels, thereby enabling emissions reductions in other sectors. The rapid deployment of AFOLU measures is essential in all pathways staying within the limits of the remaining budget for a 1.5°C target (*high confidence*). Where carefully and appropriately implemented, AFOLU mitigation measures are uniquely positioned to deliver substantial co-benefits and help address many of the wider challenges associated with land management. If AFOLU measures are deployed badly then, when taken together with the increasing need to produce sufficient food, feed, fuel and wood, they may exacerbate trade-offs with the conservation of habitats, adaptation, biodiversity and other services. At the same time the capacity of the land to support these functions may be threatened by climate change itself (*high confidence*). {IPCC AR6 WGI, Figure SPM.7; IPCC AR6 WGII, 7.1, 7.6}

The AFOLU (managed land) sector, on average, accounted for 13–21% of global total anthropogenic greenhouse gas (GHG) emissions in the period 2010–2019 (*medium confidence*). At the same time managed and natural terrestrial ecosystems were a carbon sink, absorbing around one third of anthropogenic CO₂ emissions (*medium confidence*). Estimated anthropogenic net CO₂ emissions from AFOLU (based on book-keeping models) result in a net source of $+5.9 \pm 4.1$ GtCO₂ yr⁻¹ between 2010 and 2019 with an unclear trend. Based on FAOSTAT or national GHG inventories, the net CO₂ emissions from AFOLU were 0.0 to $+0.8$ GtCO₂ yr⁻¹ over the same period. There is a discrepancy in the reported CO₂ AFOLU emissions magnitude because alternative methodological approaches that incorporate different assumptions are used. If the managed and natural responses of all land to both anthropogenic environmental change and natural climate variability, estimated to be a *gross* sink of -12.5 ± 3.2 GtCO₂ yr⁻¹ for the period 2010–2019, are included with land use emissions, then land overall, constituted a *net* sink of -6.6 ± 5.2 GtCO₂ yr⁻¹ in terms of CO₂ emissions (*medium confidence*). {7.2, 7.2.2.5, Table 7.1; IPCC AR6 WGI}

AFOLU CO₂ emissions fluxes are mainly driven by land use change (CO₂ LULUCF), and account for about half of total net AFOLU emissions. The rate of deforestation has generally declined, while global tree cover and global forest growing stock levels are likely increasing (*medium confidence*). There are substantial regional differences, with losses of carbon generally observed in tropical regions and gains in temperate and

boreal regions. Agricultural methane (CH₄) and nitrous oxide (N₂O) emissions are estimated to average 157 ± 47.1 MtCH₄ yr⁻¹ and 6.6 ± 4.0 MtN₂O yr⁻¹ or 4.2 ± 1.3 and 1.8 ± 1.1 GtCO₂-eq yr⁻¹ (using IPCC AR6 GWP100 values for CH₄ and N₂O) respectively between 2010 and 2019. AFOLU CH₄ emissions continue to increase (*high confidence*), the main source of which is enteric fermentation from ruminant animals (*high confidence*). Similarly, AFOLU N₂O emissions are increasing, dominated by agriculture, notably from manure application, nitrogen deposition, and nitrogen fertiliser use (*high confidence*). In addition to being a source and sink for GHG emissions, land plays an important role in climate through albedo effects, evapotranspiration and volatile organic compounds (VOCs) and their mix, although the combined role in total climate forcing is unclear and varies strongly with bioclimatic region and management type. {2.4.2.5, 7.2, 7.2.1, 7.2.3, 7.3}

The AFOLU sector offers significant near-term mitigation potential at relatively low cost but cannot compensate for delayed emission reductions in other sectors (*high evidence, medium agreement*). The AFOLU sector can provide 20–30% (interquartile range) of the global mitigation needed for a 1.5°C or 2°C pathway towards 2050 (*robust evidence, medium agreement*), though there are highly variable mitigation strategies for how AFOLU potential can be deployed for achieving climate targets. The estimated *likely* economic ($< \text{USD}100$ tCO₂-eq⁻¹) AFOLU sector mitigation potential is 8 to 14 GtCO₂-eq yr⁻¹ between 2020 and 2050, with the bottom end of this range representing the mean from integrated assessment models (IAMs) and the upper end representing the mean estimate from global sectoral studies. The economic potential is about half of the technical potential from AFOLU, and about 30–50% could be achieved under USD20 tCO₂-eq⁻¹. The implementation of robust measurement, reporting and verification processes is paramount to improving the transparency of net-carbon-stock changes per land unit to prevent misleading assumptions or claims on mitigation. {7.1, 7.4, 7.5}

Between 2020 and 2050, mitigation measures in forests and other natural ecosystems provide the largest share of the economic (up to USD100 tCO₂-eq⁻¹) AFOLU mitigation potential, followed by agriculture and demand-side measures (*high confidence*). In the global sectoral studies, the protection, improved management, and restoration of forests, peatlands, coastal wetlands, savannas and grasslands have the potential to reduce emissions and/or sequester 7.3 mean (3.9–13.1 range) GtCO₂-eq yr⁻¹. Agriculture provides the second largest share of the mitigation potential, with 4.1 (1.7–6.7) GtCO₂-eq yr⁻¹ (up to USD100 tCO₂-eq⁻¹) from cropland and grassland soil carbon management, agroforestry, use of biochar, improved rice cultivation, and livestock and nutrient management. Demand-side measures including shifting to sustainable healthy diets, reducing food waste, and building with wood and biochemicals and bio-textiles have a mitigation potential of 2.2 (1.1–3.6) GtCO₂-eq yr⁻¹.

¹ Global databases make different choices about which emissions and removals occurring on land are considered anthropogenic. Currently, net CO₂ land fluxes from land reported by global book-keeping models used here differ from those from the aggregate global net emissions based on national GHG inventories. This difference, which has been considered in the literature, mainly reflects differences in how anthropogenic forest sinks and areas of managed land are defined. Other reasons for this difference, which are more difficult to quantify, can arise from the limited representation of land management in global models and varying levels of accuracy and completeness of estimated LULUCF fluxes in national GHG inventories. Neither method is inherently preferable. This chapter reports estimates from different databases and approaches, but uses CO₂ LULUCF from book-keeping models to report overall emissions to ensure consistency and comparability across chapters.

Most mitigation options are available and ready to deploy. Emissions reductions can be unlocked relatively quickly, whereas CDR needs upfront investment. Sustainable intensification in agriculture, shifting diets, and reducing food waste could enhance efficiencies and reduce agricultural land needs, and are therefore critical for enabling supply-side measures such as reforestation, restoration, as well as decreasing CH₄ and N₂O emissions from agricultural production. In addition, emerging technologies (e.g., vaccines or inhibitors) have the potential to substantially increase CH₄ mitigation potential beyond current estimates. AFOLU mitigation is not only relevant in countries with large land areas. Many smaller countries and regions, particularly with wetlands, have disproportionately high levels of AFOLU mitigation potential density. {7.4, 7.5}

The economic and political feasibility of implementing AFOLU mitigation measures is hampered by persistent barriers. Assisting countries to overcome barriers will help to achieve significant short-term mitigation (*medium confidence*). Finance forms a critical barrier to achieving these gains as currently mitigation efforts rely principally on government sources and funding mechanisms which do not provide sufficient resources to enable the economic potential to be realised. Differences in cultural values, governance, accountability and institutional capacity are also important barriers. Climate change could also emerge as a barrier to AFOLU mitigation, although the IPCC AR6 WGI contribution to AR6 indicated that an increase in the capacity of natural sinks may occur, despite changes in climate (*medium confidence*). The continued loss of biodiversity makes ecosystems less resilient to climate change extremes and this may further jeopardise the achievement of the AFOLU mitigation potentials indicated in this chapter (IPCC AR6 WGII and IPBES) (*high confidence*). {7.4, 7.6; IPCC AR6 WGI, Figure SPM.7}

Bioenergy and other bio-based options represent an important share of the total mitigation potential. The range of recent estimates for the technical bioenergy potential when constrained by food security and environmental considerations is 5–50 and 50–250 EJ yr⁻¹ by 2050 for residues and dedicated biomass production system respectively. These estimates fall within previously estimated ranges (*medium agreement*). Poorly planned deployment of biomass production and afforestation options for in-forest carbon sequestration may conflict with environmental and social dimensions of sustainability (*high confidence*). The global technical CDR potential of BECCS by 2050 (considering only the technical capture of CO₂ and storage underground) is estimated at 5.9 mean (0.5–11.3) GtCO₂ yr⁻¹, of which 1.6 (0.8–3.5) GtCO₂ yr⁻¹ is available at below USD100 tCO₂⁻¹ (*medium confidence*). Bioenergy and other bio-based products provide additional mitigation through the substitution of fossil fuels fossil-based products (*high confidence*). These substitution effects are reported in other sectors. Wood used in construction may reduce emissions associated with steel and concrete use. The agriculture and forestry sectors can devise management approaches that enable biomass production and use for energy in conjunction with the production of food and timber, thereby reducing the conversion pressure on natural ecosystems (*medium confidence*). {7.4}

The deployment of all land-based mitigation measures can provide multiple co-benefits, but there are also risks and trade-offs from misguided or inappropriate land management (*high confidence*). Such risks can best be managed if AFOLU mitigation is pursued in response to the needs and perspectives of multiple stakeholders to achieve outcomes that maximise synergies while limiting trade-offs (*medium confidence*). The results of implementing AFOLU measures are often variable and highly context specific. Depending on local conditions (e.g., ecosystem, climate, food system, land ownership) and management strategies (e.g., scale, method), mitigation measures have the potential to positively or negatively impact biodiversity, ecosystem functioning, air quality, water availability and quality, soil productivity, rights infringements, food security, and human well-being. Mitigation measures addressing GHGs may also affect other climate forcers such as albedo and evapotranspiration. Integrated responses that contribute to mitigation, adaptation, and other land challenges will have greater likelihood of being successful (*high confidence*); measures which provide additional benefits to biodiversity and human well-being are sometimes described as 'Nature-Based Solutions'. {7.1, 7.4, 7.6}

AFOLU mitigation measures have been well understood for decades but deployment remains slow and emissions trends indicate unsatisfactory progress despite beneficial contributions to global emissions reduction from forest-related options (*high confidence*). Globally, the AFOLU sector has so far contributed modestly to net mitigation, as past policies have delivered about 0.65 GtCO₂ yr⁻¹ of mitigation during 2010–2019 or 1.4% of global gross emissions (*high confidence*). The majority (>80%) of emission reduction resulted from forestry measures (*high confidence*). Although the mitigation potential of AFOLU measures is large from a biophysical and ecological perspective, its feasibility is hampered by lack of institutional support, uncertainty over long-term additionality and trade-offs, weak governance, fragmented land ownership, and uncertain permanence effects. Despite these impediments to change, AFOLU mitigation options are demonstrably effective and with appropriate support can enable rapid emission reductions in most countries. {7.4, 7.6}

Concerted, rapid and sustained effort by all stakeholders, from policy makers and investors to land owners and managers is a pre-requisite to achieving high levels of mitigation in the AFOLU sector (*high confidence*). To date USD0.7 billion yr⁻¹ is estimated to have been spent on AFOLU mitigation. This is well short of the more than USD400 billion yr⁻¹ that is estimated to be necessary to deliver the up to 30% of global mitigation effort envisaged in deep mitigation scenarios (*medium confidence*). This estimate of the global funding requirement is smaller than current subsidies provided to agriculture and forestry. Making this funding available would require a change in flows of money and determination of who pays. A gradual redirection of existing agriculture and forestry subsidies would greatly advance mitigation. Effective policy interventions and national (investment) plans as part of Nationally Determined Contributions (NDCs), specific to local circumstances and needs, are

urgently needed to accelerate the deployment of AFOLU mitigation options. These interventions are effective when they include funding schemes and long-term consistent support for implementation with governments taking the initiative together with private funders and non-state actors. {7.6}

Realising the mitigation potential of the AFOLU sector depends strongly on policies that directly address emissions and drive the deployment of land-based mitigation options, consistent with carbon prices in deep mitigation scenarios (*high confidence*). Examples of successful policies and measures include establishing and respecting tenure rights and community forestry, improved agricultural management and sustainable intensification, biodiversity conservation, payments for ecosystem services, improved forest management and wood chain usage, bioenergy, voluntary supply chain management efforts, consumer behaviour campaigns, private funding and joint regulatory efforts to avoid, for example, leakage. The efficacy of different policies, however, will depend on numerous region-specific factors. In addition to funding, these factors include governance, institutions, long-term consistent execution of measures, and the specific policy setting (*high confidence*). {7.6}

There is a discrepancy, equating to 5.5 GtCO₂ yr⁻¹ between alternative methods of accounting for anthropogenic land CO₂ fluxes. Reconciling these methods greatly enhances the credibility of AFOLU-based emissions offsetting. It would also assist in assessing collective progress in a global stocktake (*high confidence*). The principal accounting approaches are national GHG inventories (NGHGI) and global modelling approaches. NGHGI, based on IPCC guidelines, consider a much larger area of forest to be under human management than global models. NGHGI consider the fluxes due to human-induced environmental change on this area to be anthropogenic and are thus reported. Global models,² in contrast, consider these fluxes to be natural and are excluded from the total reported anthropogenic land CO₂ flux. To enable a like-with-like comparison, the remaining cumulative global CO₂ emissions budget can be adjusted (*medium confidence*). In the absence of these adjustments, collective progress would appear better than it is. {Cross-Chapter Box 6 in this chapter, 7.2}

Addressing the many knowledge gaps in the development and testing of AFOLU mitigation options can rapidly advance the likelihood of achieving sustained mitigation (*high confidence*). Research priorities include improved quantification of anthropogenic and natural GHG fluxes and emissions modelling, better understanding of the impacts of climate change on the mitigation potential, permanence and additionality of estimated mitigation actions, and improved (real time and cheap) measurement, reporting and verification. There is a need to include a greater suite of mitigation measures in IAMs, informed by more realistic assessments that take into account local circumstances and socio-economic factors and cross-sector synergies and trade-offs. Finally, there is a critical need for more targeted research to develop appropriate country-level, locally specific, policy and land management response options. These options could support more specific NDCs with

AFOLU measures that enable mitigation while also contributing to biodiversity conservation, ecosystem functioning, livelihoods for millions of farmers and foresters, and many other Sustainable Development Goals (SDGs) (*high confidence*). {7.7}

² Bookkeeping models and dynamic global vegetation models.

7.1 Introduction

7.1.1 Key Findings from Previous Reports

Agriculture, Forestry and Other Land Uses (AFOLU) is unique due to its capacity to mitigate climate change through greenhouse gas (GHG) emission reductions, as well as enhance removals (IPCC 2019). However, despite the attention on AFOLU since early 1990s it was reported in the IPCC Special Report on Climate Change and Land (SRCCL) as accounting for almost a quarter of anthropogenic emission (IPCC, 2019), with three main GHGs associated with AFOLU; carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O). Overall emission levels had remained similar since the publication of AR4 (Nabuurs et al. 2007). The diverse nature of the sector, its linkage with wider societal, ecological and environmental aspects and the required coordination of related policy, was suggested to make implementation of known and available supply- and demand-side mitigation measures particularly challenging (IPCC 2019). Despite such implementation barriers, the considerable mitigation potential of AFOLU as a sector on its own and its capacity to contribute to mitigation within other sectors was emphasised, with land-related measures, including bioenergy, estimated as capable of contributing between 20% and 60% of the total cumulative abatement to 2030 identified within transformation pathways (IPCC 2018). However, the vast mitigation potential from AFOLU initially portrayed in literature and in Integrated Assessment Models (IAMs), as explored in the IPCC Special Report on Climate Change of 1.5°C (SR1.5), is being questioned in terms of feasibility (Roe et al. 2021) and a more balanced perspective on the role of land in mitigation is developing, while at the same time, interest by private investors in land-based mitigation is increasing fast.

The SRCCL (IPCC 2019) outlined with *medium evidence* and *medium agreement* that supply-side agriculture and forestry measures had an economic (at USD100 tCO₂-eq⁻¹) mitigation potential of 7.2–10.6 GtCO₂-eq⁻¹ in 2030 (using GWP100 and multiple IPCC values for CH₄ and N₂O) of which about a third was estimated as achievable at <USD20 tCO₂-eq⁻¹. Agricultural measures were reported as sensitive to carbon price, with cropland and grazing land soil organic carbon management having the greatest potential at USD20 tCO₂-eq⁻¹ and restoration of organic soils at USD100 tCO₂-eq⁻¹. Forestry measures were less sensitive to carbon price, but varied regionally, with reduced deforestation, forest management and afforestation having the greatest potential depending on region. Although demand-side measures related to food could in theory make a large contribution to mitigation, in reality the contribution has been very small. Overall, the dependency of mitigation within AFOLU on a complex range of factors, from population growth, economic and technological developments, to the sustainability of mitigation measures and impacts of climate change, was suggested to make realisation highly challenging (IPCC 2019).

Land can only be part of the solution alongside rapid emission reduction in other sectors (IPCC 2019). It was recognised that land supports many ecosystem services on which human existence, well-being and livelihoods ultimately depend. Yet over-exploitation of land resources was reported as driving considerable and unprecedented

rate of biodiversity loss, and wider environmental degradation (IPBES 2019b; IPCC 2019). Urgent action to reverse this trend was deemed crucial in helping to accommodate the increasing demands on land and enhance climate change adaptation capacity. There was *high confidence* that global warming was already causing an increase in the frequency and intensity of extreme weather and climate events, impacting ecosystems, food security, disturbances and production processes, with existing (and new) carbon stocks in soils and biomass at serious risk. The impact of land cover on regional climate (through biophysical effects) was also highlighted, although there was no confidence regarding impacts on global climate.

Since the IPCC Fifth Assessment Report (AR5), the share of AFOLU to anthropogenic GHG emissions had remained largely unchanged at 13–21% of total GHG emissions (*medium confidence*), though uncertainty in estimates of both sources and sinks of CO₂, exacerbated by difficulties in separating natural and anthropogenic fluxes, was emphasised. Models indicated land (including the natural sink) to have *very likely* provided a net removal of CO₂ between 2007 and 2016. As in AR5, land cover change, notably deforestation, was identified as a major driver of anthropogenic CO₂ emissions while agriculture was a major driver of the increasing anthropogenic CH₄ and N₂O emissions.

In terms of mitigation, without reductions in overall anthropogenic emissions, increased reliance on large-scale land-based mitigation was predicted, which would add to the many already competing demands on land. However, some mitigation measures were suggested to not compete with other land uses, while also having multiple co-benefits, including adaptation capacity and potential synergies with some Sustainable Development Goals (SDGs). As in AR5, there was large uncertainty surrounding mitigation within AFOLU, in part because current carbon stocks and fluxes are unclear and subject to temporal variability. Additionally, the non-additive nature of individual measures that are often inter-linked and the highly context specific applicability of measures, causes further uncertainty. Many AFOLU measures were considered well-established and some achievable at low to moderate cost, yet contrasting economic drivers, insufficient policy, lack of incentivisation and institutional support to stimulate implementation among the many stakeholders involved, in regionally diverse contexts, was recognised as hampering realisation of potential.

None the less, the importance of mitigation within AFOLU was highlighted in all IPCC reports, with modelled scenarios demonstrating the considerable potential role and land-based mitigation forming an important component of pledged mitigation in Nationally Determined Contributions (NDCs) under the Paris Agreement. The sector was identified as the only one in which large-scale carbon dioxide removal (CDR) may currently and at short term be possible (e.g., through afforestation/reforestation or soil organic carbon management). This CDR component was deemed crucial to limit climate change and its impacts, which would otherwise lead to enhanced release of carbon from land. However, the SRCCL emphasised that mitigation cannot be pursued in isolation. The need for integrated response options, that mitigate and adapt to climate change, but also deal with land degradation and desertification, while enhancing food and fibre

security, biodiversity and contributing to other SDGs has been made clear (IPCC 2019; IPBES 2019a; IPBES-IPCC 2021).

7.1.2 Boundaries, Scope and Changing Context of the Current Report

This chapter assesses GHG fluxes between land and the atmosphere due to AFOLU, the associated drivers behind these fluxes, mitigation response options and related policy, at time scales of 2030 and 2050. Land and its management has important links with other sectors and therefore associated chapters within this report, notably concerning the provision of food, feed, fuel or fibre for human consumption and societal well-being (Chapter 5), for bioenergy (Chapter 6), the built environment (Chapter 9), transport (Chapter 10) and industry (Chapter 11). Mitigation within these

sectors may in part, be dependent on contributions from land and the AFOLU sector, with interactions between all sectors discussed in Chapter 12. This chapter also has important links with IPCC AR6 WGII regarding climate change impacts and adaptation. Linkages are illustrated in Figure 7.1.

As highlighted in both AR5 and the SRCCL, there is a complex interplay between land management and GHG fluxes as illustrated in Figure 7.2, with considerable variation in management regionally, as a result of geophysical, climatic, ecological, economic, technological, institutional and socio-cultural diversity. The capacity for land-based mitigation varies accordingly. The principal focus of this chapter is therefore, on evaluating regional land-based mitigation potential, identifying applicable AFOLU mitigation measures, estimating associated costs and exploring policy options that could enable implementation.

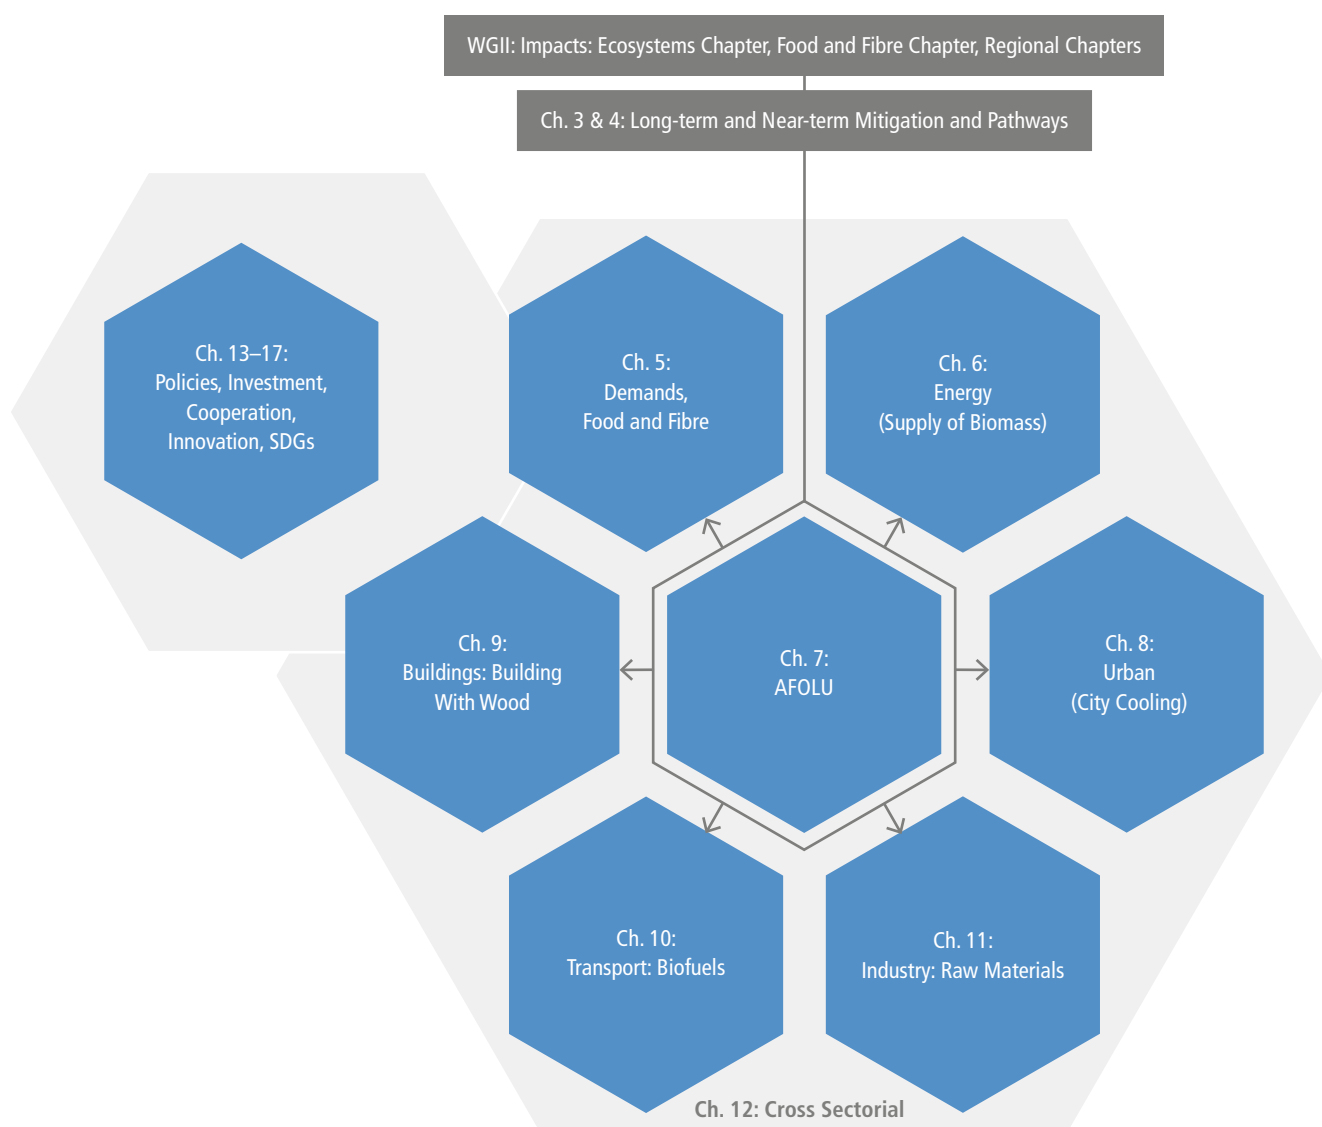

Figure 7.1 | Linkage between Chapter 7 and other chapters within this report, as well as to IPCC AR6 WGII. Mitigation potential estimates in this chapter consider potential emission reductions and removals only within the AFOLU sector itself, and not the substitution effects from biomass and bio-based products in sectors such as Energy, Transport, Industry, Buildings, nor biophysical effects of, for example, cooling of cities. These are covered in their respective chapters.

Figure 7.2 | Summarised representation of interactions between land management, its products in terms of food and fibre, and land-atmospheric GHG fluxes. For legibility reasons only a few of the processes and management measures are depicted.

Mitigation measures are broadly categorised as those relating to (i) forests and other ecosystems (ii) agriculture (iii) biomass production for products and bioenergy and (iv) demand-side levers. Assessment is made in the context that land-mitigation is expected to contribute roughly 25% of the 2030 mitigation pledged in Nationally Determined Contributions (NDCs) under the Paris Agreement (Grassi et al. 2017), yet very few countries have provided details on how this will be achieved. In light of AR5 and the SRCCL findings, that indicate large land-based mitigation potential, considerable challenges to its realisation, but also a clear nexus at which humankind finds itself, whereby current land management, driven by population growth and consumption patterns, is undermining the very capacity of land, a finite resource, to support wider critical functions and services on which humankind depends. Mitigation within AFOLU is occasionally and wrongly perceived as an opportunity for in-action within other sectors. AFOLU simply cannot compensate for mitigation shortfalls in other sectors. As the outcomes of many critical challenges (UNEP 2019), including biodiversity loss (IPBES 2019a) and soil degradation (FAO and ITPS 2015), are inextricably linked with how we manage land, the evaluation and assessment of AFOLU is crucial. This chapter aims to address three core topics:

1. What is the latest estimated (economic) mitigation potential of AFOLU measures according to both sectoral studies and integrated assessment models, and how much of this may be realistic within each global region?
2. How do we realise the mitigation potential, while minimising trade-offs and risks and maximising co-benefits that can enhance food and fibre security, conserve biodiversity and address other land challenges?

3. How effective have policies been so far and what additional policies or incentives might enable realisation of mitigation potential and at what costs?

This chapter first outlines the latest trends in AFOLU fluxes and the methodology supporting their estimation (Section 7.2). Direct and indirect drivers behind emission trends are discussed in Section 7.3. Mitigation measures, their costs, co-benefits, trade-offs, estimated regional potential and contribution within integrated global mitigation scenarios, is presented in Sections 7.4 and 7.5 respectively. Assessment of associated policy responses and links with SDGs are explored in Section 7.6. The chapter concludes with gaps in knowledge (Section 7.7) and frequently asked questions.

7.2 Historical and Current Trends in GHG Emission and Removals; Their Uncertainties and Implications for Assessing Collective Climate Progress

The biosphere on land and in wetlands is a source and sink of CO_2 and CH_4 , and a source of N_2O due to both natural and anthropogenic processes that happen simultaneously and are therefore difficult to disentangle (IPCC 2010; Angelo and Du Plessis 2017; IPCC 2019). AFOLU is the only GHG sector to currently include anthropogenic sinks. A range of methodological approaches and data have been applied to estimating AFOLU emissions and removals, each developed for their own purposes, with estimates varying accordingly. Since the SRCCL (Jia et al. 2019), emissions estimates have been updated (Sections 7.2.2 and 7.2.3), while the assessment of biophysical processes and short-lived

climate forcers (Section 7.2.4) is largely unchanged. Further progress has been made on the implications of differences in AFOLU emissions estimates for assessing collective climate progress (Section 7.2.2.2 and Cross-Chapter Box 6 in this chapter).

7.2.1 Total Net GHG Flux from AFOLU

National greenhouse gas inventory (NGHGI) reporting following the IPCC 1996 guidelines (IPCC 1996), separates the total anthropogenic AFOLU flux into: (i) net anthropogenic flux from Land Use, Land-Use Change, and Forestry (LULUCF) due to both change in land cover and land management; and (ii) the net flux from Agriculture. While fluxes of CO₂ (Section 7.2.2) are predominantly from LULUCF and fluxes of CH₄ and N₂O (Section 7.2.3) are predominantly from agriculture, fluxes of all three gases are associated with both sub-sectors. However, not all methods separate them consistently according to these sub-sectors, thus here we use the term AFOLU,

separate by gas and implicitly include CO₂ emissions that stem from the agriculture part of AFOLU, though these account for a relatively small portion.

Total global net anthropogenic GHG emissions from AFOLU were $11.9 \pm 4.4 \text{ GtCO}_2\text{-eq yr}^{-1}$ on average over the period 2010–2019, around 21% of total global net anthropogenic GHG emissions (Table 7.1 and Figure 7.3, using the sum of bookkeeping models for the CO₂ component). When using FAOSTAT/NGHGI's CO₂ flux data, then the contribution of AFOLU to total emissions amounts to 13% of global emissions.

This AFOLU flux is the net of anthropogenic emissions of CO₂, CH₄ and N₂O, and anthropogenic removals of CO₂. The contribution of AFOLU to total emissions varies regionally with highest in Latin America and Caribbean with 58% and lowest in Europe and North America with each 7% (Chapter 2, Section 2.2.3). There is a discrepancy in the reported CO₂ AFOLU emissions magnitude because alternative methodological

Figure 7.3 | Subdivision of the total AFOLU emissions from Table 7.1 by activity and gas for the period 1990 to 2019. Positive values are emissions from land to atmosphere, negative values are removals. Panel A shows emissions divided into major activity and gases. Note that 'biomass burning' is only the burning of agriculture residues in the fields. The indicated growth rates between 1990–2000, 2000–2010, 2010–2019 are annualised across each time period. Panel B illustrates regional emissions in the years 1990, 2000, 2010, 2019. AFOLU CO₂ (green shading) represents all AFOLU CO₂ emissions. It is the mean from three bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020) as presented in the Global Carbon Budget (Friedlingstein et al. 2020) and is *not directly comparable* to LULUCF in NGHGI (Section 7.2.2). Data on CH₄ and N₂O emissions are from the EDGAR database (Crippa et al. 2021). See Sections 7.2.2 and 7.2.3 for comparison of different datasets. All values expressed are as CO₂-eq with GWP100 values: CH₄ = 27, N₂O = 273.

Table 7.1 | Net anthropogenic emissions (annual averages for 2010–2019^a) from Agriculture, Forestry and Other Land Use (AFOLU). For context, the net flux due to the natural response of land to climate and environmental change is also shown for CO₂ in column E. Positive values represent emissions, negative values represent removals.

Anthropogenic						Natural response	Natural and anthropogenic
Gas	Units	AFOLU Net anthropogenic emissions ^h	Non-AFOLU anthropogenic GHG emissions ^{d, f}	Total net anthropogenic emissions (AFOLU + non-AFOLU) by gas	AFOLU as a % of total net anthropogenic emissions by gas	Natural land sinks including natural response of land to anthropogenic environmental change and climate variability ^e	Net land-atmosphere CO ₂ flux (i.e., anthropogenic AFOLU + natural fluxes across entire land surface)
		A	B	C = A+B	D = (A/C) * 100	E	F=A+E
CO ₂	GtCO ₂ -eq yr ⁻¹	5.9 ± 4.1 ^{b, f} (book-keeping models, managed soils and pasture). 0 to 0.8 (NGHGI/FAOSTAT data)	36.2 ± 2.9	42.0 ± 29.0	14%	-12.5 ± 3.2	-6.6 ± 4.6
CH ₄	MtCH ₄ yr ⁻¹	157.0 ± 47.1 ^c	207.5 ± 62.2	364.4 ± 109.3		— ⁱ	
	GtCO ₂ -eq yr ⁻¹	4.2 ± 1.3 ^g	5.9 ± 1.8	10.2 ± 3.0	41%		
N ₂ O	MtN ₂ O yr ⁻¹	6.6 ± 4.0 ^c	2.8 ± 1.7	9.4 ± 5.6			
	GtCO ₂ -eq yr ⁻¹	1.8 ± 1.1 ^g	0.8 ± 0.5	2.6 ± 1.5	69%		
Total ^j	GtCO ₂ -eq yr ⁻¹	11.9 ± 4.4 (CO ₂ component based on book-keeping models, managed soils and pasture)	44 ± 3.4	55.9 ± 6.1	21%		

^a Estimates are given until 2019 as this is the latest date when data are available for all gases, consistent with Chapter 2, this report. Positive fluxes are emission from land to the atmosphere. Negative fluxes are removals.

^b Net anthropogenic flux of CO₂ are due to land-use change such as deforestation and afforestation and land management, including wood harvest and regrowth, peatland drainage and fires, cropland and grassland management. Average of three bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020), complemented by data on peatland drainage and fires from FAOSTAT (Prosperi et al. 2020) and GFED4s (van der Werf et al. 2017). Bookkeeping based CO₂-LULUCF emissions (5.7±4.0) are consistent with AR6 WGI and Chapter 2 of this report. The value of 5.9(±4.1) includes CO₂ emissions from urea application to managed soils and pasture. Comparisons with other estimates are discussed in 7.2.2. Based on NGHGs and FAOSTAT, the range is 0 to 0.8 GtCO₂ yr⁻¹.

^c CH₄ and N₂O emission estimates and assessed uncertainty of 30 and 60% respectively, are based on Emissions Database for Global Atmospheric Research (EDGAR) data (Crippa et al. 2021) in accordance with Chapter 2, this report (Sections 2.2.1.3 and 2.2.1.4). Both FAOSTAT (Tubiello 2019; USEPA 2019; FAO 2021a) and the USA EPA (USEPA 2019) also provide data on agricultural non-CO₂ emissions, however, mean global CH₄ and N₂O values considering the three databases are within the uncertainty bounds of EDGAR. EDGAR only considers agricultural and not overall AFOLU non-CO₂ emissions. Agriculture is estimated to account for approximately 89 and 96% of total AFOLU CH₄ and N₂O emissions respectively. See Section 7.2.3 for further discussion.

^d Total non-AFOLU emissions are the sum of total CO₂-eq emissions values for energy, industrial sources, waste and other emissions with data from the Global Carbon Project for CO₂, including international aviation and shipping, and from the PRIMAP database for CH₄ and N₂O averaged over 2007–2014, as that was the period for which data were available.

^e The modelled CO₂ estimates include natural processes in vegetation and soils and how they respond to both natural climate variability and to human-induced environmental changes, for example, the response of vegetation and soils to environmental changes such as increasing atmospheric CO₂ concentration, nitrogen deposition, and climate change (indirect anthropogenic effects) on *both managed and unmanaged lands*. The estimate shown represents the average from 17 Dynamic Global Vegetation Models with 1SD uncertainty (Friedlingstein et al. 2020).

^f The NGHGs take a different approach to calculating 'anthropogenic' CO₂ fluxes than the models (Section 7.2.2). In particular the sinks due to environmental change (indirect anthropogenic fluxes) on managed lands are generally treated as anthropogenic in NGHGs and non-anthropogenic in models such as bookkeeping and IAMs. A reconciliation of the results between IAMs and NGHGs is presented in Cross-Chapter Box 6 in this chapter. If applied to this table, it would transfer approximately -5.5 GtCO₂ yr⁻¹ (a sink) from Column E (which would become -7.0 GtCO₂ yr⁻¹) to Column A (which would then be 0.4 GtCO₂ yr⁻¹).

^g All values expressed in units of CO₂-eq are based on IPCC AR6 100-year Global Warming Potential (GWP100) values with climate-carbon feedbacks (CH₄ = 27, N₂O = 273) (Chapter 2, Supplementary Material 2.SM.3; IPCC AR6 WGI Section 7.6).

^h For assessment of cross-sector fluxes related to the food sector, see Chapter 12.

ⁱ While it is acknowledged that soils are a natural CH₄ sink (Jackson et al. 2020) with soil microbial removals estimated to be 30 ± 19 MtCH₄ yr⁻¹ for the period 2008–2017 (according to bottom-up estimates), natural CH₄ sources are considerably greater (371 (245–488) MtCH₄ yr⁻¹) resulting in natural processes being a net CH₄ source (IPCC AR6 WGI Section 5.2.2). The soil CH₄ sink is therefore omitted from Column E.

^j Total GHG emissions concerning non-AFOLU sectors and all sectors combined (Columns B and C) include fluorinated gases in addition to CO₂, CH₄ and N₂O. Therefore, total values do not equal the sum of estimates for CO₂, CH₄ and N₂O.

approaches that incorporate different assumptions are used (Section 7.2.2.2). While there is *low agreement* in the trend of global AFOLU CO₂ emissions over the past few decades (Section 7.2.2), they have remained relatively constant (*medium confidence*) (Chapter 2). Average non-CO₂ emission (aggregated using GWP100 IPCC AR6 values) from agriculture have risen from 5.2 ± 1.4 GtCO₂-eq yr⁻¹ for the period 1990 to 1999, to 6.0 ± 1.7 GtCO₂-eq yr⁻¹ for the period 2010 to 2019 (Crippa et al. 2021) (Section 7.2.3).

To present a fuller understanding of land–atmosphere interactions, Table 7.1 includes an estimate of the natural sink of land to atmospheric CO₂ (Jia et al. 2019) (IPCC AR6 WGI Chapter 5). Land fluxes respond naturally to human-induced environmental change (e.g., climate change, and the fertilising effects of increased atmospheric CO₂ concentration and nitrogen deposition), known as ‘indirect anthropogenic effects’, and also to ‘natural effects’ such as climate variability (IPCC 2010) (Table 7.1 and Section 7.2.2). This showed a removal of -12.5 ± 3.2 GtCO₂ yr⁻¹ (*medium confidence*) from the atmosphere during 2010–2019 according to global dynamic global vegetation model (DGVM) models (Friedlingstein et al. 2020) 31% of total anthropogenic net emissions of CO₂ from all sectors. It is likely that the NGHIs and FAOSTAT implicitly cover some part of this sink and thus provide a net CO₂ AFOLU balance with some 5 GtCO₂ lower net emissions than according to bookkeeping models, with the overall net CO₂ value close to being neutral. Model results

and atmospheric observations concur that, when combining both anthropogenic (AFOLU) and natural processes on the entire land surface (the total ‘land–atmosphere flux’), the land was a global net sink for CO₂ of -6.6 ± 4.6 GtCO₂ yr⁻¹ with a range for 2010 to 2019 from -4.4 to -8.4 GtCO₂ yr⁻¹. (Rödenbeck et al. 2003, 2018; Chevallier et al. 2005; Feng et al. 2016; van der Laan-Luijkx et al. 2017; Niwa et al. 2017; Patra et al. 2018). The natural land sink is *highly likely* to be affected by both future AFOLU activity and climate change (IPCC AR6 WGI Box 5.1 and Figure SPM. 7), whereby under more severe climate change, the amount of carbon stored on land would still increase although the relative share of the emissions that land takes up, declines.

7.2.2 Flux of CO₂ from AFOLU, and the Non-anthropogenic Land Sink

7.2.2.1 Global Net AFOLU CO₂ Flux

Comparison of estimates of the global net AFOLU flux of CO₂ from diverse approaches (Figure 7.4) show differences on the order of several GtCO₂ yr⁻¹. When considering the reasons for the differences, and an approach to reconcile them (Grassi et al. 2021) (Section 7.2.2.3), there is *medium confidence* in the magnitude of the net AFOLU CO₂ flux. There is a discrepancy in the reported CO₂

Figure 7.4 | Global net CO₂ flux due to AFOLU estimated using different methods for the period 1960 to 2019 (GtCO₂ yr⁻¹). Positive numbers represent emissions. **Light-blue line:** The mean from 17 DGVMs all using the same driving data under TrendyV9 used within the Global Carbon Budget 2020 and including different degrees of management (Bastos et al. 2020; Friedlingstein et al. 2020). **Brown line:** Data downloaded 6 June 2021 from FAOSTAT (FAO 2021b; <http://www.fao.org/faostat/>) comprising: net emissions from (i) forest land converted to other land, (ii) net emissions from organic soils in cropland, grassland and from biomass burning, including peat fires and peat draining (Prosperi et al. 2020) and (iii) net emissions from forest land remaining forest land, which includes managed forest lands (Tubiello et al. 2020). **Yellow line:** Net flux estimate from National Greenhouse Gas Inventories (NGHGI) based on country reports to the UNFCCC for LULUCF (Grassi et al. 2021) which include land-use change, and flux in managed lands. **Red EO line:** The 2001–2019 average net CO₂ flux from non-intact forest-related emissions and removals based on ground and Earth Observation data (EO) (Harris et al. 2021). Data to mask non-intact forest were used in the tropics (Turubanova et al. 2018) and extra-tropics (Potapov et al. 2017). **Dark blue line:** the mean estimate and minimum and maximum (dark-blue shading) from three bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020). These include land cover change (e.g., deforestation, afforestation), forest management including wood harvest and land degradation, shifting cultivation, regrowth of forests following wood harvest or abandonment of agriculture, grassland management, agricultural management. Emissions from peat burning and draining are added from external datasets (see text). Both the DGVM and bookkeeping global data is available at: <https://www.icos-cp.eu/science-and-impact/global-carbon-budget/2020> (accessed on 4 October 2021). Data consistent with IPCC AR6 WGI Chapter 5. Dotted lines denote the linear regression from 2000 to 2019. Trends are statistically significant ($P < 0.05$) with exception for the NGHGI trend ($P < 0.01$).

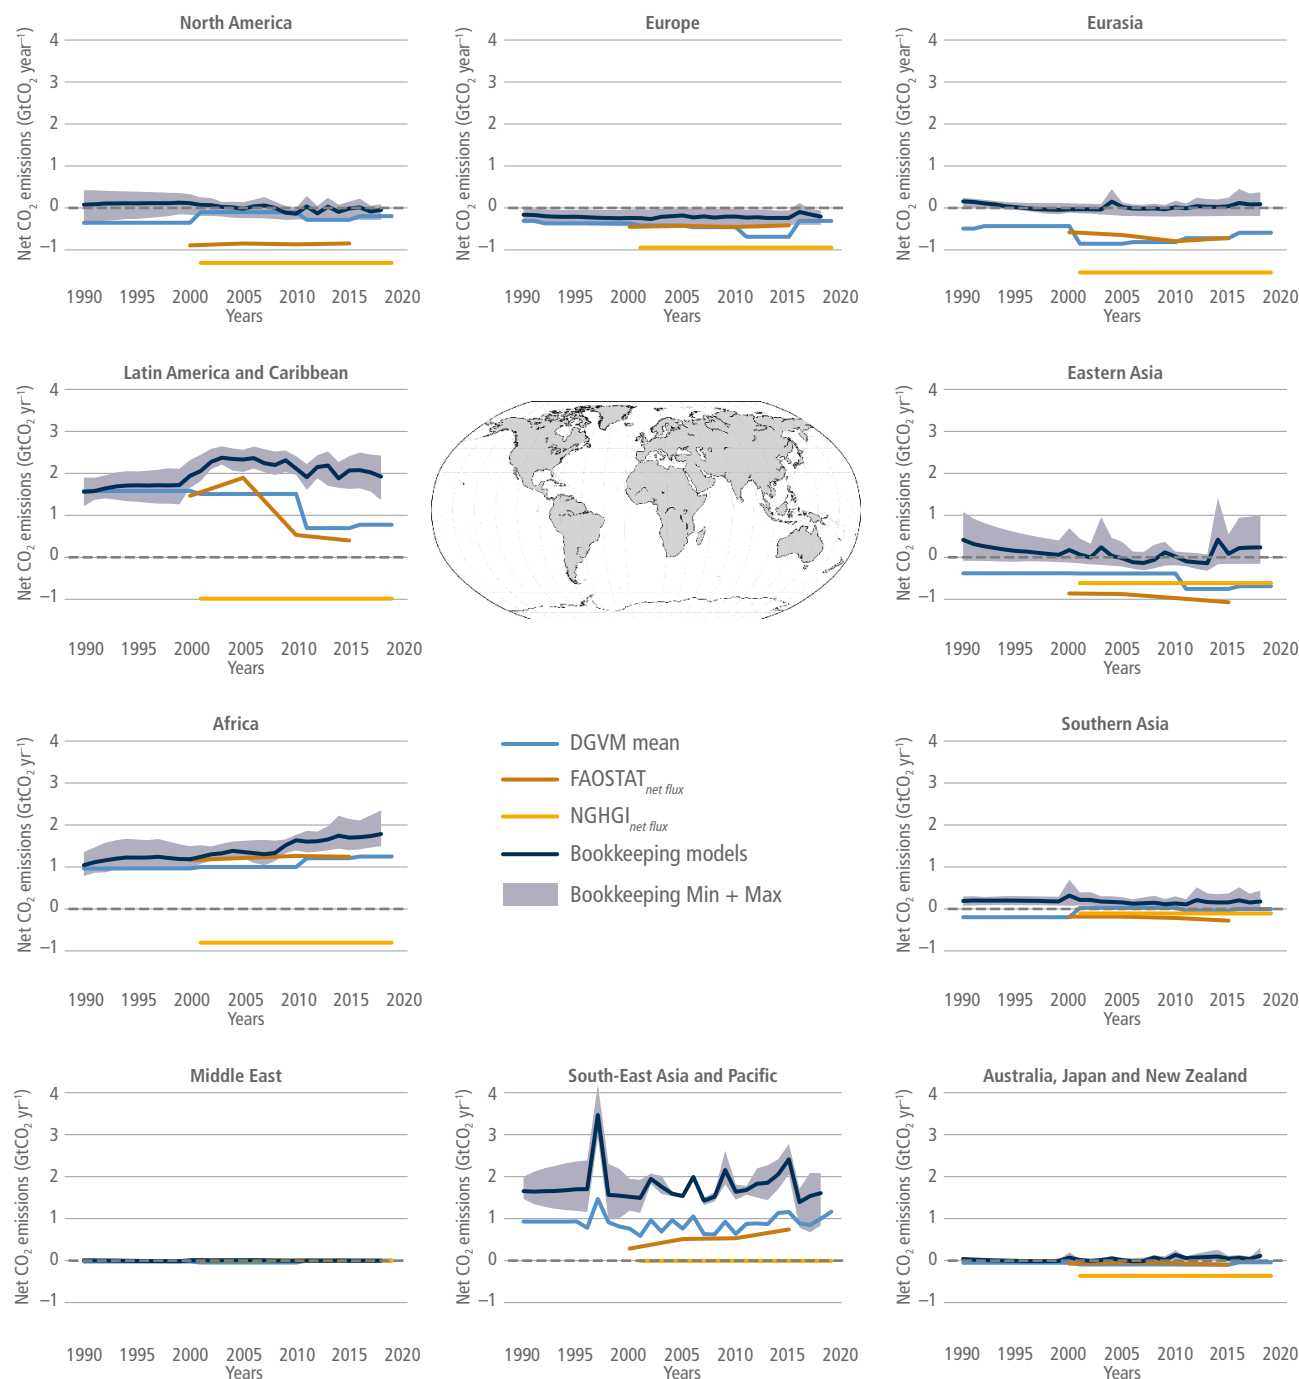

Figure 7.5 | Regional net flux of CO₂ due to AFOLU estimated using different methods for the period 1990–2019 (GtCO₂ yr⁻¹). Positive numbers represent emissions. The upper-central panel depicts the world map shaded according to the IPCC AR6 regions corresponding to the individual graphs. For each regional panel; **brown line:** Total net flux data from FAOSTAT (Tubiello et al. 2020); **yellow line:** Net emissions estimates from National Greenhouse Gas Inventories based on country reports to the UNFCCC for LULUCF (Grassi et al. 2021); **dark-blue line:** The mean estimate and minimum and maximum (dark-blue shading) from three bookkeeping models. (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020). Regional estimates from bookkeeping models are available at: <https://zenodo.org/record/5548333#.YVwJB2LMJPY> (Minx et al. 2021). See the legend in Figure 7.4 for a detailed explanation of flux components for each dataset.

AFOLU emissions magnitude because alternative methodological approaches that incorporate different assumptions are used (Section 7.2.2.2). While the mean of the bookkeeping and DGVM model's show a small increase in global CO₂ net emissions since year 2000, individual models suggest opposite trends (Friedlingstein et al. 2020). The latest FAOSTAT and NGHGI estimates show a small reduction in net emission. Overall, the trends are unclear.

Regionally (Figure 7.5), there is *high confidence* of net emissions linked to deforestation in Latin America, Africa and South-East Asia from 1990 to 2019. There is *medium confidence* in trends indicating a decrease in net emissions in Latin America since 2005 linked to reduced gross deforestation emissions, and a small increase in net emissions related to increased gross deforestation emissions in Africa since 2000 (Figure 7.5). There is *high confidence* regarding the net

AFOLU CO₂ sink in Europe due to forest regrowth and known other sinks in managed forests, and *medium confidence* of a net sink in North America and Eurasia since 2010.

7.2.2.2 Why Do Various Methods Deliver Difference in Results?

The processes responsible for fluxes from land have been divided into three categories (IPCC 2006, 2010): (i) the *direct human-induced effects* due to changing land cover and land management; (ii) the *indirect human-induced effects* due to anthropogenic environmental change, such as climate change, CO₂ fertilisation, nitrogen deposition, and so on; and (iii) *natural effects*, including climate variability and a background natural disturbance regime (e.g., wildfires, windthrows, diseases or insect outbreaks).

Global models estimate the anthropogenic land CO₂ flux considering only the impact of direct effects, and only those areas that were subject to intense and direct management such as clear-cut harvest. It is important to note, that DGVMs also estimate the non-anthropogenic land CO₂ flux (Land Sink) that results from indirect and natural effects (Table 7.1). In contrast, estimates of the anthropogenic land CO₂ flux in NGHGs (LULUCF) include the impact of direct effects and, in most cases, of indirect effects on a much greater area considered 'managed' than global models (Grassi et al. 2021).

The approach used by countries follows the IPCC methodological guidance for NGHGs (IPCC 2006, 2019). Since separating direct, indirect and natural effects on the land CO₂ sink is impossible with direct observation such as national forest inventories (IPCC 2010), upon which most NGHGs are based, the IPCC adopted the 'managed land' concept as a pragmatic proxy to facilitate NGHGI reporting. Anthropogenic land GHG fluxes (direct and indirect effects) are defined as all those occurring on managed land, that is, where human interventions and practices have been applied to perform production, ecological or social functions (IPCC 2006, 2019). GHG fluxes from unmanaged land are not reported in NGHGs because they are assumed to be non-anthropogenic. Countries report NGHGI data with a range of methodologies, resolution and completeness, dependent on capacity and available data, consistent with IPCC guidelines (IPCC 2006, 2019) and subject to an international review or assessment processes.

The FAOSTAT approach is conceptually similar to NGHGs. FAOSTAT data on forests are based on country reports to FAO-FRA 2020 (FAO 2020a), and include changes in biomass carbon stock in 'forest land' and 'net forest conversions' in five-year intervals. 'Forest land' may include unmanaged natural forest, leading to possible overall overestimation of anthropogenic fluxes for both sources and sinks, though emissions from deforestation are likely underestimated (Tubiello et al. 2020). FAOSTAT also estimate emissions from forest fires and other land uses (organic soils), following IPCC methods (Prosperi et al. 2020). The FAO-FRA 2020 (FAO 2020b) update leads to estimates of larger sinks in Russia since 1991, and in China and the USA from 2011, and larger deforestation emissions in Brazil and smaller in Indonesia than FRA 2015 (FAO 2015; Tubiello et al. 2020).

The bookkeeping models by Houghton and Nassikas (2017), Hansis et al. (2015), and Gasser et al. (2020) and the DGVMs used in the Global Carbon Budget (Friedlingstein et al. 2020) use either the LUH2 dataset (Hurtt et al. 2020), HYDE (Goldewijk et al. 2017), FRA 2015 (FAO 2015) or a combination. The LUH2 dataset includes a new wood harvest reconstruction, new representation of shifting cultivation, crop rotations, and management information including irrigation and fertiliser application. The area of forest subject to harvest in LUH2 is much less than the area of forest considered 'managed' in the NGHGs (Grassi et al. 2018). The model datasets do not yet include the FAO FRA 2020 update (FAO 2020a). The DGVMs consider CO₂ fertilisation effects on forest growth that are sometimes confirmed from the ground-based forest inventory networks (Nabuurs et al. 2013) and sometimes not at all (van der Sleen et al. 2015).

Further, the DGVMs and bookkeeping models do not include a wide range of practices which are implicitly covered by the inventories; for example: forest dynamics (Pugh et al. 2019; Le Noë et al. 2020), forest management including wood harvest (Nabuurs, et al. 2013; Arneth et al. 2017), agricultural and grassland practices (Pugh et al. 2015; Sanderman et al. 2017; Pongratz et al. 2018); or, for example, fire management (Andela et al. 2017; Arora and Melton 2018).

Increasingly, higher emissions estimates are expected from DGVMs compared to bookkeeping models, because DGVMs include a loss of additional sink capacity of $3.3 \pm 1.1 \text{ GtCO}_2 \text{ yr}^{-1}$ on average over 2009–2018, which is increasing with larger climate and CO₂ impacts (Friedlingstein et al. 2020). This arises because the DGVM methodological setup requires a reference simulation including climate and environmental changes but without any land-use change such as deforestation, so DGVMs implicitly include the sink capacity forests would have developed in response to environmental changes on areas that in reality have been cleared (Gitz and Ciais 2003; Pongratz et al. 2014) (IPCC AR6 WGI Chapter 5).

Carbon emissions from peat burning have been estimated based on the Global Fire Emission Database (GFED4s; van der Werf et al. 2017). These were included in the bookkeeping model estimates and added 2.0 GtC over 1960–2019 (e.g., causing the peak in South-East Asia in 1998) (Figure 7.5). Within the Global Carbon Budget (Friedlingstein et al. 2020), peat drainage from agriculture accounted for an additional 8.6 GtC from 1960–2019 according to FAOSTAT (Conchedda and Tubiello, 2020) used by two of the bookkeeping models (Hansis et al. 2015; Gasser et al. 2020).

Remote-sensing products provide valuable spatial and temporal land-use and biomass data globally (including in remote areas), at potentially high spatial and temporal resolutions, that can be used to calculate CO₂ fluxes, but have mostly been applied only to forests at the global or even regional scale. While such data can strongly support monitoring reporting and verification, estimates of forest carbon fluxes directly from Earth Observation (EO) data vary considerably in both their magnitude and sign (i.e., whether forests are a net source or sink of carbon). For the period 2005–2017, net tropical forest carbon fluxes were estimated as $-0.4 \text{ GtCO}_2 \text{ yr}^{-1}$ (Fan et al. 2019); $0.58 \text{ GtCO}_2 \text{ yr}^{-1}$ (Grace et al. 2014); $1.6 \text{ GtCO}_2 \text{ yr}^{-1}$ (Baccini et al. 2017) and $2.87 \text{ GtCO}_2 \text{ yr}^{-1}$ (Achard et al. 2014). Differences

can in part be explained by spatial resolution of the datasets, the definition of 'forest' and the inclusion of processes and methods used to determine degradation and growth in intact and secondary forests, or the changes in algorithm over time (Palahí et al. 2021). A recent global study integrated ground observations and remote sensing data to map forest-related GHG emissions and removals at a high spatial resolution (30 m spatial scale), although it only provides an average estimate of annual carbon loss over 2001–2019 (Harris et al. 2021). The estimated net global forest carbon sink globally was $-7.66 \text{ GtCO}_2 \text{ yr}^{-1}$, being $-1.7 \text{ GtCO}_2 \text{ yr}^{-1}$ in the tropics only.

Remote sensing products can help to attribute changes to anthropogenic activity or natural inter-annual climate variability (Fan et al. 2019; Wigneron et al. 2020). Products with higher spatial resolution make it easier to determine forest and carbon dynamics in relatively small-sized managed forests (e.g., Y. Wang et al. 2020;

Heinrich et al. 2021; Reiche et al. 2021). For example, secondary forest regrowth in the Brazilian Amazon offset 9 to 14% of gross emissions due to deforestation¹ (Aragão et al. 2018; Silva Junior et al. 2021). Yet disturbances such as fire and repeated deforestation cycles due to shifting cultivation over the period 1985 to 2017, were found to reduce the regrowth rates of secondary forests by 8 to 55% depending on the climate region of regrowth (Heinrich et al. 2021).

7.2.2.3 Implications of Differences in AFOLU CO₂ Fluxes Between Global Models and National Greenhouse Gas Inventories (NGHGs), and Reconciliation

There is about $5.5 \text{ GtCO}_2 \text{ yr}^{-1}$ difference in the anthropogenic AFOLU estimates between NGHGs and global models (this number relates to an IAMs comparison for the period 2005–2015 – see Cross-Chapter Box 6 in this chapter; for comparison with other

a) 'Anthropogenic CO₂ flux' conceptual inconsistency problem

	Bookkeeping, DGVMs, IAMs			NGHGs	
	'Land Use' Anthropogenic CO ₂ flux defined as arising from land-use change, harvest and regrowth			'LULUCF' Anthropogenic CO ₂ flux defined as occurring in areas defined as 'managed'	
	Managed land	Unmanaged land		Managed land	Unmanaged land
Direct human-induced effects	✓		≠	✓	
Indirect human-induced effects; Natural effects				✓	

b) Solution via disaggregation of DGVM results

	Bookkeeping, IAMs 'Land Use'			DGVMs 'Land Sink' CO ₂ flux associated to the natural response of any land to environmental change			Adjusted models' result (NGHGI-comparable)	
	Managed land	Unmanaged land		Managed land	Unmanaged land		Managed land	Unmanaged land
Direct human-induced effects	✓		+			=	✓	
Indirect human-induced effects; Natural effects				✓			✓	

= Fluxes considered by each respective method
 ✓ = Considered in the comparison

Figure 7.6 | Main conceptual differences between global models (bookkeeping models, IAMs and DGVMs) and NGHGs definitions of what is considered the 'anthropogenic' land CO₂ flux, and proposed solution (from Grassi et al. 2021). (a) Differences in defining the anthropogenic land CO₂ flux by global models ('land use') and NGHGs ('LULUCF'), including the attribution of processes responsible for land fluxes (IPCC 2006; 2010) in managed and unmanaged lands. The anthropogenic land CO₂ flux by global models typically includes only the CO₂ flux due to 'direct effects' (land-use change, harvest, regrowth). By contrast, most NGHGs consider anthropogenic all fluxes occurring in areas defined as 'managed', including also the sink due to 'indirect effects' (climate change, atmospheric CO₂ increase, N deposition etc.) and due to 'natural effects' (climate variability, background natural disturbances). (b) Proposed solution to the inconsistency, via disaggregation of the 'Land Sink' flux from DGVMs into CO₂ fluxes occurring in managed and in unmanaged lands. The sum of 'land use' flux (direct effects from bookkeeping models or IAMs) and the 'Land Sink' (indirect effects from DGVMs) in managed lands produces an adjusted global model CO₂ flux which is conceptually more comparable with LULUCF fluxes from NGHGs. Note that the figure may in some cases be an oversimplification, in other words, not all NGHGs include all recent indirect effects.

models see Figure 7.4). Reconciling the differences, in other words, making estimates comparable, can build confidence in land-related CO₂ estimates, for example for the purpose of assessing collective progress in the context of the Global Stocktake (Cross-Chapter Box 6 in this chapter). The difference largely results from greater estimated CO₂ in NGHGs, mostly occurring in forests (Grassi et al. 2021). This difference is potentially a consequence of: (i) simplified and/or incomplete representation of management in global models (Popp et al. 2017; Pongratz et al. 2018), for example, concerning impacts of forest management in biomass expansion and thickening (Nabuurs et al. 2013; Grassi et al. 2017), (ii) inaccurate and/or incomplete estimation of LULUCF fluxes in NGHGs (Grassi et al. 2017), especially in developing countries, primarily in non-forest land uses and in soils, and (iii) conceptual differences in how global models and NGHGs define ‘anthropogenic’ CO₂ flux from land (Grassi et al. 2018). The impacts of (i) and (ii) are difficult to quantify and result in uncertainties that will decrease slowly over time through improvements of both models and NGHGs. By contrast, the inconsistencies in (iii) and its resulting biases were assessed as explained below.

Since changing the NGHGs’ approach is impractical, an interim method to translate and adjust the output of global models was outlined for reconciling a bookkeeping model and NGHGs (Grassi et al. 2018). More recently, an improved version of this approach has been applied to the future mitigation pathways estimated by IAMs (Grassi et al. 2021), with the implications for the Global Stocktake discussed in Cross-Chapter Box 6 in this chapter. This method implies a post-processing of current global models’ results that addresses two components of the conceptual differences in the ‘anthropogenic’ CO₂ flux; (i) how the impact of human-induced environmental changes (indirect effects) are considered, and (ii) the extent of forest area considered ‘managed’. Essentially, this approach adds DGVM estimates of CO₂ fluxes due to indirect effects from countries’ managed forest area (using non-intact forest area maps as a proxy) to the original global models’ anthropogenic land CO₂ fluxes (Figure 7.6).

Cross-Chapter Box 6 | Implications of Reconciled Anthropogenic Land CO₂ Fluxes for Assessing Collective Climate Progress in the Global Stocktake

Authors: Giacomo Grassi (Italy/European Union), Joeri Rogelj (Belgium/Austria), Joanna I. House (United Kingdom), Alexander Popp (Germany), Detlef van Vuuren (the Netherlands), Katherine Calvin (the United States of America), Shinichiro Fujimori (Japan), Petr Havlík (Austria/the Czech Republic), Gert-Jan Nabuurs (the Netherlands)

The Global Stocktake aims to assess countries’ collective progress towards the long-term goals of the Paris Agreement in the light of the best available science. Historic progress is assessed based on NGHGs, while expectations of future progress are based on country climate targets (e.g., NDCs for 2025 or 2030 and long-term strategies for 2050). Scenarios consistent with limiting warming well-below 2°C and 1.5°C developed by IAMs (Chapter 3) are expected to play a key role as benchmarks against which countries’ aggregated future mitigation pledges will be assessed. This, however, implies that estimates by IAMs and country data used to measure progress are comparable.

In fact, there is about 5.5 GtCO₂ yr⁻¹ difference during 2005–2015 between global anthropogenic land CO₂ net flux estimates of IAMs and aggregated NGHGs, due to different conceptual approaches to what is ‘anthropogenic’. This approach and its implications when comparing climate targets with global mitigation pathways are illustrated in this Box Figure 1a–e.

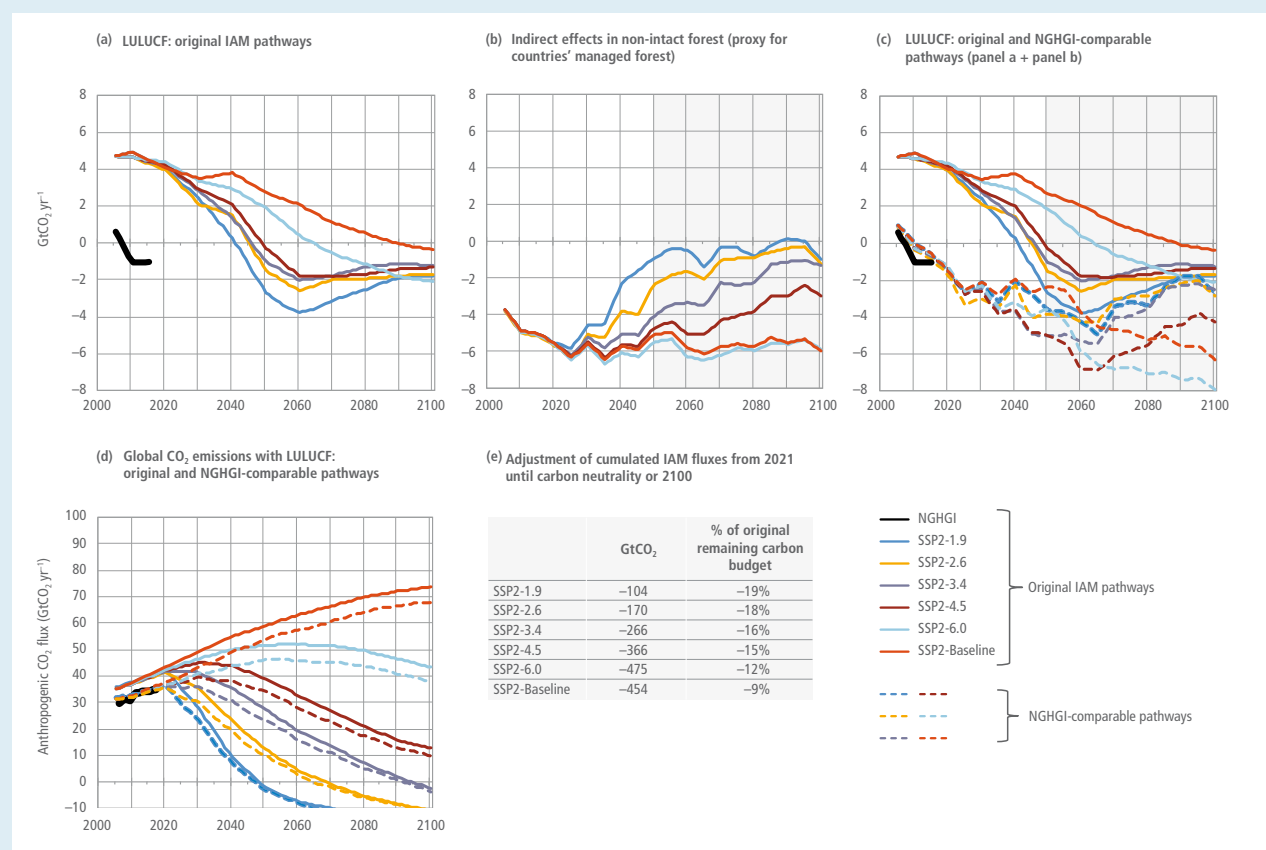

By adjusting the original IAM output (Cross-Chapter Box 6, Figure 1a) with the indirect effects from countries’ managed forest (Cross-Chapter Box 6, Figure 1b, estimated by DGVMs, see also Figure 7.6), NGHGI-comparable pathways can be derived (Cross-Chapter Box 6, Figure 1c). The resulting apparent increase in anthropogenic sink reflects simply a reallocation of a CO₂ flux previously labelled as natural, and thus does not reflect a mitigation action. These changes do not affect non-LULUCF emissions. However, since the atmosphere concentration is a combination of CO₂ emissions from LULUCF and from fossil fuels, the proposed land-related adjustments also influence the NGHGI-comparable economy-wide (all sector) CO₂ pathways (Cross-Chapter Box 6, Figure 1d).

This approach does not imply a change in the original decarbonisation pathways, nor does it suggest that indirect effects should be considered in the mitigation efforts. It simply ensures that a like-with-like comparison is made: if countries’ climate targets use the NGHGI definition of anthropogenic emissions, this same definition can be applied to derive NGHGI-comparable future CO₂ pathways. This would have an impact on the NGHGI-comparable remaining carbon or GHG budget (i.e., the allowable emissions until net zero CO₂ or GHG emissions consistent with a certain climate target). For example, for SSP2-1.9 and SSP2-2.6 (representing pathways in line with 1.5°C and well-below 2°C limits under SSP2 assumptions), carbon budget is 170 GtCO₂-eq lower than the original remaining carbon budget according to the models’ approach (Cross-Chapter Box 6, Figure 1e). Similarly, the remaining carbon (or GHG) budgets in Chapter 3 (this report), as well as the net zero carbon (or GHG) targets, could only be used in combination with the definition of anthropogenic emissions as used by the IAMs (Cross-Chapter Box 3 in Chapter 3). In the absence of these adjustments, collective progress would appear better than it is.

Cross-Chapter Box 6 (continued)

The UNEP's annual assessment of the global 2030 'emission gap' between aggregated country NDCs and specific target mitigation pathways (UNEP 2020), is only affected to a limited degree. This is because some estimates of global emissions under the NDCs already use the same land-use definitions as the IAM mitigation pathways (Rogelj et al. 2017), and because historical data of global NDC estimates is typically harmonised to the historical data of global mitigation pathway projections (Rogelj et al. 2011). This latter procedure, however, is agnostic to the reasons for the observed mismatch, and often uses a constant offset. The adjustment described here allows this mismatch to be resolved by drawing on a scientific understanding of the underlying reasons, and thus provides a more informed and accurate basis for estimating the emission gap.

The approach to deriving a NGHGI-comparable emission pathways presented here can be further refined with improved estimates of the future forest sink. Its use would enable a more accurate assessment of the collective progress achieved and of mitigation pledges under the Paris Agreement.

Cross-Chapter Box 6, Figure 1 | Impact on global mitigation pathways of adjusting the modelled anthropogenic land CO₂ fluxes to be comparable with National Greenhouse Gas Inventories (NGHGIs) (from Grassi et al. 2021). (a) The mismatch between global historical LULUCF CO₂ net flux from NGHGIS (black), and the original (un-adjusted) modelled flux historically and under future mitigation pathways for SSP2 scenarios from Integrated Assessment Models (IAMs, Chapter 3). (b) Fluxes due to indirect effects of environmental change on areas equivalent to countries' managed forest (i.e., those fluxes generally considered 'anthropogenic' by countries and 'natural' by global models). (c) Original modelled (solid line) LULUCF mitigation pathways adjusted to be NGHGI-comparable (dashed line), for example, by adding the indirect effects in panel b. The indirect effects in panel b decline over time with increasing mitigation ambition, mainly because of the weaker CO₂ fertilisation effect. In panel c, the dependency of the adjusted LULUCF pathways on the target becomes less evident after 2030, because the indirect effects in countries' managed forest (which are progressively more uncertain with time, as highlighted by the grey areas) compensate the effects of the original pathways. (d) NGHGI-comparable pathways for global CO₂ emissions from all sectors including LULUCF (obtained by combining global CO₂ pathways without LULUCF – where no adjustment is needed – and the NGHGI-comparable CO₂ pathways for LULUCF (Gütschow et al. 2019; Grassi et al. 2017)). (e) Cumulative impact of the adjustments from 2021 until net zero CO₂ emissions or 2100 (whatever comes first) on the remaining carbon budget.

7.2.3 CH₄ and N₂O Flux From AFOLU

Trends in atmospheric CH₄ and N₂O concentrations and the associated sources, including land and land use are discussed in Sections 5.2.2 and 5.2.3 of the IPCC AR6 WGI. Regarding AFOLU, the SRCCL and AR5 (Jia et al. 2019; Smith et al. 2014) identified three global non-CO₂ emissions data sources: EDGAR (Crippa et al. 2021), FAOSTAT (FAO 2021a; Tubiello, 2019) and the USA EPA (USEPA 2019). Methodological differences have been previously discussed (Jia et al. 2019). In accordance with Chapter 2, this report, EDGAR data are used in Table 7.1 and Figure 7.3. It is important to note that in terms of AFOLU sectoral CH₄ and N₂O emissions, only FAOSTAT provides data on AFOLU emissions, while EDGAR and USEPA data consider just the agricultural component. However, the mean of values across the three databases for both CH₄ and N₂O, fall within the assessed uncertainty bounds (30 and 60% for CH₄ and N₂O respectively, Section 2.2.1, in this report) of EDGAR data. NGHGs annually submitted to the UNFCCC (Section 7.2.2.3) provide national AFOLU CH₄ and N₂O data, as included in the SRCCL (Jia et al. 2019). Aggregation of NGHGs to indicate global emissions must be considered with caution, as not

all countries compile inventories, nor submit annually. Additionally, NGHGs may incorporate a range of methodologies for CH₄ and N₂O accounting (e.g., van der Weerden et al. 2016; Ndung'u et al. 2019; Thakuri et al. 2020), making comparison difficult. The analysis of complete AFOLU emissions presented here, is based on FAOSTAT data. For agricultural specific discussion, analysis considers EDGAR, FAOSTAT and USEPA data.

7.2.3.1 Global AFOLU CH₄ and N₂O Emissions

Using FAOSTAT data, the SRCCL estimated average CH₄ emissions from AFOLU to be $161.2 \pm 43 \text{ MtCH}_4 \text{ yr}^{-1}$ for the period 2007–2016, representing 44% of total anthropogenic CH₄ emissions, with agriculture accounting for 88% of the AFOLU component (Jia et al. 2019). The latest data (FAO 2021a, 2020b) highlight a trend of growing AFOLU CH₄ emissions, with a 10% increase evident between 1990 and 2019, despite year-to-year variation. Forestry and other land use (FOLU) CH₄ emission sources include biomass burning on forest land and combustion of organic soils (peatland fires) (FAO 2020c). The agricultural share of AFOLU CH₄ emissions remains relatively

Figure 7.7 | Estimated global mean agricultural CH₄ (top), N₂O (middle) and aggregated CH₄ and N₂O (using CO₂-eq according to GWP100 AR6 values). (Bottom) emissions for three decades according to EDGAR v6.0 (Crippa et al. 2021), FAOSTAT (FAO 2021a) and USEPA (USEPA 2019) databases. Latest versions of databases indicate historic emissions to 2019, 2019 and 2015 respectively, with average values for the post–2010 period calculated accordingly. For CH₄, emissions classified as ‘Other Ag.’ within USEPA data, are re-classified as ‘Agricultural Biomass Burning’. Despite CH₄ emissions from agricultural soils also being included, this category was deemed to principally concern biomass burning on agricultural land and classified accordingly. For N₂O, emissions classified within EDGAR as direct and indirect emissions from managed soils, and indirect emissions from manure management are combined under ‘Agricultural Soils’. Emissions classified by FAOSTAT as from manure deposition and application to soils, crop residues, drainage of organic soils and synthetic fertilisers are combined under ‘Agricultural Soils’, while emissions reported as ‘Other Ag.’ under USEPA data are re-classified as ‘Agricultural Biomass Burning’.

unchanged, with the latest data indicating agriculture to have accounted for 89% of emissions on average between 1990 and 2019. The SRCCL reported with *medium evidence* and *high agreement* that ruminants and rice production were the most important contributors to overall growth trends in atmospheric CH₄ (Jia et al. 2019). The latest data confirm this in terms of agricultural emissions, with agreement between databases that agricultural CH₄ emissions continue to increase and that enteric fermentation and rice cultivation remain the main sources (Figure 7.7). The proportionally higher emissions from rice cultivation indicated by EDGAR data compared to the other databases, may result from the use of a Tier 2 methodology for this source within EDGAR (Janssens-Maenhout et al. 2019).

The SRCCL also noted a trend of increasing atmospheric N₂O concentration, with *robust evidence* and *high agreement* that agriculture accounted for approximately two-thirds of overall global anthropogenic N₂O emissions. Average AFOLU N₂O emissions were reported to be $8.7 \pm 2.5 \text{ MtN}_2\text{O yr}^{-1}$ for the period 2007–2016, accounting for 81% of total anthropogenic N₂O emissions, with agriculture accounting for 95% of AFOLU N₂O emissions (Jia et al. 2019). A recent comprehensive review confirms agriculture as the principal driver of the growing atmospheric N₂O concentration (Tian et al. 2020). The latest FAOSTAT data (FAO 2020b, 2021a) document a 25% increase in AFOLU N₂O emissions between 1990 and 2019,

with the average share from agriculture remaining approximately the same (96%). Agricultural soils were identified in the SRCCL and in recent literature as a dominant emission source, notably due to nitrogen fertiliser and manure applications to croplands, and manure production and deposition on pastures (Jia et al. 2019; Tian et al. 2020). There is agreement within latest data that agricultural soils remain the dominant source (Figure 7.7).

Aggregation of CH₄ and N₂O to CO₂ equivalence (using GWP100 IPCC AR6 values), suggests that AFOLU emissions increased by 15% between 1990 and 2019, though emissions showed trend variability year to year. Agriculture accounted for 91% of AFOLU emissions on average over the period (FAO 2020b, 2021a). EDGAR (Crippa et al. 2021), FAOSTAT (FAO 2021a) and USEPA (USEPA 2019) data suggest aggregated agricultural emissions (CO₂-eq) to have increased since 1990, by 19% (1990–2019), 15% (1990–2019) and 21% (1990–2015) respectively, with all databases identifying enteric fermentation and agricultural soils as the dominant agricultural emissions sources.

7.2.3.2 Regional AFOLU CH₄ and N₂O Emissions

FAOSTAT data (FAO 2020b, 2021a) indicate Africa (+44%), followed by Southern Asia (+29%) to have the largest growth in AFOLU CH₄ emissions between 1990 and 2019 (Figure 7.8). Eurasia was

Figure 7.8 | Estimated average AFOLU CH₄ (top) and N₂O (bottom) emissions for three decades according to FAOSTAT data by ten global regions, with disaggregation of agricultural emissions (FAO 2020b, 2021a). Note for N₂O: emissions from manure deposition and application to soils, crop residues and synthetic fertilisers are combined under 'Agriculture: Soils'.

characterised by notable emission reductions (–58%), principally as a result of a sharp decline (–63%) between 1990 and 1999. The average agricultural share of AFOLU emissions between 1990 and 2019 ranged from 66% in Africa to almost 100% in the Middle East.

In agreement with AR5 (Smith et al. 2014), the SRCCL identified Asia as having the largest share (37%) of emissions from enteric fermentation and manure management since 2000, but Africa to have the fastest growth rate. Asia was identified as responsible for 89% of rice cultivation emissions, which were reported as increasing (Jia et al. 2019). Considering classification by ten IPCC regions, data suggest enteric fermentation to have dominated emissions in all regions since 1990, except in South-East Asia and Pacific, where rice cultivation forms the principal source (FAO 2021; USEPA 2019). The different databases broadly indicate the same regional CH₄ emission trends, though the indicated absolute change differs due to methodological differences (Section 7.2.3.1). All databases indicate considerable emissions growth in Africa since 1990 and that this region recorded the greatest regional increases in emissions from both enteric fermentation and rice cultivation since 2010. Additionally, FAOSTAT data suggest that emissions from agricultural biomass burning account for a notably high proportion of agricultural CH₄ emissions in Africa (Figure 7.8).

The latest data suggest growth in AFOLU N₂O emissions in most regions between 1990 and 2019, with Southern Asia demonstrating highest growth (+74%) and Eurasia, greatest reductions (–51%), the latter mainly a result of a 61% reduction between 1990 and 2000 (FAO 2020b, 2021a). Agriculture was the dominant emission source in all regions, its proportional average share between 1990 and 2019 ranging from 87% in Africa, to almost 100% in the Middle East (Figure 7.8).

The SRCCL provided limited discussion on regional variation in agricultural N₂O emissions but reported with *medium confidence* that certain regions (North America, Europe, East and South Asia) were notable sources of grazing land N₂O emissions (Jia et al. 2019). The AR5 identified Asia as the largest source and as having the highest growth rate of N₂O emissions from synthetic fertilisers between 2000 and 2010 (Smith et al. 2014). Latest data indicate agricultural N₂O emission increases in most regions, though variation between databases prevents definitive conclusions on trends, with Africa, Southern Asia, and Eastern Asia suggested to have had greatest growth since 1990 according to EDGAR (Crippa et al. 2021), FAOSTAT (FAO 2021a) and USEPA (USEPA 2019) data respectively. However, all databases indicate that emissions declined in Eurasia and Europe from 1990 levels, in accordance with specific environmental regulations put in place since the late 1980s (Tubiello 2019; European Environment Agency 2020; Tian et al. 2020), but generally suggest increases in both regions since 2010.

7.2.4 Biophysical Effects and Short-lived Climate Forcers

Despite new literature, general conclusions from the SRCCL and WGI-AR6 on biophysical effects and short-lived climate

forcers remain the same. Changes in land conditions from land cover change or land management jointly affect water, energy, and aerosol fluxes (biophysical fluxes) as well as GHG fluxes (biogeochemical fluxes) exchanged between the land and atmosphere (*high agreement, robust evidence*) (Anderson et al. 2011; O'Halloran et al. 2012; Alkama and Cescatti 2016; Naudts et al. 2016; Erb et al. 2017). There is *high confidence* that changes in land condition do not just have local impacts but also have non-local impacts in adjacent and more distant areas (Pielke et al. 2011; Mahmood et al. 2014) which may contribute to surpassing climate tipping points (Nepstad et al. 2008; Brando et al. 2014). Non-local impacts may occur through: GHG fluxes and subsequent changes in radiative transfer, changes in atmospheric chemistry, thermal, moisture and surface pressure gradients creating horizontal transport (advection) (de Vrese et al. 2016; Davin and de Noblet-Ducoudré 2010) and vertical transport (convection and subsidence) (Devaraju et al. 2018). Although regional and global biophysical impacts emerge from model simulations (Davin and de Noblet-Ducoudré 2010; de Vrese et al. 2016; Devaraju et al. 2018), especially if the land condition has changed over large areas, there is *very low agreement* on the location, extent and characteristics of the non-local effects across models. Recent methodological advances, empirically confirmed changes in temperature and precipitation owing to distant changes in forest cover (Cohn et al. 2019; Meier et al. 2021).

Following changes in land conditions, CO₂, CH₄ and N₂O fluxes are quickly mixed into the atmosphere and dispersed, resulting in the biogeochemical effects being dominated by the biophysical effects at local scales (*high confidence*) (Y. Li et al. 2015; Alkama and Cescatti 2016). Afforestation/reforestation (Lejeune et al. 2018; Strandberg and Kjellström 2019), urbanisation (Li and Bou-Zeid 2013) and irrigation (Mueller et al. 2016 and Thiery et al. 2017) modulate the likelihood, intensity, and duration of many extreme events including heatwaves (*high confidence*) and heavy precipitation events (*medium confidence*) (Haberlie et al. 2015). There is *high confidence* and *high agreement* that afforestation in the tropics (Perugini et al. 2017), irrigation (Alter et al. 2015; Mueller et al. 2016) and urban greening result in local cooling, *high agreement* and *medium confidence* on the impact of tree growth form (deciduous vs evergreen) (Naudts et al. 2016; Luyssaert et al. 2018 and Schwaab et al. 2020), and *low agreement* on the impact of wood harvest, fertilisation, tillage, crop harvest, residue management, grazing, mowing, and fire management on the local climate.

Studies of biophysical effects have increased since AR5 reaching *high agreement* for the effects of changes in land condition on surface albedo (Leonardi et al. 2015). *Low confidence* remains in proposing specific changes in land conditions to achieve desired impacts on local, regional and global climates due to: a poor relationship between changes in surface albedo and changes in surface temperature (Davin and de Noblet-Ducoudré 2010), compensation and feedbacks among biophysical processes (Bonan 2016; Kallioikoski et al. 2020), climate and seasonal dependency of the biophysical effects (Bonan 2016), omission of short-lived chemical forcers (Unger 2014; Kallioikoski et al. 2020), and study domains often being too small to document possible conflicts between local and non-local effects (Swann et al. 2012; Hirsch et al. 2018).

7.3 Drivers

Since AR5 several global assessments (IPBES 2018a; NYDF Assessment Partners 2019; UNEP 2019; IPCC 2019) and studies (e.g., Tubiello 2019; Tian et al. 2020) have reported on drivers (natural and anthropogenic factors that affect emissions and sinks of the land-use sector) behind AFOLU emissions trends, and associated projections for the coming decades. The following analysis aligns with the drivers typology used by IPBES (2019b) and the Global Environmental Outlook (UNEP 2019). Drivers are divided into direct drivers resulting from human decisions and actions concerning land use and land-use change, and indirect drivers that operate by altering the level or rate of change of one or more direct drivers. Although drivers of emissions in agriculture and FOLU are presented separately, they are interlinked, operating in many complex ways at different temporal and spatial scales, with outcomes depending on their interactions. For example, deforestation in tropical forests is a significant component of sectorial emissions. A review of deforestation drivers' studies published between 1996 and 2013, indicated a wide range of factors associated with deforestation rates across many analyses and studies, covering different regions (Busch and Ferretti-Gallon 2017) (Figure 7.9). Higher agricultural prices were identified as a key driver of deforestation, while law enforcement, area protection, and ecosystem services payments were found to be important drivers of reduced deforestation, while timber activity did not show a consistent impact.

7.3.1 Anthropogenic Direct Drivers: Deforestation, Conversion of Other Ecosystems, and Land Degradation

The global forest area in 2020 is estimated at 4.1 billion ha, representing 31% of the total land area (FAO 2020a). Most forests are situated in the tropics (45%), followed by boreal (27%), temperate (16%) and subtropical (11%) domains. Considering regional distribution of global forest area, Europe and the Russian Federation accounts for 25%, followed by South America (21%), North and Central America (19%), Africa (16%), Asia (15%) and Oceania (5%). However, a significant share (54%) of the world's forest area concerns five countries – The Russian Federation, Brazil, Canada, the USA and China (FAO 2020a). Forest loss rates differ among regions though the global trend is towards a net forest loss (UNEP 2019). The global forest area declined by about 178 Mha in the 30 years from 1990 to 2020 (FAO 2020a). The rate of net forest loss has decreased since 1990, a result of reduced deforestation in some countries and forest gains in others. The annual net loss of forest area declined from 7.8 Mha in 1990–2000, to 5.2 Mha in 2000–2010, to 4.7 Mha in 2010–2020, while the total growing stock in global forests increased (FAO 2020a). The rate of decline in net forest loss during the last decade was due mainly to an increase in the rate of forest gain (i.e., afforestation and the natural expansion of forests).

Figure 7.9 | Association of driver variables with more or less deforestation. Source: reproduced with permission from Busch and Ferretti-Gallon (2017).

Globally, the area of the more open, other wooded land is also of significant importance, with almost 1 billion hectares (FAO 2020a). The area of other wooded land decreased by 30.6 Mha between 1990 and 2020 with larger declines between 1990–2000 (FAO 2020a). There are still significant challenges in monitoring the area of other wooded land, largely associated with difficulties in measuring tree-canopy cover in the range of 5–10%. The global area of mangroves, one of the most productive terrestrial ecosystems (Neogi 2020a), has also experienced a significant decline (Thomas et al. 2017; Neogi 2020b), with a decrease of 1.0 Mha between 1990 and 2020 (FAO 2020a) due to agriculture and aquaculture (Bhattarai 2011; Ajonina et al. 2014; Webb et al. 2014; Giri et al. 2015; Thomas et al. 2017; Fauzi et al. 2019). Some relevant direct drivers affecting emissions and removal in forests and other ecosystems are discussed in proceeding sections.

7.3.1.1 Conversion of Natural Ecosystems to Agriculture

Previous IPCC reports identify land-use change as an important driver of emissions and agriculture as a key driver of land-use change, causing both deforestation and wetland drainage (P. Smith et al. 2019a). The AR5 reported a trend of declining global agricultural land area since 2000 (Smith et al. 2014). The latest data (FAO 2021b) indicate a 2% reduction in the global agricultural area between 2000 and 2019 (Figure 7.10). This area includes (though is not limited to) land under permanent and temporary crops or pasture, temporary fallow and natural meadows and pasture utilised for grazing or agricultural purposes (FAO 2021b), although the extent of land used for grazing may not be fully captured (Fetzel et al. 2017). Data indicate changes in how agricultural land is used. Between 2000 and 2019, the area classified as permanent meadow and pasture decreased (–6%) while cropland area (under arable production and temporary crops) increased (+2%). A key driver of this change has been a general trend of intensification, including in livestock production (Barger et al. 2018; OECD/FAO 2019; UNEP 2019), whereby less grazing land is supporting increasing livestock numbers in conjunction with greater use of crops as livestock feed (Barger et al. 2018). The share of feed crops, such as maize and soybean, of global crop production is projected to grow as the demand for animal feed increases with further intensification of livestock production (OECD/FAO 2019). Despite increased demand for food, feed, fuel and fibre from a growing human population (FAO 2019b), global agricultural land area is projected to remain relatively stable during the next decade, with increases in production expected to result from agricultural intensification (OECD/FAO 2019).

Despite a decline in global agricultural area, the latest data document some regional expansion between 2000 and 2019, specifically in Africa (+3%) and Asia and the Pacific (+1%). Agricultural area declined in all other regions, notably in developed countries (–9%), due to multiple factors including among others, urbanisation (see Section 7.3.1.2).

7.3.1.2 Infrastructure Development and Urbanisation

Although built-up areas (defined as cities, towns, villages and human infrastructure) occupy a relatively small fraction of land (around 1% of global land), since 1975 urban clusters (i.e., urban centres as well as surrounding suburbs) have expanded approximately 2.5 times (UNEP 2019; Chapter 8, this report). Regional differences are striking. Between 1975 and 2015, built-up areas doubled in size in Europe while urban population remained relatively constant. In Africa built-up areas grew approximately fourfold, while urban population tripled (UNEP 2019). Trends indicate that rural-to-urban migration will continue and accelerate in developing countries increasing environmental pressure in spite of measures to mitigate some of the impacts (e.g., by preserving or enhancing natural systems within cities, for example, lakes or natural and urban green infrastructures (UNEP 2019). If current population densities within cities remain stable, the extent of built-up areas in developed countries is expected to increase by 30% and triple in developing countries between 2000 and 2050 (Barger et al. 2018).

Urban expansion leads to landscape fragmentation and urban sprawl with effects on forest resources and land use (Ünal et al. 2019) while interacting with other drivers. For example, in the Brazilian Amazon, the most rapid urban growth occurs within cities that are located near rural areas that produce commodities (minerals or crops) and are connected to export corridors (Richards and VanWey 2015). Urbanisation, coastal development and industrialisation also play crucial roles in the significant loss of mangrove forests (Hirales-Cota 2010; Richards and Friess 2016; Rivera-Monroy et al. 2017). Among infrastructural developments, roads are one of the most consistent and most considerable factors in deforestation, particularly in tropical frontiers (Pfaff et al. 2007; Rudel et al. 2009; Ferretti-Gallon and Busch 2014). The development of roads may also bring subsequent impacts on further development intensity due to increasing economic activities (see Chapter 8) mostly in the tropics and subtropics, where the expansion of road networks increases access to remote forests that act as refuges for biodiversity (Campbell et al. 2017) (Box 7.1). Logging is one of the main drivers of road construction in tropical forests (Kleinschroth and Healey 2017) which leads to more severe long-term impacts that include increased fire incidence, soil erosion, landslides, and sediment accumulation in streams, biological invasions, wildlife poaching, illicit land colonisation, illegal logging and mining, land grabbing and land speculation (Laurance et al. 2009; Alamgir et al. 2017).

Box 7.1 | Case Study: Reducing the Impacts of Roads on Deforestation

Summary

Rapidly expanding roads, particularly in tropical regions, are linked to forest loss, degradation, and fragmentation because the land becomes more generally accessible. Increase of land values of areas adjacent to roads also drives speculation and deforestation related to land tenure (Fearnside 2015). If poorly planned, infrastructure can facilitate fires, illegal mining, and wildlife poaching with consequences for GHG emissions and biodiversity conservation. However, some initiatives are providing new approaches for better planning and then limit environmental and societal impacts.

Background

Although the number and extent of protected areas has increased markedly in recent decades (Watson et al. 2014), many other indicators reveal that nature is in broad retreat. For example, the total area of intact wilderness is declining rapidly worldwide (Watson et al. 2016), 70% of the world's forests are now less than 1 km from a forest edge (Haddad et al. 2015), the extent of tropical forest fragmentation is accelerating exponentially (Taubert et al. 2018). One of the most direct and immediate driver of deforestation and biodiversity decline is the dramatic expansion of roads and other transportation infrastructure (Laurance et al. 2014a; Laurance and Arrea 2017; Alamgir et al. 2017).

Case description

From 2010 to 2050, the total length of paved roads is projected to increase by 25 million km (Dulac 2013) including large infrastructure-expansion schemes in Asia (Laurance and Arrea 2017; Lechner et al. 2018) and in South America (Laurance et al. 2001; Killeen 2007), as well as widespread illegal or unplanned road building (Laurance et al. 2009; Barber et al. 2014). For example, in the Amazon, 95% of all deforestation occurs within 5.5 km of a road, and for every km of legal road there are nearly three km of illegal roads (Barber et al. 2014).

Interactions and limitations

More than any other proximate factor, the dramatic expansion of roads is determining the pace and patterns of habitat disruption and its impacts on biodiversity (Laurance et al. 2009; Laurance and Arrea 2017). Much road expansion is poorly planned. Environmental Impact Assessments (EIAs) for roads and other infrastructure are typically too short term and superficial to detect rare species or assess long-term or indirect impacts of projects (Flyvbjerg 2009; Laurance and Arrea 2017). Another limitation is the consideration of each project in isolation from other existing or planned developments (Laurance et al. 2014b). Hence, EIAs alone are inadequate for planning infrastructure projects and assessing their broader environmental, social, and financial impacts and risks (Laurance et al. 2015a; Alamgir et al. 2017, 2018).

Lessons

The large-scale, proactive land-use planning is an option for managing the development of modern infrastructure. Approaches such as the 'Global Roadmap' scheme (Laurance and Balmford 2013; Laurance et al. 2014a) Strategic Environmental Assessments (Fischer 2007) can be used to evaluate the relative costs and benefits of infrastructure projects, and to spatially prioritise land uses to optimise human benefits while limited new infrastructure in areas of intact or critical habitats. For example, the Global Roadmap strategy has been used in parts of South-East Asia (Sloan et al. 2018), Indochina (Balmford et al. 2016), and sub-Saharan Africa (Laurance et al. 2015b) to devise land-use zoning that can help optimise the many risks and rewards of planned infrastructure projects.

7.3.1.3 Extractive Industry Development

The extent and scale of mining is growing due to increased global demand (UNEP 2019). Due to declining ore grades, more ore needs to be processed to meet demand, with extensive use of open cast mining. A low-carbon future may be more mineral intensive with, for example, clean energy technologies requiring greater inputs in comparison to fossil-fuel-based technologies (Hund et al. 2020). Mining presents cumulative environmental impacts, especially in intensively mined regions (UNEP 2019). The impact of mining on deforestation varies considerably across minerals and countries. Mining causes significant changes to the environment, for example, through mining infrastructure establishment, soil erosion, urban

expansion to support a growing workforce and development of mineral commodity supply chains (Sonter et al. 2015). The increasing consumption of gold in developing countries, increased prices, and uncertainty in financial markets is identified as driving gold mining and associated deforestation in the Amazon region (Alvarez-Berrios and Mitchell Aide 2015; Dezécache et al. 2017; Asner and Tupayachi 2017; Espejo et al. 2018). The total estimated area of gold mining throughout the region increased by about 40% between 2012 and 2016 (Asner and Tupayachi 2017). In the Brazilian Amazon, mining significantly increased forest loss up to 70 km beyond mining lease boundaries, causing 11,670 km² of deforestation between 2005 and 2015, representing 9% of all Amazon forest loss during this time (Sonter et al. 2015).

Mining is also an important driver of deforestation in African and Asian countries. In the Democratic Republic of Congo, where the second-largest area of tropical forest in the world occurs, mining-related deforestation exacerbated by violent conflict (Butsic et al. 2015). In India, mining has contributed to deforestation at a district level, with coal, iron and limestone having had the most adverse impact on forest area loss (Ranjan 2019). Gold mining is also identified as a driver of deforestation in Myanmar (Papworth et al. 2017).

7.3.1.4 Fire Regime Changes

Wildland fires account for approximately 70% of the global biomass burned annually (van der Werf et al. 2017) and constitute a large global source of atmospheric trace gases and aerosols (Gunsch et al. 2018) (IPCC WGI AR6). Although fires are part of the natural system, the frequency of fires has increased in many areas, exacerbated by decreases in precipitation, including in many regions with humid and temperate forests that rarely experience large-scale fires naturally. Natural and human-ignited fires affect all major biomes, from peatlands through shrublands to tropical and boreal forests, altering ecosystem structure and functioning (Argañaraz et al. 2015; Nunes et al. 2016; Remy et al. 2017; Mancini et al. 2018; Aragão et al. 2018; Engel et al. 2019; Rodríguez Vázquez et al. 2021). However, the degree of incidence and regional trends are quite different and a study over 14 years indicated, on average, the largest fires in Australia, boreal North America and Northern Hemisphere Africa (Andela et al. 2019). More than half of the terrestrial surface of the Earth has fire regimes outside the range of natural variability, with changes in fire frequency and intensity posing major challenges for land restoration and recovery (Barger et al. 2018). In some ecosystems, fire prevention might lead to accumulation of large fuel loads that enable wildfires (Moreira et al. 2020a).

About 98 Mha of forest and savannahs are estimated to have been affected by fire in 2015 (FAO and UNEP 2020). Fire is a prevalent forest disturbance in the tropics where about 4% of the total forest and savannah area in that year was burned and more than two-thirds of the total area affected was in Africa and South America; mostly open savanna types (FAO and UNEP 2020). Fires have many different causes, with land clearing for agriculture the primary driver in tropical regions, for example, clearance for industrial oil-palm and paper-pulp plantations in Indonesia (Chisholm et al. 2016), or for pastures in the Amazon (Barlow et al. 2020). Other socio-economic factors are also associated with wildfire regimes such as land-use conflict and socio-demographic aspects (Nunes et al. 2016; Mancini et al. 2018). Wildfire regimes are also changing by the influence of climate change, with wildfire seasons becoming longer, wildfire average size increases in many areas and wildfires occurring in areas where they did not occur before (Jolly et al. 2015; Artés et al. 2019). Human influence has likely increased fire weather in some regions of all inhabited continents (IPCC AR6 WGI Technical Summary) and, in the last years, fire seasons of unprecedented magnitude occurred in diverse regions as California (Goss et al. 2020), the Mediterranean basin (Ruffault et al. 2020), Canada (Kirchmeier-Young et al. 2019) with unprecedented fires in British Columbia in 2021, the Arctic and Siberia (McCarty et al. 2020), Brazilian Amazon (Silva et al. 2021) and Pantanal (Leal Filho et al. 2021), Chile (Bowman et al. 2019) and

Australia (Ward et al. 2020; Gallagher et al. 2021). Lightning plays an important role in the ignition of wildfires, with the incidence of lightning igniting wildfires predicted to increase with rises in global average air temperature (Worden et al. 2017).

7.3.1.5 Logging and Fuelwood Harvest

The area of forest designated for production has been relatively stable since 1990. Considering forest uses, about 30% (1.2 billion ha) of all forests is used primarily for production (wood and non-wood forest products), about 10% (424 Mha) is designated for biodiversity conservation, 398 Mha for the protection of soil and water, and 186 Mha is allocated for social services (recreation, tourism, education research and the conservation of cultural and spiritual sites) (FAO and UNEP 2020). While the rate of increase in the area of forest allocated primarily for biodiversity conservation has slowed in the last ten years, the rate of increase in the area of forest allocated for soil and water protection has grown since 1990, and notably in the last ten years. Global wood harvest (including from forests, other wooded land and trees outside forests) was estimated to be almost 4.0 billion m³ in 2018 (considering both industrial roundwood and fuelwood) (FAO, 2019). Overall, wood removals are increasing globally as demand for, and the consumption of wood products grows annually by 1% in line with growing populations and incomes with this trend expected to continue in coming decades. When done in a sustainable way, more regrowth will occur and is stimulated by management, resulting in a net sink. However illegal and unsustainable logging (i.e., harvesting of timber in contravention of the laws and regulations of the country of harvest) is a global problem with significant negative economic (e.g., lost revenue), environmental (e.g., deforestation, forest degradation, GHG emissions and biodiversity losses) and social impact (e.g., conflicts over land and resources, disempowerment of local and indigenous communities) (World Bank 2019). Many countries around the world have introduced regulations for the international trade of forest products to reduce illegal logging, with significant and positive impacts (Guan et al. 2018).

Over-extraction of wood for timber and fuelwood is identified as an important driver of mangrove deforestation and degradation (Bhattarai 2011; Ajonina et al. 2014; Webb et al. 2014; Giri et al. 2015; Thomas et al. 2017; Fauzi et al. 2019). Unsustainable selective logging and over-extraction of wood is a substantial form of forest and mangrove degradation in many tropical and developing countries, with emissions associated with the extracted wood, incidental damage to the surrounding forest and from logging infrastructure (Bhattarai 2011; Ajonina et al. 2014; Webb et al. 2014; Pearson et al. 2014, Giri et al. 2015; Thomas et al. 2017; Fauzi et al. 2019). Traditional fuelwood and charcoal continue to represent a dominant share of total wood consumption in low-income countries (Barger et al. 2018). Regionally, the percentage of total wood harvested used as fuelwood varies from 90% in Africa, 62% in Asia, 50% in South America to less than 20% in Europe, North America and Oceania. Under current projections, efforts to intensify wood production in plantation forests, together with increases in fuel-use efficiency and electrification, are suggested to only partly alleviate the pressure on native forests (Barger et al. 2018). Nevertheless, the area of forest under management plans has increased in all regions since 2000

by 233 Mha (FAO 2020e). In regions representing the majority of industrial wood production, forests certified under sustainable forest management programmes accounted for 51% of total managed forest area in 2017, an increase from 11% in 2000 (ICFPA 2021).

7.3.2 Anthropogenic Direct Drivers – Agriculture

7.3.2.1 Livestock Populations and Management

Enteric fermentation dominates agricultural CH₄ emissions (Section 7.2.3) with emissions being a function of both ruminant animal numbers and productivity (output per animal). In addition to enteric fermentation, both CH₄ and N₂O emissions from manure management (i.e., manure storage and application) and deposition on pasture, make livestock the main agricultural emissions source (Tubiello 2019). The AR5 reported increases in populations of all major livestock categories between the 1970s and 2000s, including ruminants, with increasing numbers directly linked with increasing CH₄ emissions (Smith et al. 2014). The SRCCL identified managed pastures as a disproportionately high N₂O emissions source within grazing lands, with *medium confidence* that increased manure production and deposition was a key driver (Jia et al. 2019). The latest data (FAO 2021c) indicate continued global livestock population growth between 1990 and 2019 (Figure 7.10), including increases of 18% in cattle and buffalo numbers, and 30% in sheep and goat numbers, corresponding with CH₄ emission trends. Data also indicate increased productivity per animal for example, average increases of 16% in beef, 17% in pig meat and 70% in whole (cow) milk per respective animal between 1990 and 2019 (FAO 2021c). Despite these advances leading to reduced emissions per unit of product (calories, meat and milk) (FAO 2016; Tubiello 2019), increased individual animal productivity generally requires increased inputs (e.g., feed) and this generates increased emissions (Beauchemin et al. 2020). Manipulation of livestock diets, or improvements in animal genetics or health may counteract some of this. In addition, the production of inputs to facilitate increased animal productivity, may indirectly drive further absolute GHG emissions along the feed supply chain.

Although there are several potential drivers (McDermott et al. 2010; Alary et al. 2015), increased livestock production is principally in response to growth in demand for animal-sourced food, driven by a growing human population (FAO, 2019) and increased consumption resulting from changes in affluence, notably in middle-income countries (Godfray et al. 2018). Available data document increases in total meat and milk consumption by 24 and 22% respectively between 1990 and 2013, as indicated by average annual per capita supply (FAO 2017a). Updated data indicate that trends of increasing consumption continued between 2014 and 2018 (FAO 2021d). Sustained demand for animal-sourced food is expected to drive further livestock sector growth, with global production projected to expand by 14% by 2029, facilitated by maintained product prices and lower feed prices (OECD/FAO 2019).

7.3.2.2 Rice Cultivation

In addition to livestock, both AR5 and the SRCCL identified paddy rice cultivation as an important emissions source (Smith et al. 2014), with *medium evidence* and *high agreement* that its expansion is a key driver of growing trends in atmospheric CH₄ concentration (Jia et al. 2019). The latest data indicate the global harvested area of rice to have grown by 11% between 1990 and 2019, with total paddy production increasing by 46%, from 519 Mt to 755 Mt (FAO 2021c). Global rice production is projected to increase by 13% by 2028 compared to 2019 levels (OECD/FAO 2019). However, yield increases are expected to limit cultivated area expansion, while dietary shifts from rice to protein as a result of increasing per capita income, is expected to reduce demand in certain regions, with a slight decline in related emissions projected to 2030 (USEPA 2019).

Between 1990 and 2019, Africa recorded the greatest increase (+160%) in area under rice cultivation, followed by Asia and the Pacific (+6%), with area reductions evident in all other regions (FAO 2021c) broadly corresponding with related regional CH₄ emission (Figures 7.3 and 7.8). Data indicate the greatest growth in consumption (average annual supply per capita) between 1990 and 2013 to have occurred in Eastern Europe and West Central Asia (+42%) followed by Africa (+25%), with little change (+1%) observed in Asia and the Pacific (FAO 2017a). Most of the projected increase in global rice consumption is in Africa and Asia (OECD/FAO 2019).

7.3.2.3 Synthetic Fertiliser Use

Both AR5 and the SRCCL described considerable increases in global use of synthetic nitrogen fertilisers since the 1970s, which was identified to be a major driver of increasing N₂O emissions (Jia et al. 2019). The latest data document a 41% increase in global nitrogen fertiliser use between 1990 and 2019 (FAO 2021e) corresponding with associated increased N₂O emissions (Figure 7.3). Increased fertiliser use has been driven by pursuit of increased crop yields, with for example, a 61% increase in average global cereal yield per hectare observed during the same period (FAO 2021c), achieved through both increased fertiliser use and varietal improvements. Increased yields are in response to increased demand for food, feed, fuel and fibre crops which in turn has been driven by a growing human population (FAO, 2019), increased demand for animal-sourced food and bioenergy policy (OECD/FAO 2019). Global crop production is projected to increase by almost 15% over the next decade, with low income and emerging regions with greater availability of land and labour resources expected to experience the strongest growth, and account for about 50% of global output growth (OECD/FAO 2019). Increases in global nitrogen fertiliser use are also projected, notably in low income and emerging regions (USEPA 2019).

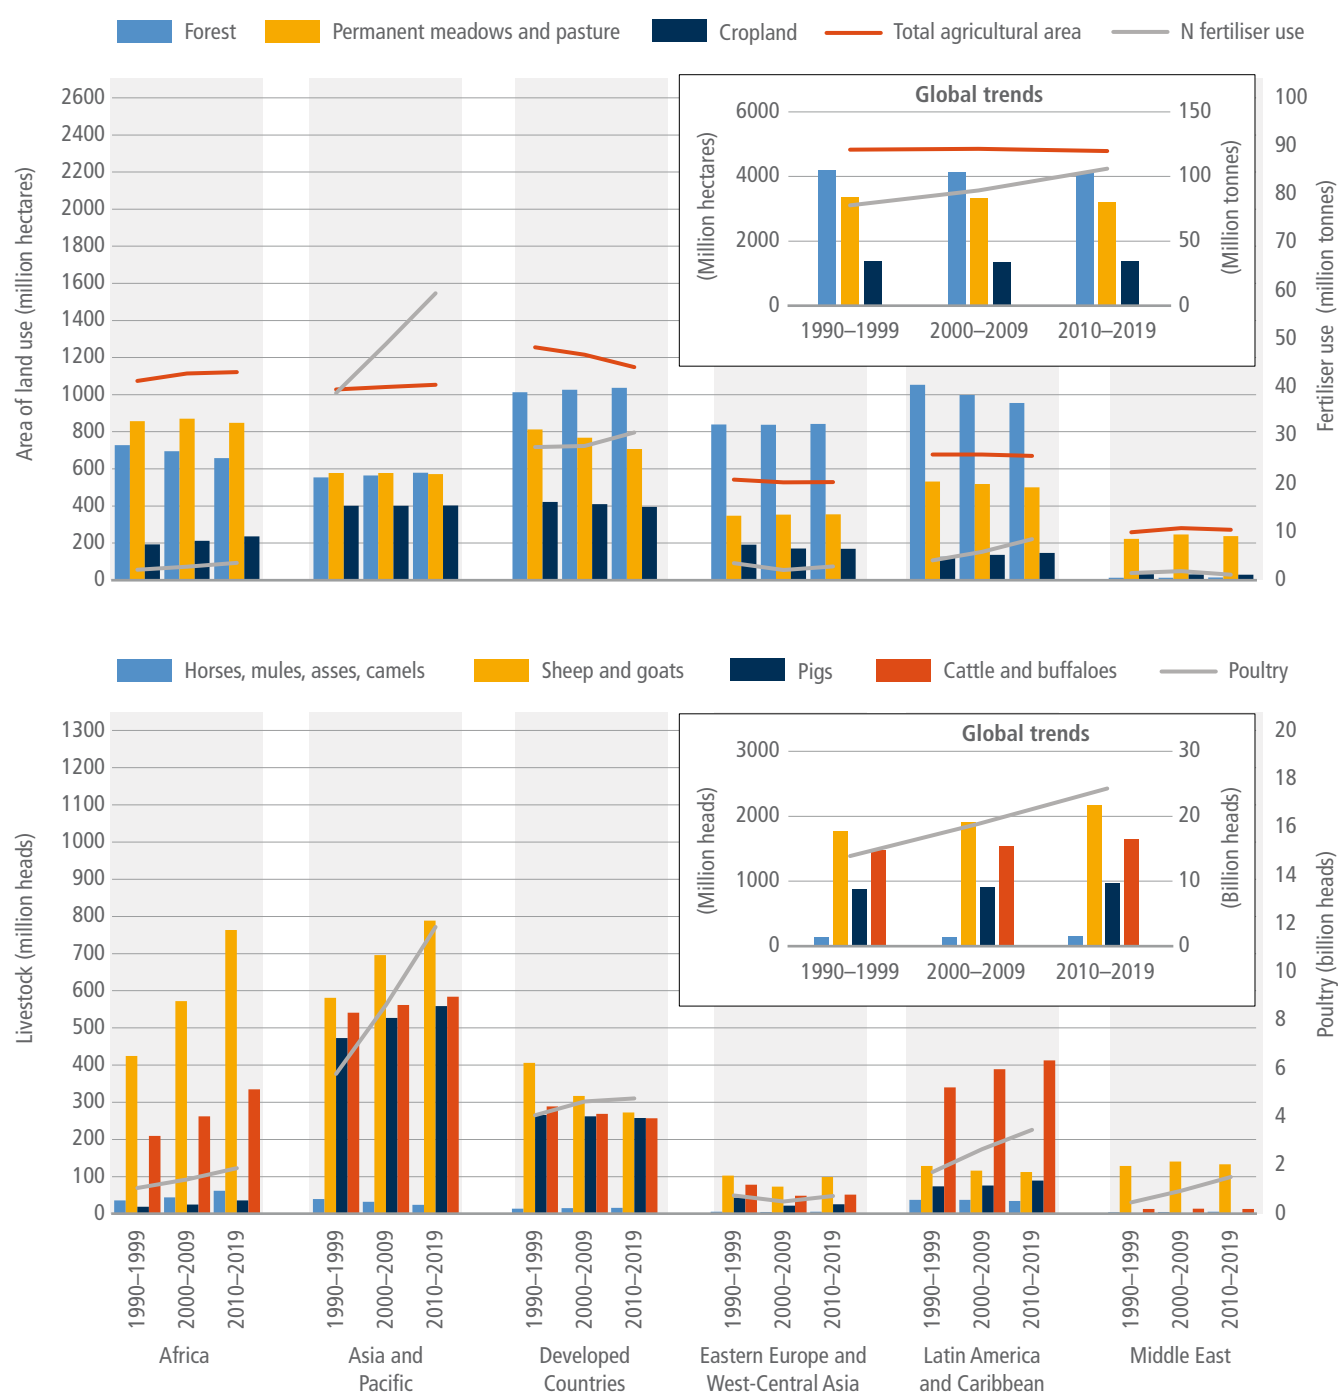

Figure 7.10 | Trends in average global and regional land area under specific land uses (FAO 2021b), inorganic nitrogen fertiliser use (FAO 2021e) (top) and number of livestock (FAO 2021c) (bottom) for three decades. For land use classification 'cropland' represents the FAOSTAT category 'arable land' which includes land under temporary crops, meadow, pasture and fallow. 'Forest' and 'permanent meadow and pasture' follow FAOSTAT categories.

7.3.3 Indirect Drivers

The indirect drivers behind how humans both use and impact natural resources are outlined in Table 7.2. Specifically; demographic,

economic and cultural, scientific and technological, and institutional and governance drivers. These indirect drivers not only interact with each other at different temporal and spatial scales but are also subject to impacts and feedbacks from the direct drivers (Barger et al. 2018).

Table 7.2 | Indirect drivers of anthropogenic land and natural resource use patterns.

Demography	<p>Global and regional trends in population growth: There was a 43% increase in global population between 1990 and 2018. The greatest growth was observed in Africa and the Middle East (+104%) and least growth in Eastern Europe and West-Central Asia (+7%) (FAO 2019b).</p> <p>Global and regional projections: Population is projected to increase by 28% between 2018 and 2050 reaching 9.7 billion (FAO 2019). The world's population is expected to become older, more urbanised and live in smaller households (UNEP 2019).</p> <p>Human migration: Growing mobility and population are linked to human migration, a powerful driver of changes in land and resource use patterns at decadal time scales, with the dominant flow of people being from rural areas to urban settlements over the past few decades, notably in the developing world (Adger et al. 2015; Barger et al. 2018).</p>
Economic development and cultural factors	<p>Changes in land use and management come from individual and social responses to economic opportunities (e.g., demand for a particular commodity or improved market access), mediated by institutions and policies (e.g., agricultural subsidies and low-interest credit or government-led infrastructure projects) (Barger et al. 2018).</p> <p>Projections on consumption: If the future global population adopts a per capita consumption rate similar to that of the developed world, the global capacity to provide land-based resources will be exceeded (Barger et al. 2018). Economic growth in the developing world is projected to double the global consumption of forest and wood products by 2030, with demand likely to exceed production in many developing and emerging economies in Asia and Africa within the next decade (Barger et al. 2018).</p> <p>Global trade: Market distorting agricultural subsidies and globalisation increases pressure on land systems and functions, with global trade and capital flow influencing land use, notably in developing countries (Furumo and Aide 2017; Yao et al. 2018; Pendrill et al. 2019a; UNEP 2019; OECD/FAO 2019). Estimates suggest that between 29 and 39% of emissions from deforestation in the tropics resulted from the international trade of agricultural commodities (Pendrill et al. 2019a).</p>
Science and technology	<p>Technological factors operates in conjunction with economic drivers of land use and management, whether through intensified farming techniques and biotechnology, high-input approaches to rehabilitating degraded land (e.g., Lin et al. 2017; Guo et al. 2020) or through new forms of data collection and monitoring (e.g., Song et al. 2018; Thyagarajan and Vignesh 2019; Arévalo et al. 2020).</p> <p>Changes in farming and forestry systems: Changes can have both positive and negative impacts regarding multiple factors, including GHG emission trends. Fast advancing technologies shape production and consumption, and drive land-use patterns and terrestrial ecosystems at various scales. Innovation is expected to help drive increases in global crop production during the next decade (OECD/FAO 2019). For example, emerging gene editing technologies, may advance crop breeding capabilities, though are subject to biosafety, public acceptance and regulatory approval (Jaganathan et al. 2018; Chen et al. 2019; Schmidt et al. 2020). Technological changes were significant for the expansion of soybean in Brazil by adapting to different soils and photoperiods (Abrahão and Costa 2018). In Asia, technological development changed agriculture with significant improvements in production and adaptation to climate change (Thomson et al. 2019; Giller and Ewert 2019; Anderson et al. 2020; Cassman and Grassini 2020). Developments such as precision agriculture and drip irrigation have facilitated more efficient agrochemical and water use (UNEP 2019).</p> <p>Research and development are central to forest restoration strategies that have become increasingly important around the world as costs vary depending on methods used, from natural regeneration with native tree species to active restoration using site preparation and planting (Löf et al. 2019). In addition, climate change poses the challenge about tree species selection in the future. Innovations in the forest sector also form the basis of a bioeconomy associated with bioproducts and new processes (Verkerk et al. 2020) (Cross-Working Group Box 3 in Chapter 12).</p> <p>Emerging mitigation technologies: Chemically synthesised methanogen inhibitors for ruminants are expected to be commercially available in some countries within the next two years and have considerable CH₄ mitigation potential (McGinn et al. 2019; Melgar et al. 2020; Beauchemin et al. 2020; Reisinger et al. 2021) (Section 7.4.3). There is growing literature (in both academic and non-academic spheres) on the biological engineering of protein. Although in its infancy and subject to investment, technological development, regulatory approval and consumer acceptance, it is suggested to have the potential to disrupt current livestock production systems and land use (Stephens et al. 2018; Ben-Arye and Levenberg 2019; RethinkX 2019; Post et al. 2020). The extent to which this is possible and the overall climate benefits are unclear (Lynch and Pierrehumbert 2019; Chriki and Hocquette 2020).</p>
Institutions and governance	<p>Institutional factors often moderate the relevance and impact of changes in economic and demographic variables related to resource exploitation and use. Institutions encompass the rule of law, legal frameworks and other social structures (e.g., civil society networks and movements) determining land management (e.g., formal and informal property rights, regimes and their enforcement); information and knowledge exchange systems; local and traditional knowledge and practice systems (Barger et al. 2018).</p> <p>Land rights: Land tenure often allows communities to exercise traditional governance based on traditional ecological knowledge, devolved and dynamic access rights, judicious use, equitable distribution of benefits (Mantyka-Pringle et al. 2017; Wynberg 2017; Thomas et al. 2017), biodiversity (Contreras-Negrete et al. 2014) and fire and grazing management (Levang et al. 2015; Varghese et al. 2015).</p> <p>Agreements and Finance: Since AR5, global agreements were reached on climate change, sustainable development goals, and the mobilisation of finance for development and climate action. Several countries adopted policies and commitments to restore degraded land (Barger et al. 2018). The UN Environment Programme (UNEP) and the Food and Agriculture Organization of the UN (FAO), launched the UN Decade on Ecosystem Restoration (https://www.decadeonrestoration.org/).</p> <p>Companies have also made pledges to reduce impacts on forests and on the rights of local communities as well as eliminating deforestation from their supply chains. The finance sector, a crucial driver behind action (Section 7.6, Box 7.12), has also started to make explicit commitments to avoiding environmental damage (Barger et al. 2018) and net zero targets (Forest Trends Ecosystem Marketplace 2021), though investment is sensitive to market outlook.</p>

7.4 Assessment of AFOLU Mitigation Measures Including Trade-offs and Synergies

AFOLU mitigation or land-based climate change mitigation (used in this chapter interchangeably) are a variety of land management or demand management practices that reduce GHG emissions and/or enhance carbon sequestration within the land system (i.e., in forests, wetlands, grasslands, croplands and pasturelands). If implemented with benefits to human well-being and biodiversity, land-based mitigation measures are often referred to as nature-based solutions and/or natural climate solutions (Glossary). Measures that result in a net removal of GHGs from the atmosphere and storage in either living or dead organic material, or in geological stores, are known as CDR, and in previous IPCC reports were sometimes referred to as greenhouse gas removal (GGR) or negative emissions technologies (NETs) (Rogelj et al. 2018a; Jia et al. 2019). This section evaluates current knowledge and latest scientific literature on AFOLU mitigation measures and potentials, including land-based CDR measures. Section 7.4.1 provides an overview of the approaches for estimating mitigation potential, the co-benefits and risks from land-based mitigation measures, estimated global and regional mitigation potential and associated costs according to literature published over the last decade. Subsequent subsections assess literature on 20 key AFOLU mitigation measures specifically providing:

- A description of activities, co-benefits, risks and implementation opportunities and barriers.
- A summary of conclusions in the IPCC Fifth Assessment Report (AR5) and IPCC Special Reports (Special Report on Climate Change of 1.5°C (SR1.5), Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) and Special Report on Climate Change and Land (SRCL)).
- An overview of literature and developments since the AR5 and IPCC Special Reports.
- An assessment and conclusion based on current evidence.

Measures are categorised as supply-side activities in: (i) forests and other ecosystems (Section 7.4.2); (ii) agriculture (Section 7.4.3); (iii) bioenergy and other land-based energy technologies (Section 7.4.4); as well as (iv) demand-side activities (Section 7.4.5 and Figure 7.11). Several information boxes are dispersed within the section and provide supporting material, including case studies exploring a range of topics from climate-smart forestry in Europe (Box 7.2), agroforestry in Brazil (Box 7.3), climate-smart village approaches (Box 7.4), farm systems approaches (Box 7.5), mitigation within Indian agriculture (Box 7.6), and bioenergy and BECCS mitigation calculations (Box 7.7). Novel measures, including enhanced weathering and novel foods are covered in Chapter 12, this report. In addition, as mitigation within AFOLU concerns land management and use of land resources, AFOLU measures impact other sectors. Accordingly, AFOLU measures are also discussed in other sectoral chapters within this report, notably demand-side solutions (Chapter 5), bioenergy and bioenergy with carbon capture and storage (BECCS) (Chapter 6), the use of wood products and biomass in buildings (Chapter 9), and CDR measures, food systems and land related impacts, risks and opportunities of mitigation measures (Chapter 12).

7.4.1 Introduction and Overview of Mitigation Potential

7.4.1.1 Estimating Mitigation Potentials

Mitigation potentials for AFOLU measures are estimated by calculating the scale of emissions reductions or carbon sequestration against a counterfactual scenario without mitigation activities. The types of mitigation potential estimates in recent literature include: (i) technical potential (the biophysical potential or amount possible with current technologies); (ii) economic potential (constrained by costs, usually by a given carbon price (Table 7.3); (iii) sustainable potential (constrained by environmental safeguards and/or natural resources, e.g., limiting natural forest conversion), and (iv) feasible potential (constrained by environmental, socio-cultural, and/or institutional barriers), however, there are no set definitions used in literature. In addition to types of mitigation estimates, there are two AFOLU mitigation categories often calculated: supply-side measures (land management interventions) and demand-side measures (interventions that require a change in consumer behaviour).

Two main approaches to estimating mitigation potentials include: (i) studies on individual measures and/or sectors – henceforth referred to as sectoral assessments, and (ii) integrated assessment models (IAM). Sectoral assessments include studies focusing on one activity (e.g., agroforestry) based on spatial and biophysical data, as well as econometric and optimisation models for a sector, for example, the forest or agriculture sector, and therefore cover a large suite of practices and activities while representing a broad body of literature. Sectoral assessments, however, rarely capture cross-sector interactions or impacts, making it difficult to completely account for land competition, trade-offs, and double counting when aggregating sectoral estimates across different studies and methods (Smith et al. 2014; Jia et al. 2019). On the other hand, IAMs assess the climate impact of multiple and interlinked practices across sectors and therefore, can account for interactions and trade-offs (including land competition, use of other resources and international trade) between them. However, the number of land-based measures used in IAMs are limited compared with the sectoral portfolio (Figure 7.11). The resolution of land-based measures in IAMs are also generally coarser compared to some sectoral estimates, and as such, may be less robust for individual measures (Roe et al. 2021). Given the differences between and strengths and weaknesses of the two approaches, it is helpful to compare the estimates from both. We combine estimates from both approaches to establish an updated range of global land-based mitigation potential.

For the 20 land-based mitigation measures outlined in this section, the mitigation potential estimates are largely derived from sectoral approaches, and where data is available, are compared to IAM estimates. Integrated assessment models and the emissions trajectories, cost-effectiveness and trade-offs of various mitigation pathways are detailed in Section 7.5. It should be noted that the underlying literature for sectoral as well as IAM mitigation estimates consider GWP100 IPCC AR5 values ($\text{CH}_4 = 28$, $\text{N}_2\text{O} = 265$) as well as GWP100 IPCC AR4 values ($\text{CH}_4 = 25$, $\text{N}_2\text{O} = 298$) to convert CH_4 and N_2O to $\text{CO}_2\text{-eq}$. Where possible, we note the various GWP100

values (in IAM estimates, and the wetlands and agriculture sections), however in some instances, the varying GWP100 values used across studies prevents description of non-CO₂ gases in native units as well as conversion to AR6 GWP100 (CH₄ = 27, N₂O = 273) CO₂-eq values to aggregate sectoral assessment estimates.

7.4.1.2 Co-benefits and Risks

Land interventions have interlinked implications for climate mitigation, adaptation, food security, biodiversity, ecosystem services, and other environmental and societal challenges (Section 7.6.5). Therefore, it is important to consider the net effect of mitigation measures for achieving both climate and non-climate goals (Section 7.1).

While it is helpful to assess the general benefits, risks and opportunities possible for land-based mitigation measures (L.G. Smith et al. 2019), their efficacy and scale of benefit or risk largely depends on the type of activity undertaken, deployment strategy (e.g., scale, method), and context (e.g., soil, biome, climate, food system, land ownership) that vary geographically and over time (*robust evidence, high agreement*) (L.G. Smith et al. 2019; P. Smith et al. 2019a; Hurlbert et al. 2019) (Section 12.5). Impacts of land-based mitigation measures are therefore highly context specific and conclusions from specific studies may not be universally applicable. If implemented at appropriate scales and in a sustainable manner, land-based mitigation practices have the capacity to reduce emissions and sequester billions of tonnes of carbon from the atmosphere over coming decades, while also preserving or enhancing biodiversity, water quality and supply, air quality, soil fertility, food and wood security, livelihoods, resilience to droughts, floods and other natural disasters, and positively contributing to ecosystem health and human well-being (*high confidence*) (Toensmeier 2016; Karlsson et al. 2020).

Overall, measures in the AFOLU sector are uniquely positioned to deliver substantial co-benefits. However, the negative consequences of inappropriate or misguided design and implementation of measures may be considerable, potentially impacting for example, mitigation permanence, longevity, and leakage, biodiversity, wider ecosystem functioning, livelihoods, food security and human well-being (Section 7.6) (AR6 WGII, Box 2.2). Land-based mitigation may also face limitations and trade-offs in achieving sustained emission reductions and/or removals due to other land challenges including climate change impacts. It is widely recognised that land-use planning that is context-specific, considers other sustainable development goals, and is adaptable over time can help achieve land-based mitigation that maximises co-benefits, avoids or limits trade-offs, and delivers on international policy goals including the SDGs, Land Degradation Neutrality, and Convention on Biological Diversity (Section 7.6; Chapter 12).

Potential co-benefits and trade-offs are outlined for each of the 20 land-based mitigation measures in the proceeding sub-sections and summarised in Figure 7.12. Section 7.6.5. discusses general links with ecosystem services, human well-being and adaptation, while Chapter 12 (Section 12.5) provides an in-depth assessment of the land related impacts, risks and opportunities associated with mitigation

options across sectors, including positive and negative effects on land resources, water, biodiversity, climate, and food security.

7.4.1.3 Overview of Global and Regional Technical and Economic Potentials in AFOLU

IPCC AR5 (2014). In the AR5, the economic mitigation potential of supply-side measures in the AFOLU sector was estimated at 7.18–10.60 GtCO₂-eq yr⁻¹ in 2030 with carbon prices up to USD100 tCO₂-eq⁻¹, about a third of which could be achieved at <USD20 tCO₂-eq⁻¹ (*medium evidence, medium agreement*) (Smith et al. 2014). The AR5 provided a summary table of individual AFOLU mitigation measures, but did not conduct a detailed assessment for each.

IPCC SRCCL (2019). The SRCCL assessed the full range of technical, economic and sustainability mitigation potentials in AFOLU for the period 2030–2050 and identified reduced deforestation and forest degradation to have greatest potential for reducing supply-side emissions (0.4 to 5.8 GtCO₂-eq yr⁻¹) (*high confidence*) followed by combined agriculture measures, 0.3 to 3.4 GtCO₂-eq yr⁻¹ (*medium confidence*) (Jia et al. 2019). For the demand-side estimates, shifting towards healthy, sustainable diets (0.7 to 8.0 GtCO₂-eq yr⁻¹) (*high confidence*) had the highest potential, followed by reduced food loss and waste (0.8 to 4.5 GtCO₂-eq yr⁻¹) (*high confidence*). Measures with greatest potential for CDR were afforestation/reforestation (0.5 to 10.1 GtCO₂-eq yr⁻¹) (*medium confidence*), soil carbon sequestration in croplands and grasslands (0.4 to 8.6 GtCO₂-eq yr⁻¹) (*medium confidence*) and BECCS (0.4 to 11.3 GtCO₂-eq yr⁻¹) (*medium confidence*). The SRCCL did not explore regional potential, associated feasibility nor provide detailed analysis of costs.

IPCC AR6. This assessment concludes the likely range of global land-based mitigation potential is approximately 8–14 GtCO₂-eq yr⁻¹ between 2020–2050 with carbon prices up to USD100 tCO₂-eq⁻¹, about half of the technical potential (*medium evidence, medium agreement*). About 30–50% could be achieved <USD20 tCO₂-eq⁻¹ (Table 7.3). The global economic potential estimates in this assessment are slightly higher than the AR5 range. Since AR5, there have been numerous new global assessments of sectoral land-based mitigation potential (Fuss et al. 2018; Griscom et al. 2017, 2020; Roe et al. 2019; Jia et al. 2019; Griscom et al. 2020; Roe et al. 2021) as well as IAM estimates of mitigation potential (Riahi et al. 2017; Popp et al. 2017; Rogelj et al. 2018a; Frank et al. 2019; Johnston and Radeloff 2019; Baker et al. 2019), expanding the scope of AFOLU mitigation measures included and substantially improving the robustness and spatial resolution of mitigation estimates. A recent development is an assessment of country-level technical and economic (USD100 tCO₂-eq⁻¹) mitigation potential for 20 AFOLU measures, including for demand-side and soil organic carbon sequestration in croplands and grasslands, not estimated before (Roe et al. 2021). Estimates on costs, feasibility, sustainability, benefits, and risks have also been developed for some mitigation measures, and they continue to be active areas of research. Developing more refined sustainable potentials at a country-level will be an important next step. Although most mitigation estimates still do not consider the impact of future climate change, there are some emerging studies

that do (Sonntag et al. 2016; Doelman et al. 2019). Given the IPCC WG1 finding that the land sink is continuing to increase although its efficiency is decreasing with climate change, it will be critical to better understand how future climate will affect mitigation potentials, particularly from CDR measures.

Across global sectoral studies, the economic mitigation potential (up to USD100 tCO₂-eq⁻¹) of supply-side measures in AFOLU for the period 2020–2050 is 11.4 mean (5.6–19.8 full range) GtCO₂-eq yr⁻¹,

about 50% of the technical potential of 24.2 (4.9–58) GtCO₂-eq yr⁻¹ (Table 7.3). Adding 2.1 GtCO₂-eq yr⁻¹ from demand-side measures (accounting only for diverted agricultural production to avoid double counting with land-use change effects), total land-based mitigation potential up to USD100 tCO₂-eq⁻¹ is 13.6 (6.7–23.4) GtCO₂-eq yr⁻¹. This estimate aligns with the most recent regional assessment (Roe et al. 2021), which found the aggregate global mitigation potential of supply and demand-side measures to be 13.8 ± 3.1 GtCO₂-eq yr⁻¹ up to USD100 tCO₂-eq⁻¹ for the period 2020–2050. Across integrated

Table 7.3 | Estimated annual mitigation potential (GtCO₂-eq yr⁻¹) in 2020–2050 of AFOLU mitigation options by carbon price. Estimates reflect sectoral studies based on a comprehensive literature review updating data from (Roe et al. 2019) and integrated assessment models using the IPCC AR6 database (Section 7.5). Values represent the mean, and full range of potential. Sectoral mitigation estimates are averaged for the years 2020–2050 to capture a wider range of literature, and the IAM estimates are given for 2050 as many model assumptions delay most land-based mitigation to mid-century. The sectoral potentials are the sum of global estimates for the individual measures listed for each option. IAM potentials are given for mitigation options with available data; for example, net land-use CO₂ for total forests and other ecosystems, and land sequestration from A/R, but not reduced deforestation (protect). Sectoral estimates predominantly use GWP100 IPCC AR5 values (CH₄ = 28, N₂O = 265), although some use GWP100 IPCC AR4 values (CH₄ = 25, N₂O = 298); and the IAMs use GWP100 IPCC AR6 values (CH₄ = 27, N₂O = 273). The sectoral and IAM estimates reflected here do not account for the substitution effects of avoiding fossil fuel emissions nor emissions from other more energy intensive resources/materials. For example, BECCS estimates only consider the carbon dioxide removal (CDR) via geological storage component and not potential mitigation derived from the displacement of fossil fuel use in the energy sector. Mitigation potential from substitution effects are included in the other sectoral chapters like energy, transport, buildings and industry. The total AFOLU sectoral estimate aggregates potential from agriculture, forests and other ecosystems, and diverted agricultural production from avoided food waste and diet shifts (excluding land-use impacts to avoid double counting). Because of potential overlaps between measures, sectoral values from BECCS and the full value chain potential from demand-side measures are not summed with AFOLU. IAMs account for land competition and resource optimisation and can therefore sum across all available categories to derive the total AFOLU potential. Key: ND = no data; Sectoral = as assessed by sectoral literature review; IAM = as assessed by integrated assessment models; EJ = exajoule primary energy.

Mitigation option	Estimate type	<USD20 tCO ₂ -eq ⁻¹	<USD50 tCO ₂ -eq ⁻¹	<USD100 tCO ₂ -eq ⁻¹	Technical
Agriculture total	Sectoral	0.9 (0.5–1.4)	1.6 (1–2.4)	4.1 (1.7–6.7)	11.2 (1.6–28.5)

assessment models (IAMs), the economic potential for land-based mitigation (Agriculture, LULUCF and BECCS) for USD100 tCO₂-eq⁻¹ is 7.9 mean (4.1–17.3 range) GtCO₂-eq yr⁻¹ in 2050 (Table 7.3). We add the estimate for BECCS here to provide the full land-based potential, as IAMs optimise land allocation based on costs, which displaces land-based CDR activities for BECCS. Combining both IAM and sectoral approaches, the likely range is therefore 7.9–13.6 (rounded to 8–14) GtCO₂-eq yr⁻¹ up to USD100 tCO₂-eq⁻¹ between 2020–2050. Considering both IAM and sectoral economic potential estimates, land-based mitigation could have the capacity to make the AFOLU sector net negative in GHG emissions from 2036 (Figure 7.12), although there are highly variable mitigation strategies for how AFOLU potential can be deployed for achieving climate targets (Illustrative Mitigation Pathways in Section 7.5.5). Economic potential estimates, which reflect a public willingness to pay, may be more relevant for policy making compared with technical potentials which reflect a theoretical maximum that may not be feasible or sustainable.

Among the mitigation options, the protection, improved management, and restoration of forests and other ecosystems (wetlands, savannas and grasslands) have the largest potential to reduce emissions and/or sequester carbon at 7.3 (3.9–13.1) GtCO₂-eq yr⁻¹ (up to USD100 tCO₂-eq⁻¹), with measures that ‘protect’ having the single highest total mitigation and mitigation densities (mitigation per area) in AFOLU (Table 7.3 and Figure 7.11). Agriculture provides the second largest share of mitigation, with 4.1 (1.7–6.7) GtCO₂-eq yr⁻¹ potential (up to USD100 tCO₂-eq⁻¹), from soil carbon management in croplands and grasslands, agroforestry, biochar, rice cultivation, and livestock and nutrient management (Table 7.3 and Figure 7.11). Demand-side measures including shifting to sustainable healthy diets, reducing food waste, and improving wood products can mitigate 2.2 (1.1–3.6) GtCO₂-eq yr⁻¹ when accounting only for diverted agricultural production from diets and food waste to avoid double counting with measures in forests and other ecosystems (Table 7.3 and Figure 7.11). The potential of demand-side measures increases three-fold, to 6.5 (4–9.5) GtCO₂-eq yr⁻¹ when accounting for the entire value chain including land-use effects, but would overlap with other measures and is therefore not additive.

Most mitigation options are available and ready to deploy. Emissions reductions can be unlocked relatively quickly, whereas CDR need upfront investment to generate sequestration over time. The protection of natural ecosystems, carbon sequestration in agriculture, sustainable healthy diets and reduced food waste have especially high co-benefits and cost efficiency. Avoiding the conversion of carbon-rich primary peatlands, coastal wetlands and forests is particularly important as most carbon lost from those ecosystems are irrecoverable through restoration by the 2050 timeline of achieving net zero carbon emissions (Goldstein et al. 2020). Sustainable intensification, shifting diets, reducing food waste could enhance efficiencies and reduce agricultural land needs, and are therefore critical for enabling supply-side measures such as reduced deforestation, restoration, as well as reducing N₂O and CH₄ emissions from agricultural production – as seen in the Illustrative Mitigation Pathway (IMP-SP) (Section 7.5.6). Although agriculture measures that reduce non-CO₂, particularly of CH₄, are important for

near-term emissions reductions, they have less economic potential due to costs. Demand-side measures may be able to deliver non-CO₂ emissions reductions more cost efficiently.

Regionally, economic mitigation potential up to USD100 tCO₂-eq⁻¹ is estimated to be greatest in tropical countries in Asia and Pacific (34%), Latin America and the Caribbean (24%), and Africa and the Middle East (18%) because of the large potential from reducing deforestation and sequestering carbon in forests and agriculture (Figure 7.11). However, there is also considerable potential in Developed Countries (18%) and more modest potential in Eastern Europe and West-Central Asia (5%). These results are in line with the IAM regional mitigation potentials (Figure 7.11). The protection of forests and other ecosystems is the dominant source of mitigation potential in tropical regions, whereas carbon sequestration in agricultural land and demand-side measures are important in Developed Countries and Asia and Pacific. The restoration and management of forests and other ecosystems is more geographically distributed, with all regions having significant potential. Regions with large livestock herds (Developed Countries, Latin America) and rice paddy fields (Asia and Pacific) have potential to reduce CH₄. As expected, the highest total potential is associated with countries and regions with large land areas, however when considering mitigation density (total potential per hectare), many smaller countries, particularly those with wetlands have disproportionately high levels of mitigation for their size (Roe et al. 2021). As global commodity markets connect regions, AFOLU measures may create synergies and trade-offs across the world, which could make national demand-side measures for example, important in mitigating supply-side emissions elsewhere (Kallio et al. 2018).

Although economic potentials provide more realistic, near-term climate mitigation compared to technical potentials, they still do not account for feasibility barriers and enabling conditions that vary by region and country. For example, according to most models, including IAMs, avoided deforestation is the cheapest land-based mitigation option (Table 7.3, Sections 7.5.3 and 7.5.4), however implementing interventions aimed at reducing deforestation (including REDD+) often have higher transaction and implementation costs than expected due to various barriers and enabling conditions (Luttrell et al. 2018) (Section 7.6). The feasibility of implementing AFOLU mitigation measures, including those with multiple co-benefits, depends on varying economic, technological, institutional, socio-cultural, environmental and geophysical barriers (*high confidence*) (L.G. Smith et al. 2019). The section for each individual mitigation measure provides an overview of co-benefits and risks associated with the measure and Section 7.6.6 outlines key enabling factors and barriers for implementation.

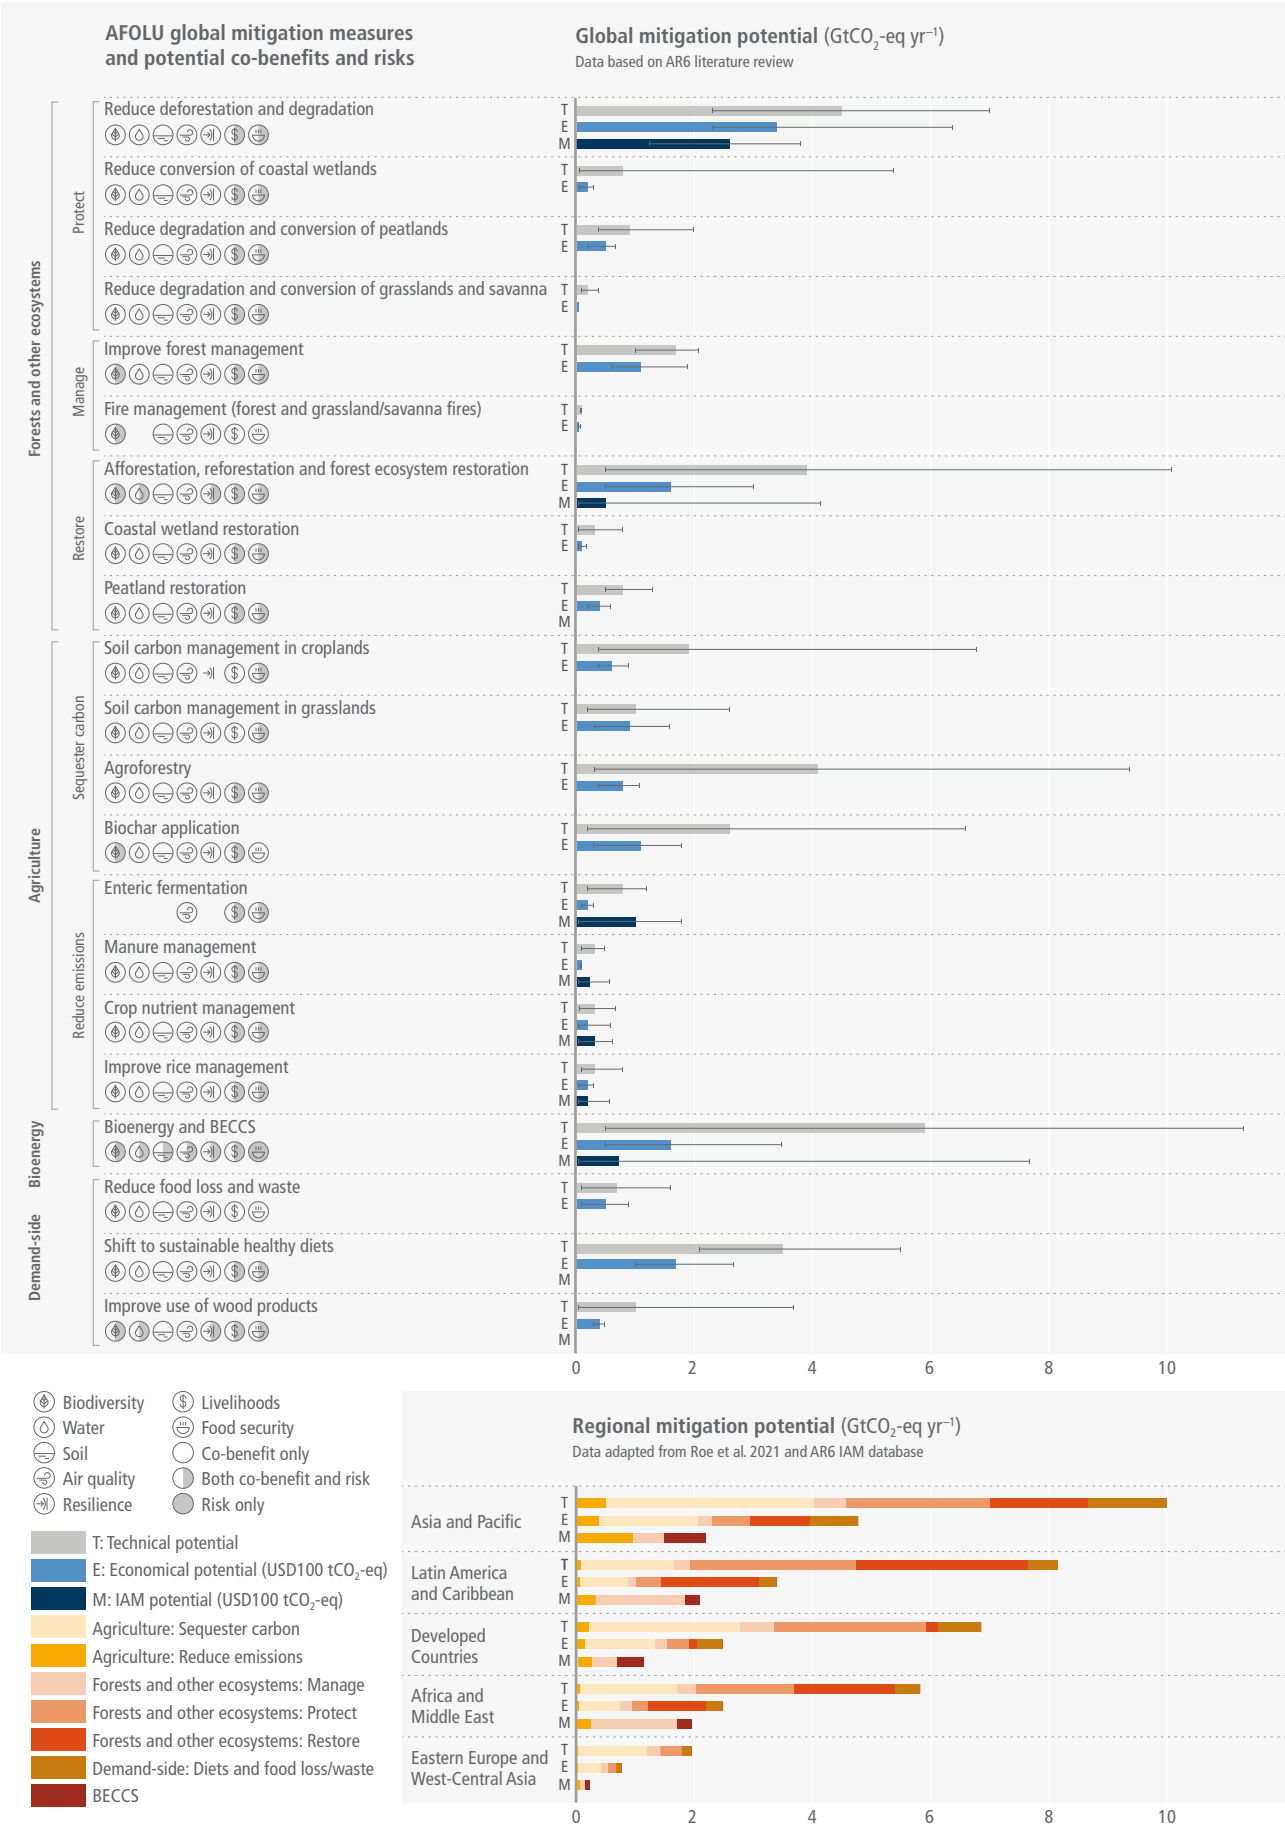

Figure 7.11 | Global and regional mitigation potential (GtCO₂-eq yr⁻¹) in 2020–2050 for 20 land-based measures.

Figure 7.11 (continued): Global and regional mitigation potential (GtCO₂-eq yr⁻¹) in 2020–2050 for 20 land-based measures. (a) Global estimates represent the mean (bar) and full range (error bars) of the economic potential (up to USD100 tCO₂-eq⁻¹) based on a comprehensive literature review of sectoral studies (references are outlined in the sub-section for each measure in Sections 7.4.2–7.4.5). Potential co-benefits and trade-offs for each of the 20 measures are summarised in icons. (b) Regional estimates illustrate the mean technical (T) and economic (E) (up to USD100 tCO₂-eq⁻¹) sectoral potential based on data from (Roe et al. 2021). IAM economic potential (M) (USD100 tCO₂-eq⁻¹) data is from the IPCC AR6 database.

Figure 7.12 | Historic land sector GHG flux estimates and illustrative AFOLU mitigation pathways to 2050, based on data presented in Sections 7.2, 7.4 and 7.5. Historic trends consider both **A** anthropogenic (AFOLU) GHG fluxes (GtCO₂-eq yr⁻¹) according to FAOSTAT (FAO 2021a; 2021b) and **B** the estimated natural land CO₂ sink according to (Friedlingstein et al. 2020). Note that for the anthropogenic net land CO₂ flux component, several approaches and methods are described within the literature (Section 7.2.2) with a wide range in estimates. For clarity, only one dataset (FAOSTAT) is illustrated here. It is not intended to indicate preference for one particular method over others. Historic flux trends are illustrated to 2019, the latest year for which data is available. Projected economic mitigation potential (at costs of up to USD100 tCO₂-eq⁻¹) includes estimates from IAMs and sectoral studies (Table 7.3). The 'sectoral studies' are disaggregated into several cumulative parts: first 'sectoral studies' involves measures in agriculture, forests and other ecosystems, then an additional BECCS share ('+ BECCS'), then the additional effect of demand-side measures and BECCS ('+BECCS and demand-side measures'). The latter only accounting for diverted agricultural production to avoid double counting. Projected mitigation assumes adoption of measures to achieve increasing, linear mitigation, reaching average annual potential in 2050, although this does not reflect deployment rates for most measures. For illustrative purposes, a pathway to projected emissions in 2050 according to a scenario of current policy (C7 – above 3.0°C – Model: GCAM 5.3) is additionally included for reference.

7.4.2 Forests and Other Ecosystems

7.4.2.1 Reduce Deforestation and Degradation

Activities, co-benefits, risks and implementation opportunities and barriers. Reducing deforestation and forest degradation conserves existing carbon pools in forest vegetation and soil by avoiding tree cover loss and disturbance. Protecting forests involves controlling the drivers of deforestation (such as commercial and subsistence agriculture, mining, urban expansion) and forest degradation (such as overharvesting including fuelwood collection, poor harvesting practices, overgrazing, pest outbreaks, and extreme wildfires), as well as by establishing well designed, managed and funded protected areas (Barber et al. 2014), improving law

enforcement, forest governance and land tenure, supporting community forest management and introducing forest certification (P. Smith et al. 2019a). Reducing deforestation provides numerous and substantial co-benefits, preserving biodiversity and ecosystem services (e.g., air and water filtration, water cycling, nutrient cycling) more effectively and at lower costs than afforestation/reforestation (Jia et al. 2019). Potential adverse side effects of these conservation measures include reducing the potential for agriculture land expansion, restricting the rights and access of local people to forest resources, or increasing the dependence of local people to insecure external funding. Barriers to implementation include unclear land tenure, weak environmental governance, insufficient funds, and increasing pressures associated to agriculture conversion, resource exploitation and infrastructure development (Sections 7.3 and 7.6).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. Reducing deforestation and forest degradation represents one of the most effective options for climate change mitigation, with technical potential estimated at 0.4–5.8 GtCO₂ yr⁻¹ by 2050 (*high confidence*) (SRCCL, Chapters 2 and 4, and Table 6.14). The higher technical estimate represents a complete halting of land-use conversion in forests and peatland forests (i.e., assuming recent rates of carbon loss are saved each year) and includes vegetation and soil carbon pools. Ranges of economic potentials for forestry ranged in AR5 from 0.01–1.45 GtCO₂ yr⁻¹ for USD20 tCO₂⁻¹ to 0.2–13.8 GtCO₂ yr⁻¹ for USD100 tCO₂⁻¹ by 2030 with reduced deforestation dominating the forestry mitigation potential LAM and MAF, but very little potential in OECD-1990 and EIT (IPCC AR5).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Since the SRCCL, several studies have provided updated and convergent estimates of economic mitigation potentials by region (Busch et al. 2019; Griscom et al. 2020; Austin et al. 2020; Roe et al. 2021). Tropical forests and savannas in Latin America provide the largest share of mitigation potential (3.9 GtCO₂ yr⁻¹ technical, 2.5 GtCO₂ yr⁻¹ at USD100 tCO₂⁻¹) followed by South-East Asia (2.2 GtCO₂ yr⁻¹ technical, 1.5 GtCO₂ yr⁻¹ at USD100 tCO₂⁻¹) and Africa (2.2 GtCO₂ yr⁻¹ technical, 1.2 GtCO₂ yr⁻¹ at USD100 tCO₂⁻¹) (Roe et al. 2021). Tropical forests continue to account for the highest rates of deforestation and associated GHG emissions. While deforestation shows signs of decreasing in several countries, in others, it continues at a high rate or is increasing (Turubanova et al. 2018). Between 2010–2020, the rate of net forest loss was 4.7 Mha yr⁻¹ with Africa and South America presenting the largest shares (3.9 Mha and 2.6 Mha, respectively) (FAO 2020a).

A major uncertainty in all studies on avoided deforestation potential is their reliance on future reference levels that vary across studies and approaches. If food demand increases in the future, for example, the area of land deforested will likely increase, suggesting more technical potential for avoiding deforestation. Transboundary leakage due to market adjustments could also increase costs or reduce effectiveness of avoiding deforestation (e.g., Ingalls et al. 2018; Gingrich et al. 2019). Regarding forest regrowth, there are uncertainties about the time for the secondary forest carbon saturation (Houghton and Nassikas 2017; Zhu et al. 2018). Permanence of avoided deforestation may also be a concern due to the impacts of climate change and disturbance of other biogeochemical cycles on the world's forests that can result in future potential changes in terrestrial ecosystem productivity, climate-driven vegetation migration, wildfires, forest regrowth and carbon dynamics (Ballantyne et al. 2012; Kim et al. 2017b; Lovejoy and Nobre 2018; Aragão et al. 2018).

Critical assessment and conclusion. Based on studies since AR5, the technical mitigation potential for reducing deforestation and degradation is significant, providing 4.5 (2.3–7) GtCO₂ yr⁻¹ globally by 2050, of which 3.4 (2.3–6.4) GtCO₂ yr⁻¹ is available at below USD100 tCO₂⁻¹ (*medium confidence*) (Figure 7.11). Over the last decade, hundreds of subnational initiatives that aim to reduce deforestation related emissions have been implemented across the tropics (Section 7.6). Reduced deforestation is a significant piece of the NDCs in the Paris Agreement (Seddon et al. 2020) and keeping the temperature below 1.5°C (Crusius 2020). Conservation of forests

provides multiple co-benefits linked to ecosystem services, biodiversity and sustainable development (Section 7.6.). Still, ensuring good governance, accountability (e.g., enhanced monitoring and verification capacity; Bos 2020), and the rule of law are crucial for implementing forest-based mitigation options. In many countries with the highest deforestation rates, insecure land rights often are significant barriers for forest-based mitigation options (Gren and Zeleke 2016; Essl et al. 2018).

7.4.2.2 Afforestation, Reforestation and Forest Ecosystem Restoration

Activities, co-benefits, risks and implementation opportunities and barriers. Afforestation and reforestation (A/R) are activities that convert land to forest, where reforestation is on land that has previously contained forests, while afforestation is on land that historically has not been forested (Box 7.2). Forest restoration refers to a form of reforestation that gives more priority to ecological integrity as well, even though it can still be a managed forest. Depending on the location, scale, and choice and management of tree species, A/R activities have a wide variety of co-benefits and trade-offs. Well-planned, sustainable reforestation and forest restoration can enhance climate resilience and biodiversity, and provide a variety of ecosystem services including water regulation, microclimatic regulation, soil erosion protection, as well as renewable resources, income and livelihoods (Locatelli et al. 2015; Stanturf et al. 2015; Ellison et al. 2017; Verkerk et al. 2020). Afforestation, when well planned, can help address land degradation and desertification by reducing runoff and erosion and lead to cloud formation however, when not well planned, there are localised trade-offs such as reduced water yield or biodiversity (Teuling et al. 2017; Ellison et al. 2017). The use of non-native species and monocultures may have adverse impacts on ecosystem structure and function, and water availability, particularly in dry regions (Ellison et al. 2017). A/R activities may change the surface albedo and evapotranspiration regimes, producing net cooling in the tropical and subtropical latitudes for local and global climate and net warming at high latitudes (Section 7.4.2). Very large-scale implementation of A/R may negatively affect food security since an increase in global forest area can increase food prices through land competition (Kreidenweis et al. 2016).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The AR5 did not provide a new specification of A/R potential, but referred to IPCC AR4 mostly for forestry measures (Nabuurs et al. 2007). The AR5 did view the feasible A/R potential from a diets change scenario that released land for reforestation and bioenergy crops. The AR5 provided top-down estimates of costs and potentials for forestry mitigation options – including reduced deforestation, forest management, afforestation, and agroforestry, estimated to contribute between 1.27 and 4.23 GtCO₂ yr⁻¹ of economically viable abatement in 2030 at carbon prices up to USD100 tCO₂-eq⁻¹ (Smith et al. 2014).

The SRCCL remained with a reported wide range of mitigation potential for A/R of 0.5–10.1 GtCO₂ yr⁻¹ by 2050 (*medium confidence*) (Kreidenweis et al. 2016; Griscom et al. 2017; Hawken 2017; Fuss et al. 2018; Roe et al. 2019) (SRCCL Chapters 2 and 6). The higher estimate represents a technical potential of reforesting all areas where forests are the native cover type (reforestation), constrained by food security and biodiversity considerations, considering above and below-ground

carbon pools and implementation on a rather theoretical maximum of 678 Mha of land (Griscom et al. 2017; Roe et al. 2019). The lower estimates represent the minimum range from an Earth System Model and a sustainable global CDR potential (Fuss et al. 2018). Climate change will affect the mitigation potential of reforestation due to impacts in forest growth and composition, as well as changes in disturbances including fire. However, none of the mitigation estimates included in the SRCCL account for climate impacts.

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Since SRCCL, additional studies have been published on A/R mitigation potential by Bastin et al. (2019), Lewis et al. (2019), Doelman et al. (2019), Favero et al. (2020) and Austin et al. (2020). These studies are within the range reported in the SRCCL stretching the potentials at the higher range. The rising public interest in nature-based solutions, along with high profile initiatives being launched (UN Decade on Restoration announced in 2019, the Bonn challenge on 150 million ha of restored forest in 2020 and the one trillion trees campaign launched by the World Economic Forum in 2020), has prompted intense discussions on the scale, effectiveness, and pitfalls of A/R and tree planting for climate mitigation (Luyssaert et al. 2018; Bond et al. 2019; Anderegg et al. 2020; Heilmayr et al. 2020; Holl and Brancalion 2020). The sometimes sole attention on afforestation and reforestation – suggesting it may solve the climate problem to large extent, in combination with the very high estimates of potentials – have led to polarisation in the debate, resulting in criticism to these measures or an emphasis on nature restoration only (Lewis et al. 2019). Our assessment based on most recent literature produced regional economic mitigation potential at USD100 tCO₂⁻¹ estimate of 100–400 MtCO₂ yr⁻¹ in Africa, 210–266 MtCO₂ yr⁻¹ in Asia and Pacific, 291 MtCO₂-eq yr⁻¹ in Developed Countries (87% in North America), 30 MtCO₂-eq yr⁻¹ in Eastern Europe and West-Central Asia, and 345–898 MtCO₂-eq yr⁻¹ in Latin America and Caribbean (Roe et al. 2021), which totals to about 1200 MtCO₂ yr⁻¹, leaning to the lower range of the potentials in earlier IPCC reports. A recent global assessment of the aggregate costs for afforestation and reforestation suggests that at USD100 tCO₂⁻¹, 1.6 GtCO₂ yr⁻¹ could be sequestered globally for an annual cost of USD130 billion (Austin et al. 2020). Sectoral studies that are able to deal with local circumstances and limits estimate A/R potentials at 20 MtCO₂ yr⁻¹ in Russia (Eastern Europe and West-Central Asia) (Romanovskaya et al. 2020) and 64 MtCO₂ yr⁻¹ in Europe (Nabuurs et al. 2017). (Domke et al. 2020) estimated for the USA an additional 20% sequestration rate from tree planting to achieve full stocking capacity of all understocked productive forestland, in total reaching 187 MtCO₂ yr⁻¹ sequestration. A new study on costs in the USA estimates 72–91 MtCO₂ yr⁻¹ could be sequestered between now and 2050 for USD100 tCO₂⁻¹ (Wade et al. 2019). The tropical and subtropical latitudes are the most effective for forest restoration in terms of carbon sequestration because of the rapid growth and lower albedo of the land surface compared with high latitudes (Lewis et al. 2019). Costs may be higher if albedo is considered in North America, Russia, and Africa (Favero et al. 2017). In addition, a wide variety of sequestration rates have been collected and published in the IPCC Good Practice Guidance for the AFOLU sector (IPCC 2006).

Critical assessment and conclusion. There is *medium confidence* that the global technical mitigation potential

of afforestation and reforestation activities by 2050 is 3.9 (0.5–10.1) GtCO₂ yr⁻¹, and the economic mitigation potential (<USD100 tCO₂⁻¹) is 1.6 (0.5–3.0) GtCO₂ yr⁻¹ (requiring about 200 Mha). Per hectare a long (about 100 year) sustained effect of 5–10 t CO₂ ha⁻¹ yr⁻¹ is realistic with ranges between 1–20 t(CO₂) ha⁻¹ yr⁻¹. Not all sectoral studies rely on economic models that account for leakage (Murray et al. 2004; Sohngen and Brown 2004), suggesting that technical potential may be overestimated.

7.4.2.3 Improved Forest Management

Activities, co-benefits, risks and implementation opportunities and barriers. Improved sustainable forest management of already managed forests can lead to higher forest carbon stocks, better quality of produced wood, continuously produced wood, while maintaining and enhancing the forest carbon stock, and can also partially prevent and counteract the impacts of disturbances (Kurz et al. 2008; Marlon et al. 2012; Abatzoglou and Williams 2016; Seidl et al. 2017; Nabuurs et al. 2017; Tian et al. 2018; Ekholm 2020). Furthermore, it can provide benefits for climate change adaptation, biodiversity conservation, microclimatic regulation, soil erosion protection and water and flood regulation with reduced lateral carbon fluxes (Ashton et al. 2012; Martinez-Mena et al. 2019; Verkerk et al. 2020). Often, in existing (managed) forests with existing carbon stocks, large changes per hectare cannot be expected, although many forest owners may respond to carbon price incentives (Favero et al. 2020; Ekholm 2020). The full mitigation effects can be assessed in conjunction with the overall forest and wood use system i.e., carbon stock changes in standing trees, soil, harvested wood products (HWPs) and its bioenergy component with the avoided emissions through substitution. Forest management strategies aimed at increasing the biomass stock may have adverse side effects, such as decreasing the stand-level structural complexity, large emphasis on pure fast-growing stands, risks for biodiversity and resilience to natural disasters.

Generally, measures can consist of one or combination of longer rotations, less intensive harvests, continuous-cover forestry, mixed stands, more adapted species, selected provenances, high quality wood assortments, and so on. Further, there is a trade-off between management in various parts of the forest product value chain, resulting in a wide range of results on the role of managed forests in mitigation (Agostini et al. 2013; Braun et al. 2016; Soimakallio et al. 2016; Gustavsson et al. 2017; Erb et al. 2017; Favero et al. 2020; Hurmekoski et al. 2020). Some studies conclude that reduction in forest carbon stocks due to harvest exceeds for decades the joint sequestration of carbon in harvested wood product stocks and emissions avoided through wood use (Soimakallio et al. 2016; Seppälä et al. 2019), whereas others emphasise country level examples where investments in forest management have led to higher growing stocks while producing more wood (Schulze et al. 2020; Ouden et al. 2020; Cowie et al. 2021).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. In the SRCCL, forest management activities have the potential to mitigate 0.4–2.1 GtCO₂-eq yr⁻¹ by 2050 (*medium confidence*) (SRCCL: Griscom et al. 2017; Roe et al. 2019). The higher estimate stems from

assumptions of applications on roughly 1.9 billion ha of already managed forest which can be seen as very optimistic. It combines both natural forest management as well as improved plantations, on average with a small net additional effect per hectare, not including substitution effects in the energy sector nor the buildings sector.

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). The area of forest under management plans has increased in all regions since 2000 by 233 Mha (FAO 2020e). The roughly 1 billion ha of secondary and degraded forests would be ideal to invest in and develop a sustainable sector that pays attention to biodiversity, wood provision and climate mitigation at the same time. This all depends on the effort made, the development of expertise, know-how in the field, nurseries with adapted provenances, etc as was also found for Russian climate-smart forestry options (Leskinen et al. 2020). Regionally, recently updated economic mitigation potential at USD100 tCO₂⁻¹ have 179–186 MtCO₂-eq yr⁻¹ in Africa, 193–313 MtCO₂-eq yr⁻¹ in Asia and Pacific, 215–220 MtCO₂-eq yr⁻¹ in Developed Countries, 82–152 MtCO₂-eq yr⁻¹ in Eastern Europe and West-Central Asia, and 62–204 MtCO₂-eq yr⁻¹ in Latin America and Caribbean (Roe et al. 2021).

Regional studies can take into account the local situation better: Russia Romanovskaya et al. (2020) estimate the potential of forest fires management at 220–420 MtCO₂ yr⁻¹, gentle logging technology at 15–59, reduction of wood losses at 61–76 MtCO₂ yr⁻¹. In North America, (Austin et al. 2020) estimate that in the next 30 years, forest management could contribute 154 MtCO₂ yr⁻¹ in the USA and Canada with 81 MtCO₂ yr⁻¹ available at less than USD100 tCO₂⁻¹. In one production region (British Columbia) a cost-effective portfolio of scenarios was simulated that directed more of the harvested wood to longer-lived wood products, stopped burning of harvest residues and instead produced bioenergy to displace fossil fuel burning, and reduced harvest levels in regions with low disturbance rates. Net GHG emissions were reduced by an average of –9 MtCO₂-eq yr⁻¹

(Smyth et al. 2020). In Europe, climate-smart forestry could mitigate an additional 0.19 GtCO₂ yr⁻¹ by 2050 (Nabuurs et al. 2017), in line with the regional estimates in (Roe et al. 2021).

In the tropics, estimates of the pantropical climate mitigation potential of natural forest management (a light intensity management in secondary forests), across three tropical regions (Latin America, Africa, Asia), is around 0.66 GtCO₂-eq yr⁻¹ with Asia responding for the largest share followed by Africa and Latin America (Roe et al. 2021). Selective logging occurs in at least 20% of the world's tropical forests and causes at least half of the emissions from tropical forest degradation (Asner et al. 2005; Blaser and Kuehli 2011; Pearson et al. 2017). Reduced-impact logging for climate (RIL-C; promotion of reduced wood waste, narrower haul roads, and lower impact skidding equipment) has the potential to reduce logging emissions by 44% (Ellis et al. 2019), while also providing timber production.

Critical assessment and conclusion. There is *medium confidence* that the global technical mitigation potential for improved forest management by 2050 is 1.7 (1–2.1) GtCO₂ yr⁻¹, and the economic mitigation potential (<USD100 tCO₂⁻¹) is 1.1 (0.6–1.9) GtCO₂ yr⁻¹. Efforts to change forest management do not only require, for example, a carbon price incentive, but especially require knowledge, institutions, skilled labour, good access and so on. These requirements outline that although the potential is of medium size, we estimate a feasible potential towards the lower end. The net effect is also difficult to assess, as management changes impact not only the forest biomass, but also the wood chain and substitution effects. Further, leakage can arise from efforts to change management for carbon sequestration. Efforts, for example to set aside large areas of forest, may be partly counteracted by higher harvesting pressures elsewhere (Kallio et al. 2018). Studies such as (Austin et al. 2020) implicitly account for leakage and thus suggest higher costs than other studies. We therefore judge the mitigation potential at medium potential with medium agreement.

Box 7.2 | Climate-smart Forestry in Europe

Summary

European forests have been regarded as prospering and increasing for the last five decades. However, these views also changed recently. Climate change is putting a large pressure on mono species and high stocked areas of Norway spruce in Central Europe (Hlásny et al. 2021; Senf and Seidl 2021) with estimates of mortality reaching 200 million m³, biodiversity under pressure, the Mediterranean area showing a weak sector and harvesting pressure in the Baltics and north reaching maxima achievable. A European strategy for unlocking the EU's forests and forest sector potential was needed at the time of developing the LULUCF regulation and was based on the concept of 'climate-smart forestry' (CSF) (Nabuurs et al. 2017; Verkerk et al. 2020).

Background

The idea behind CSF is that it considers the whole value chain from forest to wood products and energy, illustrating that a wide range of measures can be applied to provide positive incentives for more firmly integrating climate objectives into the forest and forest sector framework. CSF is more than just storing carbon in forest ecosystems; it builds upon three main objectives; (i) reducing and/or removing GHG emissions; (ii) adapting and building diverse forests for forest resilience to climate change; and (iii) sustainably increasing forest productivity and incomes. These three CSF objectives can be achieved by tailoring policy measures and actions to regional circumstances in member states' forest sectors.

*Box 7.2 (continued)***Case description**

The 2015 annual mitigation effect of EU-28 forests via contributions to the forest sink, material substitution and energy substitution is estimated at 569 MtCO₂ yr⁻¹, or 13% of total current EU emissions. With the right set of incentives in place at EU and member states levels, it was found that the EU-28 has the potential to achieve an additional combined mitigation impact through the implementation of CSF of 441 MtCO₂ yr⁻¹ by 2050. Also, with the Green Deal and its biodiversity and forest strategy, more emphasis will be placed on forests, forest management and the provision of renewables. It is the diversity of measures (from strict reserves to more intensively managed systems while adapting the resource) that will determine the success. Only with co-benefits in, for example, nature conservation, soil protection, and provision of renewables, wood for buildings and income, the mitigation and adaptation measures will be successful.

Interactions, limitations and lessons

Climate-smart forestry is now taking shape across Europe with various research and implementation projects (Climate Smart Forest and Nature Management, 2021). Pilots and projects are being implemented by a variety of forest owners, some with more attention on biodiversity and adaptation, some with more attention on production functions. They establish examples and in longer term the outreach to the 16 million private owners in Europe. However, the right triggers and incentives are often still lacking. For example, adapting the spruce forest areas in Central Europe to climate change requires knowledge about different species, biodiversity and different management options and eventually use in industry. It requires alternative species to be available from the nurseries, as well as improved monitoring to assess the success and steer activities.

7.4.2.4 Fire Management (Forest and Grassland/ Savanna Fires)

Activities, co-benefits, risks and implementation opportunities and barriers. Fire management objectives include safeguarding life, property, and resources through the prevention, detection, control, restriction, and management of fire for diverse purposes in natural ecosystems (SRCCL, Chapter 6). Controlled burning is an effective economic method of reducing fire danger and stimulating natural regeneration. Co-benefits of fire management include reduced air pollution compared to much larger, uncontrolled fires, prevention of soil erosion and land degradation, biodiversity conservation in rangelands, and improvement of forage quality (Hurteau and Brooks 2011; Falk 2017; Hurteau et al. 2019). Fire management is still challenging because it is not only fire suppression at times of fire, but especially proper natural resource management in between fire events. Furthermore, it is challenging because of legal and policy issues, equity and rights concerns, governance, capacity, and research needs (Wiedinmyer and Hurteau 2010; Goldammer 2016; Russell-Smith et al. 2017). It will increasingly be needed under future enhanced climate change.

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. In the SRCCL, fire management is among the nine options that can deliver medium-to-large benefits across multiple land challenges (climate change mitigation, adaptation, desertification, land degradation, and food security) (*high confidence*). Total emissions from fires have been on the order of 8.1 GtCO₂-eq yr⁻¹ in terms of gross biomass loss for the period 1997–2016 (SRCCL, Chapter 2, and Cross-Chapter Box 3 in Chapter 2). Reduction in fire CO₂ emissions was calculated to enhance land carbon sink by 0.48 GtCO₂-eq yr⁻¹ for the 1960–2009 period (Arora and Melton 2018) (SRCCL, Table 6.16).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL)

Savannas. Savannas constitute one of the most fire-prone vegetation types on Earth and are a significant source of GHG emissions. Savanna fires contributed 62% (4.92 PgCO₂-eq yr⁻¹) of gross global mean fire emissions between 1997 and 2016. Regrowth from vegetation postfire sequesters the CO₂ released into the atmosphere, but not the CH₄ and N₂O emissions which contributed an approximate net of 2.1 PgCO₂-eq yr⁻¹ (Lipsett-Moore et al. 2018). Therefore, implementing prescribed burning with low intensity fires, principally in the early dry season, to effectively manage the risk of wildfires occurring in the late dry season is associated with reducing emissions (Whitehead et al. 2014). Considering this fire management practice, estimates of global opportunities for emissions reductions were estimated at 69.1 MtCO₂-eq yr⁻¹ in Africa (29 countries, with 20 least developed African countries accounting for 74% of the mitigation potential), 13.3 MtCO₂-eq yr⁻¹ in South America (six countries), and 6.9 MtCO₂-eq yr⁻¹ in Australia and Papua New Guinea (Lipsett-Moore et al. 2018). In Australia, savanna burning emissions abatement methodologies have been available since 2012, and abatement has exceeded 9.3 MtCO₂-eq mainly through the management of low intensity early dry season fire. Until September 2021, 78 projects were registered (Australian Government, Clean Energy Regulator, 2021).

Forests. Fire is also a prevalent forest disturbance (Falk et al. 2011; Scott et al. 2014; Andela et al. 2019). About 98 Mha of forest were affected by fire in 2015, affecting about 4% of the tropical (dry) forests, 2% of the subtropical forests, and 1% of temperate and boreal forests (FAO 2020a). Between 2001–2018, remote sensing data showed that tree-covered areas correspond to about 29% of the total area burned by wildfires, most in Africa. Prescribed fires are also applied routinely in forests worldwide for fuel reduction and

ecological reasons (Kalies and Yocom Kent 2016). Fire resilience is increasingly managed in Southwestern USA forest landscapes, which have experienced droughts and widespread, high-severity wildfires (Keeley et al. 2019). In these forests, fire exclusion management, coupled with a warming climate, has led to increasingly severe wildfires (Hurteau et al. 2014). However, the impacts of prescribed fires in forests in reducing carbon emissions are still inconclusive. Some positive impacts of prescribed fires are associated with other fuel reduction techniques (Loudermilk et al. 2017; Flanagan et al. 2019; Stephens et al. 2020), leading to maintaining carbon stocks and reducing carbon emissions in the future where extreme fire weather events are more frequent (Krofcheck et al. 2018, 2019; Hurteau et al. 2019; Bowman et al. 2020a,b; Goodwin et al. 2020). Land management approaches will certainly need to consider the new climatic conditions (e.g., the proportion of days in fire seasons with the potential for unmanageable fires more than doubling in some regions in northern and eastern boreal forest) (Wotton et al. 2017).

Critical assessment and conclusion. There is *low confidence* that the global technical mitigation potential for grassland and savanna fire management by 2050 is 0.1 (0.09–0.1) GtCO₂ yr⁻¹, and the economic mitigation potential (<USD100 tCO₂⁻¹) is 0.05 (0.03–0.07) GtCO₂ yr⁻¹. Savanna fires produce significant emissions globally, but prescribed fires in the early dry season could mitigate emissions in different regions, particularly Africa. Evidence is less clear for fire management of forests, with the contribution of GHG mitigation depending on many factors that affect the carbon balance (e.g., Simmonds et al. 2021). Although prescribed burning is promoted to reduce uncontrolled wildfires in forests, the benefits for the management of carbon stocks are unclear, with different studies reporting varying results especially concerning its long-term effectiveness (Wotton et al. 2017; Bowman et al. 2020b). Under increasing climate change however, an increased attention on fire management will be necessary.

7.4.2.5 Reduce Degradation and Conversion of Grasslands and Savannas

Activities, co-benefits, risks and implementation opportunities and barriers. Grasslands cover approximately 40.5% of the terrestrial area (i.e., 52.5 million km²) divided as 13.8% woody savanna and savanna; 12.7% open and closed shrub; 8.3% non-woody grassland; and 5.7% is tundra (White et al. 2000). Sub-Saharan Africa and Asia have the most extensive total area, 14.5 and 8.9 million km², respectively. A review by Conant et al. (2017) reported based on data on grassland area (FAO 2013) and grassland soil carbon stocks (Sombroek et al. 1993) a global estimate of about 343 PgC (in the top 1 m), nearly 50% more than is stored in forests worldwide (FAO 2007). Reducing the conversion of grasslands and savannas to croplands prevents soil carbon losses by oxidation, and to a smaller extent, biomass carbon loss due to vegetation clearing (SRCCL, Chapter 6). Restoration of grasslands through enhanced soil carbon sequestration, including (i) management of vegetation, (ii) animal management, and (iii) fire management, was also included in the SRCCL and is covered in Section 7.4.3.1. Similar to other measures that reduce conversion, conserving carbon stocks in grasslands and savannas can be achieved by controlling conversion

drivers (e.g., commercial and subsistence agriculture, see Section 7.3) and improving policies and management. In addition to mitigation, conserving grasslands provide various socio-economic, biodiversity, water cycle and other environmental benefits (Claassen et al. 2010; Ryals et al. 2015; Bengtsson et al. 2019). Annual operating costs, and opportunity costs of income foregone by undertaking the activities needed for avoiding conversion of grasslands making costs one of the key barriers for implementation (Lipper et al. 2010).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The SRCCL reported a mitigation potential for reduced conversion of grasslands and savannas of 0.03–0.12 GtCO₂-eq yr⁻¹ (Griscom et al. 2017; IPCC 2019) considering the higher loss of soil organic carbon in croplands (Sanderman et al. 2017). Assuming an average starting soil organic carbon stock of temperate grasslands (Poeplau et al. 2011), and the mean annual global cropland conversion rates (1961–2003) (Krause et al. 2017), the equivalent loss of soil organic carbon over 20 years would be 14 GtCO₂-eq, for example, 0.7 GtCO₂ yr⁻¹ (SRCCL, Chapter 6). IPCC AR5 and AR4 did not explicitly consider the mitigation potential of avoided conversion of grasslands-savannas but the management of grazing land is accounted for considering plant, animal, and fire management with a mean mitigation potential of 0.11–0.80 tCO₂-eq ha⁻¹ yr⁻¹ depending on the climate region. This resulted in 0.25 GtCO₂-eq yr⁻¹ at USD20 tCO₂⁻¹ to 1.25 GtCO₂-eq yr⁻¹ at USD100 tCO₂⁻¹ by 2030.

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Unlike most of the measures covered in Section 7.4, there are currently no global, spatially explicit mitigation potential estimates for reduced grassland conversion to generate technical and economic potentials by region. Literature developments since AR5 and SRCCL are studies that provide mitigation estimates in one or a few countries or regions. Modelling experiments comparing Californian forests and grasslands found that grasslands resulted in a more resilient carbon sink than forests to future climate change (Dass et al. 2018). However, previous studies indicated that precipitation is a key controller of the carbon storage in these grasslands, with the grassland became a carbon sink in 2005, when the region received relatively high spring precipitation (Ma et al. 2007). In North America, grassland conversion was the source for 77% of all new croplands from 2008–2012 (Lark et al. 2015). Avoided conversion of North American grasslands to croplands presents an economic mitigation potential of 0.024 GtCO₂-eq yr⁻¹ and technical potential of 0.107 GtCO₂-eq yr⁻¹ (Fargione et al. 2018). This potential is related mainly to root biomass and soils (81% of emissions from soils). Estimates of GHG emissions from any future deforestation in Australian savannas also point to the potential mitigation of around 0.024 GtCO₂-eq yr⁻¹ (Bristow et al. 2016). The expansion of the Soy Moratorium (SoyM) from the Brazilian Amazon to the Cerrado (Brazilian savannas) would prevent the direct conversion of 3.6 Mha of native vegetation to soybeans by 2050 and avoid the emission of 0.02 GtCO₂-eq yr⁻¹ (Soterroni et al. 2019).

Critical assessment and conclusion. There is *low confidence* that the global technical mitigation potential for reduced grassland and savanna conversion by 2050 is 0.2 (0.1–0.4) GtCO₂ yr⁻¹, and the

economic mitigation potential ($< \text{USD}100 \text{ tCO}_2\text{-eq yr}^{-1}$) is $0.04 \text{ GtCO}_2 \text{ yr}^{-1}$. Most of the carbon sequestration potential is in below-ground biomass and soil organic matter. However, estimates of potential are still based on few studies and vary according to the levels of soil carbon, and ecosystem productivity (e.g., in response to rainfall distribution). Conservation of grasslands presents significant benefits for desertification control, especially in arid areas (SRCL, Chapter 3). Policies supporting avoided conversion can help protect at-risk grasslands, reduce GHG emissions, and produce positive outcomes for biodiversity and landowners (Ahlering et al. 2016). In comparison to tropical rainforest regions that have been the primary target for mitigation policies associated to natural ecosystems (e.g., REDD+), conversion grasslands and savannas has received less national and international attention, despite growing evidence of concentrated cropland expansion into these areas with impacts of carbon losses.

7.4.2.6 Reduce Degradation and Conversion of Peatlands Activities, Co-benefits, Risks and Implementation Barriers

Peatlands are carbon-rich wetland ecosystems with organic soil horizons in which soil organic matter concentration exceeds 30% (dry weight) and soil carbon concentrations can exceed 50% (Page and Baird 2016, Boone Kauffman et al. 2017). Reducing the conversion of peatlands avoids emissions of above- and below-ground biomass and soil carbon due to vegetation clearing, fires, and peat decomposition from drainage. Similar to deforestation, peatland carbon stocks can be conserved by controlling the drivers of conversion and degradation (e.g., commercial and subsistence agriculture, mining, urban expansion) and improving governance and management. Reducing conversion is urgent because peatland carbon stocks accumulate slowly and persist over millennia; loss of existing stocks cannot be easily reversed over the decadal time scales needed to meet the Paris Agreement (Goldstein et al. 2020). The main co-benefits of reducing conversion of peatlands include conservation of a unique biodiversity including many critically endangered species, provision of water quality and regulation, and improved public health through decreased fire-caused pollutants (Griscom et al. 2017). Although reducing peatland conversion will reduce land availability for alternative uses including agriculture or other land-based mitigation, drained peatlands constitute a small share of agricultural land globally while contributing significant emissions (Joosten 2009). Mitigation through reduced conversion of peatlands therefore has a high potential of avoided emissions per hectare (Roe et al. 2019).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCL); mitigation potential, costs, and pathways. In the SRCL (Chapters 2 and 6), it was estimated that avoided peat impacts could deliver $0.45\text{--}1.22 \text{ GtCO}_2\text{-eq yr}^{-1}$ technical potential by 2030–2050 (*medium confidence*) (Hooijer et al. 2010; Griscom et al. 2017; Hawken 2017). The mitigation potential estimates cover tropical peatlands and include CO_2 , N_2O and CH_4 emissions. The mitigation potential is derived from quantification of losses of carbon stocks due to land conversion, shifts in GHG fluxes, alterations in net ecosystem productivity, input factors such as fertilisation needs, and biophysical climate impacts (e.g., shifts in albedo, water cycles, etc.). Tropical peatlands account for only about 10% of peatland area

and about 20% of peatland carbon stock but about 80% of peatland carbon emissions, primarily from peatland conversion in Indonesia (about 60%) and Malaysia (about 10%) (Hooijer et al. 2010; Page et al. 2011; Leifeld and Menichetti 2018). While the total mitigation potential of peatland conservation is considered moderate, the per hectare mitigation potential is the highest among land-based mitigation measures (Roe et al. 2019).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCL). Recent studies continue to report high carbon stocks in peatlands and emphasise the vulnerability of peatland carbon after conversion. The carbon stocks of tropical peatlands are among the highest of any forest, $1,211\text{--}4,257 \text{ tCO}_2\text{-eq ha}^{-1}$ in the Peruvian Amazon (Bhomia et al. 2019) and $1,956\text{--}14,757 \text{ tCO}_2\text{-eq ha}^{-1}$ in Indonesia (Novita et al. 2021). Ninety percent of tropical peatland carbon stocks are vulnerable to emission during conversion and may not be recoverable through restoration; in contrast, boreal and temperate peatlands hold similar carbon stocks ($1,439\text{--}5,619 \text{ tCO}_2\text{-eq ha}^{-1}$) but only 30% of northern carbon stocks are vulnerable to emission during conversion and irrecoverable through restoration (Goldstein et al. 2020). A recent study shows global mitigation potential of about $0.2 \text{ GtCO}_2\text{-eq yr}^{-1}$ at costs up to $\text{USD}100 \text{ tCO}_2\text{-eq yr}^{-1}$ (Roe et al. 2021). Another study estimated that 72% of mitigation is achieved through avoided soil carbon impacts, with the remainder through avoided impacts to vegetation (Bossio et al. 2020). Recent model projections show that both peatland protection and peatland restoration (Section 7.4.2.7) are needed to achieve a 2°C mitigation pathway and that peatland protection and restoration policies will have minimal impacts on regional food security (Leifeld et al. 2019, Humpenöder et al. 2020). Global studies have not accounted for extensive peatlands recently reported in the Congo Basin, estimated to cover $145,500 \text{ km}^2$ and contain 30.6 PgC , as much as 29% of total tropical peat carbon stock (Dargie et al. 2017). These Congo peatlands are relatively intact; continued preservation is needed to prevent major emissions (Dargie et al. 2019). In northern peatlands that are underlain by permafrost roughly 50% of the total peatlands north of 23° latitude, (Hugelius et al. 2020), climate change (i.e., warming) is the major driver of peatland degradation (e.g., through permafrost thaw) (Schoor et al. 2015, Goldstein et al. 2020). However, in non-permafrost boreal and temperate peatlands, reduction of peatland conversion is also a cost-effective mitigation strategy. Peatlands are sensitive to climate change and there is *low confidence* about the future peatland sink globally (SRCL, Chapter 2). Permafrost thaw may shift northern peatlands from a net carbon sink to net source (Hugelius et al. 2020). Uncertainties in peatland extent and the magnitude of existing carbon stocks, in both northern (Loisel et al. 2014) and tropical (Dargie et al. 2017) latitudes limit understanding of current and future peatland carbon dynamics (Minasny et al. 2019).

Critical assessment and conclusion. Based on studies to date, there is *medium confidence* that peatland conservation has a technical potential of $0.86 (0.43\text{--}2.02) \text{ GtCO}_2\text{-eq yr}^{-1}$ of which $0.48 (0.2\text{--}0.68) \text{ GtCO}_2\text{-eq yr}^{-1}$ is available at $\text{USD}100 \text{ tCO}_2\text{-eq yr}^{-1}$ (Figure 7.11). High per hectare mitigation potential and high rate of co-benefits particularly in tropical countries, support the effectiveness

of this mitigation strategy (Roe et al. 2019). Feasibility of reducing peatland conversion may depend on countries' governance, financial capacity and political will.

7.4.2.7 Peatland Restoration

Activities, co-benefits, risks and implementation barriers. Peatland restoration involves restoring degraded and damaged peatlands, for example through rewetting and revegetation, which both increases carbon accumulation in vegetation and soils and avoids ongoing CO₂ emissions. Peatlands only account for about 3% of the terrestrial surface, predominantly occurring in boreal ecosystems (78%), with a smaller proportion in tropical regions (13%), but may store about 600 GtC or 21% of the global total soil organic carbon stock of about 3000 Gt (Page et al. 2011; Leifeld and Menichetti 2018). Peatland restoration delivers co-benefits for biodiversity, as well as regulating water flow and preventing downstream flooding, while still allowing for extensive management such as paludiculture (Tan et al. 2021). Rewetting of peatlands also reduces the risk of fire, but may also mobilise salts and contaminants in soils (van Diggelen et al. 2020) and in severely degraded peatlands, restoration of peatland hydrology and vegetation may not be feasible (Andersen et al. 2017). At a local level, restoration of peatlands drained for agriculture could displace food production and damage local food supply, although impacts to regional and global food security would be minimal (Humpenöder et al. 2020). Collaborative and transparent planning processes are needed to reduce conflict between competing land uses (Tanneberger et al. 2020b). Adequate resources for implementing restoration policies are key to engage local communities and maintain livelihoods (Resosudarmo et al. 2019; Ward et al. 2021).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. Large areas (0.51 Mkm²) of global peatlands are degraded of which 0.2 Mkm² are tropical peatlands (Griscom et al. 2017; Leifeld and Menichetti 2018). According to the SRCCL, peatland restoration could deliver technical mitigation potentials of 0.15 – 0.81 GtCO₂-eq yr⁻¹ by 2030–2050 (*low confidence*) (Couwenberg et al. 2010; Griscom et al. 2017) (Chapters 2 and 6 of the SRCCL), though there could be an increase in methane emissions after restoration (Jauhiainen et al. 2008). The mitigation potential estimates cover global peatlands and include CO₂, N₂O and CH₄ emissions. Peatlands are highly sensitive to climate change (*high confidence*), however there are currently no studies that estimate future climate effects on mitigation potential from peatland restoration.

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). The most recent literature and reviews indicate with *high confidence* that restoration would decrease CO₂ emissions and with *medium confidence* that restoration would decrease net GHG emissions from degraded peatlands (Wilson et al. 2016; Ojanen and Minkinen 2020; van Diggelen et al. 2020). Although rewetting of drained peatlands increases CH₄ emissions, this effect is often outweighed by decreases in CO₂ and N₂O emissions but depends very much on local circumstances (Günther et al. 2020). Restoration and rewetting of almost all drained peatlands is needed by 2050 to

meet 1.5°C–2°C pathways which is unlikely to happen (Leifeld et al. 2019); immediate rewetting and restoration minimises the warming from cumulative CO₂ emissions (Nugent et al. 2019).

According to recent data, the technical mitigation potential for global peatland restoration is estimated at 0.5–1.3 GtCO₂-eq yr⁻¹ (Leifeld and Menichetti 2018; Griscom et al. 2020; Bossio et al. 2020; Roe et al. 2021) (Figure 7.11), with 80% of the mitigation potential derived from improvements to soil carbon (Bossio et al. 2020). The regional mitigation potentials of all peatlands outlined in Roe et al. (2021) reflect the country-level estimates from (Humpenöder et al. 2020).

Climate mitigation effects of peatland rewetting depend on the climate zone and land use. Recent analysis shows the strongest mitigation gains from rewetting drained temperate and boreal peatlands used for agriculture and drained tropical peatlands (Ojanen and Minkinen 2020). However, estimates of emission factors from rewetting drained tropical peatlands remain uncertain (Wilson et al. 2016; Murdiyarso et al. 2019). Topsoil removal, in combination with rewetting, may improve restoration success and limit CH₄ emissions during restoration of highly degraded temperate peatlands (Zak et al. 2018). In temperate and boreal regions, co-benefits mentioned above are major motivations for peatland restoration (Chimner et al. 2017; Tanneberger et al. 2020a).

Critical assessment and conclusion. Based on studies to date, there is *medium confidence* that peatland restoration has a technical potential of 0.79 (0.49–1.3) GtCO₂-eq yr⁻¹ (median) of which 0.4 (0.2–0.6) GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂⁻¹. The large land area of degraded peatlands suggests that significant emissions reductions could occur through large-scale restoration especially in tropical peatlands. There is *medium confidence* in the large carbon stocks of tropical peat forests (1956–14,757 tCO₂-eq ha⁻¹) and large rates of carbon loss associated with land cover change (640–1650 tCO₂-eq ha⁻¹) (Goldstein et al. 2020; Novita et al. 2021). However, large-scale implementation of tropical peatland restoration will likely be limited by costs and other demands for these tropical lands.

7.4.2.8 Reduce Conversion of Coastal Wetlands

Activities, co-benefits, risks and implementation barriers. Reducing conversion of coastal wetlands, including mangroves, marshes and seagrass ecosystems, avoids emissions from above and below ground biomass and soil carbon through avoided degradation and/or loss. Coastal wetlands occur mainly in estuaries and deltas, areas that are often densely settled, with livelihoods closely linked to coastal ecosystems and resources (Moser et al. 2012). The carbon stocks of these highly productive ecosystems are sometimes referred to as 'blue carbon'. Loss of existing stocks cannot be easily reversed over decadal time scales (Goldstein et al. 2020). The main drivers of conversion include intensive aquaculture, agriculture, salt ponds, urbanisation and infrastructure development, the extensive use of fertilisers, and extraction of water resources (Lovelock et al. 2018). Reduced conversion of coastal wetlands has many co-benefits, including biodiversity conservation, fisheries production, soil stabilisation, water flow and water quality regulation, flooding

and storm surge prevention, and increased resilience to cyclones (Windham-Myers et al. 2018a; UNEP 2020). Risks associated with the mitigation potential of coastal wetland conservation include uncertain permanence under future climate scenarios, including the effects of coastal squeeze, where coastal wetland area may be lost if upland area is not available for migration as sea levels rise (Lovelock and Reef 2020) (AR6 WGII, Section 3.4.2.5). Preservation of coastal wetlands also conflicts with other land use in the coastal zone, including aquaculture, agriculture, and human development; economic incentives are needed to prioritise wetland preservation over more profitable short-term land use. Integration of policies and efforts aimed at coastal climate mitigation, adaptation, biodiversity conservation, and fisheries, for example through integrated coastal zone management and marine spatial planning, will bundle climate mitigation with co-benefits and optimise outcomes (Herr et al. 2017).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. Coastal wetlands contain high, yet variable, organic carbon stocks, leading to a range of estimates of the global mitigation potential of reduced conversion. The SRCCL (Chapter 2) and SROCC (Chapter 5), report a technical mitigation potential of 0.15–5.35 GtCO₂-eq yr⁻¹ by 2050 (Pendleton et al. 2012; Lovelock et al. 2017; Howard et al. 2017; Griscom et al. 2017). The mitigation potential is derived from quantification of losses of carbon stocks in vegetation and soil due to land conversion, shifts in GHG fluxes associated with land use, and alterations in net ecosystem productivity. The wide range in estimates mostly relate to the scope (all coastal ecosystems vs mangroves only) and different assumptions on decomposition rates. Loss rates of coastal wetlands have been estimated at 0.2–3% yr⁻¹, depending on the vegetation type and location (Atwood et al. 2017; Howard et al. 2017).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Global technical mitigation potential for conservation of coastal wetlands from recent literature have focused on protection of mangroves; estimates range from 0.06–2.25 GtCO₂-eq yr⁻¹ (Griscom et al. 2020; Bossio et al. 2020) with 80% of the mitigation potential derived from improvements to soil carbon (Bossio et al. 2020). Regional potentials (Roe et al. 2021) reflect mangrove protection; marsh and seagrass protection were not included due to lack of country-level data on marsh and seagrass distribution and conversion.

Global estimates show mangroves have the largest per hectare carbon stocks (see IPCC AR6 WGII Box 3.4 for estimates of carbon stocks, burial rates and ecosystem extent for coastal wetland ecosystems). Mean ecosystem carbon stock in mangroves is 3131 tCO₂-eq ha⁻¹ among the largest carbon stocks on Earth. Recent studies emphasise the variability in total ecosystem carbon stocks for each wetland type, based on species and climatic and edaphic conditions (Kauffman et al. 2020; Bedulli et al. 2020; Ricart et al. 2020; Alongi et al. 2020; F. Wang et al. 2021), and highlight the vulnerability of soil carbon below 1 m depth (Arifanti et al. 2019). Sea level strongly influences coastal wetland distribution, productivity, and sediment accretion; therefore, sea level rise will impact carbon accumulation and

persistence of existing carbon stocks (Macreadie et al. 2019) (IPCC AR6 WGII Box 3.4).

Recent loss rates of mangroves are 0.16–0.39% yr⁻¹ and are highest in South-East Asia (Hamilton and Casey 2016; Friess et al. 2019; Hamilton and Casey 2016). Assuming loss of soil carbon to 1 m depth after deforestation, avoiding mangrove conversion has the technical potential to mitigate approximately 23.5–38.7 MtCO₂-eq yr⁻¹ (Ouyang and Lee 2020); note, this potential is additional to reduced conversion of forests (Griscom et al. 2020) (Section 7.4.2.1). Regional estimates show that about 85% of mitigation potential for avoided mangrove conversion is in South-East Asia and Pacific (32 MtCO₂-eq yr⁻¹ at USD100 tCO₂⁻¹), 10% is in Latin American and the Caribbean (4 MtCO₂-eq yr⁻¹), and approximately 5% in other regions (Griscom et al. 2020; Roe et al. 2021).

Key uncertainties remain in mapping extent and conversion rates for salt marshes and seagrasses (McKenzie et al. 2020). Seagrass loss rates were estimated at 1–2% yr⁻¹ (Dunic et al. 2021) with stabilisation in some regions (de los Santos et al. 2019) (AR6 WGII, Section 3.4.2.5); however, loss occurs non-linearly and depends on site-specific context. Tidal marsh extent and conversion rates remains poorly estimated, outside of the USA, Europe, South Africa, and Australia (Mcowen et al. 2017; Macreadie et al. 2019).

Critical assessment and conclusion. There is *medium confidence* that coastal wetland protection has a technical potential of 0.8 (0.06–5.4) GtCO₂-eq yr⁻¹ of which 0.17 (0.06–0.27) GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂⁻¹. There is a *high certainty (robust evidence, high agreement)* that coastal ecosystems have among the largest carbon stocks of any ecosystem. As these ecosystems provide many important services, reduced conversion of coastal wetlands is a valuable mitigation strategy with numerous co-benefits. However, the vulnerability of coastal wetlands to climatic and other anthropogenic stressors may limit the permanence of climate mitigation.

7.4.2.9 Coastal Wetland Restoration

Activities, co-benefits, risks and implementation barriers. Coastal wetland restoration involves restoring degraded or damaged coastal wetlands including mangroves, salt marshes, and seagrass ecosystems, leading to sequestration of 'blue carbon' in wetland vegetation and soil (SRCCL, Chapter 6; SROCC, Chapter 5). Successful approaches to wetland restoration include: (i) passive restoration, the removal of anthropogenic activities that are causing degradation or preventing recovery; and (ii) active restoration, purposeful manipulations to the environment in order to achieve recovery to a naturally functioning system (Elliott et al. 2016) (IPCC AR6 WGII Chapter 3). Restoration of coastal wetlands delivers many valuable co-benefits, including enhanced water quality, biodiversity, aesthetic values, fisheries production (food security), and protection from rising sea levels and storm impacts (Barbier et al. 2011; Hochard et al. 2019; Sun and Carson 2020; Duarte et al. 2020). Of the 0.3 Mkm² coastal wetlands globally, 0.11 Mkm² of mangroves are considered feasible for restoration (Griscom et al. 2017). Risks associated with coastal wetland restoration include uncertain permanence under future climate scenarios (IPCC AR6 WGII, Box 3.4), partial offsets of mitigation

through enhanced methane and nitrous oxide release and carbonate formation, and competition with other land uses, including aquaculture and human settlement and development in the coastal zone (SROCC, Chapter 5). To date, many coastal wetland restoration efforts do not succeed due to failure to address the drivers of degradation (van Katwijk et al. 2016). However, improved frameworks for implementing and assessing coastal wetland restoration are emerging that emphasise the recovery of ecosystem functions (Zhao et al. 2016; Cadier et al. 2020). Restoration projects that involve local communities at all stages and consider both biophysical and socio-political context are more likely to succeed (Brown et al. 2014; Wylie et al. 2016).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The SRCCL reported that mangrove restoration has the technical potential to mitigate $0.07 \text{ GtCO}_2 \text{ yr}^{-1}$ through rewetting (Crooks et al. 2011) and take up $0.02\text{--}0.84 \text{ GtCO}_2 \text{ yr}^{-1}$ from vegetation biomass and soil enhancement through 2030 (*medium confidence*) (Griscom et al. 2017). The SROCC concluded that cost-effective coastal blue carbon restoration had a potential of about $0.15\text{--}0.18 \text{ GtCO}_2\text{-eq yr}^{-1}$, a low global potential compared to other ocean-based solutions but with extensive co-benefits and limited adverse side effects (Gattuso et al. 2018).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Recent studies emphasise the time frame needed to achieve the full mitigation potential (Duarte et al. 2020; Taillardat et al. 2020). The first project-derived estimate of the net GHG benefit from seagrass restoration found $1.54 \text{ tCO}_2\text{-eq} (0.42 \text{ MgC}) \text{ ha}^{-1} \text{ yr}^{-1}$ 10 years after restoration began (Oreska et al. 2020); comparable to the default emission factor in the Wetlands Supplement (Kennedy et al. 2014). Recent studies of rehabilitated mangroves also indicate that annual carbon sequestration rates in biomass and soils can return to natural levels within decades of restoration (Cameron et al. 2019; Sidik et al. 2019). A meta-analysis shows increasing carbon sequestration rates over the first 15 years of mangrove restoration with rates stabilising at $25.7 \pm 7.7 \text{ tCO}_2\text{-eq} (7.0 \pm 2.1 \text{ MgC}) \text{ ha}^{-1} \text{ yr}^{-1}$ through forty years, although success depends on climate, sediment type, and restoration methods (Sasmito et al. 2019). Overall, 30% of mangrove soil carbon stocks and 50–70% of marsh and seagrass carbon stocks are unlikely to recover within 30 years of restoration, underscoring the importance of preventing conversion of coastal wetlands (Goldstein et al. 2020) (Section 7.4.2.8).

According to recent data, the technical mitigation potential for global coastal wetland restoration is $0.04\text{--}0.84 \text{ GtCO}_2\text{-eq yr}^{-1}$ (Griscom et al. 2020; Bossio et al. 2020; Roe et al. 2021) with 60% of the mitigation potential derived from improvements to soil carbon (Bossio et al. 2020). Regional potentials based on country-level estimates from Griscom et al. (2020) show the technical and economic (up to USD100 tCO_2^{-1}) potential of mangrove restoration; seagrass and marsh restoration was not included due to lack of country-level data on distribution and conversion (but see McKenzie et al. 2020 for updates on global seagrass distribution). Although global potential is relatively moderate, mitigation can be quite significant for countries with extensive coastlines (e.g., Indonesia, Brazil) and for small island states where coastal wetlands have been shown to comprise 24–34%

of their total national carbon stock (Donato et al. 2012). Furthermore, non-climatic co-benefits can strongly motivate coastal wetland restoration worldwide (UNEP 2021a). Major successes in both active and passive restoration of seagrasses have been documented in North America and Europe (Lefcheck et al. 2018; de los Santos et al. 2019; Orth et al. 2020); passive restoration may also be feasible for mangroves (Cameron et al. 2019).

There is high site-specific variation in carbon sequestration rates and uncertainties regarding the response to future climate change (Jennerjahn et al. 2017; Nowicki et al. 2017) (IPCC AR6 WGII Box 3.4). Changes in distributions (Kelleway et al. 2017; Wilson and Lotze 2019), methane release (Al-Haj and Fulweiler 2020), carbonate formation (Saderne et al. 2019), and ecosystem responses to interactive climate stressors are not well-understood (Short et al. 2016; Fitzgerald and Hughes 2019; Lovelock and Reef 2020).

Critical assessment and conclusion. There is *medium confidence* that coastal wetland restoration has a technical potential of $0.3 (0.04\text{--}0.84) \text{ GtCO}_2\text{-eq yr}^{-1}$ of which $0.1 (0.05\text{--}0.2) \text{ GtCO}_2\text{-eq yr}^{-1}$ is available up to USD100 tCO_2^{-1} . There is *high confidence* that coastal wetlands, especially mangroves, contain large carbon stocks relative to other ecosystems and *medium confidence* that restoration will reinstate pre-disturbance carbon sequestration rates. There is *low confidence* on the response of coastal wetlands to climate change; however, there is *high confidence* that coastal wetland restoration will provide a suite of valuable co-benefits.

7.4.3 Agriculture

7.4.3.1 Soil Carbon Management in Croplands and Grasslands

Activities, co-benefits, risks and implementation opportunities and barriers. Increasing soil organic matter in croplands are agricultural management practices that include (i) crop management: for example, high input carbon practices such as improved crop varieties, crop rotation, use of cover crops, perennial cropping systems (including agroforestry; see Section 7.4.3.3), integrated production systems, crop diversification, agricultural biotechnology; (ii) nutrient management including fertilisation with organic amendments/green manures (Section 7.4.3.6); (iii) reduced tillage intensity and residue retention, (iv) improved water management: including drainage of waterlogged mineral soils and irrigation of crops in arid/semi-arid conditions, (v) improved rice management (Section 7.4.3.5) and (vi) biochar application (P. Smith et al. 2019a) (Section 7.4.3.2). For increased soil organic matter in grasslands, practices include (i) *management of vegetation*: including improved grass varieties/sward composition, deep rooting grasses, increased productivity, and nutrient management, (ii) *livestock management*: including appropriate stocking densities fit to carrying capacity, fodder banks, and fodder diversification, and (iii) *fire management*: improved use of fire for sustainable grassland management, including fire prevention and improved prescribed burning (Smith et al. 2014, 2019b). All these measures are recognised as Sustainable Soil Management Practices by FAO (Baritz et al. 2018). While there are co-benefits for livelihoods, biodiversity, water provision and food security (P. Smith et al. 2019a),

and impacts on leakage, indirect land-use change and foregone sequestration do not apply (since production is not displaced), the climate benefits of soil carbon sequestration in croplands can be negated if achieved through additional fertiliser inputs (potentially causing increased N_2O emissions; (Guenet et al. 2021), and both saturation and permanence are relevant concerns. When considering implementation barriers, soil carbon management in croplands and grasslands is a low-cost option at a high level of technology readiness (it is already widely deployed globally) with low socio-cultural and institutional barriers, but with difficulty in monitoring and verification proving a barrier to implementation (Smith et al. 2020a).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. Building on AR5, the SRCCL reported the global mitigation potential for soil carbon management in croplands to be 1.4–2.3 $\text{GtCO}_2\text{-eq yr}^{-1}$ (Smith et al. 2014), though the full literature range was 0.3–6.8 $\text{GtCO}_2\text{-eq yr}^{-1}$ (Sommer and Bossio 2014; Powlson et al. 2014; Dickie et al. 2014b; Henderson et al. 2015; Herrero et al. 2016; Paustian et al. 2016; Zomer et al. 2016; Frank et al. 2017; Conant et al. 2017; Griscom et al. 2017; Hawken 2017; Sanderman et al. 2017; Fuss et al. 2018; Roe et al. 2019). The global mitigation potential for soil organic carbon management in grasslands was assessed to be 1.4–1.8 $\text{GtCO}_2\text{-eq yr}^{-1}$, with the full literature range being 0.1–2.6 $\text{GtCO}_2\text{-eq yr}^{-1}$ (Herrero et al. 2013; 2016; Conant et al. 2017; Roe et al. 2019). Lower values in the range represented economic potentials, while higher values represented technical potentials – and uncertainty was expressed by reporting the whole range of estimates. The SR1.5 outlined associated costs reported in literature to range from USD –45 to 100 tCO_2^{-1} , describing enhanced soil carbon sequestration as a cost-effective measure (IPCC 2018). Despite significant mitigation potential, there is limited inclusion of soil carbon sequestration as a response option within IAM mitigation pathways (Rogelj et al. 2018a).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). No recent literature has been published which conflict with the mitigation potentials reported in the SRCCL. Relevant papers include Lal et al. (2018) which estimated soil carbon sequestration potential to be 0.7–4.1 $\text{GtCO}_2\text{-eq yr}^{-1}$ for croplands and 1.1–2.9 $\text{GtCO}_2\text{-eq yr}^{-1}$ for grasslands. Bossio et al. (2020) assessed the contribution of soil carbon sequestration to natural climate solutions and found the potential to be 5.5 $\text{GtCO}_2\text{ yr}^{-1}$ across all ecosystems, with only small portions of this (0.41 $\text{GtCO}_2\text{-eq yr}^{-1}$ for cover cropping in croplands; 0.23, 0.15, 0.15 $\text{GtCO}_2\text{-eq yr}^{-1}$ for avoided grassland conversion, optimal grazing intensity and legumes in pastures, respectively) arising from croplands and grasslands. Regionally, soil carbon management in croplands is feasible anywhere, but effectiveness can be limited in very dry regions (Sanderman et al. 2017). For soil carbon management in grasslands the feasibility is greatest in areas where grasslands have been degraded (e.g., by overgrazing) and soil organic carbon is depleted. For well managed grasslands, soil carbon stocks are already high and the potential for additional carbon storage is low. Roe et al. (2021) estimate the greatest economic (up to USD100 tCO_2^{-1}) potential between 2020 and 2050 for croplands to be in Asia and the Pacific (339.7 $\text{MtCO}_2\text{ yr}^{-1}$) and for grasslands, in Developed Countries (253.6 $\text{MtCO}_2\text{ yr}^{-1}$).

Critical assessment and conclusion. In conclusion, there is *medium confidence* that enhanced soil carbon management in croplands has a global technical mitigation potential of 1.9 (0.4–6.8) $\text{GtCO}_2\text{ yr}^{-1}$, and in grasslands of 1.0 (0.2–2.6) $\text{GtCO}_2\text{ yr}^{-1}$, of which, 0.6 (0.4–0.9) and 0.9 (0.3–1.6) $\text{GtCO}_2\text{ yr}^{-1}$ is estimated to be available at up to USD100 tCO_2^{-1} respectively. Regionally, soil carbon management in croplands and grasslands is feasible anywhere, but effectiveness can be limited in very dry regions, and for grasslands it is greatest in areas where degradation has occurred (e.g., by overgrazing) and soil organic carbon is depleted. Barriers to implementation include regional capacity for monitoring and verification (especially in developing countries), and more widely through concerns over saturation and permanence.

7.4.3.2 Biochar

Activities, co-benefits, risks and implementation opportunities and barriers. Biochar is produced by heating organic matter in oxygen-limited environments (pyrolysis and gasification) (Lehmann and Joseph 2012). Feedstocks include forestry and sawmill residues, straw, manure and biosolids. When applied to soils, biochar is estimated to persist from decades to thousands of years, depending on feedstock and production conditions (J. Wang et al. 2016; Singh et al. 2015). Biochar systems producing biochar for soil application plus bioenergy, generally give greater mitigation than bioenergy alone and other uses of biochar, and are recognised as a CDR strategy. Biochar persistence is increased through interaction with clay minerals and soil organic matter (Fang et al. 2015). Additional CDR benefits arise through ‘negative priming’ whereby biochar stabilises soil carbon and rhizodeposits (Weng et al. 2015; J. Wang et al. 2016; Archanjo et al. 2017; Hagemann et al. 2017; Han Weng et al. 2017; Weng et al. 2018). Besides CDR, additional mitigation can arise from displacing fossil fuels with pyrolysis gases, lower soil N_2O emissions (Cayuela et al. 2014, 2015; Song et al. 2016; He et al. 2017; Verhoeven et al. 2017; Borchard et al. 2019), reduced nitrogen fertiliser requirements due to reduced nitrogen leaching and volatilisation from soils (Liu et al. 2019; Borchard et al. 2019), and reduced GHG emissions from compost when biochar is added (Agyarko-Mintah et al. 2017; Wu et al. 2017). Biochar application to paddy rice has resulted in substantial reductions (20–40% on average) in N_2O (Song et al. 2016; Awad et al. 2018; Liu et al. 2018) (Section 7.4.3.5) and smaller reduction in CH_4 emissions (Song et al. 2016; Kammann et al. 2017; Kim et al. 2017a; He et al. 2017; Awad et al. 2018). Potential co-benefits include yield increases particularly in sandy and acidic soils with low cation exchange capacity (Woelf et al. 2016; Jeffery et al. 2017); increased soil water-holding capacity (Omondi et al. 2016), nitrogen use efficiency (Liu et al. 2019; Borchard et al. 2019), biological nitrogen fixation (Van Zwieten et al. 2015); adsorption of organic pollutants and heavy metals (e.g., Silvani et al. 2019); odour reduction from manure handling (e.g., Hwang et al. 2018) and managing forest fuel loads (Puettmann et al. 2020). Due to its dark colour, biochar could decrease soil albedo (Meyer et al. 2012), though this is insignificant under recommended rates and application methods. Biochar could reduce enteric CH_4 emissions when fed to ruminants (Section 7.4.3.4). Barriers to upscaling include insufficient investment, limited large-scale production facilities, high production costs at small scale, lack of agreed approach to monitoring, reporting

and verification, and limited knowledge, standardisation and quality control, restricting user confidence (Gwenzi et al. 2015).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. Biochar is discussed as a mitigation option in AR5 and CDR strategy in the SR1.5. Consideration of potential was limited as biochar is not included in IAMs. The SRCCL estimated mitigation potential of 0.03–6.6 GtCO₂-eq yr⁻¹ by 2050 based on studies with widely varying assumptions, definitions of potential, and scope of mitigation processes included (SRCCL, Chapters 2 and 4: (Roberts et al. 2010; Pratt and Moran 2010; Hristov et al. 2013; Lee and Day 2013; Dickie et al. 2014a; Hawken 2017; Fuss et al. 2018; Powell and Lenton 2012; Woolf et al. 2010).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Developments include mechanistic understanding of ‘negative priming’ and biochar-soil-microbes-plant interactions (DeCiucies et al. 2018; Fang et al. 2019). Indirect climate benefits are associated with persistent yield response to biochar (Kätterer et al. 2019; Ye et al. 2020), improved crop water use efficiency (Du et al. 2018; Gao et al. 2020) and reduced GHG and ammonia emissions from compost and manure (Sanchez-Monedero et al. 2018; Bora et al. 2020a,b; Zhao et al. 2020). A quantification method based on biochar properties is included in the IPCC guidelines for NGHGs (Domke et al. 2019). Studies report a range of biochar responses, from positive to occasionally adverse impacts, including on GHG emissions, and identify risks (Tisserant and Cherubini 2019). This illustrates the expected variability (Lehmann and Rillig 2014) of responses, which depend on the biochar type and climatic and edaphic characteristics of the site (Zygourakis 2017). Biochar properties vary with feedstock, production conditions and post-production treatments, so mitigation and agronomic benefits are maximised when biochars are chosen to suit the application context (Mašek et al. 2018). A recent assessment finds greatest economic potential (up to USD100 tCO₂⁻¹) between 2020 and 2050 to be in Asia and the Pacific (793 MtCO₂ yr⁻¹) followed by Developed Countries (447 MtCO₂ yr⁻¹) (Roe et al. 2021). Mitigation through biochar will be greatest where biochar is applied to responsive soils (acidic, low fertility), where soil N₂O emissions are high (intensive horticulture, irrigated crops), and where the syngas co-product displaces fossil fuels. Due to the early stage of commercialisation, mitigation estimates are based pilot-scale facilities, leading to uncertainty. However, the long-term persistence of biochar carbon in soils has been widely studied (Singh et al. 2012; Fang et al. 2019; Zimmerman and Ouyang 2019). The greatest uncertainty is the availability of sustainably-sourced biomass for biochar production.

Critical assessment and conclusion. Biochar has significant mitigation potential through CDR and emissions reduction, and can also improve soil properties, enhancing productivity and resilience to climate change (*medium agreement, robust evidence*). There is *medium evidence* that biochar has a technical potential of 2.6 (0.2–6.6) GtCO₂-eq yr⁻¹, of which 1.1 (0.3–1.8) GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂⁻¹. However, mitigation and agronomic co-benefits depend strongly on biochar properties and the soil to which biochar is applied (*strong agreement, robust evidence*). While biochar could provide moderate to large mitigation potential, it is not yet included in IAMs, which has restricted comparison and integration with other CDR strategies.

7.4.3.3 Agroforestry

Activities, co-benefits, risks and implementation opportunities and barriers. Agroforestry is a set of diverse land management systems that integrate trees and shrubs with crops and/or livestock in space and/or time. Agroforestry accumulates carbon in woody vegetation and soil (Ramachandran Nair et al. 2010) and offers multiple co-benefits such as increased land productivity, diversified livelihoods, reduced soil erosion, improved water quality, and more hospitable regional climates (Ellison et al. 2017; Kuyah et al. 2019; Mbow et al. 2020; Zhu et al. 2020). Incorporation of trees and shrubs in agricultural systems, however, can affect food production, biodiversity, local hydrology and contribute to social inequality (Amadu et al. 2020; Fleischman et al. 2020; Holl and Brancalion 2020). To minimise risks and maximise co-benefits, agroforestry should be implemented as part of support systems that deliver tools, and information to increase farmers’ agency. This may include reforming policies, strengthening extension systems and creating market opportunities that enable adoption (Jamnadass et al. 2020; Sendzimir et al. 2011; P. Smith et al. 2019a). Consideration of carbon sequestration in the context of food and fuel production, as well as environmental co-benefits at the farm, local, and regional scales can further help support decisions to plant, regenerate and maintain agroforestry systems (Kumar and Nair 2011; Miller et al. 2020). In spite of the advantages, biophysical and socio-economic factors can limit the adoption (Pattanayak et al. 2003). Contextual factors may include, but are not limited to; water availability, soil fertility, seed and germplasm access, land policies and tenure systems affecting farmer agency, access to credit, and to information regarding the optimum species for a given location.

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The SRCCL estimated the global technical mitigation potential of agroforestry, with medium confidence, to be between 0.08 and 5.6 GtCO₂-eq yr⁻¹ by 2050 (Griscom et al. 2017; Dickie et al. 2014a; Zomer et al. 2016; Hawken 2017). Estimates are derived from syntheses of potential area available for various agroforestry systems, for example, windbreaks, farmer managed natural regeneration, and alley cropping and average annual rates of carbon accumulation. The cost-effective economic potential, also with medium confidence, is more limited at 0.3–2.4 GtCO₂-eq yr⁻¹ (Zomer et al. 2016; Griscom et al. 2017; Roe et al. 2019). Despite this potential, agroforestry is currently not considered in integrated assessment models used for mitigation pathways (Section 7.5).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Updated estimates of agroforestry’s technical mitigation potential and synthesised estimates of carbon sequestration across agroforestry systems have since been published. The most recent global analysis estimates technical potential of 9.4 GtCO₂-eq yr⁻¹ (Chapman et al. 2020) of agroforestry on 1.87 and 1.89 billion ha of crop and pasture lands below median carbon content, respectively. This estimate is at least 68% greater than the largest estimate reported in the SRCCL (Hawken 2017) and represents a new conservative upper bound as Chapman et al. (2020) only accounted for above-ground carbon. Considering both above- and below-ground carbon of windbreaks, alley cropping and silvopastoral systems at a more limited areal extent (Griscom et al. 2020), the economic potential of agroforestry

was estimated to be only about 0.8 GtCO₂-eq yr⁻¹. Variation in estimates primarily result from assumptions on the agroforestry systems including, extent of implementation and estimated carbon sequestration potential when converting to agroforestry.

Regional estimates of mitigation potential are scant with agroforestry options differing significantly by geography (Feliciano et al. 2018). For example, multi-strata shaded coffee and cacao are successful in the humid tropics (Somarriba et al. 2013; Blaser et al. 2018), silvopastoral systems are prevalent in Latin American (Peters et al. 2013; Landholm et al. 2019) while agrosilvopastoral systems, shelterbelts, hedgerows, and windbreaks are common in Europe (Joffre et al. 1988; Rigueiro-Rodriguez 2009). At the field scale, agroforestry accumulates between 0.59 and 6.24 t ha⁻¹ yr⁻¹ of carbon above-ground. Below-ground carbon often constitutes 25% or more of the potential carbon gains in agroforestry systems (De Stefano and Jacobson 2018; Cardinael et al. 2018). Roe et al. (2021) estimate greatest regional economic (up to USD100 tCO₂⁻¹) mitigation potential for the period 2020–2050 to be in Asia and the Pacific (368.4 MtCO₂-eq yr⁻¹) and Developed Countries (264.7 MtCO₂-eq yr⁻¹).

Recent research has also highlighted co-benefits and more precisely identified implementation barriers. In addition to aforementioned co-benefits, evidence now shows that agroforestry can improve soil

health, regarding infiltration and structural stability (Muchane et al. 2020); reduces ambient temperatures and crop heat stress (Arenas-Corraliza et al. 2018; Sida et al. 2018); increases groundwater recharge in drylands when managed at moderate density (Ilstedt et al. 2016; Bargués-Tobella et al. 2020); positively influences human health (Rosenstock et al. 2019); and can improve dietary diversity (McMullin et al. 2019). Along with previously mentioned barriers, low social capital, assets, and labour availability have been identified as pertinent to adoption. Practically all barriers are interdependent and subject to the context of implementation.

Critical assessment and conclusion. There is medium confidence that agroforestry has a technical potential of 4.1 (0.3–9.4) GtCO₂-eq yr⁻¹ for the period 2020–2050, of which 0.8 (0.4–1.1) GtCO₂-eq yr⁻¹ is available at USD100 tCO₂⁻¹. Despite uncertainty around global estimates due to regional preferences for management systems, suitable land availability, and growing conditions, there is high confidence in agroforestry's mitigation potential at the field scale. With countless options for farmers and land managers to implement agroforestry, there is medium confidence in the feasibility of achieving estimated regional mitigation potential. Appropriately matching agroforestry options, to local biophysical and social contexts is important in maximising mitigation and co-benefits, while avoiding risks (Sinclair and Coe 2019).

Box 7.3 | Case Study: Agroforestry in Brazil – CANOPIES

Summary

Brazilian farmers are integrating trees into their croplands in various ways, ranging from simple to highly complex agroforestry systems. While complex systems are more effective in the mitigation of climate change, trade-offs with scalability need to be resolved for agroforestry systems to deliver on their potential. The Brazilian-Dutch CANOPIES project (Janssen 2020) is exploring transition pathways to agroforestry systems optimised for local ecological and socio-economic conditions.

Background

The climate change mitigation potential of agroforestry systems is widely recognised (Zomer et al. 2016; FAO 2017b) and Brazilian farmers and researchers are pioneering diverse ways of integrating trees into croplands, from planting rows of eucalyptus trees in pastures up to highly complex agroforests consisting of >30 crop and tree species. The degree of complexity influences the multiple functions that farmers and societies can attain from agroforestry: the more complex it is, the more it resembles a natural forest with associated benefits for its carbon storage capacity and its habitat quality for biodiversity (Santos et al. 2019). However, trade-offs exist between the complexity and scalability of agroforestry as complex systems rely on intensive manual labour to achieve high productivity (Tscharntke et al. 2011). To date, mechanisation of structurally diverse agroforests is scarce and hence, efficiencies of scale are difficult to achieve.

Case description

These synergies and trade-offs between complexity, multifunctionality and scalability are studied in the CANOPIES (Co-existence of Agriculture and Nature: Optimisation and Planning of Integrated Ecosystem Services) project, a collaboration between Wageningen University (NL), the University of São Paulo and EMBRAPA (both Brazil). Soil and management data are collected on farms of varying complexity to evaluate carbon sequestration and other ecosystem services, economic performance and labour demands.

Interactions and limitations

The trade-off between complexity and labour demand is less pronounced in EMBRAPA's integrated crop-livestock-forestry (ICLF) systems, where grains and pasture are planted between widely spaced tree rows. Here, barriers for implementation relate mostly to livestock and grain farmers' lack of knowledge on forestry management and financing mechanisms⁵ (Gil et al. 2015). Additionally, linking these financing mechanisms to carbon sequestration remains a Monitoring, Reporting and Verification challenge (Smith et al. 2020b).

Box 7.3 (continued)

Lessons

Successful examples of how more complex agroforestry can be upscaled do exist in Brazil. For example, on farm trials and consistent investments over several years have enabled Rizoma Agro to develop a citrus production system that integrates commercial and native trees in a large-scale multi-layered agroforestry system. The success of their transition resulted in part from their corporate structure that allowed them to tap into the certified Green Bonds market (CBI 2020). However, different transition strategies need to be developed for family farmers and their distinct socio-economic conditions.

7.4.3.4 Enteric Fermentation

Activities, co-benefits, risks and implementation opportunities and barriers. Mitigating CH₄ emissions from enteric fermentation can be direct (i.e., targeting ruminal methanogenesis and emissions per animal or unit of feed consumed) or indirect, by increasing production efficiency (i.e., reducing emission intensity per unit of product). Measures can be classified as those relating to (i) feeding, (ii) supplements, additives and vaccines, and (iii) livestock breeding and wider husbandry (Jia et al. 2019). Co-benefits include enhanced climate change adaptation and increased food security associated with improved livestock breeding (Smith et al. 2014). Risks include mitigation persistence, ecological impacts associated with improving feed quality and supply, or potential toxicity and animal welfare issues concerning feed additives. Implementation barriers include feeding/administration constraints, the stage of development of measures, legal restrictions on emerging technologies and negative impacts, such as the previously described risks (Smith et al. 2014; Jia et al. 2019; P. Smith et al. 2019a).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The AR5 indicated medium (5–15%) technical mitigation potential from both feeding and breeding related measures (Smith et al. 2014). More recently, the SRCCL estimated with *medium confidence*, a global potential of 0.12–1.18 GtCO₂-eq yr⁻¹ between 2020 and 2050, with the range reflecting technical, economic and sustainability constraints (SRCCL, Chapter 2: Hristov et al. 2013; Dickie et al. 2014a; Herrero et al. 2016; Griscom et al. 2017). The underlying literature used a mixture of IPCC GWP100 values for CH₄, preventing conversion of CO₂-eq to CH₄. Improved livestock feeding and breeding were included in IAM emission pathway scenarios within the SRCCL and SR1.5, although it was suggested that the full mitigation potential of enteric CH₄ measures is not captured in current models (Rogelj et al. 2018b; IPCC 2018).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Recent reviews generally identify the same measures as those outlined in the SRCCL, with the addition of early life manipulation of the ruminal biome (Grossi et al. 2019; Eckard and Clark 2020; Thompson and Rowntree 2020; Beauchemin et al. 2020; Ku-Vera et al. 2020; Honan et al. 2021). There is *robust evidence and high agreement* that chemically synthesised inhibitors are promising emerging near-term measures (Patra 2016; Jayanegara et al. 2018; Van Wesemael et al. 2019; Beauchemin et al.

2020) with high (e.g., 16–70% depending on study) mitigation potential reported (e.g., Hristov et al. 2015; McGinn et al. 2019; Melgar et al. 2020) and commercial availability expected within two years in some countries (Reisinger et al. 2021). However, their mitigation persistence (McGinn et al. 2019), cost (Carroll and Daigneault 2019; Alvarez-Hess et al. 2019) and public acceptance (Jayasundara et al. 2016) or regulatory approval is currently unclear while administration in pasture-based systems is likely to be challenging (Patra et al. 2017; Leahy et al. 2019). Research into other inhibitors/feeds containing inhibitory compounds, such as macroalga or seaweed (Chagas et al. 2019; Kinley et al. 2020; Roque et al. 2019), shows promise, although concerns have been raised regarding palatability, toxicity, environmental impacts and the development of industrial-scale supply chains (Abbott et al. 2020; Vijn et al. 2020). In the absence of CH₄ vaccines, which are still under development (Reisinger et al. 2021) pasture-based and non-intensive systems remain reliant on increasing production efficiency (Beauchemin et al. 2020). Breeding of low emitting animals may play an important role and is a subject under ongoing research (Pickering et al. 2015; Jonker et al. 2018; López-Paredes et al. 2020).

Approaches differ regionally, with more focus on direct, technical options in Developed Countries, and improved efficiency in developing countries (Caro Torres et al. 2016; Mottet et al. 2017b; MacLeod et al. 2018; Frank et al. 2018). A recent assessment finds greatest economic (up to USD100 tCO₂-eq⁻¹) potential (using the IPCC AR4 GWP100 value for CH₄) for 2020–2050 in Asia and the Pacific (32.9 MtCO₂-eq yr⁻¹) followed by Developed Countries (25.5 MtCO₂-eq yr⁻¹) (Roe et al. 2021). Despite numerous country and sub-sector specific studies, most of which include cost analysis (Hasegawa and Matsuoka 2012; Hoa et al. 2014; Jilani et al. 2015; Eory et al. 2015; Pradhan et al. 2017; Pellerin et al. 2017; Ericksen and Crane 2018; Habib and Khan 2018; Kashangaki and Ericksen 2018; Salmon et al. 2018; Brandt et al. 2019b; Kiggundu et al. 2019; Kavanagh et al. 2019; Mosnier et al. 2019; Pradhan et al. 2019; Sapkota et al. 2019; Carroll and Daigneault 2019; Leahy et al. 2019; Dioha and Kumar 2020), sectoral assessment of regional technical and notably economic (Beach et al. 2015; USEPA 2019) potential is restricted by lack comprehensive and comparable data. Therefore, verification of regional estimates indicated by global assessments is challenging. Feed quality improvement, which may have considerable potential in developing countries (Caro et al. 2016; Mottet et al. 2017a), may have negative wider impacts. For example, potential land-use change and greater emissions associated with production of concentrates (Brandt et al. 2019b).

Critical review and conclusion. Based on studies to date, using a range of IPCC GWP100 values for CH₄, there is *medium confidence* that activities to reduce enteric CH₄ emissions have a global technical potential of 0.8 (0.2–1.2) GtCO₂-eq yr⁻¹, of which 0.2 (0.1–0.3) GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂-eq⁻¹ (Figure 7.11). The CO₂-eq value may also slightly differ if the GWP100 IPCC AR6 CH₄ value was uniformly applied within calculations. Lack of comparable country and sub-sector studies to assess the context applicability of measures, associated costs and realistic adoption likelihood, prevents verification of estimates.

7.4.3.5 Improve Rice Management

Activities, co-benefits, risks and implementation opportunities and barriers. Emissions from rice cultivation mainly concern CH₄ associated with anaerobic conditions, although N₂O emission also occur via nitrification and denitrification processes. Measures to reduce CH₄ and N₂O emissions include (i) improved water management (e.g., single drainage and multiple drainage practices), (ii) improved residue management, (iii) improved fertiliser application (e.g., using slow release fertiliser and nutrient specific application), and (iv) soil amendments (including biochar and organic amendments) (Pandey et al. 2014; Kim et al. 2017b; Yagi et al. 2020; Sriphirom et al. 2020). These measures not only have mitigation potential but can improve water use efficiency, reduce overall water use, enhance drought adaptation and overall system resilience, improve yield, reduce production costs from seed, pesticide, pumping and labour, increase farm income, and promote sustainable development (Quynh and Sander 2015; Yamaguchi et al. 2017; Tran et al. 2018; Sriphirom et al. 2019). However, in terms of mitigation of CH₄ and N₂O, antagonistic effects can occur, whereby water management can enhance N₂O emissions due to creation of alternate wet and dry conditions (Sriphirom et al. 2019), with trade-offs between CH₄ and N₂O during the drying period potentially offsetting some mitigation benefits. Barriers to adoption may include site-specific limitations regarding soil type, percolation and seepage rates or fluctuations in precipitation, water canal or irrigation infrastructure, paddy surface level and rice field size, and social factors including farmer perceptions, pump ownership, and challenges in synchronising water management between neighbours and pumping stations (Quynh and Sander 2015; Yamaguchi et al. 2017; Yamaguchi et al. 2019).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The AR5 outlined emissions from rice cultivation of 0.49–0.723 GtCO₂-eq yr⁻¹ in 2010 with an average annual growth of 0.4% yr⁻¹. The SRCCL estimated a global mitigation potential from improved rice cultivation of 0.08–0.87 GtCO₂-eq yr⁻¹ between 2020 and 2050, with the range representing the difference between technical and economic constraints, types of activities included (e.g., improved water management and straw residue management) and GHGs considered (Dickie et al. 2014a; Beach et al. 2015; Paustian et al. 2016; Griscom et al. 2017; Hawken 2017) (SRCCL, Chapter 2).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Since AR5 and the SRCCL, studies on mitigation have principally focused on water and nutrient management practices with the aim of improving overall sustainability as well as measurements of site-specific emissions to help improve the resolution of regional estimates. Intensity of emissions show considerable spatial and temporal variation, dependent on site specific factors including degradation of soil organic matter, management of water levels in the field, the types and amount of fertilisers applied, rice variety and local cultivation practices. Variation in CH₄ emissions have been found to range from 0.5–41.8 mg m² hr⁻¹ in South-East Asia (Sander et al. 2014; Chidthaisong et al. 2018; Setyanto et al. 2018; Sibayan et al. 2018; J. Wang et al. 2018; Maneepitak et al. 2019), 0.5–37.0 mg m² hr⁻¹ in Southern and Eastern Asia (Zhang et al. 2010; Wang et al. 2012; Oo et al. 2018; J. Wang et al. 2018; Takakai et al. 2020), and 0.5–10.4 mg m² hr⁻¹ in North America (J. Wang et al. 2018). Current studies on emissions of N₂O also showed high variation in the range of 0.13–654 ug/m²/hr (Akiyama et al. 2005; Islam et al. 2018; Kritee et al. 2018; Zschornack et al. 2018; Oo et al. 2018).

Recent studies on water management have highlighted the potential to mitigate GHG emissions, while also enhancing water use efficiency (Tran et al. 2018). A meta-analysis on multiple drainage systems found that Alternative Wetting and Drying (AWD) with irrigation management, can reduce CH₄ emissions by 20–30% and water use by 25.7%, though this resulted in a slight yield reduction (5.4%) (Carrijo et al. 2017). Other studies have described improved yields associated with AWD (Tran et al. 2018). Water management for both single and multiple drainage can (most likely) reduce methane emissions by about 35% but increase N₂O emissions by about 20% (Yagi et al. 2020). However, N₂O emissions occur only under dry conditions, therefore total reduction in terms of net GWP is approximately 30%. Emissions of N₂O are higher during dry seasons (Yagi et al. 2020) and depend on site specific factors as well as the quantity of fertiliser and organic matter inputs into the paddy rice system. Variability of N₂O emissions from single and multiple drainage can range from 0.06–33 kg/ha (Hussain et al. 2015; Kritee et al. 2018). AWD in Vietnam was found to reduce both CH₄ and N₂O emissions by 29–30 and 26–27% respectively with the combination of net GWP about 30% as compared to continuous flooding (Tran et al. 2018). Overall, greatest average economic mitigation potential (up to USD100 tCO₂-eq⁻¹) between 2020 and 2050 is estimated to be in Asia and the Pacific (147.2 MtCO₂-eq yr⁻¹) followed by Latin America and the Caribbean (8.9 MtCO₂-eq yr⁻¹) using the IPCC AR4 GWP100 value for CH₄ (Roe et al. 2021).

Critical assessment and conclusion. There is *medium confidence* that improved rice management has a technical potential of 0.3 (0.1–0.8) GtCO₂-eq yr⁻¹ between 2020 and 2050, of which 0.2 (0.05–0.3) GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂-eq⁻¹ (Figure 7.11). Improving rice cultivation practices will not only reduce GHG emissions, but also improve production sustainability in terms of resource utilisation including water consumption and fertiliser application. However, emission reductions show high variability and are dependent on site specific conditions and cultivation practices.

7.4.3.6 Crop Nutrient Management

Activities, co-benefits, risks and implementation opportunities and barriers. Improved crop nutrient management can reduce N_2O emissions from cropland soils. Practices include optimising fertiliser application delivery, rates and timing, utilising different fertiliser types (i.e., organic manures, composts and synthetic forms), and using slow or controlled-released fertilisers or nitrification inhibitors (Smith et al. 2014; Griscom et al. 2017; P. Smith et al. 2019a). In addition to individual practices, integrated nutrient management that combines crop rotations including intercropping, nitrogen biological fixation, reduced tillage, use of cover crops, manure and bio-fertiliser application, soil testing and comprehensive nitrogen management plans, is suggested as central for optimising fertiliser use, enhancing nutrient uptake and potentially reducing N_2O emissions (Bationo et al. 2012; Lal et al. 2018; Bolinder et al. 2020; Jensen et al. 2020; Namatsheve et al. 2020). Such practices may generate additional mitigation by indirectly reducing synthetic fertiliser manufacturing requirements and associated emissions, though such mitigation is accounted for in the Industry Sector and not considered in this chapter. Tailored nutrient management approaches, such as 4R nutrient stewardship, are implemented in contrasting farming systems and contexts and supported by best management practices to balance and match nutrient supply with crop requirements, provide greater stability in fertiliser performance and to minimise N_2O emissions and nutrient losses from fields and farms (Fixen 2020; Maaz et al. 2021). Co-benefits of improved nutrient management can include enhanced soil quality (notably when manure, crop residues or compost is utilised), carbon sequestration in soils and biomass, soil water holding capacity, adaptation capacity, crop yields, farm incomes, water quality (from reduced nitrate leaching and eutrophication), air quality (from reduced ammonia emissions) and in certain cases, it may facilitate land sparing (Sapkota et al. 2014; Johnston and Bruulsema 2014; Zhang et al. 2017; P. Smith et al. 2019a; Mbow et al. 2019).

A potential risk under certain circumstances, is yield reduction, while implementation of practices should consider current soil nutrient status. There are significant regional imbalances, with some regions experiencing nutrient surpluses from over fertilisation and others, nutrient shortages and chronic deficiencies (FAO 2021e). Additionally, depending on context, practices may be inaccessible, expensive or require expertise to implement (Hedley 2015; Benson and Moguees 2018) while impacts of climate change may influence nutrient use efficiency (Amouzou et al. 2019) and therefore, mitigation potential.

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The SRCCL broadly identified the same practices as outlined in AR5 and estimated that improved cropland nutrient management could mitigate between 0.03 and 0.71 $\text{GtCO}_2\text{-eq yr}^{-1}$ between 2020 and 2050 (SRCCL Chapter 2) (Dickie et al. 2014a; Beach et al. 2015; Paustian et al. 2016; Griscom et al. 2017; Hawken 2017).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Research since the SRCCL highlights the mitigation potential and co-benefits of adopting improved nutrient management strategies, notably precision fertiliser application methods and nutrient expert systems, and applicability in both large-scale mechanised and small-scale systems (USEPA 2019; Hijbeek et al. 2019; Griscom et al. 2020; Tian et al. 2020; Aryal et al. 2020; Sapkota et al. 2021). Improved crop nutrient management is feasible in all regions, but effectiveness is context dependent. Sub-Saharan Africa has one of the lowest global fertiliser consumption rates, with increased fertiliser use suggested as necessary to meet projected future food requirements (Mueller et al. 2012; ten Berge et al. 2019; Adam et al. 2020; Falconnier et al. 2020). Fertiliser use in Developed Countries is already high (Figure 7.10) with increased nutrient use efficiency among the most promising mitigation measures (Roe et al. 2019; Hijbeek et al. 2019). Considering that Asia and Pacific, and Developed Countries accounted for the greatest share of global nitrogen fertiliser use, it is not surprising that these regions are estimated to have greatest economic mitigation potential (up to USD100 $\text{tCO}_2\text{-eq}^{-1}$) between 2020 and 2050, at 161.8 and 37.1 $\text{MtCO}_2\text{-eq yr}^{-1}$ respectively (using the IPCC AR4 GWP100 value for N_2O) (Roe et al. 2021).

Critical assessment and conclusion. There is *medium confidence* that crop nutrient management has a technical potential of 0.3 (0.06–0.7) $\text{GtCO}_2\text{-eq yr}^{-1}$ of which 0.2 (0.05–0.6) $\text{GtCO}_2\text{-eq yr}^{-1}$ is available up to USD100 $\text{tCO}_2\text{-eq}^{-1}$. This value is based on GWP100 using a mixture of IPCC values for N_2O and may slightly differ if calculated using AR6 values. The development of national roadmaps for sustainable fertiliser (nutrient) management can help in scaling-up related practices and in realising this potential. Crop nutrient management measures can contribute not only to mitigation, but food and nutrition security and wider environmental sustainability goals.

Box 7.4 | Case Study: The Climate-smart Village Approach

Summary

The climate-smart villages (CSV) approach aims to generate local knowledge, with the involvement of farmers, researchers, practitioners, and governments, on climate change adaptation and mitigation while improving productivity, food security, and farmers' livelihoods (Aggarwal et al. 2018). This knowledge feeds a global network that includes 36 climate-smart villages in South and South-East Asia, West and East Africa, and Latin America.

Background

It is expected that agricultural production systems across the world will change in response to climate change, posing significant challenges to the livelihoods and food security of millions of people (Kennedy et al. 2014). Maintaining agricultural growth while minimising climate shocks is crucial to building a resilient food production system and meeting sustainable development goals in vulnerable countries.

Case description

The CSV approach seeks an integrated vision so that sustainable rural development is the final goal for rural communities. At the same time, it fosters the understanding of climate change with the implementation of adaptation and mitigation actions, as much as possible. Rural communities and local stakeholders are the leaders of this process, where scientists facilitate their knowledge to be useful for the communities and learn at the same time about challenges but also the capacity those communities have built through time. The portfolio includes weather-smart activities, water-smart practices, seed/breed smart, carbon-/nutrient-smart practices, and institutional-/market-smart activities.

Interactions and limitations

The integration of technologies and services that are suitable for the local conditions resulted in many gains for food security and adaptation and for mitigation where appropriate. It was also shown that, in all regions, there is considerable yield advantage when a portfolio of technologies is used, rather than the isolated use of technologies (Govaerts et al. 2005; Zougmore et al. 2014). Moreover, farmers are using research results to promote their products as climate-smart leading to increases in their income (Acosta-Alba et al. 2019). However, climatic risk sites and socio-economic conditions together with a lack of resource availability are key issues constraining agriculture across all five regions.

Lessons

- i. Understanding the priorities, context, challenges, capacity, and characteristics of the territory and the communities regarding climate, as well as the environmental and socio-economic dimensions, is the first step. Then, understanding climate vulnerability in their agricultural systems based on scientific data but also listening to their experience will set the pathway to identify climate-smart agriculture (CSA) options (practices and technologies) to reduce such vulnerability.
- ii. Building capacity is also a critical element of the CSV approach, rural families learn about the practices and technologies in a neighbour's house, and as part of the process, families commit to sharing their knowledge with other families, to start a scaling-out process within the communities. Understanding the relationship between climate and their crop is key, as well as the use of weather forecasts to plan their agricultural activities.

The assessment of the implementation of the CSA options should be done together with community leaders to understand changes in livelihoods and climate vulnerability. Also, knowledge appropriation by community leaders has led to farmer-to-farmer knowledge exchange within and outside the community (Ortega Fernandez and Martínez-Barón 2018).

7.4.3.7 Manure Management

Activities, co-benefits, risks and implementation opportunities and barriers. Manure management measures aim to mitigate CH₄ and N₂O emissions from manure storage and deposition. Mitigation of N₂O considers both direct and indirect (i.e., conversion of ammonia and nitrate to N₂O) sources. According to the SRCCL, measures may include (i) anaerobic digestion, (ii) applying nitrification or urease inhibitors to stored manure or urine patches, (iii) composting,

(iv) improved storage and application practices, (v) grazing practices and (vi) alteration of livestock diets to reduce nitrogen excretion (Mbow et al. 2019; Jia et al. 2019). Implementation of manure management with other livestock and soil management measures can enhance system resilience, sustainability, food security and help prevent land degradation (Smith et al. 2014; Mbow et al. 2019; P. Smith et al. 2019a), while potentially benefiting the localised environment, for example, regarding water quality (Di and Cameron 2016). Risks include increased N₂O emission from the application

of manure to poorly drained or wet soils, trade-offs between N_2O and ammonia emissions and potential eco-toxicity associated with some measures.

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. The AR5 reported manure measures to have high (>10%) mitigation potential. The SRCCL estimated a technical global mitigation potential between 2020 and 2050 of 0.01–0.26 GtCO₂-eq yr⁻¹, with the range depending on economic and sustainable capacity (Dickie et al. 2014a; Herrero et al. 2016) (SRCCL, Chapter 2). Conversion of estimates to native units is restricted as a mixture of GWP100 values was used in underlying studies. Measures considered were typically more suited to confined production systems (Jia et al. 2019; Mbow et al. 2019), while improved manure management is included within IAM emission pathways (Rogelj et al. 2018b).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Research published since SRCCL broadly focuses on measures relevant to intensive or confined systems (e.g., (Hunt et al. 2019; Kavanagh et al. 2019; Sokolov et al. 2020; Im et al. 2020; Adghim et al. 2020; Mostafa et al. 2020), highlighting co-benefits and risks. For example, measures may enhance nutrient recovery, fertiliser value (Sefeedpari et al. 2019; Ba et al. 2020; Yao et al. 2020) and secondary processes such as biogas production (Shin et al. 2019). However, the potential antagonistic relationship between GHG and ammonia mitigation and need for appropriate management is emphasised (Aguirre-Villegas et al. 2019; Grossi et al. 2019; Kupper et al. 2020; Ba et al. 2020). In some circumstances, fugitive emissions may reduce the potential mitigation benefits of biogas production (Scheutz and Fredenslund 2019; Bakkaloglu et al. 2021), while high implementation cost is identified as an adoption barrier, notably of anaerobic digestion (Liu and Liu 2018; Niles and Wiltshire 2019; Ndambi et al. 2019; Ackrill and Abdo 2020; Adghim et al. 2020). Nitrification inhibitors have been found to be effective at reducing N_2O emissions from pasture deposited urine (López-Aizpún et al. 2020), although the use of nitrification inhibitors is

restricted in some jurisdictions due to concerns regarding residues in food products (Di and Cameron 2016; Eckard and Clark 2020) while *limited evidence* suggests eco-toxicity risk under certain circumstances (Kösler et al. 2019). Some forage crops may naturally contain inhibitory substances (Simon et al. 2019, 2020; de Klein et al. 2020), though this warrants further research (Podolyan et al. 2020; Gardiner et al. 2020).

Country specific studies provide insight into regionally applicable measures, with emphasis on small-scale anaerobic digestion (e.g., dome digesters), solid manure coverage and daily manure spreading in Asia and the Pacific, and Africa (Hasegawa and Matsuoka 2012; Hoa et al. 2014; Jilani et al. 2015; Hasegawa et al. 2016; Pradhan et al. 2017; Ericksen and Crane 2018; Pradhan et al. 2019; Kiggundu et al. 2019; Dioha and Kumar 2020). Tank/lagoon covers, large-scale anaerobic digestion, improved application timing, nitrogen inhibitor application to urine patches, soil-liquid separation, reduced livestock nitrogen intake, trailing shoe, band or injection slurry spreading and acidification are emphasised in Developed Countries (Kaparaju and Rintala 2011; Eory et al. 2015; Pape et al. 2016; Jayasundara et al. 2016; Pellerin et al. 2017; Liu and Liu 2018; Lanigan et al. 2018; Carroll and Daigneault 2019; Eckard and Clark 2020). Using IPCC AR4 GWP100 values for CH₄ and N₂O, a recent assessment finds 69% (63.4 MtCO₂-eq yr⁻¹) of economic potential (up to USD100 tCO₂-eq⁻¹) between 2020–2050, to be in Developed Countries (Roe et al. 2021).

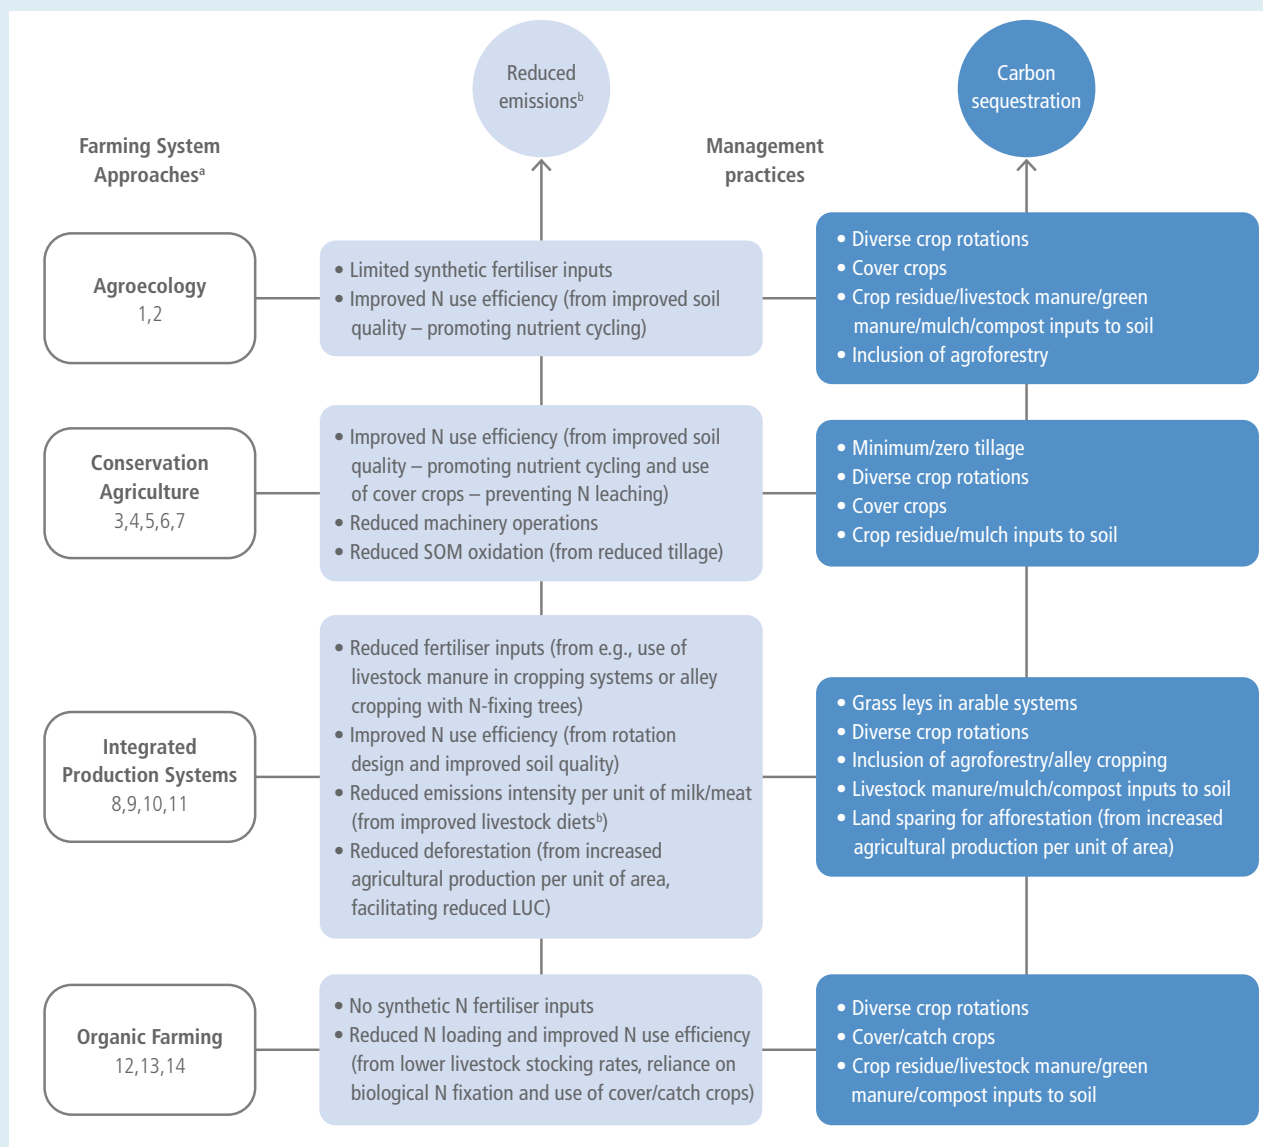

Critical assessment and conclusion. There is *medium confidence* that manure management measures have a global technical potential of 0.3 (0.1–0.5) GtCO₂-eq yr⁻¹, (using a range of IPCC GWP100 values for CH₄ and N₂O), of which 0.1 (0.09–0.1) GtCO₂-eq yr⁻¹ is available at up to USD100 tCO₂-eq⁻¹ (Figure 7.11). As with other non-CO₂ GHG mitigation estimates, values may slightly differ depending upon which IPCC GWP100 values were used. There is *robust evidence* and *high agreement* that there are measures that can be applied in all regions, but greatest mitigation potential is estimated in Developed Countries in more intensive and confined production systems.

Box 7.5 | Farming System Approaches and Mitigation

Introduction

There is *robust evidence* and *high agreement* that agriculture needs to change to facilitate environment conservation while maintaining and where appropriate, increase overall production. The SRCCL identified several farming system approaches, deemed alternative to conventional systems (Olsson et al. 2019; Mbow et al. 2019; L.G. Smith et al. 2019). These may incorporate several of the mitigation measures described in Section 7.4.3, while potentially also delivering environmental co-benefits. This Box assesses evidence specifically on the mitigation capacity of some such system approaches. The approaches are not mutually exclusive, may share similar principles or practices and can be complimentary. In all cases, mitigation may result from either (i) emission reductions or (ii) enhanced carbon sequestration, via combinations of management practices as outlined in Figure 1 within this Box. The approaches will have pros and cons concerning multiple factors, including mitigation, yield and co-benefits, with trade-offs subject to the diverse contexts and ways in which they are implemented.

Box 7.5 (continued)

Box 7.5, Figure 1 | Potential mitigation mechanisms and associated management practices. N = nitrogen, SOM = soil organic matter, LUC = land-use change. ^a The farming system approaches outlined are not necessarily mutually exclusive. ^b Only agricultural emissions are considered. Mitigation may also result from reduced production of fertilisers and agrochemicals. ^c Reduced emissions intensity per unit of milk/meat will only result in a reduction in absolute emissions where increased productivity facilitates a reduction in animal numbers. 1 = Altieri et al. 2015; 2 = Altieri and Nicholls 2017; 3 = Powlson et al. 2016; 4 = Corbeels et al. 2019; 5 = Lal 2015; 6 = Gonzalez-Sanchez et al. 2019; 7 = Thierfelder et al. 2017; 8 = Hendrickson et al. 2008; 9 = Weindl et al. 2015; 10 = Thornton and Herrero 2015; 11 = Lal al. 2020; 12 = Scialabba and Müller-Lindenlauf 2010; 13 = Goh 2011; 14 = IFOAM 2016.

Box 7.5 (continued)

Is there evidence that these approaches deliver mitigation?*Agroecology (AE) including Regenerative Agriculture (RA)*

There is limited discussion on the mitigation potential of AE (Gliessman 2013; Altieri and Nicholls 2017), but *robust evidence* that AE can improve system resilience and bring multiple co-benefits (Altieri et al. 2015; Mbow et al. 2019; Aguilera et al. 2020; Tittone 2020; Wanger et al. 2020) (AR6 WGII Box 5.10). *Limited evidence* concerning the mitigation capacity of AE at a system level (Saj et al. 2017; Snapp et al. 2021) makes conclusions difficult, yet studies into specific practices that may be incorporated, suggest AE may have mitigation potential (*medium confidence*) (Section 7.4.3). However, AE, that incorporates management practices used in organic farming (see below), may result in reduced yields, driving compensatory agricultural production elsewhere. Research into GHG mitigation by AE as a system and impacts of wide-scale implementation is required. Despite absence of a universally accepted definition (see Annex I), RA is gaining increasing attention and shares principles of AE. Some descriptions include carbon sequestration as a specific aim (Elevitch et al. 2018). Few studies have assessed mitigation potential of RA at a system level (e.g., Colley et al. 2020). Like AE, it is *likely* that RA can contribute to mitigation, the extent to which is currently unclear and by its case-specific design, will vary (*medium confidence*).

Conservation agriculture (CA)

The SRCCL noted both positive and inconclusive results regarding CA and soil carbon, with sustained sequestration dependent on productivity and residue returns (Jia et al. 2019; Mirzabaev et al. 2019; Mbow et al. 2019). Recent research is in broad agreement (Ogle et al. 2019; Corbeels et al. 2020, 2019; Gonzalez-Sanchez et al. 2019; Munkholm et al. 2020) with greatest mitigation potential suggested in dry regions (Sun et al. 2020). Theoretically, CA may facilitate improved nitrogen use efficiency (*limited evidence*) (Lal 2015; Powlson et al. 2016), though CA appears to have mixed effects on soil N₂O emission (Six et al. 2004; Mei et al. 2018). CA is noted for its adaptation benefits, with *wide agreement* that CA can enhance system resilience to climate related stress, notably in dry regions. There is evidence that CA can contribute to mitigation, but its contribution is depended on multiple factors including climate and residue returns (*high confidence*).

Integrated production systems (IPS)

The integration of different enterprises in space and time (e.g., diversified cropping, crop and livestock production, agroforestry), therefore facilitating interaction and transfer of resources between systems, is suggested to enhance sustainability and adaptive capacity (Hendrickson et al. 2008; Franzluebbers et al. 2014; Lemaire et al. 2014; Weindl et al. 2015; Gil et al. 2017; Olsson et al. 2019; Peterson et al. 2020; Walkup et al. 2020; Garrett et al. 2020). Research indicates some mitigation potential, including by facilitating sustainable intensification (Box 7.11), though benefits are likely to be highly context specific (Herrero et al. 2013; Carvalho et al. 2014; Piva et al. 2014; de Figueiredo et al. 2017; Rosenstock et al. 2014; Weindl et al. 2015; Thornton and Herrero 2015; Descheemaeker et al. 2016; Lal 2020; Guenet et al. 2021). The other systems outlined within this Box may form or facilitate IPS.

Organic farming (OF)

OF can be considered a form of AE (Lampkin et al. 2017) though it is discussed separately here as it is guided by specific principles and associated regulations (Annex I). OF is perhaps noted more for potential co-benefits, such as enhanced system resilience and biodiversity promotion, than mitigation. Several studies have reviewed the emissions footprint of organic compared to conventional systems (Mondelaers et al. 2009; Tuomisto et al. 2012; Skinner et al. 2014; Meier et al. 2015; Seufert and Ramankutty 2017; Clark and Tilman 2017; Meemken and Qaim 2018; Bellassen et al. 2021). Acknowledging potential assessment limitations (Meier et al. 2015; van der Werf et al. 2020), evidence suggests organic production to typically generate lower emissions per unit of area, while emissions per unit of product vary and depend on the product (*high agreement, medium evidence*). OF has been suggested to increase soil carbon sequestration (Gattinger et al. 2012), though definitive conclusions are challenging (Leifeld et al. 2013). Fewer studies consider impacts of large-scale conversion from conventional to organic production globally. Though context specific (Seufert and Ramankutty 2017), OF is reported to typically generate lower yields (Seufert et al. 2012; De Ponti et al. 2012; Kirchmann 2019; Biernat et al. 2020). Large-scale conversion, without fundamental changes in food systems and diets (Muller et al. 2017; Theurl et al. 2020), may lead to increases in absolute emissions from land-use change, driven by greater land requirements to maintain production (L.G. Smith et al. 2019; Leifeld 2016; Meemken and Qaim 2018).

Box 7.6 | Case Study: Mitigation Options and Costs in the Indian Agricultural Sector

Objective

To assess the technical mitigation potentials of Indian agriculture and costs under a business as usual scenario (BAU) and Mitigation scenario up to 2030 (Sapkota et al. 2019).

Results

The study shows that by 2030 under BAU scenario GHG emissions from the agricultural sector in India would be 515 MtCO₂-eq yr⁻¹ (using GWP100 and IPCC AR4 values) with a technical mitigation potential of 85.5 MtCO₂-eq yr⁻¹ through the adoption of various mitigation practices. About 80% of the technical mitigation potential could be achieved by adopting cost-saving measures. Three mitigation options, for example, efficient use of fertiliser, zero-tillage, and rice-water management, could deliver more than 50% of the total technical abatement potential. Under the BAU scenario the projected GHG emissions from major crop and livestock species is estimated at 489 MtCO₂-eq in 2030, whereas under mitigation scenario GHG emissions are estimated at 410 MtCO₂-eq implying a technical mitigation option of about 78.67 MtCO₂-eq yr⁻¹ (Box 7.6, Figure 1). Major sources of projected emissions under the BAU scenario, in order of importance, were cattle, rice, buffalo, and small ruminants. Although livestock production and rice cultivation account for a major share of agricultural emissions, the highest mitigation potential was observed in rice (about 36 MtCO₂-eq yr⁻¹) followed by buffalo (about 14 MtCO₂-eq yr⁻¹), wheat (about 11 MtCO₂-eq yr⁻¹) and cattle (about 7 MtCO₂-eq yr⁻¹). Crops such as cotton and sugarcane each offered mitigation potential of about 5 MtCO₂-eq yr⁻¹ while the mitigation potential from small ruminants (goat/sheep) was about 2 MtCO₂-eq yr⁻¹.

Sapkota et al. (2019) also estimated the magnitude of GHG savings per year through adoption of various mitigation measures, together with the total cost and net cost per unit of CO₂-eq abated. When the additional benefits of increased yield due to adoption of the mitigation measures were considered, about 80% of the technical mitigation potential (67.5 out of 85.5 MtCO₂-eq) could be achieved by cost-saving measures. When yield benefits were considered, green fodder supplements to ruminant diets were the most cost-effective mitigation measure, followed by vermicomposting and improved diet management of small ruminants. Mitigation measures such as fertigation and micro-irrigation, various methods of restoring degraded land and feed additives in livestock appear to be cost-prohibitive, even when considering yield benefits, if any. The study accounted for GHG emissions at the farm level and excluded emissions arising due to processing, marketing or consumption post farm-gate. It also did not include emissions from feed production, since livestock in India mostly rely on crop by-products and concentrates. Further the potential of laser land levelling seems exaggerated which may also be redundant with already accounted potential from 'improved water management in rice'. The mitigation potential of agroecological approaches/technologies such as natural farming which is picking up in India in recent years has also been overlooked.

Box 7.6, Figure 1 | Contribution of various crops and livestock species to total agricultural emission in 2012 (baseline) and by 2030 under business as usual (BAU) and mitigation scenarios for Indian agricultural sector. 7.4.4 Bioenergy and BECCS

Activities, co-benefits, risks and implementation opportunities and barriers. Bioenergy refers to energy products (solid, liquid and gaseous fuels, electricity, heat) derived from multiple biomass sources including organic waste, harvest residues and by-flows in the agriculture and forestry sectors, and biomass from tree plantations, agroforestry systems, lignocellulosic crops, and conventional food/feed crops. It may reduce net GHG emissions by displacing the use of coal, oil and natural gas with renewable biomass in the production of heat, electricity, and fuels. When

combined with carbon capture and storage (BECCS) and biochar production, bioenergy systems may provide CDR by durably storing biogenic carbon in geological, terrestrial, or ocean reservoirs, or in products, further contributing to mitigation (Chum et al. 2011; Cabral et al. 2019; Hammar and Levihn 2020; Emenike et al. 2020; Moreira et al. 2020b; Y. Wang et al. 2020; Johnsson et al. 2020) (Section 7.4.3.2, Chapters 3, 4, 6 and 12).

This section addresses especially aspects related to land use and biomass supply for bioenergy and BECCS. The mitigation potential presented here and in Table 7.3, includes only the CDR component of

BECCS. The additional mitigation achieved from displacing fossil fuels is covered elsewhere (Chapters 6, 8, 9, 10, 11 and 12).

Modern bioenergy systems (as opposed to traditional use of fuelwood and other low-quality cooking and heating fuels) currently provide approximately 30 EJ yr⁻¹ of primary energy, making up 53% of total renewable primary energy supply (IEA 2019). Bioenergy systems are commonly integrated within forest and agriculture systems that produce food, feed, lumber, paper and other bio-based products. They can also be combined with other AFOLU mitigation options: deployment of energy crops, agroforestry and A/R can provide biomass while increasing land carbon stocks (Sections 7.4.2.2 and 7.4.3.3) and anaerobic digestion of manure and wastewater, to reduce methane emissions, can produce biogas and CO₂ for storage (Section 7.4.3.7). But ill-deployment of energy crops can also cause land carbon losses (Hanssen et al. 2020) and increased biomass demand for energy could hamper other mitigation measures such as reduced deforestation and degradation (Sections 7.4.2.1).

Bioenergy and BECCS can be associated with a range of co-benefits and adverse side effects (Smith et al. 2016; Jia et al. 2019; Calvin et al. 2021) (Section 12.5). It is difficult to disentangle bioenergy development from the overall development in the AFOLU sector given its multiple interactions with food, land, and energy systems. It is therefore not possible to precisely determine the scale of bioenergy and BECCS deployment at which negative impacts outweigh benefits. Important uncertainties include governance systems, future food and biomaterials demand, land-use practices, energy systems development, climate impacts, and time scale considered when weighing negative impacts against benefits (Robledo-Abad et al. 2017; Turner et al. 2018b; Daioglou et al. 2019; Wu et al. 2019; Kalt et al. 2020; Hanssen et al. 2020; Calvin et al. 2021; Cowie et al. 2021) (SRCCCL, Cross-Chapter Box 7; Box 7.7). The use of municipal organic waste, harvest residues, and biomass processing by-products as feedstock is commonly considered to have relatively lower risk, provided that associated land-use practices are sustainable (Cowie et al. 2021). Deployment of dedicated biomass production systems can have positive and negative implications on mitigation and other sustainability criteria, depending on location and previous land use, feedstock, management practice, deployment strategy and scale (Rulli et al. 2016; Popp et al. 2017; Daioglou et al. 2017; Staples et al. 2017; Carvalho et al. 2017; Humpenöder et al. 2018; Fujimori et al. 2019; Hasegawa et al. 2020; Drews et al. 2020; Schulze et al. 2020; Stenzel et al. 2020; Mouratiadou et al. 2020; Buchspies et al. 2020; Hanssen et al. 2020, IPBES 2019b) (Sections 12.5 and 17.3.3.1).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. Many more stringent mitigation scenarios in AR5 relied heavily on bioenergy and BECCS. The SR1.5 reported a range for the CDR potential of BECCS (2100) at 0.5 to 5 GtCO₂-eq yr⁻¹ when applying constraints reflecting sustainability concerns, at a cost of 100–200 USD tCO₂⁻¹ (Fuss et al. 2018). The SRCCL reported a technical CDR potential for BECCS at 0.4–11.3 GtCO₂ yr⁻¹ (*medium confidence*), noting that most estimates do not include socio-economic barriers, the impacts of future climate change, or non-GHG climate forcing (IPCC. 2019). The SR1.5 and SRCCL highlighted that bioenergy and BECCS can be

associated with multiple co-benefits and adverse side effects that are context specific.

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). The role of bioenergy and BECCS in mitigation pathways has been reduced as IAM-based studies have incorporated broader mitigation portfolios and have explored non-CO₂ emissions reduction and a wider variation of underlying assumptions about socio-economic drivers and associated energy and food demand, as well as deployment limits such as land availability for A/R and for cultivation of crops used for bioenergy and BECCS (Grubler et al. 2018; Van Vuuren et al. 2018).

Increased availability of spatially explicit data and advances in the modelling of crop productivity and land use, land carbon stocks, hydrology, and ecosystem properties, have enabled more comprehensive analyses of factors that influence the contribution of bioenergy and BECCS in IAM-based mitigation scenarios, and also associated co-benefits and adverse side effects (Turner et al. 2018a; Wu et al. 2019; Li et al. 2020; Hanssen et al. 2020; Drews et al. 2020; Ai et al. 2021; Hasegawa et al. 2021). Yet, IAMs are still coarse in local land-use practices. (Daioglou et al. 2019; Wu et al. 2019; Moreira et al. 2020b). Literature complementary to IAM studies indicate opportunities for integration of biomass production systems into agricultural landscapes (e.g., agroforestry, double cropping) to produce biomass while achieving co-benefits (Section 12.5). Similarly, climate-smart forestry puts forward measures (Box 7.3) adapted to regional circumstances in forest sectors, enabling co-benefits in nature conservation, soil protection, employment and income generation, and provision of wood for buildings, bioenergy and other bio-based products (Nabuurs et al. 2017).

Studies have also investigated the extent and possible use of marginal, abandoned, and degraded lands, and approaches to help restore the productive value of these lands (Awasthi et al. 2017; Fritsche et al. 2017; Chiaramonti and Panoutsou, 2018; Fernando et al. 2018; Elbersen et al. 2019; Rahman et al. 2019; Næss et al. 2021). In the SRCCL, the presented range for degraded or abandoned land was 32–1400 Mha (Jia et al. 2019). Recent regional assessments not included in the SRCCL found up to 69 Mha in EU-28, 185 Mha in China, 9.5 Mha in Canada, and 127 Mha in the USA (Emery et al. 2017; Liu et al. 2017; Elbersen et al. 2019; Zhang et al. 2020; Vera et al. 2021). The definitions of marginal/abandoned/degraded land, and the methods used to assess such lands remain inconsistent across studies (Jiang et al. 2019), causing large variation amongst them (Jiang et al. 2021). Furthermore, the availability of such lands has been contested since they may serve other functions, such as: subsistence, biodiversity protection, and so on (Baka 2014).

Box 7.7 | Climate Change Mitigation Value of Bioenergy and BECCS

Besides emissions, and possible avoided emissions, related to the supply chain, the GHG effects of using bioenergy depend on: (i) change in GHG emissions when bioenergy substitutes another energy source; and (ii) how the associated land use and possible land-use change influence the amount of carbon that is stored in vegetation and (Calvin et al. 2021) soils over time. Studies arrive at varying mitigation potentials for bioenergy and BECCS due to the large diversity of bioenergy systems, and varying conditions concerning where and how they are deployed (Elshout 2015; Harper et al. 2018; Muri 2018; Kalt et al. 2019; Brandão et al. 2019; Buchspies et al. 2020; Cowie et al. 2021; Calvin et al. 2021). Important factors include feedstock type, land management practice, energy conversion efficiency, type of bioenergy product (and possible co-products), emissions intensity of the products being displaced, and the land use/cover prior to bioenergy deployment (Zhu et al. 2017; Staples et al. 2017; Daioglou et al. 2017; Carvalho et al. 2017; Hanssen et al. 2020; Mouratiadou et al. 2020). Studies arrive at contrasting conclusions also when similar bioenergy systems and conditions are analysed, due to different methodologies, assumptions, and parametrization (Harper et al. 2018; Kalt et al. 2019; Brandão et al. 2019; Albers et al. 2019; Buchspies et al. 2020; Bessou et al. 2020; Rolls and Forster 2020; Cowie et al. 2021).

Box 7.7, Figure 1 shows emissions associated with biomass supply (residues and crops grown on cropland not needed for food) in 2050, here designated emission-supply curves. The curves are constructed assuming that additional biomass supply consistently comes from the available land/biomass resource that has the lowest GHG emissions, for example, the marginal GHG emissions increase with increasing biomass use for bioenergy. Net negative emissions indicate cases where biomass production increases land carbon stocks.

Box 7.7, Figure 1 | Emissions associated with primary biomass supply in 2050 (residues and crops grown on cropland not needed for food), as determined from sectoral models (Daioglou et al. 2017; Kalt et al. 2020), and stylised scenarios from the EMF-33 project using Integrated Assessment Models (Rose et al. 2020). All methods include LUC (direct and indirect) emissions. Emissions associated with *Natural Regrowth* include counterfactual carbon fluxes (see text). The sectoral models include a more detailed representation of the emissions, including lifecycle emissions from fertiliser production. IAM models may include economic feedbacks such as intensification as a result of increasing prices. As an indication: for natural gas the emission factor is around 56, for coal around 95 kgCO₂ GJ⁻¹.

Box 7.7 (continued)

One curve (*EMF-33*) is determined from stylised scenarios using IAMs (Rose et al. 2020). One of the two curves determined from sectoral models, *Constant Land Cover*, reflects supply chain emissions and changes in land carbon storage caused by the biomass supply system itself. These two curves are obtained with modelling approaches compatible with the modelling protocol used for the scenarios in the AR6 database, which accounts for the land-use change and all other GHG emissions along a given transformation trajectory, enabling assessments of the warming level incurred.

The *Natural Regrowth* curve attribute additional 'counterfactual emissions' to the bioenergy system, corresponding to estimated uptake of CO₂ in a counterfactual scenario where land is not used for bioenergy but instead subject to natural vegetation regrowth. This curve does not show actual emissions from the bioenergy system, but it provides insights in the mitigation value of the bioenergy option compared to alternative land-use strategies. To illustrate, if biomass is used instead of a primary energy source with emission factor 75 kgCO₂ GJ⁻¹, and the median values in the *Natural Regrowth* curve are adopted, then the curve indicates that up to about 150 EJ of biomass can be produced and used for energy while achieving higher net GHG savings than the alternative to set aside the same land for natural vegetation regrowth (assuming same conversion factor).

The large ranges in the bars signify the importance of uncertainties and how the biomass is deployed. Variation in energy conversion efficiencies and uncertainty about magnitude, timing, and permanence of land carbon storage further complicate the comparison. Finally, not shown in Box 7.7, Figure 1, the emission-supply curves would be adjusted downwards if displacement of emission intensive energy was included or if the bioenergy is combined with CCS to provide CDR.

Critical assessment and conclusion. Recent estimates of technical biomass potentials constrained by food security and environmental considerations fall within previous ranges corresponding to *medium agreement*, (e.g., Turner et al. 2018b; Daioglou et al. 2019; Wu et al. 2019; Hansen et al. 2020; Kalt et al. 2020) arriving at 4–57 and 46–245 EJ yr⁻¹ by 2050 for residues and dedicated biomass crops, respectively. Based on studies to date, the technical net CDR potential of BECCS (including LUC and other supply chain emissions, but excluding energy carrier substitution) by 2050 is 5.9 (0.5–11.3) GtCO₂ yr⁻¹ globally, of which 1.6 (0.5–3.5) GtCO₂ yr⁻¹ is available at below USD100 tCO₂⁻¹ (*medium confidence*) (Lenton 2010; Koornneef et al. 2012; McLaren 2012; Powell and Lenton 2012; Fuss et al. 2018; Turner et al. 2018a; Hanssen et al. 2020; Roe et al. 2021) (Figure 7.11). The equivalent economic potential as derived from IAMs is 1.8 (0.2–9.9) GtCO₂ yr⁻¹ (Table 7.3).

Technical land availability does not imply that dedicated biomass production for bioenergy and BECCS is the most effective use of this land for mitigation. Further, implications of deployment for climate change mitigation and other sustainability criteria are context dependent and influenced by many factors, including rate and total scale. While governance has a critical influence on outcome, larger scale and higher expansion rate generally translates into higher risk for negative outcomes for GHG emissions, biodiversity, food security and a range of other sustainability criteria (Searchinger 2017; Vaughan et al. 2018; Rochedo et al. 2018; de Oliveira Garcia et al. 2018; Daioglou et al. 2019; Junginger et al. 2019; Galik et al. 2020; Stenzel et al. 2020).

However, literature has also highlighted how the agriculture and forestry sectors may respond to increasing demand by devising management approaches that enable biomass production for energy in conjunction with supply of food, construction timber, and other bio-

based products, providing climate change mitigation while enabling multiple co-benefits including for nature conservation (Nabuurs et al. 2017; Parodi et al. 2018; Springmann et al. 2018; Rosenzweig et al. 2020; Clark et al. 2020; Favero et al. 2020; Hanssen et al. 2020) (Section 7.4 and Cross-Working Group Box 3 in Chapter 12).

Strategies to enhance the benefits of bioenergy and BECCS include (i) management practices that protect carbon stocks and the productive and adaptive capacity of lands, as well as their environmental and social functions (van Ittersum et al. 2013, Gerssen-Gondelach et al. 2015; Moreira et al. 2020b) (ii) supply chains from primary production to final consumption that are well managed and deployed at appropriate levels (Fajardy et al. 2018; Donnison et al. 2020); and (iii) development of a cross-sectoral agenda for bio-based production within a circular economy, and international cooperation and governance of global trade in products to maximise synergies while limiting trade-offs concerning environmental, economic and social outcomes (*very high confidence*). Finally, the technical feasibility of BECCS depends on investments in and the roll-out of advanced bioenergy technologies currently not widely available (Baker et al. 2015; Daioglou et al. 2020b).

7.4.5 Demand-side Measures

7.4.5.1 Shift to Sustainable Healthy Diets

Activities, co-benefits, risks and implementation opportunities and barriers. The term 'sustainable healthy diets' refers to dietary patterns that 'promote all dimensions of individuals' health and well-being; have low environmental pressure and impact; are accessible, affordable, safe and equitable; and are culturally acceptable' (FAO and WHO 2019). In addition to climate mitigation gains,

a transition towards more plant-based consumption and reduced consumption of animal-based foods, particularly from ruminant animals, could reduce pressure on forests and land used for feed, support the preservation of biodiversity and planetary health (FAO 2018c; Theurl et al. 2020), and contribute to preventing forms of malnutrition (i.e., undernutrition, micronutrient deficiency, and obesity) in developing countries (Section 12.4). Other co-benefits include lowering the risk of cardiovascular disease, type 2 diabetes, and reducing mortality from diet-related non-communicable diseases (Toumpanakis et al. 2018; Satija and Hu 2018; Faber et al. 2020; Magkos et al. 2020). However, transition towards sustainable healthy diets could have adverse impacts on the economic stability of the agricultural sector (MacDiarmid 2013; Aschemann-Witzel 2015; Van Loo et al. 2017). Therefore, shifting toward sustainable and healthy diets requires effective food-system oriented reform policies that integrate agriculture, health, and environment policies to comprehensively address synergies and conflicts in co-lateral sectors (agriculture, trade, health, environment protection etc.) and capture spill-over effects, for example, climate change, biodiversity loss, food poverty (FAO and WHO 2019; Galli et al. 2020).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL); mitigation potential, costs, and pathways. According to the AR5, changes in human diets and consumption patterns can reduce emissions 5.3 to 20.2 GtCO₂-eq yr⁻¹ by 2050 from diverted agricultural production and avoided land-use change (Smith et al. 2014). In the SRCCL, a ‘contract and converge’ model of transition to sustainable healthy diets was suggested as an effective approach, reducing food consumption in over-consuming populations and increasing consumption of some food groups in populations where minimum nutritional needs are not met (P. Smith et al. 2019a). The total technical mitigation potential of changes in human diets was estimated as 0.7–8 GtCO₂-eq yr⁻¹ by 2050 (Tilman and Clark 2014; Springmann et al. 2016; Hawken 2017) (SRCCL, Chapter 2 and 6), ranging from a 50% adoption of healthy diets (<60g of animal-based protein) and only accounting for diverted agricultural production, to the global adoption of a vegetarian diet.

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCCL). Since the SRCCL, global studies continue to find high mitigation potential from reducing animal-source foods and increasing proportions of plant-rich foods in diets. Springmann et al. (2018) estimated that diet changes in line with global dietary guidelines for total energy intake and consumption of red meat, sugar, fruits, and vegetables, could reduce GHG emissions by 29% and other environmental impacts by 5–9% compared with the baseline in 2050. Poore and Nemecek (2018) revealed that shifting towards diets that exclude animal-source food could reduce land use by 3.1 billion ha, decrease food-related GHG emissions by 6.5 GtCO₂-eq yr⁻¹, acidification by 50%, eutrophication by 49%, and freshwater withdrawals by 19% for a 2010 reference year. Frank et al. (2019) estimated non-CO₂ emissions reductions of 0.4 GtCO₂-eq yr⁻¹ at a carbon price of USD100 tCO₂⁻¹ and 0.6 GtCO₂-eq yr⁻¹ at USD20 tCO₂⁻¹ in 2050 from shifting to lower animal-source diets (430 kcal of livestock calorie intake) in developed and emerging countries. From a systematic literature review, Ivanova et al. (2020) found mitigation potentials of 0.4–2.1 tCO₂-eq capita⁻¹

for a vegan diet, of 0.01–1.5 for a vegetarian diet, and of 0.1–2.0 for Mediterranean or similar healthy diet.

Regionally, mitigation potentials for shifting towards sustainable healthy diets (50% convergence to <60g of meat-based protein, only accounting for diverted production) vary across regions. A recent assessment finds greatest economic (up to USD100 tCO₂⁻¹) potential for 2020–2050 in Asia and the Pacific (609 MtCO₂-eq yr⁻¹) followed by Developed Countries (322 MtCO₂-eq yr⁻¹) based on IPCC AR4 GWP100 values for CH₄ and N₂O (Roe et al. 2021). In the EU, (Latka et al. 2021) found that moving to healthy diets through price incentives could bring about annual reductions of non-CO₂ emissions from agriculture of 12–111 MtCO₂-eq yr⁻¹. At the country level, recent studies show that following National Dietary Guidelines (NDG) would reduce food system GHG emissions by 4–42%, confer large health gains (1.0–1.5 million quality-adjusted life-years) and lower health care system costs (NZD 14–20 billion) in New Zealand Drew et al. (2020); reduce 28% of GHG emissions in Argentina Arrieta and González (2018); about 25% in Portugal Esteve-Llorens et al. (2020) and reduce GHG emissions, land use and blue water footprint by 15–60% in Spain (Batlle-Bayer et al. 2020). In contrast, Aleksandrowicz et al. (2019) found that meeting healthy dietary guidelines in India required increased dietary energy intake overall, which slightly increased environmental footprints by about 3–5% across GHG emissions, blue and green water footprints and land use.

Critical assessment and conclusion. Shifting to sustainable healthy diets has large potential to achieve global GHG mitigation targets as well as public health and environmental benefits (*high confidence*). Based on studies to date, there is *medium confidence* that shifting toward sustainable healthy diets has a technical potential including savings in the full value chain of 3.6 (0.3–8.0) GtCO₂-eq yr⁻¹ of which 2.5 (1.5–3.9) GtCO₂-eq yr⁻¹ is considered plausible based on a range of GWP100 values for CH₄ and N₂O. When accounting for diverted agricultural production only, the feasible potential is 1.7 (1–2.7) GtCO₂-eq yr⁻¹. A shift to more sustainable and healthy diets is generally feasible in many regions (*medium confidence*). However, potential varies across regions as diets are location- and community- specific, and thus may be influenced by local production practices, technical and financial barriers and associated livelihoods, everyday life and behavioural and cultural norms around food consumption (Meybeck and Gitz 2017; Creutzig et al. 2018; FAO 2018b). Therefore, a transition towards low-GHG emission diets and achieving their mitigation potential requires a combination of appropriate policies, financial and non-financial incentives and awareness-raising campaigns to induce changes in consumer behaviour with potential synergies between climate objectives, health and equity (Rust et al. 2020).

7.4.5.2 Reduce Food Loss and Waste

Activities, co-benefits, risks and implementation opportunities and barriers. Food loss and waste (FLW) refer to the edible parts of plants and animals produced for human consumption that are not ultimately consumed (UNEP 2021b). Food loss occurs through spoilage, spilling or other unintended consequences due to limitations in agricultural infrastructure, storage and packaging (Parfitt et al.

2010). Food waste typically takes place at the distribution (retail and food service) and consumption stages in the food supply chain and refers to food appropriate for human consumption that is discarded or left to spoil (HLPE 2014). Options that could reduce FLW include: investing in harvesting and post-harvesting technologies in developing countries, taxing and other incentives to reduce business and consumer-level waste in developed countries, mandatory FLW reporting and reduction targets for large food businesses, regulation of unfair trading practices, and active marketing of cosmetically imperfect products (van Giesen and de Hooge 2019; Sinclair Taylor et al. 2019). Other studies suggested providing options of longer-lasting products and behavioural changes (e.g., through information provision) that cause dietary and consumption changes and motivate consumers to actively make decisions that reduce FLW. Reductions of FLW along the food chain bring a range of benefits beyond GHG mitigation, including reducing environmental stress (e.g., water and land competition, land degradation, desertification), safeguarding food security, and reducing poverty (Galford et al. 2020; Venkatramanan et al. 2020). Additionally, FLW reduction is crucial for achieving SDG 12 which calls for ensuring 'sustainable consumption and production patterns' through lowering per capita global food waste by 50% at the retail and consumer level and reducing food losses along food supply chains by 2030. In line with these SDG targets, it is estimated that reducing FLW can free up several million km² of land (*high confidence*). The interlinkages between reducing FLW and food system sustainability are discussed in Chapter 12. Recent literature identifies a range of barriers to climate change mitigation through FLW reduction, which are linked to technological, biophysical, socio-economic, financial and cultural contexts at regional and local levels (Vogel and Meyer 2018; Gromko and Abdurasalova 2019; Rogissart et al. 2019; Blok et al. 2020). Examples of these barriers include infrastructural and capacity limitations, institutional regulations, financial resources, constraining resources (e.g., energy), information gaps (e.g., with retailers), and consumers' behaviour (Gromko and Abdurasalova 2019; Blok et al. 2020).

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCLL); mitigation potential, costs, and pathways. In AR5, reduced FLW was considered as a mitigation measure that could substantially lower emissions, with estimated mitigation potential of 0.6–6.0 GtCO₂-eq yr⁻¹ in the food supply chain (Smith et al. 2014). In the SRCLL, the technical mitigation potential of reducing food and agricultural waste was estimated at 0.76–4.5 GtCO₂-eq yr⁻¹ (Bajželj et al. 2014; Dickie et al. 2014b; Hawken 2017) (SRCLL, Chapter 2 and 6).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCLL). Since the SRCLL, there have been very few quantitative estimates of the mitigation potential of FLW reductions. Evidence suggests that reducing FLW together with overall food intake could have substantial mitigation potential, equating to an average of 0.3 tCO₂-eq capita⁻¹ (Ivanova et al. 2020). Some regional sectoral studies indicate that reducing FLW in the EU can reduce emissions by 186 MtCO₂-eq yr⁻¹, the equivalent of around 15% of the environmental impacts (climate, acidification, and eutrophication) of the entire food value chain (Scherhauser et al. 2018). In the UK, disruptive low-carbon innovations relating to FLW reduction were

found to be associated with potential emissions reductions ranging between 2.6 and 3.6 MtCO₂-eq (Wilson et al. 2019). Other studies investigated the effect of tax mechanisms, such as 'pay as you throw' for household waste, on the mitigation potential of reducing FLW. Generally, these mechanisms are recognised as particularly effective in reducing the amount of waste and increasing the recycling rate of households (Carattini et al. 2018; Rogissart et al. 2019). Technological FLW mitigation opportunities exist throughout the food supply chain; post-harvest opportunities for FLW reductions are discussed in Chapter 12. Based on IPCC AR4 GWP100 values for CH₄ and N₂O, greatest economic mitigation potential (up to USD100 tCO₂⁻¹) for the period 2020–2050 from FLW reduction is estimated to be in Asia and Pacific (192.3 GtCO₂-eq yr⁻¹) followed by Developed Countries (101.6 GtCO₂-eq yr⁻¹) (Roe et al. 2021). These estimates reflect diverted agricultural production and do not capture potential from avoided land-use changes.

Critical assessment and conclusion. There is *medium confidence* that reduced FLW has large global technical mitigation potential of 2.1 (0.1–5.8) GtCO₂-eq yr⁻¹ including savings in the full value chain and using GWP100 and a range of IPCC values for CH₄ and N₂O. Potentials at 3.7 (2.2–5.1) GtCO₂-eq yr⁻¹ are considered plausible. When accounting for diverted agricultural production only, the feasible potential is 0.5 (0.0–0.9) GtCO₂-eq yr⁻¹. See the section above for the joint land-use effects of food related demand-side measures which increases three-fold when accounting for the land-use effects as well. But this would overlap with other measures and is therefore not additive. Regionally, FLW reduction is feasible anywhere but its potential needs to be understood in a wider and changing socio-cultural context that determines nutrition (*high confidence*).

7.4.5.3 Improved and Enhanced Use of Wood Products

Activities, co-benefits, risks and implementation opportunities and barriers. The use of wood products refers to the fate of harvested wood for material uses and includes two distinctly different components affecting the carbon cycle, including carbon storage in wood products and material substitution. When harvested wood is used for the manufacture of wood products, carbon remains stored in these products depending on their end use and lifetime. Carbon storage in wood products can be increased through enhancing the inflow of products in use, or effectively reducing the outflow of the products after use. This can be achieved through additional harvest under sustainable management (Pilli et al. 2015; Johnston and Radeloff 2019), changing the allocation of harvested wood to long-lived wood products or by increasing products' lifetime and increasing recycling (Brunet-Navarro et al. 2017; Jasinevičius et al. 2017; Xu et al. 2018; Xie et al. 2021). Material substitution involves the use of wood for building, textiles, or other applications instead of other materials (e.g., concrete or steel, which consume more energy to produce) to avoid or reduce emissions associated with the production, use and disposal of those products it replaces.

The benefits and risks of improved and enhanced use of wood products are closely linked to forest management. First of all, the enhanced use of wood products could potentially activate or lead to improved sustainable forest management that can mitigate

and adapt (Verkerk et al. 2020). Secondly, carbon storage in wood products and the potential for substitution effects can be increased by additional harvest, but with the risk of decreasing carbon storage in forest biomass when not done sustainably (P. Smith et al. 2019a). Conversely, reduced harvest may lead to gains in carbon storage in forest ecosystems locally, but these gains may be offset through international trade of forest products causing increased harvesting pressure or even degradation elsewhere (Kastner et al. 2011; Kallio et al. 2018; Pendrill et al. 2019b). There are also environmental impacts associated with the processing, manufacturing, use and disposal of wood products (Adhikari and Ozarska 2018; Baumgartner 2019). See Section 9.6.4 of this report for additional discussion on benefits and risks.

Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCC and SRCLL); mitigation potential, costs, and pathways. There is strong evidence at the product level that wood products from sustainably managed forests are associated with less greenhouse emissions in their production, use and disposal over their life-time compared to products made from emission-intensive and non-renewable materials. However, there is still limited understanding of the substitution effects at the level of markets, countries (Leskinen et al. 2018). The AR5 did not report on the mitigation potential of wood products. The SRCLL (Chapters 2 and 6) finds that some studies indicate significant mitigation potentials for material substitution, but concludes that the global, technical mitigation potential for material substitution for construction applications ranges from 0.25–1 GtCO₂-eq yr⁻¹ (*medium confidence*) (Miner 2010; McLaren 2012; Roe et al. 2019).

Developments since AR5 and IPCC Special Reports (SR1.5, SROCC and SRCLL). Since the SRCLL, several studies have examined the mitigation potential of the enhanced and improved use of wood products. A global forest sector modelling study (Johnston and Radeloff 2019) estimated that carbon storage in wood products represented a net carbon stock increase of 0.34 GtCO₂-eq yr⁻¹ globally in 2015 and which could provide an average mitigation potential (by increasing the HWP pool) of 0.33–0.41 GtCO₂-eq yr⁻¹ for the period 2020–2050, based on the future socio-economic development (SSP scenarios) and its effect on the production and consumption of wood products. Traded feedstock provided another 0.071 GtCO₂ yr⁻¹ of carbon storage in 2015 and 0.12 GtCO₂ yr⁻¹ by 2065. These potentials exclude the effect of material substitution. Another recent study estimated the global mitigation potential of mid-rise urban buildings designed with engineered wood products at 0.04–3.7 GtCO₂ yr⁻¹ (Churkina et al. 2020). Another study (Oliver et al. 2014) estimated that using wood to substitute for concrete and steel as building materials could provide a technical mitigation potential of 0.78–1.73 GtCO₂ yr⁻¹ achieved through carbon storage in wood products and through material and energy substitution.

The limited availability or absence of estimates of the future mitigation potential of improved use of wood products for many world regions represents an important knowledge gap, especially with regards to material substitution effects. At the product level, wood products are often associated with lower fossil-based emissions from production, use and disposal, compared to products made from emission-

intensive and non-renewable materials (Sathre and O'Connor 2010; Geng et al. 2017; Leskinen et al. 2018).

Critical assessment and conclusion. Based on studies to date, there is *strong evidence* and *medium agreement* that the improved use of wood products has a technical potential of 1.0 (0.04–3.7) GtCO₂-eq yr⁻¹ and economic potential of 0.4 (0.3–0.5) GtCO₂-eq yr⁻¹. There is *strong evidence* and *high agreement* at the product level that material substitution provides on average benefits for climate change mitigation as wood products are associated with less fossil-based GHG emissions over their lifetime compared to products made from emission-intensive and non-renewable materials. However, the evidence at the level of markets or countries is uncertain and fairly limited for many parts of the world. There is *medium confidence* that material substitution and carbon storage in wood products contribute to climate change mitigation when also the carbon balances of forest ecosystems are considered of sustainably managed large areas of forests in medium term. The total future mitigation potential will depend on the forest system considered, the type of wood products that are produced and substituted and the assumed production technologies and conversion efficiencies of these products.

7.5 AFOLU Integrated Models and Scenarios

This section assesses the literature and data available on potential future GHG dynamics in the AFOLU sector, the cost-effectiveness of different mitigation measures, and consequences of climate change mitigation pathways on land-use dynamics as well as relevant sustainable development indicators at the regional and global level based on global integrated models.

Land-based mitigation options interact and create various trade-offs, and thus need to be assessed together as well as with mitigation options in other sectors, and in combination with other sustainability goals (Popp et al. 2014; Obersteiner et al. 2016; Roe et al. 2019; Van Vuuren et al. 2019; Prudhomme et al. 2020; Streffler et al. 2021). The assessments of individual mitigation measures or sectoral estimates used to estimate mitigation potential in Section 7.4, when aggregated together, do not account for interactions and trade-offs. Integrative land-use models (ILMs) combine different land-based mitigation options and are partially included in Integrated Assessment Models (IAMs) which combine insights from various disciplines in a single framework and cover the largest sources of anthropogenic GHG emissions from different sectors. Over time, ILMs and IAMs have extended their system coverage (Johnson et al. 2019). However, the explicit modelling and analysis of integrated land-use systems is relatively new compared to other sectoral assessments such as the energy system (Jia et al. 2019). Consequently, ILMs as well as IAMs differ in their portfolio and representation of land-based mitigation options, the representation of sustainability goals other than climate action as well as the interplay with mitigation in other sectors (van Soest et al. 2019; Johnson et al. 2019). These structural differences have implications for the regional and global deployment of different mitigation options as well as their sustainability impacts.

As a consequence of the relative novelty of land-based mitigation assessment in ILMs and IAMs, the portfolio of land-based mitigation options does not cover the full option space as outlined in Section 7.4. The inclusion and detail of a specific mitigation measure differs across models. Land-based mitigation options are only partially included in ILM and IAM analyses, which mostly rely on afforestation/reforestation and bioenergy with CCS (BECCS). Most ILM and IAM scenarios are based on the Shared Socio-economic Pathways (SSPs) (Riahi et al. 2017), which is a set of contrasting future scenarios widely used in the research community such as in the CMIP6 exercise, the SRCCL and the IPBES global assessment. However, the coverage of land-based mitigation options in these scenarios is mostly limited to dietary changes, higher efficiency in food processing (especially in livestock production systems), reduction of food waste, increasing agricultural productivity, methane reductions in rice paddies, livestock and grazing management for reduced methane emissions from enteric fermentation, manure management, improvement of N-efficiency, international trade, first generation of biofuels, avoided deforestation, afforestation, bioenergy and BECCS (Popp et al. 2017; Van Meijl et al. 2018; Frank et al. 2019). Hence, there are mitigation options not being broadly included in integrated pathway modelling as soil carbon, forest management, agroforestry or wetland

management (Humpenöder et al. 2020) which have the potential to alter the contribution of land-based mitigation in terms of timing, potential and sustainability consequences (Frank et al. 2017).

7.5.1 Regional GHG Emissions and Land Dynamics

In most of the assessed mitigation pathways, the AFOLU sector is of great importance for climate change mitigation as it (i) turns from a source into a sink of atmospheric CO₂ due to large-scale afforestation and reforestation, (ii) provides high amounts of biomass for bioenergy with or without CCS and (iii), even under improved agricultural management, still causes residual non-CO₂ emissions from agricultural production and (iv) interplays with sustainability dimensions other than climate action (Popp et al. 2017; Rogelj et al. 2017; Van Vuuren et al. 2018; Frank et al. 2018; Hasegawa et al. 2018; van Soest et al. 2019). Regional AFOLU GHG emissions in scenarios with <4°C warming in 2100 (scenario category C7), as shown in Figure 7.13, are shaped by considerable CH₄ and N₂O emissions throughout 2050 and 2100, mainly from ASIA and AFRICA. CH₄ emissions from enteric fermentation are largely caused by ASIA, followed by AFRICA, while CH₄ emissions from paddy rice

Figure 7.13 | Land-based regional GHG emissions and removals in 2050 (top) and 2100 (bottom) for scenarios from the AR6 Database with <1.5°C (C1, C2), <2°C (C3, C4), <3°C (C5, C6) and <4°C (C7) global warming in 2100 (scenario type is indicated by colour). The categories shown include CH₄ emissions from enteric fermentation (EntF) and rice production (Rice), N₂O emissions from animal waste management (AWM) and fertilisation (Soil). The category CO₂ Land includes CO₂ emissions from land-use change as well as removals due to afforestation/reforestation. BECCS reflects the CO₂ emissions captured from bioenergy use and stored in geological deposits. The annual GHG emission data from various models and scenarios is converted to CO₂ equivalents using GWP factors of 27 for CH₄ and 273 for N₂O. The data is summarised in boxplots (Tukey style), which show the median (vertical line), the interquartile range (IQR box) and the range of values within 1.5 × interquartile range at either end of the box (horizontal lines) across all models and scenarios. The number of data points available for each emission category, scenario type, region and year is shown at the edge of each panel. Regional definitions: AFRICA = sub-Saharan Africa, ASIA = Asia, LAM = Latin America and Caribbean, MID_EAST = Middle East, OECD90+EU = OECD 90 and EU, REF = Reforming Economies of Eastern Europe and the Former Soviet Union.

Figure 7.14 | Regional change of major land cover types by 2050 (top) and 2100 (bottom) relative to 2020 for scenarios from the AR6 Database with <1.5°C (C1, C2), <2°C (C3, C4), <3°C (C5, C6) and <4°C (C7) global warming in 2100 (scenario type is indicated by colour). The data is summarised in boxplots (Tukey style), which show the median (vertical line), the interquartile range (IQR box) and the range of values within $1.5 \times \text{IQR}$ at either end of the box (horizontal lines) across all models and scenarios. The number of data points available for each land cover type, scenario type, region and year is shown at the right edge of each panel. Regional definitions: AFRICA = sub-Saharan Africa, ASIA = Asia, LAM = Latin America and Caribbean, MID_EAST = Middle East, OECD90+EU = OECD 90 and EU, REF = Reforming Economies of Eastern Europe and the Former Soviet Union.

production are almost exclusively caused by ASIA. N_2O emissions from animal waste management and soils are more equally distributed across region.

In most regions, CH_4 and N_2O emission are both lower in mitigation pathways that limit warming to 3°C (>50%) or lower (C1–C6) compared to scenarios with $<4^\circ\text{C}$ (Popp et al. 2017; Rogelj et al. 2018a). In particular, the reduction of CH_4 emissions from enteric fermentation in ASIA and AFRICA is profound. Land-related CO_2 emissions, which include emissions from deforestation as well as removals from afforestation, are slightly negative (i.e., AFOLU systems turn into a sink) in $<1.5^\circ\text{C}$, $<2^\circ\text{C}$ and $<3^\circ\text{C}$ mitigation pathways compared to $<4^\circ\text{C}$ scenarios. Carbon sequestration via BECCS is most prominent in ASIA, LAM, AFRICA and OECD90+EU, which are also the regions with the highest bioenergy area.

Figure 7.14 indicates that regional land-use dynamics in scenarios with $<4^\circ\text{C}$ warming in 2100 are characterised by rather static agricultural land (i.e., cropland and pasture) in ASIA, LAM, OECD90+EU and REF, and increasing agricultural land in AFRICA. Bioenergy area is relatively small in all regions. Agricultural land in AFRICA expands at the cost of forests and other natural land.

The overall land dynamics in $<1.5^\circ\text{C}$, $<2^\circ\text{C}$ and $<3^\circ\text{C}$ mitigation pathways are shaped by land-demanding mitigation options such as bioenergy and afforestation, in addition to the demand for other agricultural and forest commodities. Bioenergy production and afforestation take place largely in the (partly) tropical regions ASIA, LAM and AFRICA, but also in OECD90+EU. Land for dedicated second generation bioenergy crops and afforestation displace agricultural land for food production (cropland and pasture) and other natural land. For instance, in the $<1.5^\circ\text{C}$ mitigation pathway in ASIA, bioenergy and forest area together increased by about 2.1 million km^2 between 2020 and 2100, mostly at the cost of cropland and pasture (median values). Such large-scale transformations of land use have repercussions on biogeochemical cycles (e.g., fertiliser and water) but also on the economy (e.g., food prices) and potential socio-political conditions.

7.5.2 Marginal Abatement Costs According to Integrated Assessments

In this section, Integrated Assessment Model (IAM) results from the AR6 database are used to derive marginal abatement costs which indicate the economic mitigation potential for the different gases (N_2O , CH_4 , CO_2) related to the AFOLU sector, at the global level and at

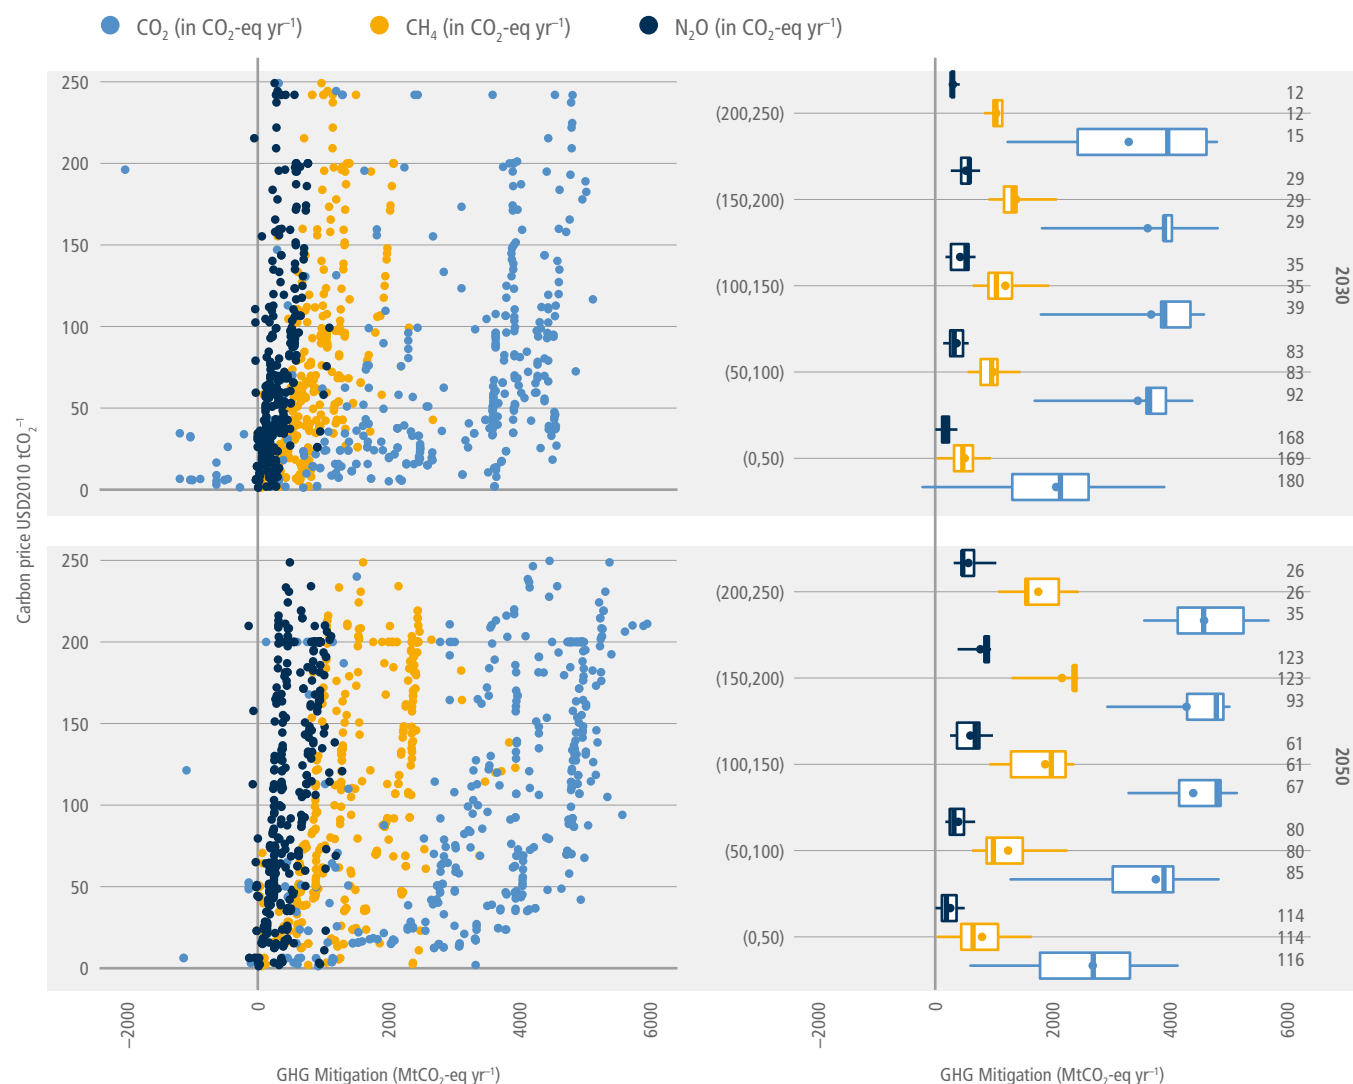

Figure 7.15 | Mitigation of CO₂, CH₄ and N₂O emissions (in CO₂-eq yr⁻¹ using IPCC AR6 GWP100 values) from the AFOLU sector for increasing carbon price levels for 2030 and 2050. In the left-hand panels, single data points are generated by comparing emissions between a policy scenario and a related benchmark scenario, and mapping these differences with the respective carbon price difference. Plots only show the price range of up to 250 USD2010 tCO₂-eq⁻¹ and the mitigation range between -2000 and 6000 MtCO₂-eq yr⁻¹ for better visibility. At the right-hand side, based on the same data as left-hand side panels, boxplots show medians (vertical line within the boxes), means (dots), 33%–66% intervals (box) and 10%–90% intervals (horizontal lines). Numbers on the very right indicate the number of observations falling into the respective price range per variable. A wide range of carbon price induced mitigation options (such as technical, structural and behavioural options in the agricultural sector, afforestation, reforestation, natural re-growth or avoided deforestation in the LULUCF sector, *excluding* carbon capture and sequestration from BECCS) are reflected in different scenarios.

the level of five world regions. This review provides a complementary view on the economic mitigation potentials estimated in Section 7.4 by implicitly taking into account the interlinkages between the land-based mitigation options themselves as well as the interlinkages with mitigation options in the other sectors such as BECCS. The review systematically evaluates a range of possible economic potential estimates across gases, time, and carbon prices.

For different models and scenarios from the AR6 database, the amount of mitigated emissions is presented together with the respective carbon price (Figure 7.15). To determine mitigation

potentials, scenarios are compared to a benchmark scenario which usually assumes business-as-usual trends and no explicit additional mitigation efforts. Scenarios have been excluded, if they do not have an associated benchmark scenario or fail the vetting according to the AR6 scenario database, or if they do not report carbon prices and CO₂ emissions from AFOLU. Scenarios with contradicting assumptions (for example, fixing some of the emissions to baseline levels) are excluded. Furthermore, only scenarios with consistent³ regional and global level results are considered. Mitigation potentials are computed by subtracting scenario specific emissions and sequestration amounts from their respective benchmark scenario values. This difference

³ Scenarios are considered consistent between global and regional results (based on R5 regions), if the sum of regional emissions (or sequestration efforts) does not deviate more than 10% from the reported global total. To take into account that small absolute values have a higher sensitivity, a deviation of 90% is allowed for absolute values below 100.

accounts for the mitigation that can be credited to the carbon price which is applied in a scenario. A few benchmark scenarios, however, apply already low carbon prices. For consistency reasons, a carbon price that is applied in a benchmark scenario is subtracted from the respective scenario specific carbon price. This may generate a bias because low carbon prices tend to have a stronger marginal impact on mitigation than high carbon prices. Scenarios with carbon prices which become negative due to the correction are not considered. The analysis considers all scenarios from the AR6 database which pass the criteria and should be considered as an ensemble of opportunity (Huppmann et al. 2018).

This approach is close to integrated assessment marginal abatement cost curves (MACCs) as described in the literature (Fujimori et al. 2016; Frank et al. 2018, 2019; Harmsen et al. 2019) in the sense that it incorporates besides the technical mitigation options also structural options, as well as behavioural changes and market feedbacks. Furthermore, indirect emission changes and interactions with other sectors can be highly relevant (Daioglou et al. 2019; Kalt et al. 2020) and are also accounted for in the presented potentials. Hereby, some sequestration efforts can occur in other sectors, while leading to less mitigation in the AFOLU sector. For instance, as an integral part of many scenarios, BECCS deployment will lead to overall emissions reductions, and even provision of CDR as a result of the interplay between three direct components (i) LULUCF emissions/sinks, (ii) reduction of fossil fuel use/emissions, (iii) carbon capture and sequestration. Since the latter two effects can compensate for the LULUCF effect, BECCS deployment in ambitious stabilisation scenarios may lead to reduced sink/increased emissions in LULUCF (Kalt et al. 2020). The same holds for trade-offs between carbon sequestration in forests versus harvested wood products both for enhancing the HWP pool and for material substitution. The strengths of the competition between biomass use and carbon sequestration will depend on the biomass feedstocks considered (Lauri et al. 2019).

In the individual cases, the accounting of all these effects is dependent on the respective underlying model and its coverage of inter-relations of different sectors and sub-sectors. The presented potentials cover a wide range of models, and additionally, a wide range of background assumptions on macro-economic, technical, and behavioural developments as well as policies, which the models have been fed with. Subsequently, the range of the resulting marginal abatement costs is relatively wide, showing the full range of expected contributions from land-use sector mitigation and sequestration in applied mitigation pathways.

At the global level, the analysis of the economic mitigation potentials from N₂O and CH₄ emissions from AFOLU (which mainly can be related to agricultural activities) and CO₂ emissions (which mainly can be related to LULUCF emissions) reveals a relatively good agreement of models and scenarios in terms of ranking between the gases. On the right-hand side panels of Figure 7.15, only small overlaps between the ranges (showing the 10–90% intervals of observations) and mainly for lower price levels, can be observed, despite all differences in underlying model structure and scenario assumptions.

N₂O emissions show the smallest economic potential of the three different gases in 2030 as well as in 2050. The mitigation potential increases until a price range of USD150–200 and to a median value of around 0.6 GtCO₂-eq yr⁻¹ mitigation in 2030 and 0.9 GtCO₂-eq yr⁻¹ in 2050, respectively, while afterwards with higher prices the expansion is very limited. Mitigation of CH₄ emissions has a higher potential, also with increasing mitigation potentials until a price range of USD150–200 in both years, with median mitigation of around 1.3 GtCO₂-eq yr⁻¹ in 2030 and around 2.4 GtCO₂-eq yr⁻¹ in 2050, respectively. The highest mitigation potentials are observed for CO₂, but also the highest ranges of observations among the three gases. In 2030, a median of 4 GtCO₂-eq yr⁻¹ mitigation potential is reported for the price range of USD200–250. In 2050, for the carbon price range of between USD100 and USD200, a median of around 4.8 GtCO₂-eq yr⁻¹ can be observed.

When compared with the sectoral estimates from Harmsen et al. (2019), the integrated assessment median potentials are broadly comparable for the N₂O mitigation potential; Harmsen et al. 2050 mitigation potential at USD125 is 0.6 GtCO₂-eq yr⁻¹ while the integrated assessment estimate for the same price range is 0.7 GtCO₂-eq yr⁻¹. The difference is substantially larger for the CH₄ mitigation potential; 0.9 GtCO₂-eq yr⁻¹ in Harmsen et al. while 2 GtCO₂-eq yr⁻¹ the median integrated assessment estimate. While the Harmsen et al. MACCs consider only technological mitigation options, integrated assessments typically include also demand side response to the carbon price and GHG efficiency improvements through structural change and international trade. These additional mitigation options can represent more than 60% of the total non-CO₂ mitigation potential in the agricultural sector, where they are more important in the livestock sector, and thus the difference between sectoral and integrated assessments is more pronounced for the CH₄ emissions (Frank et al. 2019).

Economic CO₂ mitigation potentials from land-use change and forestry are larger compared to potentials from non-CO₂ gases, and at the same time reveal high levels of variation in absolute terms. The 66th percentile in 2050 goes up to 5.2 GtCO₂-eq yr⁻¹ mitigation, while the lowest observations are even negative, indicating higher CO₂ emissions from land use in scenarios with carbon price compared to scenarios without (counterintuitive dynamics explained below).

Land use is at the centre of the interdependencies with other sectors, including energy. Some models see a strong competition between BECCS deployment with its respective demand for biomass, and CO₂ mitigation/sequestration potentials in the land sector. Biomass demand may lead to an increase in CO₂ emissions from land use despite the application of a carbon price when land-use expansion for dedicated biomass production, such as energy plantations, comes from carbon rich land use/land cover alternatives, or when increased extraction of biomass from existing land uses, such as forest management, leads to reduction of the carbon sink (Daioglou 2019; Luderer et al. 2018) and can explain the high variety of observations in some cases. Overall, the large variety of observations shows a large variety of plausible results, which can go back to different model structures and assumptions, showing a robust range of plausible outcomes (Kriegler et al. 2015).

7.5.3 Interaction Between Mitigation in the AFOLU Sector and Other SDGs in the Context of Integrated Assessments

Besides the level of biomass supply for bioenergy, the adoption of SDGs may also significantly impact AFOLU emissions and the land-use sector's ability for GHG abatement (Frank et al. 2021). Selected SDGs are found to have positive synergies for AFOLU GHG abatement and to consistently decrease GHG emissions for both agriculture and forestry, thereby allowing for even more rapid and deeper emissions cuts. In particular, the decreased consumption of animal products and less food waste (SDG 12), and the protection of high biodiversity ecosystems such as primary forests (SDG 15) deliver high synergies with GHG abatement. On the other hand, protection of highly biodiverse ecosystems from conversion (SDG 15) limits the global biomass potentials for bioenergy (Frank et al. 2021), and while several

forestry measures enhancing woody biomass supply for bioenergy may have synergies with improving ecosystems conditions, many represent a threat to biodiversity (Camia et al. 2020) (Sections 7.6.5 and 17.3.3.7, Figure 17.1 and Supplementary Material Table 17.SM.1).

7.5.4 Regional AFOLU Abatement for Different Carbon Prices

At the regional level (Figure 7.16), the highest potential from non-CO₂ emissions abatement, and mostly from CH₄, is reported for ASIA with the median of mitigation potential observations from CH₄ increasing up to a price of USD200 in the year 2050, reaching a median of 1.2 GtCO₂-eq yr⁻¹. In terms of economic potential, ASIA is followed by LAM, AFRICA, and OECD+EU, where emission reduction mainly is achieved in the livestock sector.

Figure 7.16 | Regional mitigation efforts for CO₂, CH₄ and N₂O emissions (in CO₂-eq yr⁻¹ using IPCC AR6 GWP100 values) from the AFOLU sector for increasing carbon price levels for 2030 and 2050. Underlying datapoints are generated by comparing emissions between a policy scenario and a related benchmark scenario, mapping these differences with the respective carbon price differences. Boxplots show Medians (vertical line within the boxes), Means (dots), 33%–66% intervals (box) and 10%–90% intervals (horizontal lines) for respective scenarios of carbon prices implemented in intervals of USD50 from a price of USD0 to USD250. Regions: Asia (ASIA), Latin America and Caribbean (LAM), Middle East (MIDDLE_EAST), Africa (AFRICA), Developed Countries (OECD 90 and EU) (OECD+EU) and Reforming Economies of Eastern Europe and the Former Soviet Union (REF).

The highest potentials from land-related CO₂ emissions, including avoided deforestation as well as afforestation, can be observed in LAM and AFRICA with strong responses of mitigation (indicated by the median value) to carbon prices mainly in the lower range of displayed carbon prices. In general, CO₂ mitigation potentials show a wide range of results in comparison to non-CO₂ mitigation potentials, but mostly also a higher median value. The most extreme ranges are reported for the regions LAM and AFRICA. A medium potential is reported for ASIA and OECD+EU, while REF has the smallest potential according to model submissions. These estimates reflect techno-economic potentials and do not necessarily include feasibility constraints which are discussed in Chapter 7.6.

7.5.5 Illustrative Mitigation Pathways

Different mitigation strategies can achieve the net emission reductions that would be required to follow a pathway limiting global warming, with very different consequences for the land system. Figure 7.17 shows Illustrative Mitigation Pathways (IMPs) for achieving different climate targets highlighting AFOLU mitigation strategies, resulting GHG and land-use dynamics as well as the interaction with other sectors. For consistency this chapter discusses IMPs as described in detail in chapters 1 and 3 of this report but focusing on the land-use sector. All pathways are assessed by different IAM realisations and do not only reduce GHG emissions but also use CDR options, whereas

a. Global land-based GHG emissions and removals

b. Global land-use change compared to 2020

Figure 7.17 | Evolution and breakdown of (a) global land-based GHG emissions and removals and (b) global land-use dynamics under four Illustrative Mitigation Pathways, which illustrate the differences in timing and magnitude of land-based mitigation approaches including afforestation and BECCS. All pathways are based on different IAM realisations: *ModAct* scenario (below 3.0°C, C6) from IMAGE 3.0; *IMP Neg-2.0* (limit warming to 2°C (>67%), C3) from AIM/CGE 2.2; *IMP Ren* (1.5°C with no or low overshoot, C1) from REMIND-MAgPIE 2.1–4.3; *IMP SP* (1.5°C with no or low overshoot, C1) from REMIND-MAgPIE 2.1–4.2. In panel A the categories CO₂ AFOLU, CH₄ AFOLU and N₂O AFOLU include GHG emissions from land-use change and agricultural land use (including emissions related to bioenergy production). In addition, the category CO₂ Land includes removals due to afforestation/reforestation. BECCS reflects the CO₂ emissions captured from bioenergy use and stored in geological deposits. CH₄ and N₂O emissions are converted to CO₂-eq using GWP100 factors of 27 and 273 respectively.

the amount and timing varies across pathways, as do the relative contributions of different land-based CDR options.

The scenario *ModAct* (limit warming to 3°C (>50%), C6) is based on the prolongation of current trends (SSP2) but contains measures to strengthen policies for the implementation of National Determined Contributions (NDCs) in all sectors including AFOLU (Grassi et al. 2018). This pathway shows a strong decrease of CO₂ emissions from land-use change in 2030, mainly due to reduced deforestation, as well as moderately decreasing N₂O and CH₄ emissions from agricultural production due to improved agricultural management and dietary shifts away from emissions-intensive livestock products. However, in contrast to CO₂ emissions, which turn net-negative around 2050 due to afforestation/reforestation, CH₄ and N₂O emissions persist throughout the century due to difficulties of eliminating these residual emissions based on existing agricultural management methods (Frank et al. 2017; Stevanović et al. 2017). Comparably small amounts of BECCS are applied by the end of the century. Forest area increases at the cost of other natural vegetation.

IMP-Neg is similar to *ModAct* scenario in terms of socio-economic setting (SSP2) but differs strongly in terms of the mitigation target (limit warming to 2°C (>67%), C3) and its strong focus on the supply side of mitigation measures with strong reliance on net-negative emissions. Consequently, all GHG emission reductions as well as afforestation/reforestation and BECCS-based CDR start earlier in time at a higher rate of deployment. However, in contrast to CO₂ emissions, which turn net-negative around 2030 due to afforestation/reforestation, CH₄ and N₂O emissions persist throughout the century, similar to *ModAct*, due to ongoing increasing demand for total calories and animal-based commodities (Bodirsky et al. 2020) and difficulties of eliminating these residual emissions based on existing agricultural management methods (Stevanović et al. 2017; Frank et al. 2017). In addition to abating land-related GHG emissions as well as increasing the terrestrial sink, this example also shows the potential importance of the land sector in providing biomass for BECCS and hence CDR in the energy sector. Cumulative CDR (2020–2100) amounts to 502 GtCO₂ for BECCS and 121 GtCO₂ for land-use change (including afforestation and reduced deforestation). In consequence, compared to *ModAct* scenario, competition for land is increasing and much more other natural land as well as agricultural land (cropland and pasture land) is converted to forest or bioenergy cropland with potentially severe consequences for various sustainability dimensions such as biodiversity (Hof et al. 2018) and food security (Fujimori et al. 2019).

IMP-Ren is similar to *IMP Neg-2.0* in terms of socio-economic setting (SSP2) but differs substantially in terms of mitigation target and mitigation efforts in the energy sector. Even under the more ambitious climate change mitigation target (1.5°C with no or low overshoot (OS), C1), the high share of renewable energy in *IMP Ren* strongly reduces the need for large-scale land-based CDR, which is reflected in smaller bioenergy and afforestation areas compared to *IMP Neg-2.0*. However, CH₄ and N₂O emissions from AFOLU persist throughout the century, similar to *ModAct* scenario and *IMP Neg-2.0*.

In contrast to *IMPs Neg-2.0* and *Ren*, *IMP SP* (Soergel et al. 2021; 1.5°C with no or low OS, C1) displays a future of generally low resource and energy consumption (including healthy diets with low animal-calorie shares and low food waste) as well as significant but sustainable agricultural intensification in combination with high levels of nature protection. This pathway shows a strong near-term decrease of CO₂ emissions from land-use change, mainly due to reduced deforestation, and in difference to all other *IMPs* described in this chapter strongly decreasing N₂O and CH₄ emissions from agricultural production due to improved agricultural management but also based on dietary shifts away from emissions-intensive livestock products as well as lower shares of food waste. In consequence, comparably small amounts of land are needed for land demanding mitigation activities such as BECCS and afforestation. In particular, the amount of agricultural land converted to bioenergy cropland is smaller compared to other mitigation pathways. Forest area increases either by regrowth of secondary vegetation following the abandonment of agricultural land or by afforestation/reforestation at the cost of agricultural land.

7.6 Assessment of Economic, Social and Policy Responses

7.6.1 Retrospective in Policy Efforts and Achieved Mitigation Within AFOLU

Since the establishment of the UNFCCC, international agencies, countries, sub-national units and NGO's have developed policies to facilitate and encourage GHG mitigation within AFOLU (Figure 7.18). Early guidance and policies focused on developing GHG inventory methodology with some emphasis on afforestation and reforestation projects, but the Clean Development Mechanism (CDM) in the Kyoto Protocol focused attention on emission reduction projects, mostly outside of AFOLU. As successive IPCC AR6 WGIII reports illustrated large potential for AFOLU mitigation, methods to quantify and verify carbon emission reductions emerged within several projects in the early 2000s, through both voluntary (e.g., the Chicago Climate Exchange (CCX)) and regulated (e.g., New South Wales and California) markets. The CDM dedicated large attention to LULUCF, including dedicated methodologies and bodies. The reasons for limited uptake of CDM afforestation/reforestation projects were multiple and not limited to the regulatory constraints, but also due to the low abatement potential (poor cost/performance ratio) compared to other mitigation opportunities.

Following COP 13 in Bali, effort shifted to advancing policies to reduce deforestation and forest degradation (REDD+) in developing countries. According to Simonet et al. (2019), nearly 65 Mha have been enrolled in REDD+ type programmes or projects funded through a variety of sources, including United Nations Programme on Reducing Emissions from Deforestation and Forest Degradation (UN-REDD), the World Bank Forest Carbon Partnership Facility, and bi-lateral agreements between countries with Norway being the largest donor. While there has been considerable focus on forest and

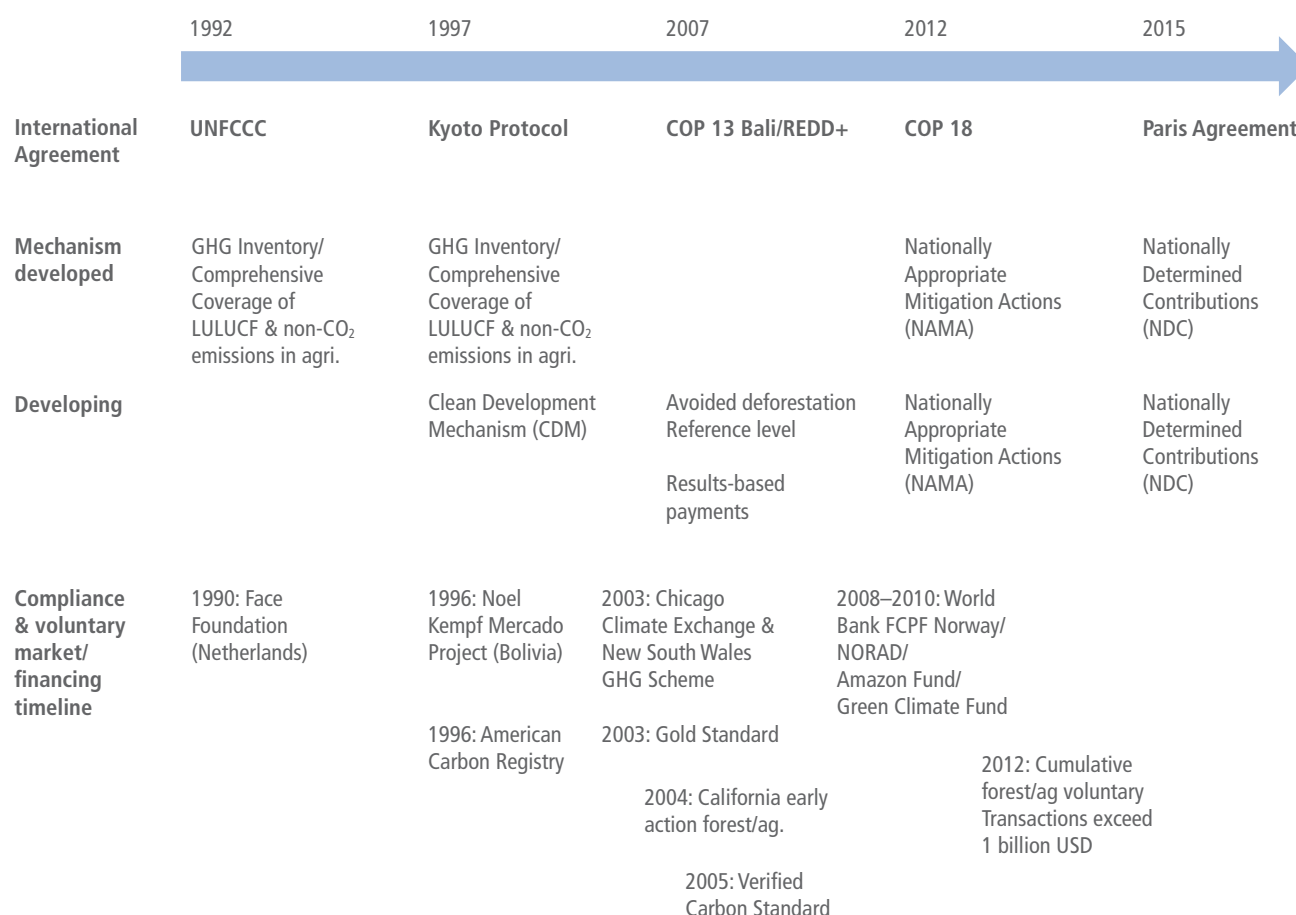

Figure 7.18 | Milestones in policy development for AFOLU measures. 'ag.' and 'agri.' = agriculture.

agricultural project-based mitigation actions, national governments were encouraged to incorporate project-based approaches with other sectoral strategies in their Nationally Appropriate Mitigation Actions (NAMAs) after 2012. NAMAs reflect the country's proposed strategy to reduce net emissions across various sectors within their economy (e.g., forests or agriculture). More recently, Nationally Determined Contributions (NDCs) indicate whether individual countries plan to use forestry and agricultural policies or related projects amongst a set of measures in other sectors, to reduce their net emissions as part of the Paris Agreement (e.g., Forsell et al. 2016; Fyson and Jeffery 2019).

The many protocols now available can be used to quantify the potential mitigation to date resulting from various projects or programs. For instance, carbon registries issue credits using protocols that typically account for additionality, permanence and leakage, thus providing evidence that the projects are a net carbon benefit to the atmosphere. Protocol development engages the scientific community, project developers, and the public over a multi-year period. Some protocols have been revised multiple times, such as the USA State of California's forest carbon protocol, which is in its fifth revision, with the latest in 2019 (see <http://www.climateactionreserve.org/how/protocols/forest/>). Credits from carbon registries feed into regulatory programs, such as the cap and trade programme in California, or

voluntary offset markets (Hamrick and Gallant 2017a). Although AFOLU measures have been deployed across a range of projects and programmes globally to reduce net carbon emissions, debate about the net carbon benefits of some projects continues (e.g., Krug 2018).

A new assessment of projects over the last two decades finds emission reductions or offsets of at least 7.9 GtCO₂-eq (using GWP100 and a mix of IPCC values for CH₄ and N₂O) over the last 12 years due to agricultural and forestry activities (Table 7.4). More than 80% of these emission reductions or offsets have been generated by forest-based activities. The total amounts to 0.66 GtCO₂ yr⁻¹ for the period 2010–2019, which is 1.2% of total global, and 5.5% of AFOLU emissions reported in Table 7.1, over the same time period (*high confidence*).

The array of activities in Table 7.4 includes the Clean Development Mechanism, REDD+ activities reported in technical annexes of country biennial update reports to the UNFCCC, voluntary market transactions, and carbon stored as a result of carbon markets in Australia, New Zealand and California in the USA. Although other countries and sub-national units have developed programmes and policies, these three regions are presented due to their focus on forest and agricultural carbon mitigation, their use of generally

accepted protocols or measures and the availability of data to quantify outcomes.

The largest share of emission reductions or carbon offsets in Table 7.4 has been from slowing deforestation and REDD+, specifically from efforts in Brazil (86% of total), which substantially reduced deforestation rates between 2004 and 2012 (Nepstad et al. 2014), as well as other countries in Latin America. With the exception of Roopsind et al. (2019), estimated reductions in carbon emissions from REDD+ in Table 7.4 are measured relative to a historical baseline. As noted in Brazil's Third Biennial Update Report (Ministry of Foreign Affairs 2019), estimates are made in accordance with established methodologies to determine the benefits of results-based REDD+ payments to Brazil. REDD+ estimates from other countries also have been derived from biennial update reports.

Regulatory markets provide the next largest share of carbon removal to date. Data from the Australia Emissions Reduction Fund are carbon credits issued in for agricultural, and vegetation and savanna burning projects. In the case of California, offset credits from forest and agricultural activities, using methods approved by a third-party certification authority (Climate Action Reserve), have been allowed as part of their state-wide cap and trade system. Transaction prices for forest and agricultural credits in California were around USD13 tCO₂⁻¹ in 2018, and represented 7.4% of total market compliance. By the end of 2018, 80 MtCO₂ had been used for compliance purposes.

For New Zealand, the carbon reduction in Table 7.4 represents forest removals that were surrendered from post-1989 forests between 2008 and the 2020. Unlike offsets in voluntary markets or in California, where permanence involves long-term contracts or insurance pools, forests in the New Zealand market liable for emissions when harvested or following land-use change. This means sellers account for future emission risks related to harvesting when they enter forests into carbon contracts. Offset prices were around USD13 tCO₂⁻¹ in 2016 but have risen to more than USD20 tCO₂⁻¹ in 2020.

The voluntary market data in Table 7.4 are offsets developed under the major standard-setting organisations, and issued from 2008–2018 (e.g., Hamrick and Gallant 2018). Note that there is some potential for double counting of voluntary offsets that may have been transacted in the California compliance market, however this would only have applied to transactions of US-issued offsets, and the largest share of annual transactions of voluntary AFOLU credits occurs with credits generated in Latin America, followed by Africa, Asia and North America. Europe and Oceania have few voluntary carbon market transactions. Within forestry and agriculture, most of the voluntary offsets were generated by forestry projects. Using historical transaction data from various *Forest Trends* reports, the offsets generated were valued at USD46.9 million yr⁻¹. Prices for voluntary offset transactions in the period 2014–2016 ranged from USD4.90 to USD5.40 tCO₂⁻¹ (Hamrick and Gallant 2017a).

Table 7.4 | Estimates of achieved emission offsets or reductions in AFOLU through 2018. Data include CDM, voluntary carbon standards, compliance markets, and reduced deforestation from official UNFCCC reports. Carbon sequestration due to other government policies not included.

Fund/mechanism	Total emission reductions or offsets (MtCO ₂ -eq)	Time frame	MtCO ₂ -eq yr ⁻¹	Financing (million USD yr ⁻¹)

^h Obtained 13/08/2020. All non-CO₂ gases are converted to CO₂-eq using IPCC GWP100 values recommended at the time the project achieved approval by the relevant organisation or agency.

Voluntary finance has amounted to USD0.5 billion over a 10-year period for development of forest and agricultural credits. The three regulatory markets quantified amount to USD2.7 billion in funding from 2010 to 2019. For the most part, this funding has focused on forest projects and programs, with agricultural projects accounting for 5–10% of the total. In total, reported funding for AFOLU projects and programmes has been USD4.4 billion over the past decade, or about USD569 million yr^{-1} (*low confidence*). The largest share of the total carbon includes efforts in the Amazon by Brazil. Government expenditures on regulatory programmes and business expenditures on voluntary programmes in Brazil (e.g., the soy or cattle moratoriums) were not included in financing estimates due to difficulties obtaining that data. If Brazil and CDM (for which we have no cost estimates) are left out of the calculation, average cost per ton has been USD3.20 tCO_2^{-1} .

The large number of policy approaches described in Table 7.4 combined with efforts by other international actors, such as the Global Environmental Facility (GEF), as well as non-state actors (e.g., eco-labelling programmes and corporate social responsibility initiatives) illustrate significant policy experimentation over the last several decades. Despite widespread effort, AFOLU measures have thus far failed to achieve the large potential for climate mitigation described in earlier IPCC WG III reports (*high confidence*). The limited gains from AFOLU to date appear largely to result from lack of investment and other institutional and social barriers, rather than methodological concerns (*high confidence*).

7.6.2 Review of Observed Policies and Policy Instruments

7.6.2.1 Economic Incentives

Emissions Trading/Carbon Taxes. While emissions trading programmes have been developed across the globe, forest and agriculture have not been included as part of the cap in any of the existing systems. However, offsets from forestry and agriculture have been included in several of the trading programs. New Zealand has a hybrid programme where carbon storage in forests can be voluntarily entered into the carbon trading program, but once entered, forests are counted both as a sink for carbon if net gains are positive, and a source when harvesting occurs. New Zealand is considering rules to include agricultural GHG emissions under a future cap (Henderson et al. 2020; see: <https://www.agmatters.nz/topics/he-waka-eke-noa/>).

The state of California has developed a formal cap and trade programme that allows a limited number of forest and agricultural offset credits to be used under the cap. All offsets must meet protocols to account for additionality, permanence and leakage. Forest projects used as offsets in California currently are located in the USA, but the California Air Resources Board adopted a tropical forest carbon standard, allowing for avoided deforestation projects from outside the USA to enter the California market (CARB 2019).

Canadian provinces have developed a range of policy options that can include carbon offsets. Quebec has an emissions trading programme that plans to allow forest and agricultural offsets generated within the province to be utilised. Alberta also allows offsets to be utilised by regulated sectors while British Columbia allows offsets to be utilised by the government for its carbon neutrality goals (Government of Alberta, 2021). Over 20 countries and regions have adopted explicit carbon taxes on carbon emission sources and fossil fuels, however, the charges have not been applied to non- CO_2 agricultural emissions (OECD 2021a). California may implement regulations on methane emissions from cattle, however, regulations if approved, will not go into effect until 2024. Institutional and trade-related barriers (e.g., leakage) likely will limit widespread implementation of taxes on emissions in the food sector globally. Many countries exempt purchases of fuels used in agricultural or fishery production from fuel or carbon taxes, thus lowering the effective tax rate imposed on those sectors (OECD 2021a). Furthermore, bioenergy, produced from agricultural products, agricultural waste, and wood is often exempted from explicit carbon taxes. Colombia recently implemented a carbon tax on liquid fuels but allowed domestically produced forestry credits to offset the tax. Colombia also is in the process of developing an emissions trading scheme (OECD 2021a).

REDD+/Payment for Ecosystem Services (PES). PES programmes for a variety of ecosystem services have long been utilised for conservation (e.g., Wunder 2007) and may now be as large as USD42 billion yr^{-1} (Salzman et al. 2018). REDD+ emerged in the early 2000s and is a widely recognised example of PES programme focused on conservation of tropical forests (Table 7.4). However, our summation of actually paid funds in Table 7.4 is much smaller than what is portrayed by Salzman et al. (2018). REDD+ may operate at the country level, or for specific programmes or forests within a country. As with other PES programs, REDD+ has evolved towards a results-based programme that involves payments that are conditioned on meeting certain successes or milestones, such as rates of deforestation (Angelsen 2017).

A large literature has investigated whether PES programmes have successfully protected habitats. Studies in the USA found limited additionality for programmes that encouraged conservation tillage practices, but stronger additionality for programmes that encouraged set-asides for grasslands or forests (Woodward et al. 2016; Claassen et al. 2018), although the set-asides led to estimated leakage of 20 up to 100% (Pfaff and Robalino 2017; Kallio et al. 2018; Wu 2000). Evidence from the EU similarly suggests that payments for some agroenvironmental practices may be additional, while others are not (Chabé-Ferret and Subervie 2013). Other studies, in particular in Latin America where many PES programmes have been implemented, have found a wide range of estimates of effectiveness (e.g., Honey-Rosés et al. 2011; Robalino and Pfaff 2013; Alix-Garcia et al. 2015; Robalino et al. 2015; Mohebalian and Aguilar 2016; Jayachandran et al. 2017; Börner et al. 2017; Burivalova et al. 2019). Despite concerns, the many lessons learned from PES programme implementation provide critical information that will help policymakers refine future PES programmes to increase their effectiveness (*medium confidence*).

While expectations that carbon-centred REDD+ would be a simple and efficient mechanism for climate mitigation have not been met (Turnhout et al. 2017; Arts et al. 2019), progress has nonetheless occurred. Measuring, monitoring and verification systems have been developed and deployed, REDD readiness programmes have improved capacity to implement REDD+ on the ground in over 50 countries, and a number of countries now have received results-based payments.

Empirical evidence that REDD+ funding has slowed deforestation is starting to emerge. Simonet et al. (2019) showed that a REDD+ project in Brazil reduced deforestation certainly until 2018, while Roopsind et al. (2019) showed that country-level REDD+ payments to Guyana encouraged reduced deforestation and increased carbon storage. Although more impact evaluation (IE) analysis needs to be conducted on REDD+ payments, these studies support the country-level estimates of carbon benefits from REDD+ shown in Table 7.4. Nearly all of the analysis of PES and REDD+ to date has focused on the presence or absence of forest cover, with little to no analysis having been conducted on forest degradation, conservation, or enhancement of forest stocks.

Agroenvironmental Subsidy Programs/PES. Climate policy for agriculture has developed more slowly than in other sectors due to concerns with food security and livelihoods, political interests, and difficulties in coordinating diffuse and diverse activities and stakeholders (e.g., nutritional health, rural development, and biodiversity conservation) (Leahy et al. 2020). However, a review of the National Adaptation Programme of Action (NAPAs), National Adaptation Plans (NAPs), NAMAs, and NDCs in the Paris Agreement suggest an increasing focus of policy makers on agriculture and food security. The vast majority of parties to the Paris Agreement recognise the significant role of agriculture in supporting a secure sustainable development pathway (Richards and VanWey 2015) with the inclusion of agriculture mitigation in 103 NDCs from a total of 160 NDC submissions. Livestock is the most frequently cited specific agricultural sub-sector, with mitigation activities generally focusing on increasing efficiency and productivity.

Agriculture is one of the most subsidised industries globally, especially in the European Union and the USA. While subsidy payments over the last 20 years have shifted modestly to programmes designed to reduce the environmental impact of the agricultural sector, only 15–20% of the more than USD700 billion spent globally on subsidies are green payments (OECD 2021b). Under the Common Agricultural Policy in the EU, up to 30% of the direct payments to farmers (Pillar 1) have been green payments (Henderson et al. 2020), including some actions that could increase carbon storage or reduce emissions. Similarly, at least 30% of the rural development payments (Pillar 2) are used for measures that reduce environmental impact, including reduction of GHG emissions and carbon storage. There is limited evidence that these policies contributed to the 20% reduction in GHG emissions from the agricultural sector in the EU between 1990 and 2018 (Baudrier et al. 2015; Eurostat 2020).

The USA spends USD4 billion yr⁻¹ on conservation programs, or 12% of net farm income (Department of Agriculture 2020). In real terms, this expenditure has remained constant for 15 years, supporting 12 Mha

of permanent grass or woodland cover in the Conservation Reserve Program (CRP), which has increased soil carbon sequestration by 3 tCO₂ ha⁻¹ yr⁻¹ (Conant et al. 2017; Paustian et al. 2019), as well as other practices that could lower net emissions. Gross GHG emissions from the agricultural sector in the US, however, have increased since 1990 (USEPA 2020) due to reductions in the area of land in the US CRP programme and changes in crop rotations, both of which caused soil carbon stocks to decline (USEPA 2020). When combined with increased non-CO₂ gas emissions, the emission intensity of US agriculture increased from 1.5 to 1.7 tCO₂ ha⁻¹ between 2005 and 2018 (*high confidence*).

China has implemented large conservation programmes that have influenced carbon stocks. For example, the Sloping Land Conversion Program, combined with other programs, has increased forest cover and carbon stocks, reduced erosion and increased other ecosystem services in China in recent years (Ouyang et al. 2016). As part of Brazil's national strategy, numerous practices to reduce GHG emissions from agriculture, and in particular from the animal agriculture industry, have been subsidised. Estimates by Manzatto et al. (2020) suggest that the programme may have reduced agricultural emissions by 169 MtCO₂ between 2010 and 2020. Given the large technical and economic potential for agroforestry to be deployed in Africa, subsidy approaches could be deployed along with other policies to enhance carbon through innovative practices such as regreening (Box 7.10).

7.6.2.2 Regulatory Approaches

Regulations on land use include direct controls on how land is used, zoning, or legally set limits on converting land from one use to another. Since the early 2000s, Brazil has deployed various regulatory measures to slow deforestation, including enforcement of regulations on land-use change in the legal Amazon area. Enforcement of these regulations, among other approaches is credited with encouraging the large-scale reduction in deforestation and associated carbon emissions after 2004 (Nepstad et al. 2014). Empirical evidence has found that regulations reduced deforestation in Brazil (Arima et al. 2014) but over time, reversals occurred when enforcement was not consistent (Azevedo et al. 2017) (Box 7.9).

Many OECD countries have strong legal frameworks that influence agricultural and forest management on both public and private land. These include for example, legal requirements to protect endangered species, implement conservation tillage, protect riparian areas, replant forests after harvest, maintain historical species composition, forest certification, and other approaches. Increasingly, laws support more widespread implementation of nature-based solutions for a range of environmental issues (e.g., see European Commission-EU 2021). The extent to which the combined influence of these regulations has enhanced carbon storage in ecosystems is not quantified although they are likely to explain some of the persistent carbon sink that has emerged in temperate forests of OECD countries (*high confidence*). In the least developed and developing countries, regulatory approaches face challenges in part because environmental issues are a lower priority than many other socio-economic issues (e.g., poverty, opportunity, essential services), and weak governance (Mayer Pelicice 2019; Walker et al. 2020) (Box 7.2).

Set asides and protected areas have been a widely utilised approach for conservation, and according to (FAO 2020d), 726 Mha (18%) of forests are in protected areas globally. A review of land sparing and land sharing policies in developing countries indicated that most of them follow land sparing models, sometimes in combination with land sharing approaches. However, there is still no clear evidence of which policy provides the best results for ecosystem services provision, conservation, and livelihoods (Mertz and Mertens 2017). The literature contains a wide range of results on the effectiveness of protected areas to reduce deforestation (Burivalova et al. 2019), with studies suggesting that protected areas provide significant protection of forests (e.g., Blackman 2015), modest protection (Andam et al. 2008), as well as increases in deforestation (Blackman 2015) and possible leakage of harvesting to elsewhere (Kallio et al. 2018). An estimate of the contributions of protected areas to mitigation between 2000 and 2012, showed that in the tropics, PAs reduced carbon emissions from deforestation by 4.88 PgC, or around 29%, when compared to the expected rates of deforestation (Bebber and Butt 2017). In that study,

the tropical Americas ($368.8 \text{ TgC yr}^{-1}$) had the largest contribution, followed by Asia (25.0 TgC yr^{-1}) and Africa (12.7 TgC yr^{-1}). The authors concluded that local factors had an important influence on the effectiveness of protected areas. For example, in the Brazilian Amazon, protected area effectiveness is affected by the government agency controlling the land (federal indigenous lands, federal PAs, and state PAs) (Herrera et al. 2019). Because protected areas limit not just land-use change, but also logging or harvesting non-timber forest products, they may be relatively costly approaches for forest conservation (*medium confidence*).

Community forest management (CFM) allows less intensive use of forest resources, while at the same time providing carbon benefits by protecting forest cover. Community forest management provides property rights to communities to manage resources in exchange for their efforts to protect those resources. In many cases, the local communities are indigenous people who otherwise would have insecure tenure due to an advancing agricultural frontier or mining

Box 7.8 | Management of Native Forests by the Menominee people in North America and Lessons From Forest Owner Associations

Summary of the case. Indigenous peoples include more than 5000 different peoples, with over 370 million people, in 70 countries on five continents (UNIPP 2012). For example, in Latin America and Caribbean, forests cover more than 80% of the area occupied by indigenous peoples (330 million hectares) (FAO and FILAC, 2021) which points to their critical role for forest governance (Garnett et al. 2018; Fa et al. 2020). The Menominee people (Wisconsin, USA) practice sustainable forestry on their reservation according to a land ethic integral to the tribal identity. The Tribe calls themselves 'The Forest Keepers', recognising that the connection of their future to the sustainable management of the forest that allowed the forest volume standing today to be higher than when timber harvesting began more than 160 years ago. Management practices are based on continuous forest inventories (Mausel et al. 2017).

Introduction to the case. Forest management and timber harvesting operations began shortly after the Menominee Indian Reservation was created by treaty in 1854. The Menominee reservation sits on about 95,000 ha of land in Wisconsin that spans multiple forest types and is more diverse than adjacent forests. The collectively maintained reservation has 87% of its land under sustained yield forestry.

Case description. The Tribe, in the 19th century, had already mastered vegetation manipulation with fire, sustainable forestry, multiple-use, ecosystem, and adaptive management. The centrepiece of the Tribe's economy has been its forest product industry, Menominee Tribal Enterprises (MTE) (Pecore 1992). A balance between growth and removals and continuous forest inventories (CFI) are central for forest management for the past 160 years, aiming not at very large volumes, but at very high-quality trees. During this same period, more than 2.3 billion board feet have been harvested from the same area, equivalent to $0.3 \text{ m}^3 \text{ ha}^{-1} \text{ yr}^{-1}$.

Interactions and limitations. In 2013, the Menominee Tribe started a collaboration with the US Forest Service to implement climate adaptation measures. The Tribe actively works to reduce the risk of forest damage and decided to further promote diversity by planting tree seedlings adapted to a warming climate (<https://toolkit.climate.gov/case-studies/and-trees-will-last-forever>). However, new challenges are related to increasing pressures on forest ecosystems such as non-native insects, pathogens, weed invasions, and the costs for continuous forest inventories to support long-term forest management.

Identified lessons. The elements of sustainability are intertwined with Menominee history, culture, spirituality, and ethics. The balance between the environment, community, and economy for the short term as well as future generations is an example of protecting the entire environment as the Menominee land is a non-fragmented remnant of the prehistoric Lake States forest which has been dramatically reduced all around the reserve (Schabel and Pecore 1997). These and other types of community forest owner associations exist all over the world. Examples are Södra in Sweden (with 52,000 forest owners) (Södra, 2021) or Waldbauernverband in North-Rhine Westphalia (with 150,000 forest owners and covering 585,000 ha) (AGDW-The Forest Owners, 2021). These are ways for small forest owners to educate, jointly put wood on the market, employ better forest management, use machinery together, and apply certification jointly. In this manner and with all their diversity of goals, they manage to maintain carbon sinks and stocks, while preserving biodiversity and producing wood.

activity. Other examples are forest owner associations like those discussed in Box 7.8. According to the Rights and Resources Initiative (2018), the area of forests under community management increased globally by 152 Mha from 2002 to 2017, with over 500 Mha under community management in 2017. Studies have now shown that improved property rights with community forest management can reduce deforestation and increase carbon storage (Deiningner and Minten 2002; Alix-Garcia et al. 2005; Alix-Garcia 2007; Bowler et al. 2012; Blackman 2015; Fortmann et al. 2017; Burivalova et al. 2019). Efforts to expand property rights, especially community forest management, have reduced carbon emissions from deforestation in tropical forests in the last two decades (*high confidence*), although the extent of carbon savings has not been quantified globally.

Bioenergy targets. Multiple policies have been enacted at national and supra-national levels to promote the use of bioenergy in the transport sector, and for bioelectricity production. Existing policies mandate or subsidise the production and use of bioenergy. In the past few years, policies have been proposed, put in place or updated in Australia (Renewable Energy Target), Brazil (RenovaBio, Nationally Determined Contribution), Canada (Clean Fuel Standard), China (Biodiesel Industrial Development Policy, Biodiesel Fuel Blend Standard), the European Union (Renewable Energy Directive II), the USA (Renewable Fuel Standards), Japan (FY2030), Russia (Energy Strategy Bill 2035), India (Revised National Policy on Biofuels), and South Africa (Biofuels Regulatory Framework).

While current policies focus on bioenergy to decarbonise the energy system, some also contain provisions to minimise the potential environmental and social trade-offs from bioenergy production. For instance, the EU Renewable Energy Directive (EU-RED II) and US Renewable Energy Standard (US-RFS) assign caps on the use of biofuels, which are associated with indirect land-use change and food-security concerns. The Netherlands has a stringent set of 36 sustainability criteria to which the certified biomass needs to comply. The EU-RED II also sets a timeline for the complete phase-out of high-risk biofuels (Section 7.4.4).

7.6.2.3 Voluntary Actions and Agreements

Forest certification programs, such as Forest Sustainability Council (FSC) or Programme for the Endorsement of Forest Certification (PEFC), are consumer driven, voluntary programmes that influence

timber harvesting practices, and may reduce emissions from forest degradation with reduced impact logging and other approaches (*medium confidence*). Forest certification has expanded globally to over 440 Mha (Kraxner et al. 2017). As the area of land devoted to certification has increased, the amount of timber produced from certified land has increased. In 2018, FSC accounted for harvests of 427 million m³ and jointly FSC and PEFC accounted for 689 million m³ in 2016 or around 40% of total industrial wood production (FAO 2018c). There is evidence that reduced impact logging can reduce carbon losses in tropical regions (Pearson et al. 2014; Ellis et al. 2019). However, there is conflicting evidence about whether forest certification reduces deforestation (e.g., Blackman et al. 2018; Tritsch et al. 2020).

Supply chain management in the food sector encourages more widespread use of conservation measures in agriculture (*high confidence*). The number of private commitments to reduce deforestation from supply chains has greatly increased in recent years, with at least 865 public commitments by 447 producers, processors, traders, manufacturers and retailers as of December, 2020 (New York Declaration on Forests 2021). Industry partnerships with NGOs, such as the Roundtable on Sustainable Palm Oil (RSPO), have become more widespread and visible in agricultural production. For example, RSPO certifies members all along the supply chain for palm oil and claims around 19% of total production. Similar sustainability efforts exist for many of the world's major agricultural products, including soybeans, rice, sugar cane, and cattle.

There is evidence that the Amazon Soy Moratorium (ASM), an industry-NGO effort whereby large industry consumers agreed voluntarily not to purchase soybeans grown on land deforested after 2006, reduced deforestation in the legal Amazon (Nepstad et al. 2014; Gibbs et al. 2015). However, recent studies have shown that some deforestation from the Amazon was displaced to the Cerrado (Brazilian savannas) region (Moffette and Gibbs 2021), which is a global hotspot for biodiversity, and has significant carbon stocks. These results illustrate the importance of broadening the scope of supply chain management to minimise or eliminate displacement (Lima et al. 2019). In addition, while voluntary efforts may improve environmental outcomes for a time, it is not clear that they are sufficient to deliver long-term reductions in deforestation, given the increases in deforestation that have occurred in the Amazon in recent years (Box 7.9). Voluntary efforts would be more effective at slowing deforestation if they present stronger linkages to regulatory or other approaches (Lambin et al. 2018).

Box 7.9 | Case Study: Deforestation Control in the Brazilian Amazon

Summary

Between 2000 and 2004, deforestation rates in the Brazilian Legal Amazon (is a socio-geographic division containing all nine Brazilian states in the Amazon basin) increased from 18,226 to 27,772 km² yr⁻¹ 2008 (INPE, 2021). A set of public policies designed in participatory process involving federal government, states, municipalities, and civil society successfully reduced deforestation rates until 2012. However, deforestation rates increased after 2013, and particularly between 2019 and 2020. Successful deforestation control policies are being negatively affected by changes in environmental governance, weak law enforcement, and polarisation of the national politics.

*Box 7.9 (Continued)***Background**

In 2004, the Brazilian federal government started the Action Plan for Prevention and Control of Deforestation in the Legal Amazon (PPCDAm) (Ministry of Environment, Government of Brazil, 2018).

The PPCDAm was a benchmark for the articulation of forest conservation policies that included central and state governments, prosecutor offices, and the civil society. The decline in deforestation after 2008 is mostly attributed to these policy options. In 2012, deforestation rates decreased to 4,571 km² yr⁻¹.

Case description

Combating deforestation was a theme in several programs, government plans, and projects not being more restricted to the environmental agenda. This broader inclusion resulted from a long process of insertion and articulation in the government dating back to 2003 while elaborating on the Sustainable Amazon Plan. In May 2003, a historic meeting took place in an Amazonian city, with the president of the Republic, state governors, ministers, and various business leaders, civil institutions, and social movements. It was presented and approved the document entitled 'Sustainable Amazonia – Guidelines and Priorities of the Ministry of Environment for the Sustainable Development of the Amazon Brazilian', containing several guidelines for conservation and sustainable use in the region. At the meeting, the Union and some states signed a Cooperation Agreement aiming to elaborate a plan for the Amazon, to be widely discussed with the various sectors of the regional and national society (Ministerio do Meio Ambiente, MMA, 2013).

Interactions and limitations

The PPCDAm had three main lines of action: (i) territorial management and land use; (ii) command and control; and (iii) promotion of sustainable practices. During the execution of the 1st and 2nd phases of the PPCDAm (2004–2011), important results in the territorial management and land-use component included, for example, the creation of 25 Mha of federal Protected Areas (PAs) located mainly in front of the expansion of deforestation, as well as the homologation of 10 Mha of Indigenous Lands. Also, states and municipalities created approximately 25 Mha, so that all spheres of government contributed to the expansion of PAs in the Brazilian Amazon. In the 'command and control' component, agencies performed hundreds of inspection operations against illegal activities (e.g., illegal logging) under strategic planning based on technical and territorial priorities. Besides, there was a significant improvement of the environmental monitoring systems, involving the analysis of satellite images to guide actions on the ground. Another policy was the restriction of public credit to enterprises linked to illegal deforestation following a resolution of the Brazilian Central Bank (2008) (Ministerio do Meio Ambiente, MMA, 2013). Also, in 2008, Brazil created the Amazon Fund, a REDD+ mechanism (Government of Brazil, n.d.).

However, the country's political polarisation has gradually eroded environmental governance, especially after the Brazilian Forest Code changes in 2012 (major environmental law in Brazil), the presidential impeachment in 2016, presidential elections in 2018, and the start of the new federal administration in 2019. Successful deforestation control policies are being negatively affected by critical changes in the political context, and weakening the environmental rule of law, forest conservation, and sustainable development programmes (for example, changes in the Amazon Fund governance in disagreement with the main donors). In 2019, the annual deforestation rate reached 10,129 km² being the first time it surpassed 10,000 km² since 2008 (INPE, 2021). Besides, there has been no effective transition from the historical economic model to a sustainable one. The lack of clarity in the ownership of land is still a major unresolved issue in the Amazon.

Lessons

The reduction of deforestation in the Brazilian Amazon was possible due to effective political and institutional support for environmental conservation. The initiatives of the Action Plan included the expansion of the protected areas network (conservation unities and indigenous lands), improvement of deforestation monitoring to the enforcement of environmental laws, and the use of economic instruments, for example, by cutting off public credit for municipalities with higher deforestation rates (Ricketts et al. 2010; Souza et al. 2013; Nepstad et al. 2014; Arima et al. 2014; Blackman and Veit 2018).

The array of public policies and social engagement was a historical and legal breakthrough in global protection. However, the broader political and institutional context and actions to reduce the representation and independent control of civil society movements in decision-making bodies weaken this structure with significant increases in deforestation rates, burnings, and forest fires.

Box 7.10 | Regreening the Sahel, Northern Africa

Case description

More than 200 million trees have regenerated on more than 5 Mha in the Sahel (Sendzimir et al. 2011). The Maradi/Zinder region of Niger is the epicentre of experimentation and scale up. This vast geographic extent generates significant mitigation potential despite the relatively modest per unit area increase in carbon of about $0.4 \text{ MgC ha}^{-1} \text{ a}^{-1}$ (Luedeling and Neufeldt 2012). In addition to the carbon benefits, these agroforestry systems decrease erosion, provide animal fodder, recharge groundwater, generate nutrition and income benefits and act as safety nets for vulnerable rural households during climate and other shocks (Bayala et al. 2014, 2015; Binam et al. 2015; Sinare and Gordon 2015; Ilstedt et al. 2016).

Lessons

A mélange of factors contributed to regreening in the Sahel. Increased precipitation, migration, community development, economic volatility and local policy reform have all likely played a role (Haglund et al. 2011; Sendzimir et al. 2011; Brandt et al. 2019a; Garrity and Bayala 2019); the easing of forestry regulations has been particularly critical in giving farmers greater control over the management and use of trees on their land (Garrity et al. 2010). This policy shift was catalysed by greater regional autonomy resulting from economic decline and coincided with successful pilots and NGO-led experimentation, cash-for-work, and training efforts to support changes in land management (Sendzimir et al. 2011). Participation of farmers in planning and implementation helped align actions with local knowledge and goals as well as market opportunities.

Regreening takes place when dormant seed or tree stumps sprout and are cultivated through the technique, called Farmer Managed Natural Regeneration (FMNR). Without planting new trees, FMNR is presumed to be cheaper than other approaches to restoration, though comparative economic analysis has yet to be conducted (Chomba et al. 2020). Relatively lower investment costs are believed to have contributed to the replication across the landscape. These factors worked together to contribute to a groundswell of action that affected rights, access, and use of local resources (Tougiani et al. 2009).

Regreening in the Sahel and the consequent transformation of the landscape has resulted from the actions of hundreds of thousands of individuals responding to social and biophysical signals (Hanan 2018). This is an example for climate change mitigation, where eliminating regulations – versus increasing them – has led to carbon dioxide removal.

7.6.2.4 Mitigation Effectiveness: Additionality, Permanence and Leakage

Additionality, permanence and leakage have been widely discussed in the forestry and agricultural mitigation literature (Murray et al. 2007), including in AR5 (Section 11.3.2 of the AR5WGIII report) and earlier assessment reports. Since the earlier assessment reports, new studies have emerged to provide new insights on the effect of these issues on the credibility of forest and agricultural mitigation. This assessment also provides additional context not considered in earlier assessments.

Typically, carbon registries will require that project developers show additionality by illustrating that the project is not undertaken as a result of a legal requirement, and that the project achieves carbon reductions above and beyond a business as usual. The protocols developed by the California Air Resources Board to ensure permanence and additionality are strong standards and may even limit participation (e.g., Ruseva et al. 2017). The business as usual is defined as past management actions by the same entity that can be verified. Additionality can thus be observed in the future as a difference from historical actions. This approach has been used by several countries in their UNFCCC Biennial Update reports to establish reductions in carbon emissions from avoided deforestation (e.g., Brazil and Indonesia).

However, alternative statistical approaches have been deployed in the literature to assess additionality with a quasi-experimental method that rely on developing a counterfactual (e.g., Andam et al. 2008; Blackman 2015; Sills et al. 2015; Fortmann et al. 2017; Roopsind et al. 2019). In several studies, additionality in avoided deforestation was established after the project had been developed by comparing land-use change in treated plots where the policy or programme was in effect with land-use change in similar untreated plot. Alternatively, synthetic matching statistically compares trends in a treated region (i.e., a region with a policy) to trends in a region without the policy, and has been applied in a region in Brazil (e.g., Sills et al. 2015), and at the country level in Guyana (Roopsind et al. 2019). While these analyses establish that many projects to reduce deforestation have overcome hurdles related to additionality (*high confidence*), there has not been a systematic assessment of the elements of project or programme design that lead to high levels of additionality. Such assessment could help developers design projects to better meet additionality criteria.

The same experimental methods have been applied to analyse additionality of the adoption of soil conservation and nutrient management practices in agriculture. Claassen et al. (2018) find that programmes to promote soil conservation are around 50% additional across the USA (i.e., 50% of the land enrolled in soil conservation programmes would not have been enrolled if not for the programme), while Woodward et al. (2016) find that adoption of conservation

tillage is rarely additional. Claassen et al. (2018) find that payments for nutrient management plans are nearly 100% additional, although there is little evidence that farmers reduce nutrient inputs when they adopt plans. It is not clear if the same policy approaches would lead to additionality in other regions.

Permanence focuses on the potential for carbon sequestered in offsets to be released in the future due to natural or anthropogenic disturbances. Most offset registries have strong permanence requirements, although they vary in their specific requirements. The Verified Carbon Standard (VCS) from the Verra programme requires a pool of additional carbon credits that provides a buffer against inadvertent losses. The Climate Action Reserve (CAR) protocol for forests requires carbon to remain on the site for 100 years. The carbon on the site will be verified at pre-determined intervals over the life of the project. If carbon is diminished on a given site, the credits for the site have to be relinquished and the project developer has to use credits from their reserve fund (either other projects or purchased credits) to make up for the loss. Estimates of leakage in forestry projects in AR5 suggest that it can range from 10% to over 90% in the USA (Murray et al. 2004), and 20–50% in the tropics (Sohngen and Brown 2004) for forest set-asides and reduced harvesting. Carbon offset protocols have made a variety of assumptions. The Climate Action Reserve (CAR) assumes it is 20% in the USA. One of the voluntary protocols (Verra) uses specific information about the location of the project to calculate a location specific leakage factor.

More recent literature has developed explicit estimates of leakage based on statistical analysis of carbon projects or programs. The literature suggests that there are two economic pathways for leakage (e.g., Roopsind et al. 2019), either through a shift in output price that occurs when outputs are affected by the policy or programme implementation, as described in (Wear and Murray 2004; Murray et al. 2004; Sohngen and Brown 2004; Gan and McCarl 2007), or through a shift in input prices and markets, such as for labour or capital, as analysed in (Andam et al. 2008; Alix-Garcia et al. 2012; Honey-Rosés et al. 2011; Fortmann et al. 2017). Estimates of leakage through product markets (e.g., timber prices) have suggested leakage of up to 90% (Sohngen and Brown 2004; Murray et al. 2004; Gan and McCarl 2007; Kallio et al. 2018), while studies that consider shifts in input markets are considerably smaller. The analysis of leakage for the Guyana programme by Roopsind et al. (2019) revealed no statistically significant leakage in Suriname. A key design feature for any programme to reduce leakage is to increase incentives for complementary mitigation policies to be implemented in areas where leakage may occur. Efforts to continue to draw more forests into carbon policy initiatives will reduce leakage over time Roopsind et al. (2019), suggesting that if NDCs continue to encompass a broader selection of policies, measures and forests over time, leakage will decline.

7.6.3 Assessment of Current Policies and Potential Future Approaches

The Paris Agreement encourages a wide range of policy approaches, including REDD+, sustainable management of forests, joint mitigation and adaptation, and emphasises the importance of non-

carbon benefits and equity for sustainable development (Martius et al. 2016). Around USD0.7 billion yr^{-1} has been invested in land-based carbon offsets (Table 7.4), but as noted in Streck (2012), there is a large funding gap between these efforts and the scale of efforts necessary to meet 1.5 or 2.0°C targets outlined in SR1.5. As Box 7.12 discusses, forestry actions could achieve up to 5.8 $\text{GtCO}_2 \text{ yr}^{-1}$ with costs rising from USD178 billion yr^{-1} to USD400 billion yr^{-1} by 2050. Over half of this investment is expected to occur in Latin America, with 13% in SE Asia and 17% in sub-Saharan Africa (Austin et al. 2020). Other studies have suggested that similar sized programmes are possible, although they do not quantify total costs (e.g., Griscom et al. 2017; Busch et al. 2019). The currently quantified efforts to reduce net emissions with forests and agricultural actions are helpful, but society will need to quickly ramp up investments to achieve carbon sequestration levels consistent with high levels of mitigation. Only 2.5% of climate mitigation funding goes to land-based mitigation options, an order of magnitude below the potential proportional contribution (Buchner et al. 2015).

To date, there has been significantly less investment in agricultural projects than forestry projects to reduce net carbon emissions (Table 7.4). For example, the economic potential (available up to USD100 tCO_2^{-1}) for soil carbon sequestration in croplands is 1.9 (0.4–6.8) $\text{GtCO}_2 \text{ yr}^{-1}$ (Section 7.4.3.1), however, less than 2% of the carbon in Table 7.4 is derived from soil carbon sequestration projects. While reductions in CH_4 emissions due to enteric fermentation constitute a large share of potential agricultural mitigation reported in Section 7.4, agricultural CH_4 emission reductions so far have been relatively modest compared to forestry sequestration. The protocols to quantify emission reductions in the agricultural sector are available and have been tested, and the main limitation appears to be the lack of available financing or the unwillingness to re-direct current subsidies (*medium confidence*).

Although quantified emission reductions in agricultural projects are limited to date, a number of OECD and economy in transition parties have reduced their net emissions through carbon storage in cropland soils since 2000. These reductions in emissions have typically resulted from policy innovations outside of the climate space, or market trends. For example, in the USA, there has been widespread adoption of conservation tillage in the last 30 years as a labour-saving crop management technique. In Europe, agricultural N_2O and CH_4 emissions have declined due to reductions in nutrient inputs and cattle numbers (Henderson et al. 2020). These reductions may be attributed to mechanism within the Common Agricultural Policy (Section 7.6.2.1), but could also be linked to higher nutrient prices in the 2000–2014 period. Other environmental policies could play a role, for example, efforts to reduce water pollution from phosphorus in The Netherlands, may ultimately reduce cattle numbers, also lowering CH_4 emissions.

Numerous developing countries have established policy efforts to abate agricultural emissions or increase carbon storage. Brazil, for instance, developed a subsidy programme in 2010 to promote sustainable development in agriculture, and practices that would reduce GHG emissions. Henderson et al. (2020) report that this programme reduced GHG emission in agricultural by up to

170 MtCO₂ between 2010 and 2018. However, the investments in low-carbon agriculture in Brazil amounted only 2% of the total funds for conventional agriculture in 2019. Programmes on deforestation in Brazil had successes and failures, as described in Box 7.9. Indonesia has engaged in a wide range of programmes in the REDD+ space, including a moratorium implemented in 2011 to prevent the conversion of primary forests and peatlands to oil palm and logging concessions (Wijaya et al. 2017; Tacconi and Muttaqin 2019; Henderson et al. 2020). Efforts to restore peatlands and forests have also been undertaken. Indonesia reports that results-based REDD+ programmes have been successful and have led to lower rates of deforestation (Table 7.4).

Existing policies focused on GHG management in agriculture and forestry is less advanced in Africa than in Latin American and Asia, however, Henderson et al. (2020) report on 10 countries in sub-Saharan Africa that have included explicit policy proposals for reducing AFOLU GHG emissions through their NDCs. These include efforts to reduce N₂O emission, increase implementation of conservation agriculture, improve livestock management, and implement forestry and grassland practices, including agroforestry

(Box 7.10). Within several of the NDCs, countries have explicitly suggested intensification as an approach to reduce emission in the livestock sector. However, it is important to note caveats associated with pursuing mitigation via intensification (Box 7.11).

The agricultural sector throughout the world is influenced by many policies that affect production practices, crop choices and land use. It is difficult to quantify the effect of these policies on reference level GHG emissions from the sector, as well as the cost estimates presented in Sections 7.4 and 7.5. The presence of significant subsidy programmes intended to improve farmer welfare and rural livelihoods makes it more difficult to implement regulatory programmes aimed at reducing net emissions in agriculture, however, it may increase the potential to implement new subsidy programmes that encourage practices aimed at reducing net emissions (*medium confidence*). For instance, in the USA, crop insurance can influence both crop choices and land use (Miao et al. 2016; Claassen et al. 2017), both of which will affect emission trends. Regulations to limit nutrient applications have not been widely considered, however, federal subsidy programmes have been implemented to encourage farmers to conduct nutrient management planning.

Box 7.11 | Sustainable Intensification Within Agriculture: Evidence and Caveats

Introduction

Sustainable intensification (SI) has received considerable attention as a suggested means of pursuing increased overall production, reducing associated environmental externalities, and potentially releasing agricultural land for alternative uses, such as forestry or rewilding (Godfray and Garnett 2014; Pretty 2018). The concept was explored within the SRCCL (SRCCL (Mbow et al. 2019), Section 5.6.4.4 and Cross-Chapter Box 6 in Chapter 5). SI is context specific and dynamic, with no universally prescribed methodology (HLPE 2019). Equal importance is given to enhancing sustainability as to achieving agricultural intensification. The former aspect is often challenging to realise, measure and maintain.

The extent of sustainable intensification

Total global agricultural land area has remained relatively stable while overall production has increased in recent decades (Section 7.3), indicating that agricultural intensification, as judged by production per unit of land (Petersen and Snapp 2015; OECD and FAO 2019) has taken place. However, changes in agricultural land use and degradation of natural resources (UNEP 2019; IPBES 2019b) suggests that not all of this intensification is sustainable. Although agricultural intensification has led to less GHG emissions compared to a scenario where that intensification had not taken place (Burney et al. 2010), absolute agriculture related emissions have continued to increase (Section 7.2). Active pursuit of SI was found to be expanding, with implementation on an increasing area, notably in developing countries (Pretty et al. 2018), yet regional agricultural area expansion at the expense of native habitat also continues in such regions (Section 7.3). Although there are specific examples of SI (Box 7.13) global progress in achieving SI is acknowledged as slow (Cassman and Grassini 2020) with potentially multiple, context specific geophysical and socio-economic barriers to implementation (Firbank et al. 2018; da Silva et al. 2021).

Preconditions to ensure sustainable intensification

Increasing the total amount of product produced by improving production efficiency (output per unit of input) does not guarantee SI. It will only be successful if increased production efficiency translates into reduced environmental and social impacts as well as increased production. For example, AR5 highlighted a growing emphasis on reducing GHG emissions per unit of product via increasing production efficiency (Smith et al. 2014), but reductions in absolute GHG emissions will only occur when production efficiency increases at a greater rate than the rate at which production increases (Clark et al. 2005).

Defined indicators are required. Measurement of SI requires multiple indicators and metrics. It can be assessed at farm, regional or global scales and temporal aspect must be considered. SI may warrant whole system redesign or land reallocation (Garnett et al. 2013; Pretty et al. 2018). Accordingly, there is *high agreement* concerning the need to consider multiple environmental and social outcomes

Box 7.11 (Continued)

at wider spatial scales, such as catchments or regions (Weltin et al. 2018; Bengochea Paz et al. 2020; Cassman and Grassini 2020). Impacts may be considered in relative terms (per area or product unit), with relationships potentially antagonistic. Both area- and product unit-based metrics are valid, relevant under different contexts and useful in approaching SI, but do not capture overall impacts and trade-offs (Garnett 2014). To reduce the risk of unsustainable intensification, quantitative data and selection of appropriate metrics to identify and guide strategies are paramount (Garnett et al. 2013; Gunton et al. 2016; Cassman and Grassini 2020).

Avoiding unsustainable intensification

It is critical that intensification does not drive expansion of unsustainable practices. Increased productivity with associated economic reward could incentivise and reward agricultural land expansion, or environmentally and socially damaging practices on existing and former agricultural land (Ceddia et al. 2013; Phalan 2018). Accordingly, coordinated policies are crucial to ensuring desired outcomes (Godfray and Garnett 2014; Reddy et al. 2020; Kassam and Kassam 2020). Barretto et al. (2013) found that in agriculturally consolidated areas, land-use intensification coincided with either a contraction of both cropland and pasture areas, or cropland expansion at the expense of pastures, both resulting in a stable farmed area. In contrast, in agricultural frontier areas, land-use intensification coincided with expansion of agricultural lands.

In conclusion, SI within agriculture is needed given the rising global population and the need to address multiple environmental and social externalities associated with agricultural activities. However, implementation requires strong stakeholder engagement, appropriate regulations, rigorous monitoring and verification and comprehensive outreach and knowledge exchange programmes.

A factor that will influence future carbon storage in so-called land-based reservoirs involves considering short- and long-term climate benefits, as well as interactions among various natural climate solution options. The benefits of various natural climate solutions depend on a variety of spatially dependent issues as well as institutional factors, including their management status (managed or unmanaged systems), their productivity, opportunity costs, technical difficulty of implementation, local willingness to consider, property rights and institutions, among other factors. Biomass energy, as described elsewhere in this chapter and in (Cross-Working Group Box 3 in Chapter 12), is a potential example of an option with trade-offs that emerge when policies favour one type of mitigation strategy over another. Bioenergy production needs safeguards to limit negative impacts on carbon stocks on the land base as is already in place in the EU Renewable Energy Directive and several national schemes in Netherlands, UK and Denmark (Buchholz et al. 2016; Khanna et al. 2017; DeCicco and Schlesinger 2018; Favero et al. 2020). It is argued that a carbon tax on only fossil fuel derived emissions, may lead to massive deployment of bioenergy, although the effects of such a policy can be mitigated when combined with policies that encourage sustainable forest management and protection of forest carbon stocks as well as forest management certification (*high confidence*) (Nabuurs et al. 2017, Baker et al. 2019 and Favero et al. 2020).

If biomass energy production expands and shifts to carbon capture and storage (e.g., BECCS) during the century, there could be a significant increase in the area of crop and forestland used for biomass energy production (Sections 7.4 and 7.5). BECCS is not projected to be widely implemented for several decades, but in the meantime, policy efforts to advance land-based measures including reforestation and restoration activities (Strassburg et al.

2020) combined with sustainable management and provision of agricultural and wood products are widely expected to increase the terrestrial pool of carbon (Cross-Working Group Box 3 in Chapter 12). Carbon sequestration policies, sustainable land management (forest and agriculture), and biomass energy policies can be complementary (Favero et al. 2017; Baker et al. 2019). However, if private markets emerge for biomass and BECCS on the scale suggested in the SR1.5, policy efforts must ramp up to substantially value, encourage, and protect terrestrial carbon stocks and ecosystems to avoid outcomes inconsistent with many SDGs (*high confidence*).

7.6.4 Barriers and Opportunities for AFOLU Mitigation

The AR5 and other assessments have acknowledged many barriers and opportunities to effective implementation of AFOLU measures. Many of these barriers and opportunities focus on the context in developing countries, where a significant portion of the world's cost-effective mitigation exists, but where domestic financing for implementation is likely to be limited. The SSPs capture some of this context, and as a result, IAMs (Section 7.5) exhibit a wide range of land-use outcomes, as well as mitigation potential. Potential mitigation, however, will be influenced by barriers and opportunities that are not considered by IAMs or by bottom-up studies reviewed here. For example, more efficient food production systems, or sustainable intensification within agriculture, and globalised trade could enhance the extent of natural ecosystems leading to lower GHG emissions from the land system and lower food prices (Popp et al. 2017), but this (or any) pathway will create new barriers to implementation and encourage new opportunities, negating potential benefits (Box 7.11). It is critically important to consider the current context in any country.

7.6.4.1 Socio-economic Barriers and Opportunities

Design and coverage of financing mechanisms. The lack of resources thus far committed to implementing AFOLU mitigation, income and access to alternative sources of income in rural households that rely on agriculture or forests for their livelihoods remains a considerable barrier to adoption of AFOLU (*high confidence*). Section 7.6.1 illustrates that to date only USD0.7 billion yr⁻¹ has been spent on AFOLU mitigation, well short of the more than USD400 billion yr⁻¹ that would be needed to achieve the economic potential described in Section 7.4. Despite long-term recognition that AFOLU can play an important role in mitigation, the *economic incentives* necessary to achieve AFOLU aspirations as part of the Paris Agreement or to maintain temperatures below 2.0°C have not emerged. Without quickly ramping up spending, the lack of funding to implement projects remains a substantial barrier (*high confidence*). Investments are critically important in the livestock sector, which has the highest emissions reduction potential among options because actions in the sector influence agriculture specific activities, such as enteric fermentation, as well as deforestation (Mayberry et al. 2019). In many countries with export-oriented livestock industries, livestock farmers control large swaths of forests or re-forestable areas. Incentive mechanisms and funding can encourage adoption of mitigation strategies, but funding is currently too low to make consistent progress.

Scale and accessibility of financing. The largest share of funding to date has been for REDD+, and many of the commitments to date suggest that there will be significant funding in this area for the foreseeable future. Funding for conservation programmes in OECD countries and China affects carbon, but has been driven

by other objectives such as water quality and species protection. Considerably less funding has been available for agricultural projects aimed at reducing carbon emissions, and outside of voluntary markets, there do not appear to be large sources of funding emerging either through international organisations, or national programs. In the agricultural sector, funding for carbon must be obtained by redirecting existing resources from non-GHG conservation to GHG measures, or by developing new funding streams (Henderson et al. 2020).

Risk and uncertainty. Most approaches to reduce emissions, especially in agriculture, require new or different technologies that involve significant time or financial investments by the implementing landholders. Adoption rates are often slow due to risk aversion among agricultural operators. Many AFOLU measures require carbon to be compensated to generate positive returns, reducing the likelihood of implementation without clear financial incentives. Research to show costs and benefits is lacking in most parts of the world.

Poverty. Mitigation and adaptation can have important implications for vulnerable people and communities, for example, mitigation activities consistent with scenarios examined in the SR1.5 could raise food and fiber prices globally (Section. 7.5). In the NDCs, 82 Parties included references to social issues (e.g., poverty, inequality, human well-being, marginalisation), with poverty the most cited factor (70 Parties). The number of hungry and food insecure people in the world is growing, reaching 821 million in 2017, or one in every nine people (FAO 2018b), and two-thirds live in rural areas (Laborde Debucquet et al. 2020). Consideration of rural poverty and food insecurity is central in AFOLU mitigation because there are a large number of farms in the world (about 570 million), and most are

Box 7.12 | Financing AFOLU Mitigation; What Are the Costs and Who Pays?

Achieving the large contribution to mitigation that the AFOLU sector can make requires public and private investment. Austin et al. (2020) estimate that in forestry, USD178 billion yr⁻¹ is needed over the next decade to achieve 5 GtCO₂ yr⁻¹, and investments need to ramp up to USD400 billion yr⁻¹ by 2050 to expand effort to 6 GtCO₂ yr⁻¹. Other land-based options, such as mangrove protection, peatland restoration, and agricultural options would increase this total cost estimate, but have smaller to negligible opportunity costs.

Financing needs in AFOLU, and in particular in forestry, include both the direct effects of any changes in activities – costs of planting or managing trees, net revenues from harvesting, costs of thinning, costs of fire management, and so on – as well as the opportunity costs associated with land-use change. Opportunity costs are a critical component of AFOLU finance, and must be included in any estimate of the funds necessary to carry out projects. They are largest, as share of total costs, in forestry because they play a prominent role in achieving high levels of afforestation, avoided deforestation, and improved forest management. In case of increasing soil carbon in croplands through reduced tillage, there are often cost savings associated with increased residues because there is less effort tilling, but the carbon effects per hectare are also modest. There could, however, be small opportunity costs in cases where residues may otherwise be marketed to a biorefinery. The effect of reduced tillage on yields varies considerably across sites and crop types, but tends to enhance yields modestly in the longer-run.

Opportunity costs are a direct financing costs for activities that require land uses to change. For instance a government can encourage planting forests on agricultural land by (a) requiring it, (b) setting up a market or market-based incentives, or (c) buying the land and doing it themselves. In each case, the required investment is the same – the planting cost plus the net foregone returns of agricultural rents – even though a different entity pays the cost. Private entities that pay for carbon credits will also bear the direct costs of planting plus the opportunity costs. In the case of avoided deforestation, opportunity costs similarly must be paid to individual actors to avoid the deforestation.

smaller than 2 hectares. It is important to better understand how different mitigation policies affect the poor.

Cultural values and social acceptance. Barriers to adoption of AFOLU mitigation will be strongest where historical practices represent long-standing traditions (*high confidence*). Adoption of new mitigation practices, however, may proceed quickly if the technologies can be shown to improve crop yields, reduce costs, or otherwise improve livelihoods (Ranjan 2019). AR6 presents new estimates of the mitigation potential for shifts in diets and reductions in food waste, but given long-standing dietary traditions within most cultures, some of the strongest barriers exist for efforts to change diets (*medium confidence*). Furthermore, the large number of undernourished who may benefit from increased calories and meat will complicate efforts to change diets. Regulatory or tax approaches will face strong resistance, while efforts to use educational approaches and voluntary measures have limited potential to slow changes in consumption patterns due to free-riders, rebound effects, and other limitations. Food loss and waste occurs across the supply chain, creating significant challenges to reduce it (FAO 2019c). Where food loss occurs in the production stage, in other words, in fields at harvest, there may be opportunities to align reductions in food waste with improved production efficiency, however, adoption of new production methods often requires new investments or changes in labour practices, both of which are barriers.

7.6.4.2 Institutional Barriers and Opportunities

Transparent and accountable governance. Good governance and accountability are crucial for implementation of forest and agriculture mitigation. Effective nature-based mitigation will require large-scale estimation, modelling, monitoring, reporting and verification of GHG inventories, mitigation actions, as well as their implications for sustainable development goals and their interactions with climate change impacts and adaptation. Efforts must be made to integrate the accounting from projects to the country level. While global datasets have emerged to measure forest loss, at least temporarily (e.g., Hansen et al. 2013), similar datasets do not yet exist for forest degradation and agricultural carbon stocks or fluxes. Most developing countries have insufficient capacity to address research needs, modelling, monitoring, reporting and data requirements (Ravindranath et al. 2017), compromising transparency, accuracy, completeness, consistency and comparability.

Opportunity for political participation of local stakeholders is barrier in most places where forest ownership rights are not sufficiently documented (Essl et al. 2018). Since incentives for self-enforcement can have an important influence on deforestation rates (Fortmann et al. 2017), weak governance and insecure property rights are significant barriers to introduction of forest carbon offset projects in developing countries, where many of the low-cost options for such projects exist (Gren and Zeleke 2016). Governance challenges exist at all levels of government, with poor coordination, insufficient information sharing, and concerns over accountability playing a prominent role within REDD+ projects and programmes (Ravikumar et al. 2015). In some cases, governments are increasingly centralising REDD+ governance and limiting the distribution of governance

functions between state and non-state actors (Zelli et al. 2017; Phelps et al. 2010). Overlap and duplication in Forest Law Enforcement, Governance and Trade (FLEGT) and REDD+ also limits governance effectiveness (Gupta et al. 2016).

Clear land tenure and land-use rights. Unclear property rights and tenure insecurity undermine the incentives to improve forest and agricultural productivity, lead to food insecurity, undermine REDD+ objectives, discourage adoption of farm conservation practices, discourage tree planting and forest management, and exacerbate conflict between different land users (Antwi-Agyei et al. 2015; Felker et al. 2017; Sunderlin et al. 2018; Borrás and Franco 2018; Riggs et al. 2018; Kansanga and Luginaah 2019). Some positive signs exist as over 500 million hectares of forests have been converted to community management with clear property rights in the past two decades (Rights and Resources Initiative 2018), but adoption of forest and agricultural mitigation practices will be limited in large remaining areas with unclear property rights (Gupta et al. 2016).

Lack of institutional capacity. Institutional complexity, or lack thereof, represents a major challenge when implementing large and complex mitigation programmes (e.g., REDD+) in agriculture, forest and other land uses (Bäckstrand et al. 2017). Without sufficient capacity, many synergies between agricultural and forest programs, or mitigation and adaptation opportunities, may be missed (Duguma et al. 2014). Another aspect of institutional complexity is the different biophysical and socio-economic circumstances as well as the public and private financial means involved in the architecture and implementation of REDD+ and other initiatives (Zelli et al. 2017).

7.6.4.3 Ecological Barriers and Opportunities

Availability of land and water. Climate mitigation scenarios in the two recent special reports (SR1.5 and SRCCL) that aim to limit global temperature increase to 2°C or less involve carbon dioxide (CO₂) removal from the atmosphere. To support large-scale CDR, these scenarios involve significant land-use change, due to afforestation/reforestation, avoided deforestation, and deployment of biomass energy with carbon capture and storage (BECCS). While a considerable amount of land is certainly available for new forests or new bioenergy crops, that land has current uses that will affect not only the costs, but also the willingness of current users or owners, to shift uses. Regions with private property rights and a history of market-based transactions may be the most feasible for land-use change or land management change to occur. Areas with less secure tenure or a land market with fewer transactions in general will likely face important hurdles that limit the feasibility of implementing novel nature-based solutions.

Implementation of nature-based solution may have local or regionally important consequences for other ecosystem services, some of which may be negative (*high confidence*). Land-use change has important implications for the hydrological cycle, and the large land-use shifts suggested for BECCS when not carried out in a carefully planned manner, are expected to increase water demands substantially across the globe (Stenzel et al. 2019; Rosa et al. 2020). Afforestation can have minor to severe consequences for surface water acidification,

depending on site-specific factors and exposure to air pollution and sea-salts (Futter et al. 2019). The potential effects of coastal afforestation on sea-salt related acidification could lead to re-acidification and damage on aquatic biota.

Specific soil conditions, water availability, GHG emission-reduction potential as well as natural variability and resilience.

Recent analysis by (Cook-Patton et al. 2020) illustrates large variability in potential rates of carbon accumulation for afforestation and reforestation options, both within biomes/ecozones and across them. Their results suggest that while there is large potential for afforestation and reforestation, the carbon uptake potential in land-based climate change mitigation efforts is highly dependent on the assumptions related to climate drivers, land use and land management, and soil carbon responses to land-use change. Less analysis has been conducted on bioenergy crop yields, however, bioenergy crop yields are also likely to be highly variable, suggesting that bioenergy supply could exceed or fall short of expectations in a given region, depending on site conditions.

The effects of climate change on ecosystems, including changes in crop yields, shifts in terrestrial ecosystem productivity, vegetation migration, wildfires, and other disturbances also will affect the potential for AFOLU mitigation. Climate is expected to reduce crop yields, increase crop and livestock prices, and increase pressure on undisturbed forest land for food production creating new barriers and increasing costs for implementation of many nature-based mitigation techniques (*medium confidence*) (IPCC AR6 WGII Chapter 5).

The observed increase in the terrestrial sink over the past half century can be linked to changes in the global environment, such as increased atmospheric CO₂ concentrations, N deposition, or changes in climate (Ballantyne et al. 2012), though not always proven from ground-based information (Vandersleen et al. 2015). While the terrestrial sink relies on regrowth in secondary forests (Houghton and Nassikas 2017), there is emerging evidence that the sink will slow in the Northern Hemisphere as forests age (Nabuurs et al. 2013), although saturation may take decades (Zhu et al. 2018). Forest management through replanting, variety selection, fertilisation, and other management techniques, has increased the terrestrial carbon sink over the last century (Mendelsohn and Sohngen 2019). Saturation of the sink in situ may not occur when, for example, substitution effects of timber usage are also considered.

Increasing concentrations of CO₂ are expected to increase carbon stocks globally, with the strongest effects in the tropics (Schimel et al. 2015; Kim et al. 2017a) (IPCC AR6 WGII Chapter 5) and economic models suggest that future sink potential may be robust to the impacts of climate change (Tian et al. 2018). However, it is uncertain if this large terrestrial carbon sink will continue in the future (Aragão et al. 2018), as it is increasingly recognised that gains due to CO₂ fertilisation are constrained by climate and increasing disturbances (Schurgers et al. 2018; Duffy et al. 2021) (IPCC AR6 WGII Chapter 5). Further, negative synergies between local impacts like deforestation and forest fires may interact with global drivers like climate change and lead to tipping points (Lovejoy and Nobre 2018). Factors that reduce permanence or slow forest growth will drive up costs of

forest mitigation measures, suggesting that climate change presents a formidable challenge to implementation of nature-based solutions beyond 2030 (*high confidence*).

In addition to climate change, Dooley and Kartha (2018) also note that technological and social factors could ultimately limit the feasibility of agricultural and forestry mitigation options, especially when deployed at large scale. Concern is greatest with widespread use of bioenergy crops, which could lead to forest losses (Harper et al. 2018). Deployment of BECCS and forest-based mitigation can be complementary (Favero et al. 2017; Baker et al. 2019), but inefficient policy approaches could lead to net carbon emissions if BECCS replaces high-carbon content ecosystems with crops.

Adaptation benefits and biodiversity conservation. Biodiversity may improve resilience to climate change impacts as more-diverse systems could be more resilient to climate change impacts, thereby maintaining ecosystem function and preserving biodiversity (Hisano et al. 2018). However, losses in ecosystem functions due species shifts or reductions in diversity may impair the positive effects of biodiversity on ecosystems. Forest management strategies based on biodiversity and ecosystems functioning interactions can augment the effectiveness of forests in reducing climate change impacts on ecosystem functioning (*high confidence*). In spite of the many synergies between climate policy instruments and biodiversity conservation, however, current policies often fall short of realising this potential (Essl et al. 2018).

7.6.4.4 Technological Barriers and Opportunities

Monitoring, reporting, and verification. Development of satellite technologies to assess potential deforestation has grown in recent years with the release of 30 m data by Hansen et al. (2013), however, this data only captures tree cover loss, and increasing accuracy over time may limit its use for trend analysis (Ceccherini et al. 2020; Palahí et al. 2021). Datasets on forest losses are less well developed for reforestation and afforestation. As Mitchell et al. (2017) point out, there has been significant improvement in the ability to measure changes in tree and carbon density on sites using satellite data, but these techniques are still evolving and improving and they are not yet available for widespread use.

Ground-based forest inventory measurements have been developed in many countries, most prominently in the Northern Hemisphere, but more and more countries are starting to develop and collect national forest inventories. Training and capacity building is going on in many developing countries under UNREDD and FAO programmes. Additional efforts to harmonise data collection methods and to make forest inventory data available to the scientific community would improve confidence in forest statistics, and changes in forest statistics over time. To some extent the Global Forest Biodiversity Initiative fills in this data gap (<https://gfbi.udl.cat/>).

7.6.5 Linkages to Ecosystem Services, Human Well-being and Adaptation (including SDGs)

The linkage between biodiversity, ecosystem services, human well-being and sustainable development is widely acknowledged (Millennium Ecosystem Assessment 2005; UNEP 2019). Loss of biodiversity and ecosystem services will have an adverse impact on quality of life, human well-being and sustainable development (IPBES 2019a). Such losses will not only affect current economic growth but also impede the capacity for future economic growth.

Population growth, economic development, urbanisation, technology, climate change, global trade and consumption, policy and governance are key drivers of global environmental change over recent decades (Kram et al. 2014; UNEP 2019; WWF 2020). Changes in biodiversity and ecosystem services are mainly driven by habitat loss, climate change, invasive species, over-exploitation of natural resources, and pollution (Millennium Ecosystem Assessment 2005). The relative importance of these drivers varies across biomes, regions, and countries. Climate change is expected to be a major driver of biodiversity loss in the coming decades, followed by commercial forestry and bioenergy production (OECD 2012; UNEP 2019). Population growth along with rising incomes and changes in consumption and dietary patterns, will exert immense pressure on land and other natural resources (IPCC 2019). Current estimates suggest that 75% of the land surface has been significantly anthropogenically altered, with 66% of the ocean area experiencing increasing cumulative impacts and over 85% of wetland area lost (IPBES 2019a). As discussed, in Section 7.3, land-use change is driven amongst others by agriculture, forestry (logging and fuelwood harvesting), infrastructural development and urbanisation, all of which may also generate localised air, water, and soil pollution (IPBES 2019a). Over a third of the world's land surface and nearly three-quarters of available freshwater resources are devoted to crop or livestock production (IPBES 2019a). Despite a slight reduction in global agricultural area since 2000, regional agricultural area expansion has occurred in Latin America and the Caribbean, Africa and the Middle East (FAO 2019c; OECD and FAO 2019). The degradation of tropical forests and biodiversity hotspots, endangers habitat for many threatened and endemic species, and reduces valuable ecosystem services. However, trends vary considerably by region. As noted in Section 7.3, global forest area declined by roughly 178 Mha between 1990 and 2020 (FAO 2020a), though the rate of net forest loss has decreased over the period, due to reduced deforestation in some countries and forest gains in others. Between 1990 to 2015, forest cover fell by almost 13% in South-East Asia, largely due to an increase in timber extraction, large-scale biofuel plantations and expansion of intensive agriculture and shrimp farms, whereas in North-East Asia and South Asia it increased by 23% and 6% respectively, through policy instruments such as joint forest management, payment for ecosystem services, and restoration of degraded forests (IPBES 2018b). It is lamenting that the area under natural forests which are rich in biodiversity and provide diverse ecosystem services decreased by 301 Mha between 1990 and 2020, decreasing in most regions except Europe and Oceania with largest losses reported in sub-Saharan Africa (FAO 2020a). The increasing trend of mining in forest and coastal areas, and in river basins for extracting has had significant negative

impacts on biodiversity, air and water quality, water distribution, and on human health (Section 7.3). Freshwater ecosystems equally face a series of combined threats including from land-use change, water extraction, exploitation, pollution, climate change and invasive species (IPBES 2019a).

7.6.5.1 Ecosystem Services

An evaluation of eighteen ecosystem services over the past five decades (1970–2019) found only four (agricultural production, fish harvest, bioenergy production and harvest of materials) to demonstrate increased performance, while the remaining fourteen, mostly concerning regulating and non-material contributions, were found to be in decline (IPBES 2019a). The value of global agricultural output (over USD3.54 trillion in 2018) had increased approximately threefold since 1970, and roundwood production (industrial roundwood and fuelwood) by 27%, between 1980 to 2018, reaching some 4 billion m³ in 2018. However, the positive trends in these four ecosystem services does not indicate long-term sustainability. If increases in agricultural production are realised through forest clearance or through increasing energy-intensive inputs, gains are likely to be unsustainable in the long run. Similarly, an increase in fish production may involve overfishing, leading to local species declines which also impacts fish prices, fishing revenues, and the well-being of coastal and fishing communities (Sumaila and Lam 2020). Climate change and other drivers are likely to affect future fish catch potential, although impacts will differ across regions (Sumaila et al. 2017; Domke et al. 2019).

The increasing trend in aquaculture production especially in South and South-East Asia through intensive methods affects existing food production and ecosystems by diverting rice fields or mangroves (Bhattacharya and Ninan 2011). Although extensive traditional fish farming of carp in central Europe can contribute to landscape management, enhance biodiversity and provide ecosystem services, there are several barriers to scale up production due to strict EU environmental regulations, vulnerability to extreme weather events, and to avian predators that are protected by EU laws, and disadvantages faced by small-scale enterprises that dominate the sector (European-Commission 2021). Bioenergy production may have high opportunity costs in land-scarce areas and compete with land used for food production which threatens food security and affects the poor and vulnerable. But these impacts will differ across scale, contexts and other factors.

Currently, land degradation is estimated to have reduced productivity in 23% of the global terrestrial area, and between USD235 billion and USD577 billion in annual global crop output is at risk because of pollinator loss (IPBES 2019a). The global trends reviewed above are based on data from 2000 studies. It is not clear whether the assessment included a quality control check of the studies evaluated and suffer from aggregation bias. For instance, a recent meta-analysis of global forest valuation studies noted that many studies reviewed had shortcomings such as failing to clearly mention the methodology and prices used to value the forest ecosystem services, double counting, data errors, and so on (Ninan and Inoue 2013). Furthermore, the criticisms against the paper by (Costanza et al.

1997), such as ignoring ecological feedbacks and non-linearities that are central to the processes that link all species to each other and their habitats, ignoring substitution effects may also apply to the global assessment (Smith 1997; Bockstael et al. 2000; Loomis et al. 2000). Land degradation has had a pronounced impact on ecosystem functions worldwide (IPBES 2018e). Net primary productivity of ecosystem biomass and of agriculture is presently lower than it would have been under a natural state on 23% of the global terrestrial area, amounting to a 5% reduction in total global net primary productivity (IPBES 2018e). Over the past two centuries, soil organic carbon, an indicator of soil health, has seen an estimated 8% loss globally (176 GtC) from land conversion and unsustainable land management practices (IPBES 2018e). Projections to 2050 predict further losses of 36 GtC from soils, particularly in sub-Saharan Africa. These losses are projected to come from the expansion of agricultural land into natural areas (16 GtC), degradation due to inappropriate land management (11 GtC) and the draining and burning of peatlands (9 GtC) and melting of permafrost (IPBES 2018e). Trends in biodiversity measured by the global living planet index between 1970 to 2016 indicate a 68% decline in monitored population of mammals, birds, amphibians, reptiles, and fish (WWF 2020). FAO's recent report on the state of the world's biodiversity for food and agriculture points to an alarming decline in biodiversity for food and agriculture including associated biodiversity such as pollination services, microorganisms which are essential for production systems (FAO 2019d). These suggest that overall ecosystem health is consistently declining with adverse consequences for good quality of life, human well-being, and sustainable development.

Although numerous studies have estimated the value of ecosystem services for different sites, ecosystems, and regions, these studies mostly evaluate ecosystem services at a single point in time (Costanza et al. 1997; Xue and Tisdell 2001; Nahuelhual et al. 2007;

de Groot et al. 2012; Ninan and Kontoleon 2016). The few studies that have assessed the trends in the value of ecosystem services provided by different ecosystems across regions and countries indicate a declining trend (Costanza et al. 2014; Kubiszewski et al. 2017). Land-use change is a major driver behind loss of biodiversity and ecosystem services in most regions (IPBES 2018b; IPBES 2018c, IPBES 2018d, Rice et al. 2018). Projected impacts of land-use change and climate change on biodiversity and ecosystem services (material and regulating services) between 2015 to 2050 were assessed to have relatively less negative impacts under global sustainability scenarios as compared to regional competition and economic optimism scenarios (IPBES 2019a). The projected impacts were based on a subset of Shared Socio-economic Pathway (SSP) scenarios and GHG emissions trajectories (RCP) developed in support of IPCC assessments. There are synergies, trade-offs and co-benefits between ecosystem services and mitigation options with impacts on ecosystem services differing by scale and contexts (*high confidence*). Measures such as conservation agriculture, agroforestry, soil and water conservation, afforestation, adoption of silvopastoral systems, can help minimise trade-offs between mitigations options and ecosystem services (Duguma et al. 2014). Climate-smart agriculture (CSA) is being promoted to enable farmers to make agriculture more sustainable and adapt to climate change (Box 7.4). However, experience with CSA in Africa has not been encouraging. For instance, a study of climate-smart cocoa production in Ghana shows that due to lack of tenure (tree) rights, bureaucratic and legal hurdles in registering trees in cocoa farms, and other barriers small cocoa producers could not realise the project benefits (Box 7.13). Experience of CSA in some other sub-Saharan African countries and other countries such as Belize too has been constrained by weak extension systems and policy implementation, and other barriers (Arakelyan et al. 2017; Kongsager 2017).

Box 7.13 | Case Study: Climate-smart Cocoa Production in Ghana

Policy objectives

- i. To promote sustainable intensification of cocoa production and enhance the adaptive capacity of small cocoa producers.
- ii. To reduce cocoa-induced deforestation and GHG emissions.
- iii. To improve productivity, incomes, and livelihoods of smallholder cocoa producers.

Policy mix

The climate-smart cocoa (CSC) production programme in Ghana involved distributing shade tree seedlings that can protect cocoa plants from heat and water stress, enhance soil organic matter and water holding capacity of soils, and provide other assistance with agroforestry, giving access to extension services such as agronomic information and agrochemical inputs. The shade tree seedlings were distributed by NGOs, government extension agencies, and the private sector free of charge or at subsidised prices and was expected to reduce pressure on forests for growing cocoa plants. The CSC programme was mainly targeted at small farmers who constitute about 80% of total farm holdings in Ghana. Although the government extension agency (Cocobod) undertook mass spraying or pruning of cocoa farms they found it difficult to access the 800,000 cocoa smallholders spread across the tropical south of the country. The project brought all stakeholders together, in other words, the government, private sector, local farmers and civil society or NGOs to facilitate the sustainable intensification of cocoa production in Ghana. Creation of a community-based governance structure was expected to promote benefit sharing, forest conservation, adaptation to climate change, and enhanced livelihood opportunities.

*Box 7.13 (continued)***Governance context***Critical enablers*

The role assigned to local government mechanisms such as Ghana's Community Resource Management Area Mechanisms (CREMAs) was expected to give a voice to smallholders who are an important stakeholder in Ghana's cocoa sector. CREMAs are inclusive because authority and ownership of natural resources are devolved to local communities who can thus have a voice in influencing CSC policy thereby ensuring equity and adapting CSC to local contexts. However, ensuring the long-term sustainability of CREMAs will help to make them a reliable mechanism for farmers to voice their concerns and aspirations, and ensure their independence as a legitimate governance structure in the long run. The private sector was assigned an important role to popularise climate-smart cocoa production in Ghana. However, whether this will work to the advantage of smallholder cocoa producers needs to be seen.

Critical barriers

The policy intervention overlooks the institutional constraints characteristic of the cocoa sector in Ghana where small farmers are dominant and have skewed access to resources and markets. Lack of secure tenure (tree rights) where the ownership of shade trees and timber vests with the state, bureaucratic and legal hurdles to register trees in their cocoa farms are major constraints that impede realisation of the expected benefits of the CSC programme. This is a great disincentive for small cocoa producers to implement CSC initiatives and nurture the shade tree seedlings and undertake land improvement measures. The state marketing board has the monopoly in buying and marketing of cocoa beans including exports which impeded CREMAs or farming communities from directly selling their produce to MNCs and traders. However, many MNCs have been involved in setting up of CREMA or similar structures, extending premium prices and non-monetary benefits (access to credit, shade tree seedlings, agrochemicals) thus indirectly securing their cocoa supply chains. A biased ecological discourse about the benefits of climate-smart agriculture and sustainable intensive narrative, complexities regarding the optimal shade levels for growing cocoa, and dependence on agrochemicals are issues that affect the success and sustainability of the project intervention. Dominance of private sector players especially MNCs in the sector may be detrimental to the interests of smallholder cocoa producers (Nasser et al. 2020).

7.6.5.2 Human Well-being and Sustainable Development Goals

Conservation of biodiversity and ecosystem services is part of the larger objective of building climate resilience and promoting good quality of life, human well-being and sustainable development. While two of the 17 SDGs directly relate to nature (SDGs 14 and 15 covering marine and terrestrial ecosystems and biodiversity), most other SDGs relating to poverty, hunger, inequality, health and well-being, clean sanitation and water, energy, and so on, are directly or indirectly linked to nature (Blicharska et al. 2019). A survey among experts to assess how 16 ecosystem services could help in achieving the SDGs relating to good environment and human well-being suggested that ecosystem services could contribute to achieving about 41 targets across 12 SDGs (Wood et al. 2018). They also indicated cross-target interactions and synergetic outcomes across many SDGs. Conservation of biodiversity and ecosystem services is critical to sustaining the well-being and livelihoods of poor and marginalised people, and indigenous communities who depend on natural resources (*high confidence*). Nature provides a broad array of goods and services that are critical to good quality of life and human well-being. Healthy and diverse ecosystems can play an important role in reducing vulnerability and building resilience to disasters and extreme weather events (SCBD 2009; The Royal Society Science Policy Centre 2014; Ninan and Inoue 2017).

Current negative trends in biodiversity and ecosystem services will undermine progress towards achieving 80% (35 out of 44) of the assessed targets of SDGs related to poverty, hunger, health, water, cities, climate, oceans and land (IPBES 2019a). However, Reyers and Selig (2020) note that the assessment by (IPBES 2019a) could only assess the consequences of trends in biodiversity and ecosystem services for 35 out of the 169 SDG targets due to data and knowledge gaps, and lack of clarity about the relationship between biodiversity, ecosystem services and SDGs.

Progress in achieving the 20 Aichi Biodiversity targets which are critical for realising the SDGs has been poor with most of the targets not being achieved or only partially realised (SCBD 2020). There could be synergies and trade-offs between ecosystem services and human well-being. For instance, a study notes that although policy interventions and incentives to enhance supply of provisioning services (e.g., agricultural production) have led to higher GDP, it may have an adverse effect on the regulatory services of ecosystems (Kirchner et al. 2015). However, we are aware of the inadequacies of traditional GDP as an indicator of well-being. In this context the Dasgupta Biodiversity Review argues for using the inclusive wealth approach to accurately measure social well-being by tracking the changes in produced, human and natural capital (Dasgupta 2021). Targets for nature (biodiversity and ecosystem services) should be refined so as to fit in with the metrics tracked by the SDGs (IPBES 2016; Rosa et al. 2017).

7.6.5.3 Land-based Mitigation and Adaptation

Combined mitigation and adaptation approaches have been highlighted throughout Section 7.4 regarding specific measures. Land-based mitigation and adaptation to the risks posed by climate change and extreme weather events can have several co-benefits as well as help promote development and conservation goals. Land-based mitigation and adaptation will not only help reduce GHG emissions in the AFOLU sector, but measures are required to closely link up with adaptation. In the central 2°C scenario, improved management of land and more efficient forest practices, a reduction in deforestation and an increase in afforestation, would account for 10% of the total mitigation effort over 2015–2050 (Keramidas et al. 2018). If managed and regulated appropriately, the Land sector could become carbon-neutral as early as 2030–2035, being a key sector for emissions reductions beyond 2025 (Keramidas et al. 2018). Nature-based solutions (NBS) with safeguards has immense potential for cost-effective adaptation to climate change; but their impacts will vary by scale and contexts (*high confidence*). Griscom et al. 2017 estimate this potential to provide 37% of cost-effective CO₂ mitigation until 2030 needed to meet 2°C goals with likely co-benefits for biodiversity. However, due to the time lag for technology deployment and natural carbon gain this mitigation potential of NBS by 2030 or 2050 can be delayed or much lower than the estimated potential (Qin et al. 2021).

7.7 Knowledge Gaps

Closing knowledge gaps and narrowing uncertainties are crucial to advance AFOLU mitigation. Knowledge gaps exist across a range of areas, from emissions accounting and mitigation measure development to integration of scientific and traditional knowledge and development and sustainable implementation strategies. The following are identified as priorities:

- Uncertainty in contemporary emissions and sinks within AFOLU is still high. There is ongoing need to develop and refine emission factors, improve activity data and facilitate knowledge exchange, concerning inventories and accounting. For example, insufficient knowledge on CO₂ emissions relating to forest management and burning or draining of organic soils (wetlands and peatlands), limits certainty on CO₂ and CH₄ fluxes.
- Improved monitoring of the land CO₂ balance is urgently needed, including impacts of land degradation and restoration efforts (e.g., in tropical and boreal regions), making use of combined remote sensing, artificial intelligence, ground-based and modelling tools (Grassi et al. 2021). Improved estimates would provide more reliable projections of nationally determined contributions to emissions reduction and enhancement of sinks, and reconciliation of national accounting and modelling results (Nabuurs et al. 2019).
- The future impacts of climate change on land systems are highly uncertain, for example, the role of permafrost thaw, tipping points, increased disturbances and enhanced CO₂ fertilisation (Friedlingstein et al. 2020). Further research into these

mechanisms is critical to better understand the permanence of mitigation measures in land sector.

- There is need to understand the role of forest management, carbon and nitrogen fertilisation and associated interactions in the current forest carbon sink that has emerged in the last 50 to 70 years. These aspects are likely to explain much of the difference between bookkeeping models and other methodologies.
- Continued research into novel and emerging mitigation measures and associated cost efficiency (e.g., CH₄ inhibitors or vaccines for ruminants) is required. In addition to developing specific measures, research is also needed into best practice regarding implementation and optimal agricultural land and livestock management at regional and country level. Further research into the feasible mitigation potential of sustainable intensification in terms of absolute GHG emissions and appropriate policy mechanisms, is required to implement and advance this strategy.
- Research into accounting systems and policy options that will enable agricultural soil and forest carbon to be utilised as offsets (voluntary or regulatory) is needed to increase financing for land-based CDR. Design of incentives that consider local institutions and novel frameworks for cooperation between private finance and public governance can encourage investment. Equally, research to adjust or remove regulations and subsidy schemes that may hamper land-based mitigation efforts, is urgently required.
- Improving mitigation potential estimates, whether derived from sectoral studies or IAMs to account for biophysical climate effects, and impacts of future climate change (e.g., mitigation permanence), biodiversity loss and corresponding feedbacks is needed. IAM ‘usability’ can be enhanced by integrating a wider set of measures and incorporating sustainability considerations.
- Research into the feasibility of improving and enhancing sustainable agricultural and forestry value chains, provision of renewable products (building with wood) and the sustainability of bioenergy is critically important. Modelled scenarios do not examine many poverty, employment and development trade-offs, which are highly context specific and vary enormously by region. Trade-off analysis and cost-benefit analysis can assist decision-making and policy.
- In-depth understanding of mitigation-SDG interactions is critical for identifying mitigation options that maximise synergies and minimise trade-offs. Mitigation measures have important synergies, trade-offs and co-benefits, impacting biodiversity and resource-use, human well-being, ecosystem services, adaptation capacity and many SDGs. In addition to exploring localised economic implementation costs, studies are needed to understand how measures will impact and interact with wider environmental and social factors across localities and contexts.

Frequently Asked Questions (FAQs)

FAQ 7.1 | Why is the Agriculture, Forestry and Other Land Uses (AFOLU) sector unique when considering GHG mitigation?

There are three principal reasons that make the AFOLU sector unique in terms of mitigation:

In contrast to other sectors, AFOLU can facilitate mitigation in several different ways. Specifically, AFOLU can (i) reduce emissions as a sector in its own right, (ii) remove meaningful quantities of carbon from the atmosphere and relatively cheaply, and (iii) provide raw materials to enable mitigation within other sectors, such as energy, industry or the built environment.

The emissions profile of AFOLU differs from other sectors, with a greater proportion of non-CO₂ gases (N₂O and CH₄). The impacts of mitigation efforts within AFOLU can vary according to which gases are targeted, as a result of the differing atmospheric lifetime of the gases and differing global temperature responses to the accumulation of the specific gases in the atmosphere.

In addition to tackling climate change, AFOLU mitigation measures have capacity, where appropriately implemented, to help address some critical, wider challenges, as well as contributing to climate change adaptation. AFOLU is inextricably linked with some of the most serious challenges that are suggested to have ever faced humanity, such as large-scale biodiversity loss, environmental degradation and the associated consequences. As AFOLU concerns land management and utilises a considerable portion of the Earth's terrestrial area, the sector greatly influences soil, water and air quality, biological and social diversity, the provision of natural habitats, and ecosystem functioning, consequently impacting many SDGs.

FAQ 7.2 | What AFOLU measures have the greatest economic mitigation potential?

Economic mitigation potential refers to the mitigation estimated to be possible at an annual cost of up to USD100 tCO₂⁻¹ mitigated. This cost is deemed the price at which society is willing to pay for mitigation and is used as a proxy to estimate the proportion of technical mitigation potential that could realistically be implemented. Between 2020 and 2050, measures concerning forests and other ecosystem are estimated to have an average annual mitigation potential of 7.3 (3.9–13.1) GtCO₂-eq yr⁻¹ at USD100 tCO₂⁻¹. At the same cost, agricultural measures are estimated to have a potential of 4.1 (1.7–6.7) GtCO₂-eq yr⁻¹. Emerging technologies, such as CH₄ vaccines and inhibitors, could sustainably increase agricultural mitigation potential in future. The diverted production effects of changes in demand (reduced food losses, diet changes and improved and enhanced wood products use), is estimated to have an economic potential of 2.2 (1.1–3.6) GtCO₂-eq yr⁻¹. However, cost forms only one constraint to mitigation, with realisation of economic potential dependent on multiple context-specific environmental and socio-cultural factors.

FAQ 7.3 | What are potential impacts of large-scale establishment of dedicated bioenergy plantations and crops and why is it so controversial?

The potential of bioenergy with carbon capture and storage (BECCS) remains a focus of debate with several studies evaluating the level at which BECCS could be sustainably implemented, published since AR5. BECCS involves sequestering carbon through plant growth (i.e., in trees or crops) and capturing the carbon generated when this biomass is processed for power or fuel. The captured carbon then requires long-term storage in for example, geological, terrestrial or ocean reservoirs, or in products. While appearing to create a net removal of carbon from the atmosphere, BECCS requires land, water and energy which can create adverse side effects at scale. Controversy has arisen because some of the models calculating the energy mix required to keep the temperature to 1.5°C have included BECCS at very large scales as a means of both providing energy and removing carbon from the atmosphere to offset emissions from industry, power, transport or heat. For example, studies have calculated that for BECCS to achieve 11.5 GtCO₂-eq per year of carbon removal in 2100, as envisaged in one scenario, 380–700 Mha or 25–46% of all the world's arable and cropland would be needed. In such a situation, competition for agricultural land seriously threatens food production and food security, while also impacting biodiversity, water and soil quality, and landscape aesthetic value. More recently however, the scenarios for BECCS have become much more realistic, though concerns regarding impacts on food security and the environment remain, while the reliability of models is uncertain due to methodological flaws. Improvements to models are required to better capture wider environmental and social impacts of BECCS in order to ascertain its sustainable contribution in emissions pathways. Additionally, the opportunity for other options that could negate very large-scale deployment of BECCS, such as other carbon dioxide removal measures or more stringent emission reductions in other sectors, could be explored within models.

Executive Summary

Although urbanisation is a global trend often associated with increased incomes and higher consumption, the growing concentration of people and activities is an opportunity to increase resource efficiency and decarbonise at scale (*very high confidence*). The same urbanisation level can have large variations in per capita urban carbon emissions. For most regions, per capita urban emissions are lower than per capita national emissions. {8.1.4, 8.3.3, 8.4, Box 8.1}

Most future urban population growth will occur in developing countries, where per capita emissions are currently low but expected to increase with the construction and use of new infrastructure and the built environment, and changes in incomes and lifestyles (*very high confidence*). The drivers of urban greenhouse gas (GHG) emissions are complex and include an interplay of population size, income, state of urbanisation, and how cities are laid out (i.e. urban form). How new cities and towns are designed, constructed, managed, and powered will lock-in behaviour, lifestyles, and future urban GHG emissions. Low-emission urbanisation can improve well-being while minimising impact on GHG emissions, but there is risk that urbanisation can lead to increased global GHG emissions through increased emissions outside the city's boundaries. {8.1.4, 8.3, Box 8.1, 8.4, 8.6}

The urban share of global GHG emissions (including carbon dioxide (CO₂) and methane (CH₄)) is substantive and continues to increase (*high confidence*). In 2015, urban emissions were estimated to be 25 GtCO₂-eq (about 62% of the global share) and in 2020, 29 GtCO₂-eq (67–72% of the global share).¹ About 100 of the highest emitting urban areas account for approximately 18% of the global carbon footprint. {8.1.6, 8.3.3}

The urban share of regional GHG emissions increased between 2000 and 2015, with much inter-region variation in the magnitude of the increase (*high confidence*). Globally, the urban share of national emissions increased 6 percentage points, from 56% in 2000 to 62% in 2015. For 2000 to 2015, the urban emissions share across AR6 WGIII regions increased from 28% to 38% in Africa, from 46% to 54% in Asia and Pacific, from 62% to 72% in Developed Countries, from 57% to 62% in Eastern Europe and West-Central Asia, from 55% to 66% in Latin America and Caribbean, and from 68% to 69% in the Middle East. {8.1.6, 8.3.3}

Per capita urban GHG emissions increased between 2000 and 2015, with cities in the Developed Countries region producing nearly seven times more per capita than the lowest emitting region (*medium confidence*). From 2000 to 2015, global urban GHG emissions per capita increased from 5.5 to 6.2 tCO₂-eq per person (an increase of 11.8%); Africa increased from 1.3 to 1.5 tCO₂-eq per person (22.6%); Asia and Pacific increased from 3.0 to

5.1 tCO₂-eq per person (71.7%); Eastern Europe and West-Central Asia increased from 6.9 to 9.8 tCO₂-eq per person (40.9%); Latin America and Caribbean increased from 2.7 to 3.7 tCO₂-eq per person (40.4%); and Middle East increased from 7.4 to 9.6 tCO₂-eq per person (30.1%). Albeit starting from the highest level, Developed Countries had a decline of 11.4 to 10.7 tCO₂-eq per person (–6.5%). {8.3.3}

The global share of future urban GHG emissions is expected to increase through 2050, with moderate to low mitigation efforts, due to growth trends in population, urban land expansion, and infrastructure and service demands, but the extent of the increase depends on the scenario and the scale and timing of urban mitigation action (*medium confidence*). In modelled scenarios, global consumption-based urban CO₂ and CH₄ emissions are projected to rise from 29 GtCO₂-eq in 2020 to 34 GtCO₂-eq in 2050 with moderate mitigation efforts (intermediate GHG emissions, SSP2–4.5), and up to 40 GtCO₂-eq in 2050 with low mitigation efforts (high GHG emissions, SSP3–7.0). With aggressive and immediate mitigation policies to limit global warming to 1.5°C (>50%) with no or limited overshoot by the end of the century (very low emissions, SSP1–1.9), including high levels of electrification, energy and material efficiency, renewable energy preferences, and socio-behavioural responses, urban GHG emissions could approach net-zero and reach a maximum of 3 GtCO₂-eq in 2050. Under a scenario with aggressive but not immediate urban mitigation policies to limit global warming to 2°C (>67%) (low emissions, SSP1–2.6), urban emissions could reach 17 GtCO₂-eq in 2050.² (Figure TS.13) {8.3.4}

Urban land areas could triple between 2015 and 2050, with significant implications for future carbon lock-in. There is a large range in the forecasts of urban land expansion across scenarios and models, which highlights an opportunity to shape future urban development towards low- or net-zero GHG emissions and minimise the loss of carbon stocks and sequestration in the agriculture, forestry and other land use (AFOLU) sector due to urban land conversion (*medium confidence*). By 2050, urban areas could increase up to 211% over the 2015 global urban extent, with the median projected increase ranging from 43% to 106%. While the largest absolute amount of new urban land is forecasted to occur in Asia and Pacific, and in Developed Countries, the highest rate of urban land growth is projected to occur in Africa, Eastern Europe and West-Central Asia, and in the Middle East. The infrastructure that will be constructed concomitant with urban land expansion will lock-in patterns of energy consumption that will persist for decades if not generations. Furthermore, given past trends, the expansion of urban areas is likely to take place on agricultural lands and forests, with implications for the loss of carbon stocks and sequestration. {8.3.1, 8.3.4, 8.4.1, 8.6}

The construction of new, and upgrading of, existing urban infrastructure through 2030 will result in significant emissions (*very high confidence*). The construction of new and upgrading

¹ These estimates are based on consumption-based accounting, including both direct emissions from within urban areas, and indirect emissions from outside urban areas related to the production of electricity, goods, and services consumed in cities. Estimates include all CO₂ and CH₄ emission categories except for aviation and marine bunker fuels, land-use change, forestry, and agriculture. {8.1, Annex I: Glossary}

² These scenarios have been assessed by WGI to correspond to intermediate, high, and very low GHG emissions.

of existing urban infrastructure using conventional practices and technologies can result in significant committed CO₂ emissions, ranging from 8.5 GtCO₂ to 14 GtCO₂ annually up to 2030 and more than double annual resource requirements for raw materials to about 90 billion tonnes per year by 2050, up from 40 billion tonnes in 2010 (*medium evidence, high agreement*). {8.4.1, 8.6}

Given the dual challenges of rising urban GHG emissions and future projections of more frequent extreme climate events, there is an urgent need to integrate urban mitigation and adaptation strategies for cities to address climate change and withstand its effects (*very high confidence*). Mitigation strategies can enhance resilience against climate change impacts while contributing to social equity, public health, and human well-being. Urban mitigation actions that facilitate economic decoupling can have positive impacts on employment and local economic competitiveness. {8.2, Cross-Working Group Box 2, 8.4}

Cities can only achieve net-zero GHG emissions through deep decarbonisation and systemic transformation (*very high confidence*). Three broad mitigation strategies have been found to be effective in reducing emissions when implemented concurrently: (i) reducing or changing urban energy and material use towards more sustainable production and consumption across all sectors, including through compact and efficient urban forms and supporting infrastructure; (ii) electrification and switching to net-zero-emissions resources; and (iii) enhancing carbon uptake and storage in the urban environment (*high evidence, high agreement*). Given the regional and global reach of urban supply chains, cities can achieve net-zero emissions only if emissions are reduced within and outside of their administrative boundaries. {8.1.6, 8.3.4, 8.4, 8.6}

Packages of mitigation policies that implement multiple urban-scale interventions can have cascading effects across sectors, reduce GHG emissions outside of a city's administrative boundaries, and reduce more emissions than the net sum of individual interventions, particularly if multiple scales of governance are included (*high confidence*). Cities have the ability to implement policy packages across sectors using an urban systems approach, especially those that affect key infrastructure based on spatial planning, electrification of the urban energy system, and urban green and blue infrastructure. The institutional capacity of cities to develop, coordinate, and integrate sectoral mitigation strategies within their jurisdiction varies by context, particularly those related to governance, the regulatory system, and budgetary control. {8.4, 8.5, 8.6}

Integrated spatial planning to achieve compact and resource-efficient urban growth through co-location of higher residential and job densities, mixed land use, and transit-oriented development (TOD) could reduce GHG emissions between 23% and 26% by 2050 compared to the business-as-usual scenario (*robust evidence, high agreement, very high confidence*). Compact cities with shortened distances between housing and jobs, and interventions that support a modal shift away from private motor

vehicles towards walking, cycling, and low-emissions shared and public transportation, passive energy comfort in buildings, and urban green infrastructure can deliver significant public health benefits and have lower GHG emissions. {8.2, 8.3.4, 8.4, 8.6}

Urban green and blue infrastructure can mitigate climate change through carbon sequestration, avoided emissions, and reduced energy use while offering multiple co-benefits (*robust evidence, high agreement*). Urban green and blue infrastructure, including urban forests and street trees, permeable surfaces, and green roofs³ offer potential to mitigate climate change directly through sequestering and storing carbon, and indirectly by inducing a cooling effect that reduces energy demand and reducing energy use for water treatment. Global urban trees store approximately 7.4 billion tonnes of carbon, and sequester approximately 217 million tonnes of carbon annually, although urban tree carbon storage and sequestration are highly dependent on biome. Among the multiple co-benefits of green and blue infrastructure are reducing the urban heat island (UHI) effect and heat stress, reducing stormwater runoff, improving air quality, and improving mental and physical health of urban dwellers. {8.2, 8.4.4}

The potential and sequencing of mitigation strategies to reduce GHG emissions will vary depending on a city's land use, spatial form, development level, and state of urbanisation (i.e., whether it is an established city with existing infrastructure, a rapidly growing city with new infrastructure, or an emerging city with infrastructure buildup (*high confidence*)). New and emerging cities will have significant infrastructure development needs to achieve high quality of life, which can be met through energy-efficient infrastructures and services, and people-centred urban design (*high confidence*). The long lifespan of urban infrastructures locks in behaviour and committed emissions. Urban infrastructures and urban form can enable socio-cultural and lifestyle changes that can significantly reduce carbon footprints. Rapidly growing cities can avoid higher future emissions through urban planning to co-locate jobs and housing to achieve compact urban form, and by leapfrogging to low-carbon technologies. Established cities will achieve the largest GHG emissions savings by replacing, repurposing, or retrofitting the building stock, targeted infilling and densifying, as well as through modal shift and the electrification of the urban energy system. New and emerging cities have unparalleled potential to become low or net-zero GHG emissions while achieving high quality of life by creating compact, co-located, and walkable urban areas with mixed land use and transit-oriented design, that also preserve existing green and blue assets. {8.2, 8.4, 8.6}

With over 880 million people living in informal settlements, there are opportunities to harness and enable informal practices and institutions in cities related to housing, waste, energy, water, and sanitation to reduce resource use and mitigate climate change (*low evidence, medium agreement*). The upgrading of informal settlements and inadequate housing to improve resilience and well-being offers a chance to create a low-carbon transition. However, there is limited quantifiable data on

³ These examples are considered to be a subset of nature-based solutions or ecosystem-based approaches.

these practices and their cumulative impacts on GHG emissions. {8.1.4, 8.2.2, Cross-Working Group Box 2, 8.3.2, 8.4, 8.6, 8.7}

Achieving transformational changes in cities for climate change mitigation and adaptation will require engaging multiple scales of governance, including governments and non-state actors, and in connection with substantive financing beyond sectoral approaches (*very high confidence*). Large and complex infrastructure projects for urban mitigation are often beyond the capacity of local municipality budgets, jurisdictions, and institutions. Partnerships between cities and international institutions, national and regional governments, transnational networks, and local stakeholders play a pivotal role in mobilising global climate finance resources for a range of infrastructure projects with low-carbon emissions and related spatial planning programmes across key sectors. {8.4, 8.5}

8.1 Introduction

8.1.1 What Is New Since AR5?

The Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change (IPCC) was the first IPCC report that had a standalone chapter on urban mitigation of climate change. The starting point for that chapter was how the spatial organisation of urban settlements affects greenhouse gas (GHG) emissions and how urban form and infrastructure could facilitate mitigation of climate change. A main finding in AR5 was that urban form shapes urban energy consumption and GHG emissions.

Since AR5, there has been growing scientific literature and policy foci on urban strategies for climate change mitigation. There are three possible reasons for this. First, according to AR5 Working Group III (WGIII) Chapter 12 on Human Settlements, Infrastructure, and Spatial Planning, urban areas generate between 71% and 76% of carbon dioxide (CO₂) emissions from global final energy use and between 67% and 76% of global energy (Seto et al. 2014). Thus, focusing on 'urban systems' (see Annex I: Glossary and Figure 8.15) addresses one of the key drivers of emissions. Second, more than half of the world population lives in urban areas, and by mid-century 7 out of 10 people on the planet will live in a town or a city (UN DESA 2019). Thus, coming up with mitigation strategies that are relevant to urban settlements is critical for successful mitigation of climate change. Third, beyond climate change, there is growing attention on cities as major catalysts of change and to help achieve the objectives outlined in multiple international frameworks and assessments.

Cities are also gaining traction within the work of the IPCC. The IPCC Special Report on Global Warming of 1.5°C (SR1.5 Chapter 4) identified four systems that urgently need to change in fundamental and transformative ways: urban infrastructure, land use and ecosystems, industry, and energy. Urban infrastructure was singled out but urban systems form a pivotal part of the other three systems requiring change (IPCC 2018a) (see 'infrastructure' in Glossary). The IPCC Special Report on Climate Change and Land (SRCL) identified cities not only as spatial units for land-based mitigation options but also places for managing demand for natural resources including food, fibre, and water (IPCC 2019).

Other international frameworks are highlighting the importance of cities. For example, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) report on nature's contribution to people is clear: cities straddle the biodiversity sphere in the sense that they present spatial units of ecosystem fragmentation and degradation while at the same time contain spatial units where the concentration of biodiversity compares favourably with some landscapes (IPBES 2019a). Cities are also featured as a key element in the transformational governance to tackle both climate change and biodiversity and ecosystem challenges in the first-ever IPCC-IPBES co-sponsored workshop report (Pörtner et al. 2021) (Section 8.5 and see 'governance' in Glossary).

The UN Sustainable Development Goals (SDGs) further underscore the importance of cities in the international arena with the inclusion

of SDG 11 on Sustainable Cities and Communities for 'inclusive, safe, resilient and sustainable' cities and human settlements (United Nations 2015; Queiroz et al. 2017; United Nations 2019). Additionally, UN-Habitat's New Urban Agenda (NUA) calls for various measures, including integrated spatial planning at the city-regional scale, to address the systemic challenges included in greening cities, among which is emissions reduction and avoidance (United Nations 2017).

Since AR5, there has also been an increase in scientific literature on urban mitigation of climate change, including more diversity of mitigation strategies than were covered during AR5 (Lamb et al. 2018), as well as a growing focus on how strategies at the urban scale can have compounding or additive effects beyond urban areas (e.g., in rural areas, land-use planning, and the energy sector).

There is more literature on using a systems approach to understand the interlinkages between mitigation and adaptation, and situating GHG emissions reduction targets within broader social, economic, and human well-being contexts and goals (Bai et al. 2018; Ürge-Vorsatz et al. 2018; Lin et al. 2021). In particular, the nexus approach, such as the water and energy nexus and the water-energy-food nexus, is increasingly being used to understand potential emissions and energy savings from cross-sectoral linkages that occur in cities (Wang and Chen 2016; Engström et al. 2017; Valek et al. 2017). There is also a growing literature that aims to quantify transboundary urban GHG emissions and carbon footprint beyond urban and national administrative boundaries (Chen et al. 2016; Hu et al. 2016). Such a scope provides a more complete understanding of how local urban emissions or local mitigation strategies can have effects on regions' carbon footprint or GHG emissions.

8.1.1.1 City Climate Action

Moreover, cities around the world are putting increasing focus on tackling climate change. Since AR5:

- Climate leadership at the local scale is growing with commitment from city decision-makers and policymakers to implement local-scale mitigation strategies (GCoM 2018, 2019; ICLEI 2019a; C40 Cities 2020a).
- More than 360 cities announced at the Paris Climate Conference that the collective impact of their commitments will lead to a reduction of up to 3.7 GtCO₂-eq (CO₂-equivalent) of urban emissions annually by 2030 (Cities for Climate 2015).
- The Global Covenant of Mayors (GCoM), a transnational network of more than 10,000 cities, has made commitments to reduce urban GHG emissions by up to 1.4–2.3 GtCO₂-eq annually by 2030 and 2.8–4.2 GtCO₂-eq annually by 2050, compared to business-as-usual (GCoM 2018, 2019).
- More than 800 cities have made commitments to achieve net-zero GHG emissions, either economy-wide or in a particular sector (NewClimate Institute and Data-Driven EnviroLab 2020).

Although most cities and other subnational actors are yet to meet their net-zero GHG or CO₂ emissions commitments, the growing numbers of those commitments, alongside organisations enabled to

facilitate reaching those targets, underscore the growing support for climate action by city and other subnational leaders.

8.1.1.2 Historical and Future Urban Emissions

One major innovation in this Assessment Report is the inclusion of historical and future urban GHG emissions. Urban emissions based on consumption-based accounting by regions has been put forth for the time frame 1990–2100 using multiple datasets with projections given in the framework of the Shared Socio-economic Pathway (SSP)–Representative Concentration Pathway (RCP) scenarios. This advance has provided a time dimension to urban footprints considering different climate scenarios with implications for urban mitigation, allowing a comparison of the way urban emissions and their reduction can evolve given different scenario contexts (see Glossary for definitions of various ‘pathways’ and ‘scenarios’ in the context of climate change mitigation, including ‘SSPs’ and ‘RCPs’).

8.1.1.3 Sustainable Development Linkages and Feasibility Assessment

Special emphasis is placed on the co-benefits of urban mitigation options, including an evaluation of linkages with the SDGs based on synergies and/or trade-offs. Urban mitigation options are further evaluated based on multiple dimensions according to the feasibility assessment (see Section 8.5.5 and Figure 8.19, and Section 8.SM.2) indicating the enablers and barriers of implementation. These advances provide additional guidance for urban mitigation.

8.1.2 Preparing for the Special Report on Cities and Climate Change in AR7

At the 43rd Session of the IPCC in 2016, the IPCC approved a Special Report on Climate Change and Cities during the Seventh Assessment Cycle of the IPCC (AR7). To stimulate scientific research knowledge exchange, the IPCC and nine global partners co-sponsored the IPCC Cities and Climate Change Science Conference, which brought together over 700 researchers, policymakers, and practitioners from 80 countries.

The conference identified key research priorities including the need for an overarching systems approach to understanding how sectors interact in cities as drivers for GHG emissions and the relationship between climate and other urban processes, as well as achieving transformation towards low-carbon and resilient futures (Bai et al. 2018). The subsequent report on the global research and action agenda identifies scale, informality, green and blue infrastructure, governance and transformation, as well as financing climate action, as areas for scientific research during the AR6 cycle and beyond (WCRP 2019).

8.1.3 The Scope of the Chapter: A Focus on Urban Systems

This chapter takes an urban systems approach and covers the full range of urban settlements, including towns, cities, and metropolitan areas. By ‘urban system’ (Figure 8.15), this chapter refers to two related concepts. First, an urban systems approach recognises that cities do not function in isolation. Rather, cities exhibit strong interdependencies across scales, whether it is within a region, a country, a continent, or worldwide. Cities are embedded in broader ecological, economic, technical, institutional, legal, and governance structures that often constrain their systemic function, which cannot be separated from wider power relations (Bai et al. 2016).

The notion of a system of cities has been around for nearly 100 years and recognises that cities are interdependent, in that significant changes in one city, such as economic activities, income, or population, will affect other cities in the system (Christaller 1933; Berry 1964; Marshall 1989). This perspective of an urban system emphasises the connections between a city and other cities, as well as between a city and its hinterlands (Hall and Hay 1980; Ramaswami et al. 2017b; Xu et al. 2018c). An important point is that growth in one city affects growth in other cities in the global, national or regional system of cities (Gabaix 1999; Scholvin et al. 2019; Knoll 2021).

Moreover, there is a hierarchy of cities (Taylor 1997; Liu et al. 2014), with very large cities at the top of the hierarchy concentrating political power and financial resources, but of which there are very few. Rather, the urban system is dominated by small and medium-sized cities and towns. With globalisation and increased interconnectedness of financial flows, labour, and supply chains, cities across the world today have long-distance relationships on multiple dimensions but are also connected to their hinterlands for resources.

The second key component of the urban systems lens identifies the activities and sectors within a city as being inter-connected – that cities are ecosystems (Rees 1997; Grimm et al. 2000; Newman and Jennings 2008; Acuto et al. 2019; Abdullah and Garcia-Chueca 2020; Acuto and Leffell 2021). This urban systems perspective emphasises linkages and interrelations within cities. The most evident example of this is urban form and infrastructure, which refer to the patterns and spatial arrangements of land use, transportation systems, and urban design. Changes in urban form and infrastructure can simultaneously affect multiple sectors, such as buildings, energy, and transport.

This chapter assesses urban systems beyond simply jurisdictional boundaries. Using an urban systems lens has the potential to accelerate mitigation beyond a single sector or purely jurisdictional approach (Section 8.4). An urban systems perspective presents both challenges and opportunities for urban mitigation strategies. It shows that any mitigation option potentially has positive or negative consequences in other sectors, other settlements, cities, or other parts of the world, and requires more careful and comprehensive considerations on the broader impacts, including equity and social justice (see Glossary for a comprehensive definition of ‘equity’ in the context of mitigation and adaptation). This chapter focuses on cities, city regions, metropolitan regions, megalopolitans, mega-urban regions, towns, and other types

of urban configurations because they are the primary sources of urban GHG emissions and tend to be where mitigation action can be most impactful.

There is no internationally agreed upon definition of 'urban', 'urban population', or 'urban area'. Countries develop their own definitions of urban, often based on a combination of population size or density, and other criteria including the percentage of population not employed in agriculture, the availability of electricity, piped water, or other infrastructures, and characteristics of the built environment, such as dwellings and built structures. This chapter assesses urban systems, which includes cities and towns. It uses a similar framework to Chapter 6 of AR6 WGII, referring to cities and urban settlements as 'concentrated human habitation centres that exist along a continuum' (Dodman et al. 2022) (for further definitions of 'urban', 'cities', 'settlements' and related terms, see Glossary, and WGII Chapter 6).

8.1.4 The Urban Century

The 21st century will be the urban century, defined by a massive increase in global urban populations and a significant building up of new urban infrastructure stock to accommodate the growing urban population. Six trends in urbanisation are especially important in the context of climate change mitigation.

First, the size and relative proportion of the urban population is unprecedented and continues to increase. As of 2018, approximately 55% of the global population lives in urban areas (about 4.3 billion people) (UN DESA 2019). It is predicted that 68% of the world population will live in urban areas by 2050. This will mean adding 2.5 billion people to urban areas between 2018 and 2050, with 90% of this increase taking place in Africa and Asia. There is a strong correlation between the level of urbanisation and the level of national income, with considerable variation and complexity in the relationship between the two (UN DESA 2019). In general, countries with levels of urbanisation of 75% or greater all have high national incomes, whereas countries with low levels of urbanisation under 35% have low national incomes (UN DESA 2019). In general, there is a clear positive correlation between the level of urbanisation and income levels (Figure 8.1 and Box 8.1).

Figure 8.14: Relationship between urbanisation level and gross national income (GNI). There is a positive and strong correlation between the urbanisation level and gross national income. High-income countries have high levels of urbanisation, on average 80%. Low-income countries have low levels of urbanisation, on average 30%. Source: UN DESA 2019, p. 42.

⁴ The countries and areas classification in the underlying report for this figure deviates from the standard classification scheme adopted by WGIII as set out in Annex II, Section 1.

Second, the geographic concentration of the world's current urban population is in emerging economies, and the majority of future urban population growth will take place in developing countries and least-developed countries (LDCs). About half of the world's urban population in 2018 lived in just seven countries, and about half of the increase in urban population through 2050 is projected to be concentrated in eight countries (UN DESA 2019) (Figure 8.2). Of these eight, seven are emerging economies where there will be a need for significant financing to construct housing, roads, and other urban infrastructure to accommodate the growth of the urban population. How these new cities of tomorrow will be designed and constructed will lock-in patterns of urban energy behaviour for decades if not generations (Sections 8.3.4 and 8.4). Thus, it is essential that urban

climate change mitigation strategies include solutions appropriate for cities of varying sizes and typologies (Section 8.6 and Figure 8.21).

Third, small and medium-sized cities and towns are a dominant type of urban settlement. In 2018, more than half (58%) of the urban population lived in cities and towns with fewer than 1 million inhabitants and almost half of the world's urban population (48%) lived in settlements with fewer than 500,000 inhabitants (Figure 8.3). Although megacities receive a lot of attention, only about 13% of the urban population worldwide lived in a megacity – an urban area with at least 10 million inhabitants (UN DESA 2019). Thus, there is a need for a wide range of strategies for urban mitigation of climate change that are appropriate for cities of varying levels of development

Figure 8.2: Urban population size in 2018 and increase in the projected urban population. In 2018, about half of the world's urban population lived in seven countries, and about half of the increase in urban population through 2050 is forecasted to concentrate in eight countries. Source: UN DESA 2019, p. 44.

Figure 8.3: Population of the world, by area of residence and size class of urban settlement for 2018. As of 2018, 4.2 billion people or 55% of the world population reside in urban settlements while 45% reside in rural areas. The coloured stacked column for the urban population represents the total number of inhabitants for a given size class of urban settlements. Megacities of 10 million or more inhabitants have a total of only 529 million inhabitants, corresponding to 12.5% of the urban population. In contrast, about 1.8 billion inhabitants reside in urban settlements with fewer than 300,000 inhabitants, corresponding to 41.5% of the urban population. The pie chart represents the respective shares for 2018, with 42% of the urban population residing in settlements with more than 1 million inhabitants, and 58% of the urban population residing in settlements with fewer than 1 million inhabitants. Almost half of the world's urban population (48%) live in settlements with fewer than 500,000 inhabitants. Source: adapted from UN DESA 2019, p. 56.

and size, especially smaller cities which often have lower levels of financial capacities than large cities.

Fourth, another trend is the rise of megacities and extended metropolitan regions. The largest cities around the world are becoming even larger, and there is a growing divergence in economic power between megacities and other large cities (Kourtit et al. 2015; Hoornweg and Pope 2017; Zhao et al. 2017b). Moreover, there is evidence that the largest city in each country has an increasing share of the national population and economy.

Fifth, population declines have been observed for cities and towns across the world, including in Poland, Republic of Korea, Japan, United States, Germany, and Ukraine. The majority of cities that have experienced population declines are concentrated in Europe. Multiple factors contribute to the decline in cities, including declining industries and the economy, declining fertility, and outmigration to larger cities. Shrinking urban populations could offer retrofitting opportunities (UNEP 2019) and increasing greenspaces (Jarzebski

et al. 2021), but the challenges for these cities differ in scope and magnitude from rapidly expanding cities.

Sixth, urbanisation in many emerging economies is characterised by informality and an informal economy (Brown and McGranahan 2016). The urban informal economy includes a wide array of activities, including but not limited to street vending, home-based enterprises, unreported income from self-employment, informal commerce, domestic service, waste-picking, and urban agriculture. The urban informal economy is large and growing. Globally, about 44% of the urban economy is informal, although there is much variation between countries and regions (ILO 2018). Emerging and developing economies have the highest percentage of the urban informal economy, with Africa (76%) and the Arab States (64%) with the largest proportion (ILO 2018). Urban informality also extends to planning, governance and institutions (Roy 2009; EU 2016; Lamson-Hall et al. 2019). Given its prevalence, it is important for urban climate change mitigation strategies to account for informality, especially in emerging and developing countries (Section 8.3.2).

8.1.5 Urbanisation in Developing Countries

Urbanisation in the 21st century will be dominated by population and infrastructure growth in developing countries, and as such it is important to highlight three aspects that are unique and especially relevant for climate change mitigation. First, urbanisation will increase in speed and magnitude. Given their significant impact on emissions, mitigation action in Asian cities, especially the large and rapidly growing cities, will have significant implications on global ambitions (Section 8.3.4).

Second, a number of cities in developing countries lack institutional, financial and technical capacities to enable local climate change action (Sharifi et al. 2017; Fuhr et al. 2018). While these capacities differ across contexts (Hickmann et al. 2017), several governance challenges are similar across cities (Gouldson et al. 2015). These factors also influence the ability of cities to innovate and effectively implement mitigation action (Nagendra et al. 2018) (Chapter 17).

Third, there are sizable economic benefits in developing country cities that can provide an opportunity to enhance political momentum and institutions (Colenbrander et al. 2016). The co-benefits approach (Section 8.2), which frames climate objectives alongside other development benefits, is increasingly seen as an important concept justifying and driving climate change action in developing countries (Sethi and Puppim de Oliveira 2018).

Large-scale system transformations are also deeply influenced by factors outside governance and institutions, such as private interests and power dynamics (Jaglin 2014; Tyfield 2014). In some cases, these private interests are tied up with international flows of capital. In India, adaptation plans involving networks of private actors and related mitigation actions have resulted in the dominance of private interests. This has led to trade-offs and adverse impacts on the poor (Chu 2016; Mehta et al. 2019).

When planning and implementing low-carbon transitions, it is important to consider the socio-economic context. An inclusive approach emphasises the need to engage non-state actors, including businesses, research organisations, non-profit organisations and citizens (Lee and Painter 2015; Hale et al. 2020). For example, engaging people in defining locally relevant mitigation targets and actions has enabled successful transformations in China (Engels 2018), Africa (Göpfert et al. 2019) and Malaysia (Ho et al. 2015). An active research and government collaboration through multiple stakeholder interactions in a large economic corridor in Malaysia led to the development and implementation of a low-carbon blueprint for the region (Ho et al. 2013). Many cities in LDCs and developing countries lack adequate urban infrastructure and housing. An equitable transformation in these cities entails prioritising energy access and basic services, including safe drinking water and sanitation, to meet basic needs of their populations.

8.1.6 Urban Carbon Footprint

Urban areas concentrate GHG fluxes because of the size of the urban population, the size and nature of the urban economy, the energy and GHGs embodied in the infrastructure (see 'embodied emissions' in Glossary), and the goods and services imported and exported to and from cities (USGCRP 2018).

8.1.6.1 Urban Carbon Cycle

In cities, carbon cycles through natural (e.g., vegetation and soils) and managed (e.g., reservoirs and anthropogenic – buildings, transportation) pools. The accumulation of carbon in urban pools, such as buildings or landfills, results from the local or global transfer of carbon-containing energy and raw materials used in the city (Churkina 2008; Pichler et al. 2017; Chen et al. 2020b). Quantitative understanding of these transfers and the resulting emissions and uptake within an urban area is essential for accurate urban carbon accounting (USGCRP 2018). Currently, urban areas are a net source of carbon because they emit more carbon than they uptake. Thus, urban mitigation strategies require a twofold strategy: reducing urban emissions of carbon into the atmosphere, and enhancing uptake of carbon in urban pools (Churkina 2012) (for a broader definition of 'carbon cycle' and related terms such as 'carbon sink,' 'carbon stock,' 'carbon neutrality,' 'GHG neutrality,' and others, see Glossary).

Burning fossil fuels to generate energy for buildings, transportation, industry, and other sectors is a major source of urban GHG emissions (Gurney et al. 2015). At the same time, most cities do not generate within their boundaries all of the resources they use, such as electricity, gasoline, cement, water, and food needed for local homes and businesses to function (Jacobs 1969), requiring consideration of GHG emissions embodied in supply chains serving cities. Furthermore, urban vegetation, soils, and aquatic systems can both emit or remove carbon from the urban atmosphere and are often heavily managed. For example, urban parks, forests, and street trees actively remove carbon from the atmosphere through growing season photosynthesis. They can become a net source of carbon most often during the dormant season or heat waves. Some of the sequestered carbon can be stored in the biomass of urban trees, soils, and aquatic systems. Urban infrastructures containing cement also uptake carbon through the process of carbonation. The uptake of carbon by urban trees is at least two orders of magnitude faster than by cement-containing infrastructures (Churkina 2012) (Section 8.4.4 and Figures 8.17 and 8.18).

8.1.6.2 Urban Emissions Accounting

Urban GHG emissions accounting can determine critical conceptual and quantitative aspects of urban GHG emissions. The accounting framework chosen can therefore predetermine the emissions responsibility, the mitigation options available, and the level of effort required to correctly account for emissions (Afionis et al. 2017).

Two main urban carbon accounting advances have occurred since AR5. The first includes efforts to better understand and clarify how the different urban GHG accounting frameworks that have emerged over

the past 15 years are interrelated, require different methodological tools, and reflect differing perspectives on emissions responsibility and quantification effort. The second main advance lies in a series of methodological innovations facilitating practical implementation, emissions verification, and scaling-up of the different GHG accounting approaches. This section provides an overview of the most used GHG urban accounting frameworks followed by a review of the advances since AR5.

Numerous studies have reviewed urban GHG accounting frameworks and methods with somewhat different nomenclatures and categorical divisions (Lin et al. 2015; Lombardi et al. 2017; Chen et al. 2019b; Arioli et al. 2020; Heinonen et al. 2020; Hachaichi and Baouni 2021; Ramaswami et al. 2021). Furthermore, accounting frameworks are reflected in multiple protocols used by urban practitioners (BSI 2013; Fong et al. 2014; ICLEI 2019b). Synthesis of these reviews and protocols, as well as the many individual methodological studies available, point to four general frameworks of urban GHG accounting: (i) territorial accounting (TA); (ii) community-wide infrastructure supply chain footprinting (CIF); and (iii and iv) consumption-based carbon footprint accounting (CBCF; Wiedmann and Minx 2008). The last, CBCF, can be further divided into accounting with a focus on household or personal consumption (iii: the personal carbon footprint, or PCF); and an approach in which one includes final consumption in an area by all consumers (iv: the areal carbon footprint, or ACF) (Heinonen et al. 2020). A number of small variations to these general categories are found in the literature (Lin et al. 2015; Chen et al. 2020a), but these four general frameworks capture the important distinctive (i.e., policy-relevant) features of urban GHG accounting.

All these approaches are foundationally rooted in the concept of urban metabolism, that is, the tracking of material and energy flows into, within, and out of cities (Wolman 1965). These frameworks all aim to quantify urban GHG emissions but reflect different perspectives on where the emission responsibility is allocated in addition to how much and which components of the GHG emissions associated with the import and export of goods and services to and from a city ('transboundary embedded/embody GHG emissions') are included in a given urban emissions account. The four frameworks share some common, overlapping GHG emission quantities and their interrelationships have been defined mathematically (Chavez and Ramaswami 2013).

A key advance since AR5 lies in understanding the different GHG accounting frameworks in terms of what they imply for responsibility—shared or otherwise—and what they imply for the depth and breadth of GHG emission reductions. TA focuses on in-city direct emission of GHGs to the atmosphere (e.g., combustion, net ecosystem exchange, methane (CH₄) leakage) within a chosen geographic area (Sovacool and Brown 2010; Gurney et al. 2019). CIF connects essential infrastructure use and demand activities in cities with their production, by combining TA emissions with the transboundary supply chain emissions associated with imported electricity, fuels, food, water, building materials, and waste management services used in cities (Ramaswami et al. 2008; Kennedy et al. 2009; Chavez and Ramaswami 2013).

CBCF considers not only the supply-chain-related GHG emissions of key infrastructure, but also emissions associated with all goods and services across a city, often removing emissions associated with goods and services exported from a city (Wiedmann et al. 2016, 2021). The distinction between the PCF and ACF variants of the CBCF is primarily associated with whether the agents responsible for the final demand are confined to only city residents (PCF) or all consumers in a city (ACF), which can include government consumers, capital formation, and other final demand categories (Heinonen et al. 2020).

A recent synthesis of these frameworks in the context of a net-zero GHG emissions target suggests that the four frameworks contribute to different aspects of decarbonisation policy and can work together to inform the overall process of decarbonisation (Ramaswami et al. 2021). Furthermore, the relative magnitude of GHG emissions for a given city resulting from the different frameworks is often a reflection of the city's economic structure as a 'consumer' or 'producer' city (Chavez and Ramaswami 2013; Sudmant et al. 2018).

The TA framework is unique in that it can be independently verified through direct measurement of GHGs in the atmosphere, offering a check on the integrity of emission estimates (Lauvaux et al. 2020; Mueller et al. 2021). It is traditionally simpler to estimate by urban practitioners given the lower data requirements, and it can be relevant to policies aimed specifically at energy consumption and mobility activities within city boundaries. However, it will not reflect electricity imported for use in cities or lifecycle emissions associated with in-city consumption of goods and services.

The CIF framework adds to the TA framework by including GHG emissions associated with electricity imports and the lifecycle GHG emissions associated with key infrastructure provisioning activities in cities, serving all homes, businesses, and industries. This widens both the number of emitting categories and the responsibility for those emissions by including infrastructure-related supply chain emissions. The CIF framework enables individual cities to connect community-wide demand for infrastructure and food with their transboundary production, strategically aligning their net-zero emissions plans with larger-scale net-zero efforts (Ramaswami and Chavez 2013; Ramaswami et al. 2021; Seto et al. 2021).

The PCF version of the CBCF shifts the focus of the consumption and associated supply chain emissions to only household consumption of goods and services (Jones and Kammen 2014). This both reduces the TA emissions considered and the supply chain emissions, excluding all emissions associated with government, capital formation, and exports. The ACF, by contrast, widens the perspective considerably, including the TA and supply chain emissions of all consumers in a city, but often removing emissions associated with exports.

An additional distinction is the ability to sum up accounts from individual cities in a region or country, for example, directly to arrive at a regional or national total. This can only be done for the TA and PCF frameworks. The ACF and CIF frameworks would require adjustment to avoid double-counting emissions (Chen et al. 2020a).

A second major area of advance since AR5 has been in methods to implement, verify and scale up the different GHG footprinting approaches. Advances have been made in six key areas: (i) advancing urban metabolism accounts integrating stocks and flows, and considering biogenic and fossil-fuel-based emissions (Chen et al. 2020b); (ii) improving fine-scale and near-real-time urban use-activity data through new urban data science (Gately et al. 2017; Gurney et al. 2019; Turner et al. 2020; Yadav et al. 2021); (iii) using atmospheric monitoring from the ground, aircraft, and satellites combined with inverse modelling to independently quantify TA emissions (Lamb et al. 2016; Lauvaux et al. 2016, 2020; Davis et al. 2017; Mitchell et al. 2018; Sargent et al. 2018; Turnbull et al. 2019; Wu et al. 2020a); (iv) improving supply chain and input-output modelling, including the use of physically based input-output models (Wachs and Singh 2018); (v) establishing the global multi-region input-output models (Lenzen et al. 2017; Wiedmann et al. 2021); and (vi) generating multi-sector use and supply activity data across all cities in a nation, in a manner where data aggregate consistently across city, province, and national scales (Tong et al. 2021) (Section 8.3).

8.2 Co-benefits and Trade-offs of Urban Mitigation Strategies

Co-benefits are ‘the positive effects that a policy or measure aimed at one objective might have on other objectives, thereby increasing the total benefits to the society or environment’ (IPCC 2018b). AR5 WGIII Chapter 12 reported a range of co-benefits associated with urban climate change mitigation strategies, including public savings, air quality and associated health benefits, and productivity increases in urban centres (Seto et al. 2014). Since AR5, evidence continues to mount on the co-benefits of urban mitigation. Highlighting co-benefits could make a strong case for driving impactful mitigation action (Bain et al. 2016), especially in developing countries, where development benefits can be the argument for faster implementation (Sethi and Puppim de Oliveira 2018). Through co-benefits, urban areas can couple mitigation, adaptation, and sustainable development while closing infrastructure gaps (Thacker et al. 2019; Kamiya et al. 2020).

The urgency of coupling mitigation and adaptation is emphasised through a special Cross-Working Group Box on ‘Cities and Climate Change’ (Section 8.2.3 and Cross-Working Group Box 2 in this chapter). This section further addresses synergies and trade-offs for sustainable development with a focus on linkages with the SDGs and perspectives for economic development, competitiveness, and equity.

8.2.1 Sustainable Development

Sustainable development is a broad concept, encompassing socio-economic and environmental dimensions, envisaging long-term permanence and improvement. While long-term effects are more related to resilience – and hence carry co-benefits and synergies with the mitigation of GHG emissions – some short-term milestones were defined by the post-2015 UN Sustainable Development Agenda SDGs, including a specific goal on climate change (SDG 13) and one on making cities inclusive, safe, resilient and sustainable (SDG 11)

(United Nations 2015). The SDGs and related indicators can be an opportunity to improve cities by using science-based decision-making and engaging a diverse set of stakeholders (Simon et al. 2016; Klopp and Petretta 2017; Kutty et al. 2020).

There are multiple ways that development pathways can be shifted towards sustainability (Section 4.3.3, Cross-Chapter Box 5 in Chapter 4, Chapter 17 and Figure 17.1). Urban areas can work to redirect development pathways towards sustainability while increasing co-benefits for urban inhabitants. Figure 8.4 indicates that mitigation options for urban systems can provide synergistic linkages across a wide range of SDGs, and some cases where linkages can produce both synergies and trade-offs. While linkages are based on context and the scale of implementation, synergies can be most significant when urban areas pursue integrated approaches where one mitigation option supports the other (Sections 8.4 and 8.6).

Figure 8.4 summarises an evaluation of the synergies and/or trade-offs with the SDGs for the mitigation options for urban systems based on Supplementary Material 8.SM.1. The evaluations depend on the specific urban context, with synergies and/or trade-offs being more significant in certain contexts than others. Urban mitigation with a view of the SDGs can support shifting pathways of urbanisation towards greater sustainability. The feasibility of urban mitigation options is also malleable and can increase with more ‘enabling conditions’ (see Glossary), provided, perhaps, through institutional (i.e., financial or governmental) support (Section 8.5). Strengthened institutional capacity that supports the coordination of mitigation options can increase linkages with the SDGs and their synergies. For example, urban land use and spatial planning for walkable and co-located densities, together with electrification of the urban energy system, can hold more benefits for the SDGs than any one of the mitigation options alone (Sections 8.4.2.3, 8.4.3.1 and 8.6).

Evidence on the co-benefits of urban mitigation measures for human health has increased significantly since AR5, especially through the use of health impact assessments, where energy savings and cleaner energy supply structures based on measures for urban planning, heating, and transport have reduced CO₂, nitrogen oxides (NO_x), and coarse particulate matter (PM₁₀) emissions (Diallo et al. 2016). Some measures, especially those related to land-use planning and transportation, have also increased opportunities for physical activity for improved health (Diallo et al. 2016). In developing countries, the co-benefits approach has been effective in justifying climate change mitigation actions at the local level (Puppim de Oliveira and Doll 2016). Mixed-use compact development with sufficient land-use diversity can have a positive influence on urban productivity (Section 8.4.2). Conversely, urban spatial structures that increase walking distances and produce car dependency have negative impacts on urban productivity considering congestion as well as energy costs (Salat et al. 2017).

There is increasing evidence that climate mitigation measures can lower health risks that are related to energy poverty, especially among vulnerable groups such as the elderly and in informal settlements (Monforti-Ferrario et al. 2018). Measures such as renewable energy-based electrification of the energy system not only reduce outdoor air

Mitigation options	Synergy												Both synergy and trade-offs				
Urban land use and spatial planning	1	3	4	5	6	7	8	9	11	13	16	15	2	10	12	14	15
Electrification of the urban energy system	1	3	4	5	6	7	8	9	11	13	16	15	2	10	12	14	15
District heating and cooling networks	1	3	4	5	6	7	8	9	11	13	16	15	2	10	12	14	15
Urban green and blue infrastructure	1	3	4	5	6	7	8	9	11	13	16	15	2	10	12	14	15
Waste prevention, minimisation and management	1	3	4	5	6	7	8	9	11	13	16	15	2	10	12	14	15
Integrating sectors, strategies and innovations	1	3	4	5	6	7	8	9	11	13	16	15	2	10	12	14	15

List of SDGs

Confidence levels

- Low confidence
- Medium confidence
- High confidence

Figure 8.4: Co-benefits of urban mitigation actions. The first column lists urban mitigation options. The second column indicates synergies with the SDGs. The third column indicates both synergies and/or trade-offs. The dots represent confidence levels with the number of dots representing levels from low to high. In the last column, confidence levels for synergies and/or trade-offs are provided separately. A plus sign (+) represents synergy and a minus sign (-) represents a trade-off. Supplementary Material 8.SM.1 provides 64 references and extends the SDG mappings that are provided in Thacker et al. (2019) and Fusco Nerini et al. (2018). Please see Table 17.SM.1 for details and Annex II for the methodology of the SDG assessment.

pollution, but also enhance indoor air quality by promoting smoke-free heating and cooking in buildings (Kjellstrom and McMichael 2013). The environmental and ecological benefits of electrification of the urban energy system include improved air quality based on a shift to non-polluting energy sources (Jacobson et al. 2018; Ajanovic and Haas 2019; Bagheri et al. 2019; Gai et al. 2020). Across 74 metropolitan areas around the world, an estimated 408,270 lives per year are saved due to air quality improvements that stem from a move to 100% renewable energy (Jacobson et al. 2020). Other studies indicate that there is potential to reduce premature mortality by up to 7000 people in 53 towns and cities, to create 93,000 new jobs, and to lower global climate costs and personal energy costs, through renewable energy transformations (Jacobson et al. 2018).

Across 146 signatories of a city climate network, local energy-saving measures led to 6596 avoided premature deaths and 68,476 years of life saved due to improved air quality (Monforti-Ferrario et al. 2018). Better air quality further reinforces the health co-benefits of climate mitigation measures based on walking and bicycling since evidence suggests that increased physical activity in urban outdoor settings with low levels of black carbon improves lung function (Laeremans et al. 2018). Physical activity can also be fostered through urban design measures and policies that promote the development of ample and well-connected parks and open spaces, and can lead to physical and mental health benefits (Kabisch et al. 2016) (Section 8.4.4 and Figure 8.18).

Cities in India, Indonesia, Vietnam, and Thailand show that reducing emissions from major sources (e.g., transport, residential burning, biomass open burning, and industry) could bring substantial co-benefits of avoided deaths from reduced PM_{2.5} (fine inhalable particulates) emissions and radiative forcing from black carbon (Pathak and Shukla 2016; Dhar et al. 2017; Permadi et al. 2017; Karlsson et al. 2020), reduced noise, and reduced traffic injuries (Kwan and Hashim 2016). Compact city policies and interventions that support a modal shift away from private motor vehicles towards walking, cycling, and low-emission public transport delivers significant public health benefits (Creutzig 2016; Ürge-Vorsatz et al. 2018). Trade-offs associated with compact development include the marginal health costs of transport air pollution (Lohrey and Creutzig 2016) and stress from traffic noise (Gruebner et al. 2017) (Section 8.4.2.3).

Urban green and blue infrastructure – a subset of nature-based solutions (NBS) – acts as both climate mitigation and adaptation measures by reducing heat stress (Kim and Coseo 2018; Privitera and La Rosa 2018; Herath et al. 2021), improving air quality, reducing noise (Scholz et al. 2018; De la Sota et al. 2019), improving urban biodiversity (Hall et al. 2017b), and enhancing well-being, including contributions to local development (Lwasa et al. 2015). Health benefits from urban forestry and green infrastructure include reduced cardiovascular morbidity, improved mental health (van den Bosch and Ode Sang 2017; Vujcic et al. 2017; Al-Kindi et al. 2020; Sharifi et al. 2021), raised birth weight (Dzhambov et al. 2014), and increased life expectancy (Jonker et al. 2014). Urban agriculture, including urban orchards, rooftop gardens, and vertical farming contribute to enhancing food security and fostering healthier diets

(Cole et al. 2018; Petit-Boix and Apul 2018; De la Sota et al. 2019) (Section 8.4.4, Figure 8.18 and Box 8.2).

8.2.2 Economic Development, Competitiveness, and Equity

Sustainable management of urban ecosystems entails addressing economic growth, equity, and good governance. In total, 102 SDG targets (99 synergies and 51 trade-offs) are identified with published evidence of relationships with urban ecosystems – out of the 169 in the 2030 Agenda (Maes et al. 2019). The targets require action in relation to urban ecosystem management, environmental improvements, equality related to basic services, long-term economic growth, economic savings, stronger governance, and policy development at multiple scales.

Mitigation measures related to different sectors can provide co-benefits and reduce social inequities. Transport-related measures, such as transportation demand management, transit-oriented development (TOD), and promotion of active transport modes provide economic co-benefits through, for example, reducing health care costs linked with pollution and cardiovascular diseases, improving labour productivity, and decreasing congestion costs (including waste of time and money) (Sharifi et al. 2021). As a case-in-point, data from cities such as Bangkok, Kuala Lumpur, Jakarta, Manila, Beijing, Mexico City, Dakar, and Buenos Aires indicate that economic costs of congestion account for a considerable share of their gross domestic product (GDP), ranging from 0.7% to 15.0% (Dulal 2017) (Section 8.4.2).

Since policy interventions can result in negative impacts or trade-offs with other objectives, fostering accessibility, equity, and inclusivity for disadvantaged groups is essential (Viguié and Hallegatte 2012; Sharifi 2020; Pörtner et al. 2021). Anti-sprawl policies that aim to increase density, or the introduction of large green areas in cities could increase property prices, resulting in trade-offs with affordable housing and pushing urban poor further away from cities (Reckien et al. 2017; Alves et al. 2019). Deliberate strategies can improve access of low-income populations to jobs, and gender-responsive transport systems that can enhance women's mobility and financial independence (Viguié and Hallegatte 2012; Lecompte and Juan Pablo 2017; Reckien et al. 2017; Priya Uteng and Turner 2019).

Low-carbon urban development that triggers economic decoupling and involves capacity-building measures could have a positive impact on employment and local competitiveness (Dodman 2009; Kalmykova et al. 2015; Chen et al. 2018b; García-Gusano et al. 2018; Hu et al. 2018; Shen et al. 2018). Sustainable and low-carbon urban development that integrates issues of equity, inclusivity, and affordability while safeguarding urban livelihoods, providing access to basic services, lowering energy bills, addressing energy poverty, and improving public health, can also improve the distributional effects of existing and future urbanisation (Friend et al. 2016; Claude et al. 2017; Colenbrander et al. 2017; Ma et al. 2018; Mrówczyńska et al. 2018; Pukšec et al. 2018; Wiktorowicz et al. 2018; Ramaswami 2020).

Depending on the context, green and blue infrastructure can also offer considerable economic co-benefits. For example, green roofs and facades and other urban greening efforts such as urban agriculture and greening streets can improve microclimatic conditions and enhance thermal comfort, thereby reducing utility and health care costs. The presence of green and blue infrastructure may also increase the economic values of nearby properties (Votsis 2017; Alves et al. 2019) (Section 8.4.4 and Figure 8.18).

Studies in the UK show that beneficiaries are willing to pay (WTP) an additional fee (up to 2% more in monthly rent) for proximity to green and blue infrastructure, with the WTP varying depending on the size and nature of the green space (Mell et al. 2013, 2016). Urban agriculture can not only reduce household food expenditure, but also provide additional sources of revenue for the city (Ayerakwa 2017; Alves et al. 2019). Based on the assessed literature, there is *high agreement* on the economic co-benefits of green and blue infrastructure, but supporting evidence is still limited (Section 8.7).

Implementing waste management and wastewater recycling measures can provide additional sources of income for citizens and local authorities. Wastewater recycling can minimise the costs associated with the renewal of centralised wastewater treatment plants (Bernstad Saraiva Schott and Cánovas 2015; Gharfalkar et al. 2015; Gonzalez-Valencia et al. 2016; Herrero and Vilella 2018; Matsuda et al. 2018; Nisbet et al. 2019). Waste management and wastewater recycling is also a pathway for inclusion of the informal sector into the urban economy with *high agreement* and *medium evidence* (Sharifi 2021). Additionally, authorities can sell energy generated from wastewater recycling to compensate for the wastewater management costs (Colenbrander et al. 2017; Gondhalekar and Ramsauer 2017). Another measure that contributes to reducing household costs is the promotion of behavioural measures such as dietary changes that can decrease the demand for costly food sources and reduce health care costs through promoting healthy diets (Hoppe et al. 2016) (Sections 8.4.5 and 8.4.6).

In addition to cost savings, various measures such as stormwater management and urban greening can enhance social equity and environmental justice. For example, the thermal comfort benefits provided by green and blue infrastructure and passive design measures can address issues related to energy poverty and unaffordability of expensive air conditioning systems for some social groups (Sharma et al. 2018; He et al. 2019). To achieve such benefits, however, the costs of integrating green and blue infrastructure and passive design measures into building design would need to be minimised. Another example is the flood mitigation benefits of stormwater management measures that can reduce impacts on urban poor who often reside in flood-prone and low-lying areas of cities (Adegun 2017; He et al. 2019). Generally, the urban poor are expected to be disproportionately affected by climate change impacts. Carefully designed measures that reduce such disproportionate impacts by involving experts, authorities and citizens would enhance social equity (Pandey et al. 2018; He et al. 2019; Mulligan et al. 2020).

8.2.3 Coupling Mitigation and Adaptation

There are numerous synergies that come from coupling urban adaptation and mitigation. A number of studies have developed methods to assess the synergies between mitigation and adaptation strategies, as well as their co-benefits (Solecki et al. 2015; Buonocore et al. 2016; Chang et al. 2017; Helgenberger and Jänicke 2017). Co-benefits occur when implementing mitigation (or adaptation) measures that have positive effects on adaptation (or mitigation) (Sharifi 2021). In contrast, the trade-offs emerge when measures aimed at improving mitigation (adaptation) undermine the ability to pursue adaptation (mitigation) targets (Sharifi 2020). The magnitude of such co-benefits and trade-offs may vary depending on various factors. A systematic review of over 50 climate change articles provides evidence that mitigation can contribute to resilience – especially to temperature changes and flooding – with varying magnitudes, depending on factors such as the type of mitigation measure and the scale of implementation (Sharifi 2019).

Measures from different sectors that can provide both mitigation and adaptation benefits involve urban planning (Section 8.4.2), buildings (Sections 8.4.3.2 and 8.4.4), energy (Section 8.4.3), green and blue infrastructure (Section 8.4.4), transportation (Section 8.4.2), socio-behavioural aspects (Section 8.4.5), urban governance (Section 8.5), waste (Section 8.4.5.2), and water (Section 8.4.6). In addition to their energy-saving and carbon-sequestration benefits, many measures can also enhance adaptation to climate threats, such as extreme heat, energy shocks, floods, and droughts (Sharifi 2021). Existing evidence is mainly related to urban green infrastructure, urban planning, transportation, and buildings. There has been more emphasis on the potential co-benefits of measures, such as proper levels of density, building energy efficiency, distributed and decentralised energy infrastructure, green roofs and facades, and public/active transport modes. Renewable-based distributed and decentralised energy systems improve resilience to energy shocks and can enhance adaptation to water stress considering the water-energy nexus. By further investment on these measures, planners and decision makers can ensure enhancing achievement of mitigation/adaptation co-benefits at the urban level (Sharifi 2021).

As for trade-offs, some mitigation efforts may increase exposure to stressors such as flooding and the urban heat island (UHI) effect (see Glossary), thereby reducing the adaptive capacity of citizens. For instance, in some contexts, high-density areas that lack adequate provision of green and open spaces may intensify the UHI effect (Pierer and Creutzig 2019; Xu et al. 2019). There are also concerns that some mitigation efforts may diminish adaptive capacity of urban poor and marginalised groups through increasing costs of urban services and/or eroding livelihood options. Environmental policies designed to meet mitigation targets through phasing out old vehicles may erode livelihood options of poor households, thereby decreasing their adaptive capacity (Colenbrander et al. 2017). Ambitious mitigation and adaptation plans could benefit private corporate interests resulting in adverse effects on the urban poor (Chu et al. 2018; Mehta et al. 2019).

Urban green and blue infrastructure such as urban trees, greenspaces, and urban waterways can sequester carbon and reduce energy demand, and provide adaptation co-benefits by mitigating the UHI effect (Berry et al. 2015; Wamsler and Pauleit 2016; WCRP 2019) (Section 8.4.4, Figure 8.18 and Box 8.2).

Cross-Working Group Box 2: Cities and Climate Change

Authors: Xuemei Bai (Australia), Vanesa Castán Broto (Spain/United Kingdom), Winston Chow (Singapore), Felix Creutzig (Germany), David Dodman (Jamaica/United Kingdom), Rafiq Hamdi (Belgium), Bronwyn Hayward (New Zealand), Şiir Kılış (Turkey), Shuaib Lwasa (Uganda), Timon McPhearson (the United States of America), Minal Pathak (India), Mark Pelling (United Kingdom), Diana Reckien (Germany), Karen C. Seto (the United States of America), Ayyoob Sharifi (Iran/Japan), Diana Ürge-Vorsatz (Hungary)

Introduction

This Cross-Working Group Box on Cities and Climate Change responds to the critical role of urbanisation as a megatrend impacting climate adaptation and mitigation. Issues associated with cities and urbanisation are covered in substantial depth within all three Working Groups (including WGI Box TS.14, WGII Chapter 6 'Cities, Settlements and Key Infrastructure', WGII regional chapters, WGII Cross-Chapter Paper 'Cities and Settlements by the Sea', and WGIII Chapter 8 'Urban Systems and Other Settlements'). This Box highlights key findings from WGII and III and substantial gaps in literature where more research is urgently needed relating to policy action in cities. It describes methods of addressing mitigation and adaptation in an integrated way across sectors and cities to advance sustainable development and equity outcomes and assesses the governance and finance solutions required to support climate-resilient responses.

Urbanisation: A megatrend driving global climate risk and potential for low-carbon and resilient futures

Severe weather events, exacerbated by anthropogenic emissions, are already having devastating impacts on people who live in urban areas, on the infrastructure that supports these communities, as well as people living in distant places (*high confidence*) (Cai et al. 2019; Folke et al. 2021). Between 2000 and 2015, the global population in locations that were affected by floods grew by 58–86 million (Tellman et al. 2021). The direct economic costs of all extreme events reached USD210–268 billion in 2020 (Aon 2021; Munich RE 2021; WMO 2021) or about USD0.7 billion per day; this figure does not include knock-on costs in supply chains (Kii 2020) or lost days of work, implying that the actual economic costs could be far higher. Depending on RCP, between half (RCP2.6) and three-quarters (RCP8.5) of the global population could be exposed to periods of life-threatening climatic conditions arising from coupled impacts of extreme heat and humidity by 2100 (Mora et al. 2017; Huang et al. 2019) (see WGII Section 6.2.2.1, WGII Figure 6.3, and WGIII Sections 8.2 and 8.3.4).

Urban systems are now global, as evidenced by the interdependencies between infrastructure, services, and networks driven by urban production and consumption; remittance flows and investments reach into rural places, shaping natural resource use far from the city and bring risk to the city when these places are impacted by climate change (WGIII Section 8.4 and Figure 8.15). This megatrend (Kourtit et al. 2015) amplifies as well as shapes the potential impacts of climate events and integrates the aims and approaches for delivering mitigation, adaptation, and sustainable development (*medium evidence, high agreement*) (Dawson et al. 2018; Tsavdaroglou et al. 2018; Zscheischler et al. 2018). For cities facing flood damage, wide-ranging impacts have been recorded on other urban areas near and far (Carter et al. 2021; Simpson et al. 2021) as production and trade is disrupted (Shughrue et al. 2020). In the absence of integrated mitigation and adaptation across and between infrastructure systems and local places, impacts that bring urban economies to a standstill can extend into supply chains and across energy networks causing power outages.

Urban settlements contribute to climate change, generating about 70% of global CO₂-eq emissions (*high confidence*) (see WGI Box TS.14, WGII Sections 6.1 and 6.2, and WGIII Section 8.3). This global impact feeds back to cities through the exposure of infrastructure, people, and business to the impacts of climate-related hazards. Particularly in larger cities, this climate feedback is exacerbated by local choices in urban design, land use, building design, and human behaviour (Viguié et al. 2020) that shape local environmental conditions. Both the local and global combine to increase hazardousness. Certain configurations of urban form and their elements can add up to 2°C to warming; concretisation of open space can increase run-off, and building height and orientation influences wind direction and strength (see WGII Section 6.3 and WGIII Section 8.4.2).

Cross-Working Group Box 2 (continued)

Designing for resilient and low-carbon cities today is far easier than retrofitting for risk reduction tomorrow. As urbanisation unfolds, its legacy continues to be the locking-in of emissions and vulnerabilities (*high confidence*) (Seto et al. 2016; Ürge-Vorsatz et al. 2018) (see WGIII Section 8.4 and Figure 8.15). Retrofitting, disaster reconstruction, and urban regeneration programmes offer scope for strategic direction changes to low-carbon and high-resilience urban form and function, so long as they are inclusive in design and implementation. Rapid urban growth means new investment, new buildings and infrastructure, new demands for energy and transport and new questions about what a healthy and fulfilling urban life can be. The USD90 trillion expected to be invested in new urban development by 2030 (NCE 2018) is a global opportunity to place adaptation and mitigation directly into urban infrastructure and planning, as well as to consider social policy including education, health care, and environmental management (Ürge-Vorsatz et al. 2018). If this opportunity is missed, and business-as-usual urbanisation persists, social and physical vulnerability will become much more challenging to address.

The benefits of actions taken to reduce GHG emissions and climate stressors diminish with delayed action, indicating the necessity for rapid responses. Delaying the same actions for increasing the resilience of infrastructure from 2020 to 2030 is estimated to have a median cost of at least USD1 trillion (Hallegatte et al. 2019) while also missing the carbon emissions reductions required in the narrowing window of opportunity to limit global warming to 1.5°C (WGI). In contrast, taking integrated actions towards mitigation, adaptation, and sustainable development will provide multiple benefits for the health and well-being of urban inhabitants and avoid stranded assets (see WGII Section 6.3, WGII Chapter 17, Cross-Chapter Box on 'Feasibility' in WGII Chapter 18, WGIII Chapter 5, and WGIII Section 8.2).

The policy-action gap: urban low-carbon and climate-resilient development

Cities are critical places to realise both adaptation and mitigation actions simultaneously with potential co-benefits that extend far beyond cities (*medium evidence, high agreement*) (Göpfert et al. 2019; Grafakos et al. 2020). Given rapid changes in the built environment, transforming the use of materials and the land intensiveness of urban development, including in many parts of the Global South, will be critical in the next decades, as well as mainstreaming low-carbon development principles in new urban development in all regions. Much of this development will be self-built and 'informal' – and new modes of governance and planning will be required to engage with this. Integrating mitigation and adaptation now rather than later, through reshaping patterns of urban development and associated decision-making processes, is a prerequisite for attaining resilient and zero-carbon cities (see WGIII Sections 8.4 and 8.6, and WGIII Figure 8.21).

While more cities have developed plans for climate adaptation and mitigation since AR5, many remain to be implemented (*limited evidence, high agreement*) (Araos et al. 2017; Aguiar et al. 2018; Olazabal and Ruiz De Gopegui 2021). A review of local climate mitigation and adaptation plans across 885 urban areas of the European Union suggests mitigation plans are more common than adaptation plans – and that city size, national legislation, and international networks can influence the development of local climate and adaptation plans with an estimated 80% of those cities with above 500,000 inhabitants having a mitigation and/or an adaptation plan (Reckien et al. 2018).

Integrated approaches to tackle common drivers of emissions and cascading risks provide the basis for strengthening synergies across mitigation and adaptation, and help manage possible trade-offs with sustainable development (*limited evidence, medium agreement*) (Grafakos et al. 2019; Landauer et al. 2019; Pierer and Creutzig 2019). An analysis of 315 local authority emission-reduction plans reveals that the most common policies cover municipal assets and structures (Palermo et al. 2020a). Estimates of emission reductions by non-state and sub-state actors in 10 high-emitting economies projected GHG emissions in 2030 would be 1.2–2.0 GtCO₂-eq yr⁻¹ or 3.8–5.5% lower compared to scenario projections for current national policies (31.6–36.8 GtCO₂-eq yr⁻¹) if the policies are fully implemented and do not change the pace of action elsewhere (Kuramochi et al. 2020). The value of integrating mitigation and adaptation is underscored in the opportunities for decarbonising existing urban areas, and investing in social, ecological, and technological infrastructure resilience (WGII Section 6.4). Integrating mitigation and adaptation is challenging (Landauer et al. 2019) but can provide multiple benefits for the health and well-being of urban inhabitants (Sharifi 2021) (See WGIII Section 8.2.3).

Effective climate strategies combine mitigation and adaptation responses, including through linking adaptive urban land use with GHG emission reductions (*medium evidence, high agreement*) (Xu et al. 2019; Patterson 2021). For example, urban green and blue infrastructure can provide co-benefits for mitigation and adaptation (Ürge-Vorsatz et al. 2018) and is an important entry point for integrating adaptation and mitigation at the urban level (Frantzeskaki et al. 2019) (see WGIII Section 8.4.4 and WGIII Figure 8.18). Grey and physical infrastructure, such as sea defences, can immediately reduce risk, but also transfer risk and limit future options. Social policy interventions including social safety nets provide financial security for the most at-risk and can manage vulnerability determined by specific hazards or independently.

Cross-Working Group Box 2 (continued)

Hazard-independent mechanisms for vulnerability reduction – such as population-wide social security – provide resilience in the face of unanticipated cascading impacts or surprise and novel climate-related hazard exposure. Social interventions can also support or be led by ambitions to reach the SDGs (Archer 2016). Climate-resilient development invites planners to develop interventions and monitor the effectiveness of outcomes beyond individual projects and across wider remits that consider sustainable development. Curbing the emission impacts of urban activities to reach net-zero emissions in the next decades, while improving the resilience of urban areas, necessitates an integrated response now.

Key gaps in knowledge include: urban-enabling environments; the role of smaller settlements, low-income communities, and informal settlements, as well as those in rental housing spread across the city; and the ways in which actions to reduce supply chain risk can be supported to accelerate equitable and sustainable adaptation in the face of financial and governance constraints (Birkmann et al. 2016; Shi et al. 2016; Rosenzweig et al. 2018; Dulal 2019).

Enabling action

Innovative governance and finance solutions are required to manage complex and interconnected risks across essential key infrastructures, networks, and services, as well as to meet basic human needs in urban areas (*medium confidence*) (Colenbrander et al. 2018a; Moser et al. 2019). There are many examples of 'ready-to-use' policy tools, technologies, and practical interventions for policymakers seeking to act on adaptation and mitigation (Bisaro and Hinkel 2018; Keenan et al. 2019; Chirambo 2021) (see WGIII Section 8.5.4). Tax and fiscal incentives for businesses and individuals can help support city-wide behaviour change towards low-carbon and risk-reducing choices. Change can start where governments have most control – often in public sector institutions and investment – but the challenge ahead requires partnership with private sector and community actors acting at scale and with accountability. Urban climate governance and finance needs to address urban inequalities at the forefront if the urban opportunity is to realise the ambition of the SDGs.

Increasing the pace of investments will put pressure on governance capability, transparency, and accountability of decision-making (*medium confidence*) (see WGII Section 6.4.5). Urban climate action that actively includes local actors is more likely to avoid unintended, negative maladaptive impacts and mobilise a wide range of local capacities. In the long run, this is also more likely to carry public support, even if some experiments and investments do not deliver the intended social benefits. Legislation, technical capacity, and governance capability are required to be able to absorb additional finance.

In recent years, about USD384 billion of climate finance has been invested in urban areas per year. This remains at about 10% of the annual climate finance that would be necessary for low-carbon and resilient urban development at a global scale (Negreiros et al. 2021). Rapid deployment of funds to stimulate economies in the recovery from COVID-19 has highlighted the pitfalls of funding expansion ahead of policy innovation and capacity building. The result can be an intensification of existing carbon-intensive urban forms – exactly the kinds of 'carbon lock-in' (see WGIII Glossary and WGIII Section 8.4.1) that have contributed to risk creation and its concentration amongst those with little public voice or economic power.

Iterative and experimental approaches to climate adaptation and mitigation decision-making grounded in data and co-generated in partnership with communities can advance low-carbon climate resilience (*medium evidence, high confidence*) (Culwick et al. 2019; Caldarice et al. 2021; van der Heijden and Hong 2021). Conditions of complexity, uncertainty, and constrained resources require innovative solutions that are both adaptive and anticipatory. Complex interactions among multiple agents in times of uncertainty makes decision-making about social, economic, governance, and infrastructure choices challenging and can lead decision-makers to postpone action. This is the case for those balancing household budgets, residential investment portfolios, and city-wide policy responsibilities. Living with climate change requires changes to business-as-usual design-making. Co-design and collaboration with communities through iterative policy experimentation can point the way towards climate-resilient development pathways (Ataöv and Peker 2021). Key to successful learning is transparency in policymaking, inclusive policy processes, and robust local modelling, monitoring, and evaluation, which are not yet widely undertaken (Sanchez Rodriguez et al. 2018; Ford et al. 2019).

The diversity of cities' experiences of climate mitigation and adaptation strategies brings an advantage for those city governments and other actors willing to 'learn together' (*limited evidence, high confidence*) (Bellinson and Chu 2019; Haupt and Coppola 2019). While contexts are varied, policy options are often similar enough for the sharing of experiments and policy champions. Sharing expertise can build on existing regional and global networks, many of which have already placed knowledge, learning, and capacity building at the centre of their agendas. Learning from innovative forms of governance and financial investment, as well as strengthening co-production of policy through inclusive access to knowledge and resources, can help address mismatches in local capacities and strengthen wider SDGs and COVID-19 recovery agendas (*limited evidence, medium agreement*). Perceptions of risk can greatly

Cross-Working Group Box 2 (continued)

influence the reallocation of capital and shift financial resources (Battiston et al. 2021). Coupling mitigation and adaptation in an integrated approach offers opportunities to enhance efficiency, increases the coherence of urban climate action, generates cost savings, and provides opportunities to reinvest the savings into new climate action projects to make all urban areas and regions more resilient.

Local governments play an important role in driving climate action across mitigation and adaptation as managers of assets, regulators, mobilisers, and catalysts of action, but few cities are undertaking transformative climate adaptation or mitigation actions (*limited evidence, medium confidence*) (Heikkinen et al. 2019). Local actors are providers of infrastructure and services, regulators of zoning, and can be conveners and champions of an integrated approach for mitigation and adaptation at multiple levels (*limited evidence, high confidence*). New opportunities in governance and finance can enable cities to pool resources together and aggregate interventions to innovate ways of mobilising urban climate finance at scale (Colenbrander et al. 2019; Simpson et al. 2019; White and Wahba 2019). However, research increasingly points towards the difficulties faced during the implementation of climate financing in situ, such as the fragmentation of structures of governance capable of managing large investments effectively (Mohammed et al. 2019) (see WGIII Section 8.5 and WGIII Chapter 13).

Scaling up transformative place-based action for both adaptation and mitigation requires enabling conditions, including land-based financing, intermediaries, and local partnerships (*medium evidence, high agreement*) (Chu et al. 2019; Chaudhuri, 2020) supported by a new generation of big data approaches. Governance structures that combine actors working at different levels with a different mix of tools are effective in addressing challenges related to implementation of integrated action while cross-sectoral coordination is necessary (Singh et al. 2020). Joint institutionalisation of mitigation and adaptation in local governance structures can also enable integrated action (Göpfert et al. 2020; Hurlimann et al. 2021). However, the proportion of international finance that reaches local recipients remains low, despite the repeated focus of climate policy on place-based adaptation and mitigation (Manuamorn et al. 2020). Green financing instruments that enable local climate action without exacerbating current forms of inequality can jointly address mitigation, adaptation, and sustainable development. Climate finance that also reaches beyond larger non-state enterprises (e.g., small and medium-sized enterprises, local communities, or non-governmental organisations (NGOs)), and is inclusive in responding to the needs of all urban inhabitants (e.g., disabled individuals, or citizens of different races or ethnicities) is essential for inclusive and resilient urban development (Colenbrander et al. 2019; Gabaldón-Estevan et al. 2019; Frenova 2021). Developing networks that can exert climate action at scale is another priority for climate finance.

The urban megatrend is an opportunity to transition global society. Enabling urban governance to avert cascading risk and achieve low-carbon, resilient development will involve the co-production of policy and planning, rapid implementation and greater cross-sector coordination, and monitoring and evaluation (*limited evidence, medium agreement*) (Di Giulio et al. 2018; Grafakos et al. 2019). New constellations of responsible actors are required to manage hybrid local-city or cross-city risk management and decarbonisation initiatives (*limited evidence, medium agreement*). These may increasingly benefit from linkages across more urban and more rural space as recognition of cascading and systemic risk brings recognition of supply chains, remittance flows, and migration trends as vectors of risk and resilience. Urban governance will be better prepared in planning, prioritising, and financing the kind of measures that can reduce GHG emissions and improve resilience at scale when they consider a view of cascading risks and carbon lock-ins globally, while also acting locally to address local limitations and capacities, including the needs and priorities of urban citizens (Colenbrander et al. 2018a; Rodrigues 2019).

8.3 Urban Systems and Greenhouse Gas Emissions

This section assesses trends in urban land use, the built environment, and urban GHG emissions, as well as forecasts for urban land use and emissions under certain scenarios to 2050 or 2100. These trends and scenarios hold implications for optimising the approaches to urban climate change mitigation discussed in Sections 8.4 and 8.6.

8.3.1 Trends in Urban Land Use and the Built Environment

Urban land use is one of the most intensive human impacts on the planet (Pouyat et al. 2007; Grimm et al. 2008). Urban land expansion to accommodate a growing urban population has resulted in the conversion of agricultural land (Pandey et al. 2018; Liu et al. 2019), deforestation (van Vliet 2019), habitat fragmentation (Liu et al. 2016b), biodiversity loss (McDonald et al. 2018, 2020), and the modification of urban temperatures and regional precipitation patterns (Li et al. 2017; Krayenhoff et al. 2018; Liu and Niyogi 2019; Zhang et al. 2019).

Urban land use and the associated built environment and infrastructure shape urban GHG emissions through the demand for materials and the ensuing energy-consuming behaviours. In particular, the structure of the built environment (i.e., its density, form, and extent) have long-lasting influence on urban GHG emissions, especially those from transport and building energy use, as well as the embodied emissions of the urban infrastructure (Butler

et al. 2014; Salat et al. 2014; Ramaswami et al. 2016; Seto et al. 2016; d'Amour et al. 2017). Thus, understanding trends in urban land use is essential for assessing energy behaviour in cities as well as long-term mitigation potential (Sections 8.4 and 8.6, and Figure 8.21).

This section draws on the literature to discuss three key trends in urban land expansion, and how those relate to GHG emissions.

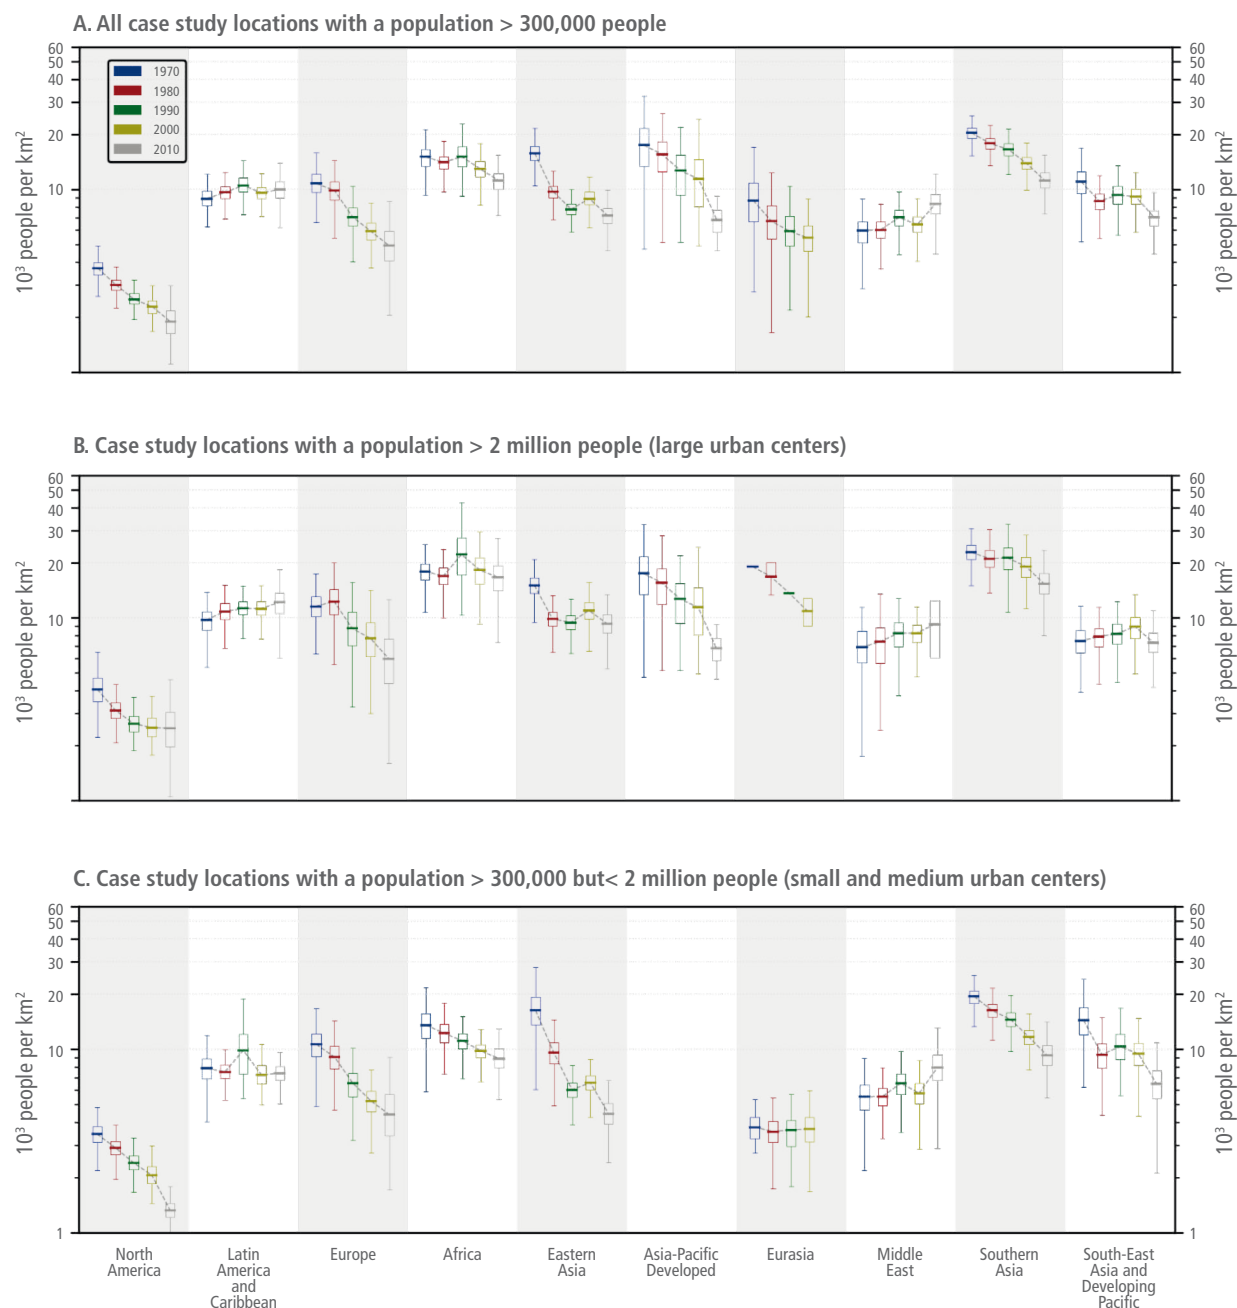

Figure 8.5: Urban population density by decade (1970–2010) grouped by the AR6 WGIII 10-region aggregation. Panel (a) displays the results from all case study locations with a population >300,000. Panels (b) and (c) show results grouped by city size: (b) cities with a population >2 million (large urban centres), and (c) those with a population >300,000 but <2 million (small and medium urban centres). Box plots show the median, first and third quartiles, and lower and upper mild outlier thresholds of bootstrapped average urban population densities at the turn of each decade. The estimates are shown on a logarithmic scale. The data shows an overall trend of declining urban population densities among all but one region in the last four decades, at varying rates – although the Latin America and Caribbean region indicates relatively constant urban population density over time. The Middle East region is the only region to present with an increase in urban population density across all city sizes. Source: adapted from Güneralp et al. (2020).

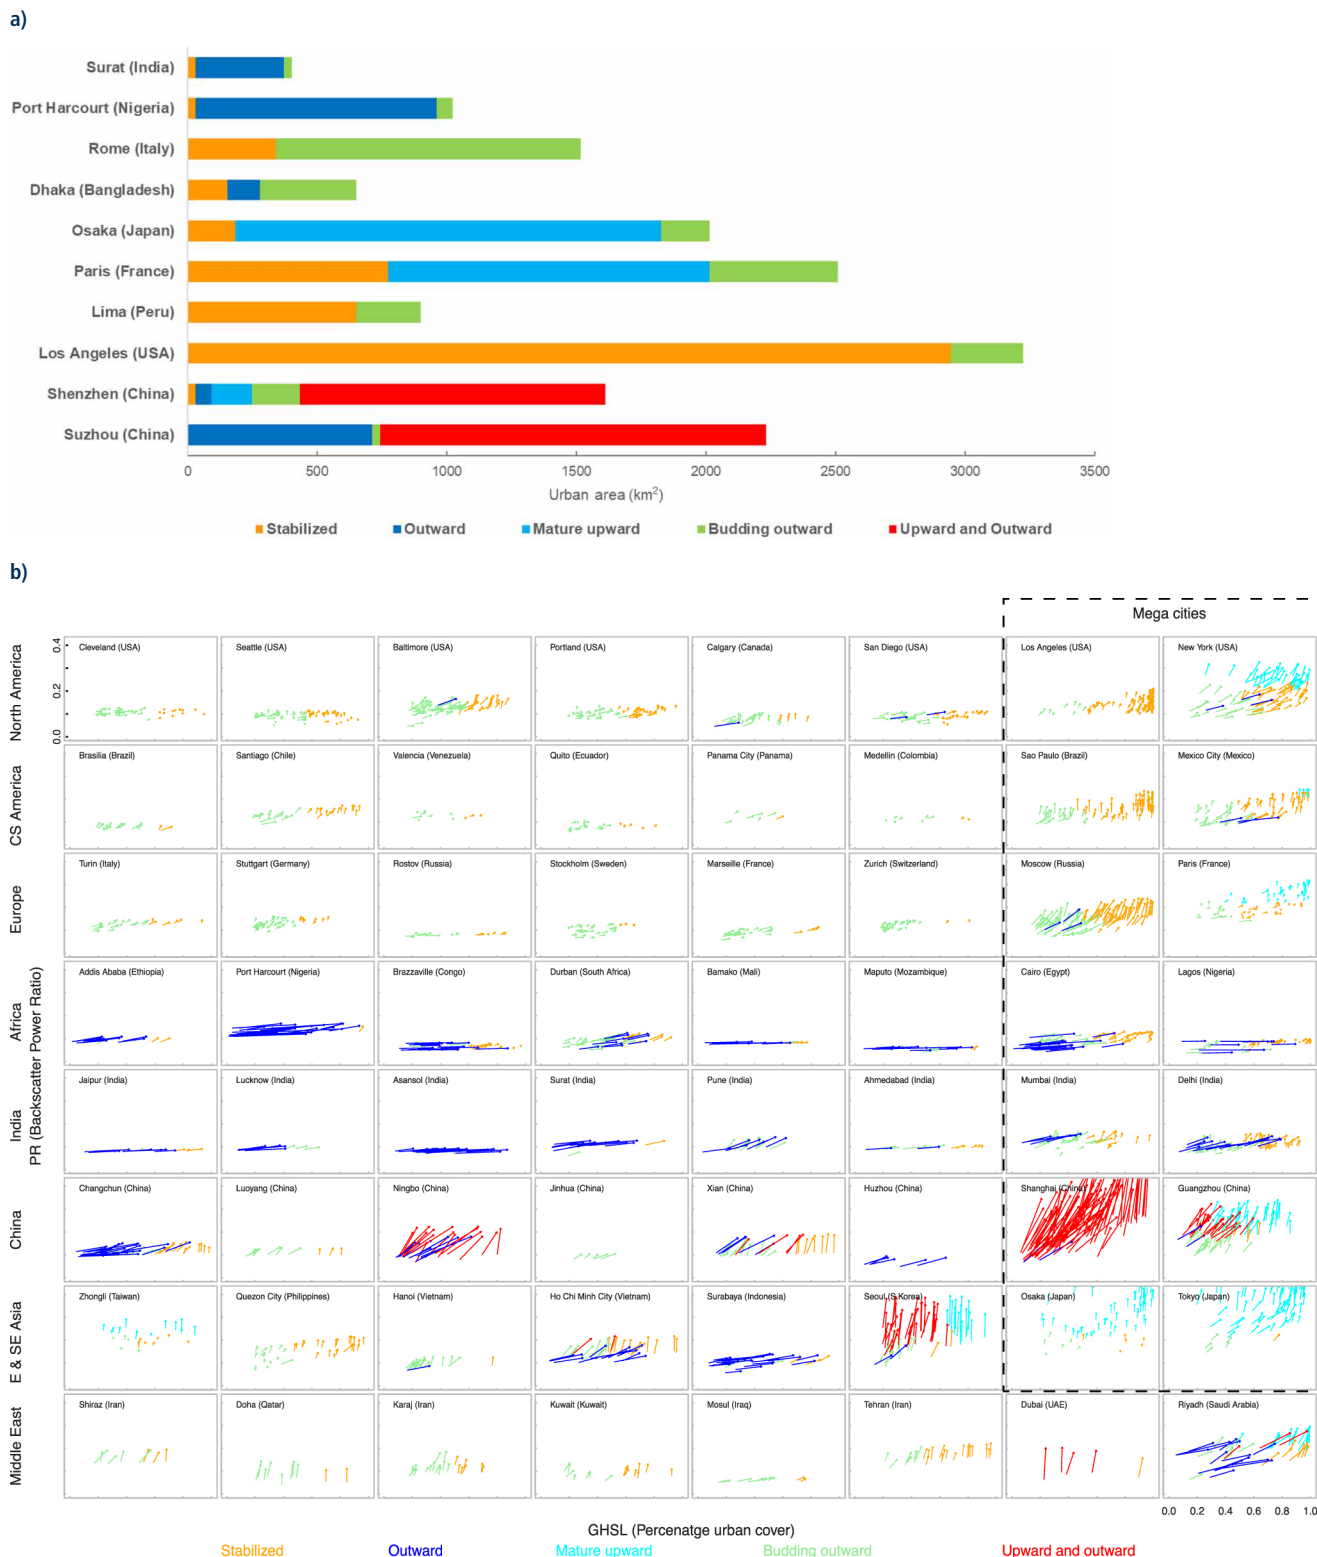

Figure 8.6: (a) Distribution of growth typologies across 10 cities, and (b) sample of 64 cities by region with different patterns of urban growth. The empirical data is based on the Global Human Settlement Layer and backscatter power ratio for different patterns of urban growth across the sample of cities. In (b), the blue arrows indicate outward urban growth. Other urban patterns indicate stabilised (orange), mature upward (light blue), budding outward (green), and upward and outward (red). Note that with few exceptions, each city is comprised of multiple typologies of urban growth. Source: Mahtta et al. (2019).

First, urban land areas are growing rapidly all around the world. From 1975 to 2015, urban settlements expanded in size approximately 2.5 times, accounting for 7.6% of the global land area (Pesaresi et al. 2016). Nearly 70% of the total urban expansion between 1992 and 2015 occurred in Asia and North America (Liu et al. 2020a). By 2015, the extent of urban and built-up lands was between 0.5% and 0.6% of the total 130 Mkm² global ice-free land use, taking up other uses such as fertile cropland and natural ecosystems.

Second, as Figure 8.5 shows, urban population densities are declining, with significant implications for GHG emissions. From 1970 to 2010, while the global urban settlement extent doubled in size (Pesaresi et al. 2016), most regions (grouped by the AR6 WGIII 10-region aggregation) exhibited a trend of decreasing urban population densities, suggesting expansive urban growth patterns. Urban population densities have consistently declined in Australia, Japan and New Zealand, and Europe, North America, and Southern Asia regions, across all city sizes. North America consistently had the lowest urban population densities. Notably, the Middle East region appears to be the only region exhibiting an overall increasing trend across all city-size groups, while Latin America and Caribbean

appears to be relatively stable for all city sizes. While the larger cities in Africa and South-East Asia and Pacific exhibit slightly stable urban population densities, the small and medium-sized cities in those regions trend toward lower urban population densities. In large urban centres of Eastern Asia and North America, rapid decreases in earlier decades seem to have tapered. Compared to larger cities, small-medium urban areas with populations of less than 2 million have more declines in urban population densities and higher rates of urban land expansion (Güneralp et al. 2020).

This decline in urban densities is paralleled by an increase in 'sprawl', or 'outward' urban development. Urban expansion occurs in either one of three dimensions: (i) outward in a horizontal manner; (ii) upward, by way of vertical growth; or (iii) infill development, where unused, abandoned, or underutilised lands within existing urban areas are developed or rehabilitated (Figure 8.20). Outward expansion results in more urban land area and occurs at the expense of other land uses (i.e., the conversion and loss of cropland or forests). Vertical expansion results in more multi-storey buildings and taller buildings, more floor space per area, and an increase in urban built-up density. Every city has some combination of outward and upward

Figure 8.7: Percent of total urban land expansion from other land covers, sorted by the AR6 WGIII 10-region aggregation (1970–2010). As urban land has expanded outward, other forms of land cover, including agriculture, 'nature' (e.g., forest, grassland, shrubland, water, and bare soil, all of which are disaggregated to the bottom half of the plot), and other land covers, have been displaced. Globally, agriculture comprises the majority (about 60%) of the land displaced by urban expansion since 1970. Forests and shrubland vegetation – important carbon stocks – also make up a significant proportion of displacement. The loss of carbon-sequestering land like forests and shrubland independently impacts climate change by reducing global carbon stocks. Eurasia is omitted because there are no case studies from that region that report land conversion data. Source: adapted from Güneralp et al. (2020).

growth in varying degrees (Mahtta et al. 2019) (Figure 8.6). That each city is comprised of different and multiple urban growth typologies suggests the need for differentiated mitigation strategies for different parts of a single city (Section 8.6 and Figure 8.21). Recent research shows that the relative combination of outward versus upward growth is a reflection of its economic and urban development (Lall et al. 2021). That is, how a city grows – whether upward or outward – is a function of its economic development level. Upward growth, or more tall buildings, is a reflection of higher land prices (Ahlfeldt and McMillen 2018; Ahlfeldt and Barr 2020).

An analysis of 478 cities with populations of more than 1 million people found that the predominant urban growth pattern worldwide is outward expansion, suggesting that cities are becoming more expansive than dense (Mahtta et al. 2019) (Figure 8.6). The study also found that cities within a geographic region exhibit remarkably similar patterns of urban growth. Some studies have found a mix of urban forms emerging around the world; an analysis of 194 cities identified an overall trend (from 1990 to 2015) toward urban forms that are a mixture of fragmented and compact (Lemoine-Rodriguez et al. 2020). The exception to this trend is a group of large cities in Australia, New Zealand, and the United States that are still predominantly fragmented. The same study also identified small to medium-sized cities as the most dynamic in terms of their expansion and change in their forms.

A third trend in is urban land growth taking place on agricultural land, carbon stocks, and other land uses (see 'carbon stock' and 'AFOLU' – agriculture, forestry, and other land uses – in Glossary). As Figure 8.7 shows, over 60% of the reported urban expansion (nearly 40,000 km²) from 1970 to 2010 was formerly agricultural land (Güneralp et al. 2020). This percentage increased to about 70% for global urban expansion that occurred between 1992 and 2015, followed by grasslands (about 12%) and forests (about 9%) (Liu et al. 2020a). In terms of percent of total urban land expansion, the largest conversion of agricultural lands to urban land uses from 1970 to 2010 took place in the Eastern Asia, and South-East Asia and Pacific regions; the largest proportional losses of natural land cover were reported for the North America and Australia, Japan and New Zealand regions (Güneralp et al. 2020). At a sub-regional level, agricultural land constituted the largest proportion of land converted to urban areas in China, India, Europe, Southeast Asian countries and the central United States between 1995 and 2015; in the eastern United States, most new urban land was converted from forests (Liu et al. 2020a). Urban expansion through 2040 may lead to the loss of almost 65 Mt of crop production – a scenario that underscores the ongoing relationship between urbanisation and AFOLU (van Vliet et al. 2017) (Chapter 7).

8.3.2 Informal Urban Settlements

About 880 million people currently live in informal settlements – defined as unplanned areas operating outside of legal and regulatory systems, where residents have no legal claim over their property and have inadequate basic services and infrastructure (United Nations 2018). Furthermore, upgrading informal settlements and inadequate housing is essential for improving resilience to climate change and well-being. Given the ubiquity of informal settlements in developing countries and LDCs, there is potential to harness informality to

accelerate transitions to low-carbon urban development. There are several key reasons for their potential to mitigate GHG emissions. First, informal urban areas may not require large investments in retrofitting as they have developed with minimal investment in large-scale infrastructure. Second, these areas exhibit flexibility of development and can potentially be transformed into an urban form that supports low- or carbon-neutral infrastructure for transportation, energy use in residential buildings, and other sectors (Baurzhan and Jenkins 2016; Henneman et al. 2016; Byrne et al. 2017; Oyewo et al. 2019).

Informal urban areas can avoid the conventional trajectory of urban development by utilising large-scale strategies, such as micro-scale technologies, modal shifts towards compact, walkable urban form, as well as decentralised or meso-scale utilities of water, sanitation, and service centres – thereby mitigating emissions associated with transport and treating wastes (Tongwane et al. 2015; Yang et al. 2018). Some specific mitigation options include spatial adjustments for walkability of neighbourhoods, low-energy-intensive mobility, low-energy-intensive residential areas, low-carbon energy sources at city scale, off-grid utilities, and electrification and enhancement of the urban ecology – all of which have multiple potential benefits (Colenbrander et al. 2017; Fang et al. 2017; Laramée et al. 2018; van der Zwaan et al. 2018; Wu et al. 2018; Silveti and Andersson 2019). Some of the co-benefits of the various mitigation options include more job opportunities and business start-ups, increased incomes, air quality improvement, and enhanced health and well-being (Gebreegziabher et al. 2014; Dagnachew et al. 2018; Keramidas et al. 2018; Adams et al. 2019; Ambole et al. 2019; Boltz et al. 2019; Moncada et al. 2019; Weimann and Oni 2019; Manga et al. 2020) (Section 8.2).

Non-networked and non-centralised urban services and infrastructure in informal settlements, including sanitation, waste, water, and electricity, serve over 60% of the urban population in developing country cities (Lawhon et al. 2018). The alternatives of disruptive, hybrid, largely non-networked multiplicity of technologies applicable at micro to meso scales have potential for low-emissions development in urban areas of developing countries (Narayana 2009; Dávila and Daste 2012; Radomes Jr and Arango 2015; Potdar et al. 2016; Grové et al. 2018). These technologies can be applied in the short term as responses with long-term influence on emissions reduction. The cumulative impact of the disruptive technologies can reduce emissions by 15–25% through enhanced emissions sinks in small and medium-sized cities (Tongwane et al. 2015; du Toit et al. 2018; Nero et al. 2018, 2019; Frantzeskaki et al. 2019; Mantey and Sakyi 2019; Singh and G. 2019).

8.3.3 Trends in Urban Greenhouse Gas Emissions

One major innovation presented in AR6 – particularly in this chapter – is the inclusion of trend data on urban GHG emissions. Using multiple datasets in conjunction with the SSP and RCP scenarios, this chapter provides an estimate of urban GHG emissions from 1990 through 2100, based on a consumption-based approach. This innovation provides, for the first time, a temporal dimension to urban footprints considering different climate scenarios with implications for urban mitigation. The new analysis presents a comparison of ways urban emissions can evolve given different scenario contexts (Section 8.3.4.2). Additionally, new research has quantified trends in

urban CO₂ emissions and their key drivers across 91 global cities from 2000 to 2018 (Luqman et al. 2021).

Figures 8.8 and 8.9 present key urban emission metrics and trends for six regions (based on the AR6 WGIII regional breakdown) – the first for the year 2015, and the latter for both 2000 and 2015.

The key trends are as follows. First, the urban share of global GHG emissions (including CO₂ and CH₄) is substantive and continues to increase (Figure 8.9). Total urban CO₂-eq emissions based on consumption-based accounting were estimated to be 25 GtCO₂-eq, or 62% of the global total in 2015, and increased to an estimated 29 GtCO₂-eq in 2020, representing about 67–72% of global emissions. This estimate includes all CO₂ and CH₄ emissions except aviation, shipping, and biogenic sources (i.e., land-use change, forestry, and agriculture). About 100 of the highest-emitting urban areas account for approximately 18% of the global carbon footprint (Moran et al. 2018). Globally, the urban share of national CO₂-eq emissions increased 6 percentage points, from 56% in 2000 to 62% in 2015.

Second, while urban CO₂ emissions were increasing in all urban areas, the dominant drivers were dependent upon development level. Emissions growth in urban areas other than in Developed Countries was driven by increases in area and per capita emissions. Across all cities, higher population densities are correlated with lower per capita GHG emissions (Luqman et al. 2021).

Third, the urban share of regional GHG emissions increased between 2000 and 2015, with much inter-region variation in the magnitude of the increase (*high confidence*) (Figure 8.9). Between 2000 and 2015, the urban emissions share across AR6 WGIII regions (6-region aggregation) increased from 28% to 38% in Africa, from 46% to 54% in Asia and Pacific, from 62% to 72% in Developed Countries, from 57% to 62% in Eastern Europe and West-Central Asia, from 55% to 66% in Latin America and Caribbean, and from 68% to 69% in the Middle East.

Between 2000 and 2015, urban population, urban CO₂-eq emissions, and national CO₂-eq emissions increased as a share of the global total in the Asia and Pacific region while the share declined for Developed Countries. The urban share of total regional CO₂-eq emissions decreased in Developed Countries from 58.2% (2000) to 40.0% (2015). Urban per capita CO₂-eq and national per capita CO₂-eq also increased in all regions except for the urban per capita CO₂-eq value in the Developed Countries region, which declined slightly.

Fourth, the global average per capita urban GHG emissions increased between 2000 and 2015, with cities in the Developed Countries region producing nearly seven times more per capita than the lowest emitting region (*medium confidence*). From 2000 to 2015, the global urban GHG emissions per capita increased from 5.5 to 6.2 tCO₂-eq per person (an increase of 11.8%), with increases across five of the six regions: Africa increased from 1.3 to 1.5 tCO₂-eq per person (22.6%); Asia and Pacific increased from 3.0 to 5.1 tCO₂-eq per person (71.7%); Eastern Europe and West-Central Asia increased from 6.9 to 9.8 tCO₂-eq per person (40.9%); Latin America and Caribbean increased from 2.7 to 3.7 tCO₂-eq per person (40.4%); and the Middle East increased from 7.4 to 9.6 tCO₂-eq per person (30.1%). Albeit starting from the highest level, Developed Countries had a decline of 11.4 to 10.7 tCO₂-eq per person (–6.5%).

In 2015, regional urban per capita consumption-based CO₂-eq emissions were lower than regional consumption-based national per capita CO₂-eq emissions in five of the six regions. These regions in order of the difference are: Developed Countries (lower by 1.0 tCO₂-eq per capita); Latin America and Caribbean (lower by 0.8 tCO₂-eq per capita); Eastern Europe and West-Central Asia (lower by 0.7 tCO₂-eq per capita); Middle East (lower by 0.4 tCO₂-eq per capita); and Africa (lower by 0.2 tCO₂-eq per capita); while higher only in the Asia and Pacific region (higher by 0.9 tCO₂-eq per capita). All regions show convergence of the urban and national per capita CO₂-eq, as the urban share of national emissions increases and dominates the regional total.

Figure 8.8: 2015 average urban greenhouse gas emissions per capita, considering carbon dioxide (CO₂) and methane (CH₄) emissions from a consumption-based perspective, alongside urban population, for regions represented in the AR6 WGIII 6-region aggregation. The average urban per capita emissions are given by the height of the bars while the width represents the urban population for a given region, based on 2015 values for both axes. Provided within the bars are the percentage shares of the urban population by region as a share of the total urban population. Source: synthesised based on data from UN DESA (2019) and Gurney et al. (2022).

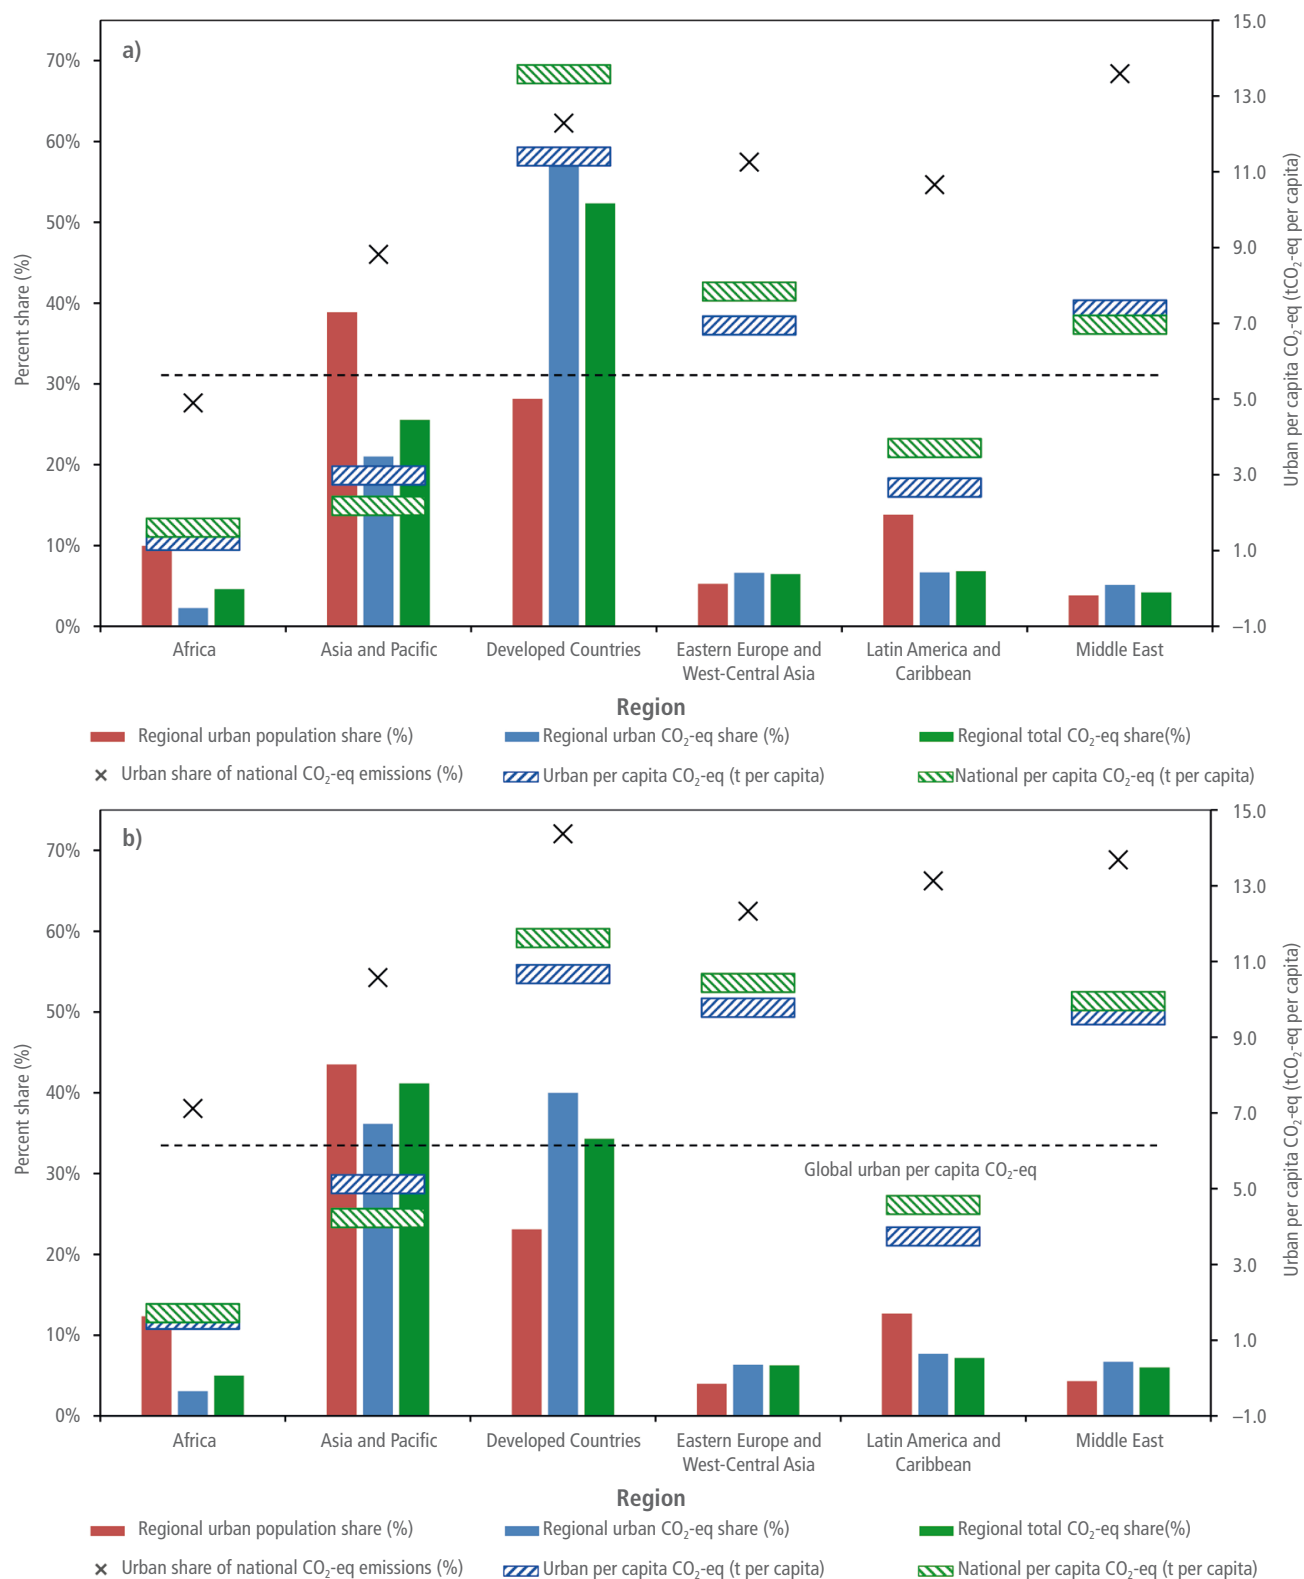

Figure 8.9: Changes in six metrics associated with urban and national-scale carbon dioxide (CO₂) and methane (CH₄) emissions represented in the AR6 WGIII 6-region aggregation, with (a) 2000 and (b) 2015. The trends in Luqman et al. (2021) were combined with the work of Moran et al. (2018) to estimate the regional urban CO₂-eq share of global urban emissions, the urban share of national CO₂-eq emissions, and the urban per capita CO₂-eq emissions by region. This estimate is derived from consumption-based accounting that includes both direct emissions from within urban areas and indirect emissions from outside urban areas related to the production of electricity, goods, and services consumed in cities. It incorporates all CO₂ and CH₄ emissions except aviation, shipping and biogenic sources (i.e., land-use change, forestry, and agriculture). The dashed grey line represents the global average urban per capita CO₂-eq emissions. The regional urban population share, regional CO₂-eq share in total emissions, and national per capita CO₂-eq emissions by region are given for comparison. Source: adapted from Gurney et al. (2022).⁵

Box 8.1: Does Urbanisation Drive Emissions?

Urbanisation can drive emissions if the process is accompanied by an income increase and higher levels of consumption (Sudmant et al. 2018). This is typically observed in countries with a large urban-rural disparity in income and basic services, and where urbanisation is accompanied by economic growth that is coupled to emissions. In addition, the outward expansion of urban land areas often results in the conversion and loss of agricultural land (Pandey et al. 2018; Liu et al. 2019), forests (Austin et al. 2019), and other vegetated areas, thereby reducing carbon uptake and storage (Quesada et al. 2018) (Section 8.3.1). Furthermore, the buildup and use of urban infrastructure (e.g., buildings, power, sanitation) requires large amounts of embodied energy and carbon (Figures 8.17 and 8.22). Building new and upgrading existing urban infrastructure could produce cumulative emissions of 226 GtCO₂ by 2050 (Bai et al. 2018).

However, for the same level of consumption and basic services, an average urban dweller often requires less energy than their rural counterparts, due to higher population densities that enable sharing of infrastructure and services, and economies of scale. Whether and to what extent such emission reduction potentials can be realised depends on how cities are designed and laid out (i.e., urban form – see Section 8.4.2) as well as how urban infrastructure is built and powered, such as the energy intensity of the city's transportation system, type and level of urban services, the share of renewable energy, as well as the broader national and international economic and energy structure that supports the function of the cities (Sections 8.4.3 and 8.6).

Although population-dense cities can be more efficient than rural areas in terms of per capita energy use, and cities contribute less GHG emissions per person than low-density suburbs (Jones and Kammen 2014), there is some, albeit *limited*, evidence that larger cities are not more efficient than smaller ones (Fragkias et al. 2013; Ribeiro et al. 2019). A number of studies comparing urban and rural residents in the same country have shown that urban residents have higher per capita energy consumption and CO₂ emissions (Chen et al. 2019a; Hachaichi and Baouni 2021). There is some evidence that the benefits of higher urban densities on reducing per capita urban GHG emissions may be offset by higher incomes, smaller household sizes, and, most importantly, higher consumption levels, thus creating a counter-effect that could increase GHG emissions with urbanisation (Gill and Moeller 2018).

Many studies have shown that the relationship between urbanisation and GHG emissions is dependent on the level and stage of urban development, and follows an inverted U-shaped relationship of the environmental Kuznets curve (Wang et al. 2016, 2022; Zhang et al. 2017; Xu et al. 2018a; Zhou et al. 2019) (Sections 8.3.1 and 8.6, and Figure 8.20). Considering existing trends, earlier phases of urbanisation accompanied by rapid industrialisation, development of secondary industries, and high levels of economic growth, are correlated with higher levels of energy consumption and GHG emissions. However, more mature phases of urbanisation, with higher levels of economic development and establishment of the service sector, are correlated with lower levels of energy consumption and GHG emissions (Khan and Su 2021).

8.3.4 Scenarios of Future Urbanisation and Greenhouse Gas Emissions

This section assesses scenarios of future urban land expansion and urban GHG emissions. These scenarios have implications for the urban climate change mitigation strategies discussed in Sections 8.4 and 8.6 – in particular, in the context of the potential mitigation and development pathways for urban areas under certain scenarios.

8.3.4.1 Urban Land Expansion and Greenhouse Gas Emissions

The uncertainties across urban land expansion forecasts, and associated SSPs, highlight an opportunity to pursue compact, low or net-zero GHG emissions development that minimises land-use competition, avoids carbon lock-in, and preserves carbon-sequestering areas like forests and grasslands (Sections 8.4. and 8.6, and Figure 8.21). Among the forecasts available are six global-scale spatially explicit studies of urban land expansion that have been published since AR5; four of the six, which present forecasts for each of the five SSPs, are considered in Table 8.1 and Figure 8.10 (Huang et al. 2019; Li et al. 2019b; Chen et al. 2020a; Gao and O'Neill 2020). All four have forecasts to 2050 but only three to 2100. One of

the two not included here (van Vliet et al. 2017) also forecasts land displacement due to urban land expansion.

Four overarching findings can be gleaned from these studies.

First, urban land areas will expand significantly by 2050 – by as much as 211% (see SSP5 forecast in Huang et al. 2019), but likely within a large potential range of about 43–106% over the 2015 extent by 2050 – to accommodate the growing urban population (Table 8.1). Globally, there are large uncertainties and variations among the studies – and between the SSPs – about the rates and extent of future urban expansion, owing to uncertainties about economic development and population growth (ranges of estimates are provided in Table 8.1). Overall, the largest urban extents are forecasted under SSP5 (fossil fuel-intensive development) for both 2050 and 2100, whereas the smallest forecasted urban extents are under SSP3 ('regional rivalry'). Forecasted global urban extents could reach between 1 and 2.2 million km² (median of 1.4 million km², a 106% increase) in 2050 under SSP5, and between 0.85 and 1.5 million km² (median of 1 million km², a 43% increase) in 2050 under SSP3. Under SSP1, which is characterised by a focus on sustainability with more compact, low-emissions development, urban extents could reach

1 million km² (range of 0.9 to 2 million km², a 49% increase) in 2050. By 2100, the forecasted urban extents reach between 1.4 and 3.6 million km² (median 2.5 million km²) under SSP5 and between 1 and 1.5 million km² (median 1.3 million km²) under SSP3. Across the studies, substantially larger amounts of urban land expansion are expected after 2050 under SSP5 compared to other SSPs.

Second, there is a wide variation in estimates of urban land expansion across regions (using the AR6 WGIII 6-region aggregation). Across all four sets of forecasts, current urban land (circa 2015) is the largest in Developed Countries and in the Asia and Pacific region, with approximately two-thirds of the current urban extent occurring in those two regions (Table 8.1 and Figure 8.10). The largest increases in urban land by 2050 are expected in the Asia and Pacific and Developed Countries regions, across all the SSPs. However, the rate of increase in urban land in Eastern Europe and West-Central Asia, Latin America and Caribbean, and the Middle East is significant and urban land could more than double by 2050. One-third of the studies conclude that the United States, China, and India will experience continued urban land expansion at least until 2050 (Huang et al. 2019; Li et al. 2019b). However, Li et al. (2019) report that, after 2050, China could experience a decrease in the rate of urban land expansion, while growth will continue for India. This is not surprising since India's urban demographic transition will only get underway after the middle of the century, when the urban population is expected to exceed the rural population. In contrast, China's urban demographic transition could be nearly complete by 2050.

Third, in spite of these general trends, there are differences in forecasted urban expansion in each region across the SSPs and studies, with Huang et al. (2019) forecasting the most future urban land expansion between 2015 and 2050. The range across

studies is significant. Under SSP1, urban land areas could increase by between 69,000 and 459,000 km² in Developed Countries, 77,000–417,000 km² in Asia and Pacific, and 28,000–216,000 km² in Africa. Under SSP3, where urban land expansion is forecasted to be the lowest, urban land areas could increase by between 23,000 and 291,000 km² in Developed Countries, 57,000–168,000 km² in Asia and Pacific, and 16,000–149,000 km² in Africa. Under SSP5, where urban land expansion is forecasted to be the highest, urban land area could increase by between 129,000 and 573,000 km² in Developed Countries, 83,000–472,000 km² in Asia and Pacific, and 40,000–222,000 km² in Africa (Huang et al. 2019; Li et al. 2019b; Chen et al. 2020a; Gao and O'Neill 2020). By 2100, however, the Developed Countries region is expected to have the most urban expansion only in SSP5. In SSP2 and SSP4, the Developed Countries and Asia and Pacific regions have about equal amounts of new urban land; in SSP3, Asia and Pacific has more new urban land forecasted.

Fourth, both the range of estimates and their implications on land-use competition and urban life point to an opportunity for urban areas to consider their urban form when developing. Under the current urbanisation trajectory, 50–63% of newly expanded urban areas are expected to occur on current croplands (Chen et al. 2020a). However, there is significant regional variation; between 2000 and 2040, 12.5% of cropland in China and 7.5% of cropland in the Middle East and North Africa could potentially be displaced due to urban expansion, compared to the world average of 3.7% (van Vliet et al. 2017). As urban clusters increase in size and greenspace is converted, future urban land expansion is expected to intensify UHIs and exacerbate night-time extreme temperatures. An urban footprint increase of 78–171% by 2050 over the urban footprint in 2015 is expected to result in average summer daytime and night-time warming in air temperature of 0.5°C–0.7°C, even up to about 3°C in certain locations (Huang

Table 8.1: Forecasts of total urban land per AR6 WGIII region (6-region aggregation) in 2050 for each SSP, with the median and range of estimates from four studies: Huang et al. (2019), Li et al. (2019), Chen et al. (2020), and Gao and O'Neill (2020). Median estimates for the 2015 urban extent are based on the mean/median of estimates in Huang et al. (2019) and Chen et al. (2020). Median and range of estimates for each SSP in 2050 are based on values derived from the four studies: Huang et al. (2019), Li et al. (2019), Chen et al. (2020), and Gao and O'Neill (2020). While each study and SSP forecast increases in urban land in each region, the range and magnitude vary. Source: data compiled from Huang et al. (2019), Li et al. (2019), Chen et al. (2020), and Gao and O'Neill (2020).

	2015 median (km ² ; range)	SSP1 median (km ² ; range)	SSP2 median (km ² ; range)	SSP3 median (km ² ; range)	SSP4 median (km ² ; range)	SSP5 median (km ² ; range)
Africa	64,423 (41,472–87,373)	97,718 (67,488–303,457)	116,486 (59,638–274,683)	96,571 (56,071–235,922)	119,971 (54,633–344,645)	138,604 (79,612–309,532)
Asia and Pacific	241,430 (167,548–315,312)	293,647 (244,575–732,303)	355,445 (236,677–624,659)	296,431 (224,520–483,335)	329,485 (240,639–632,678)	419,781 (250,670–787,257)

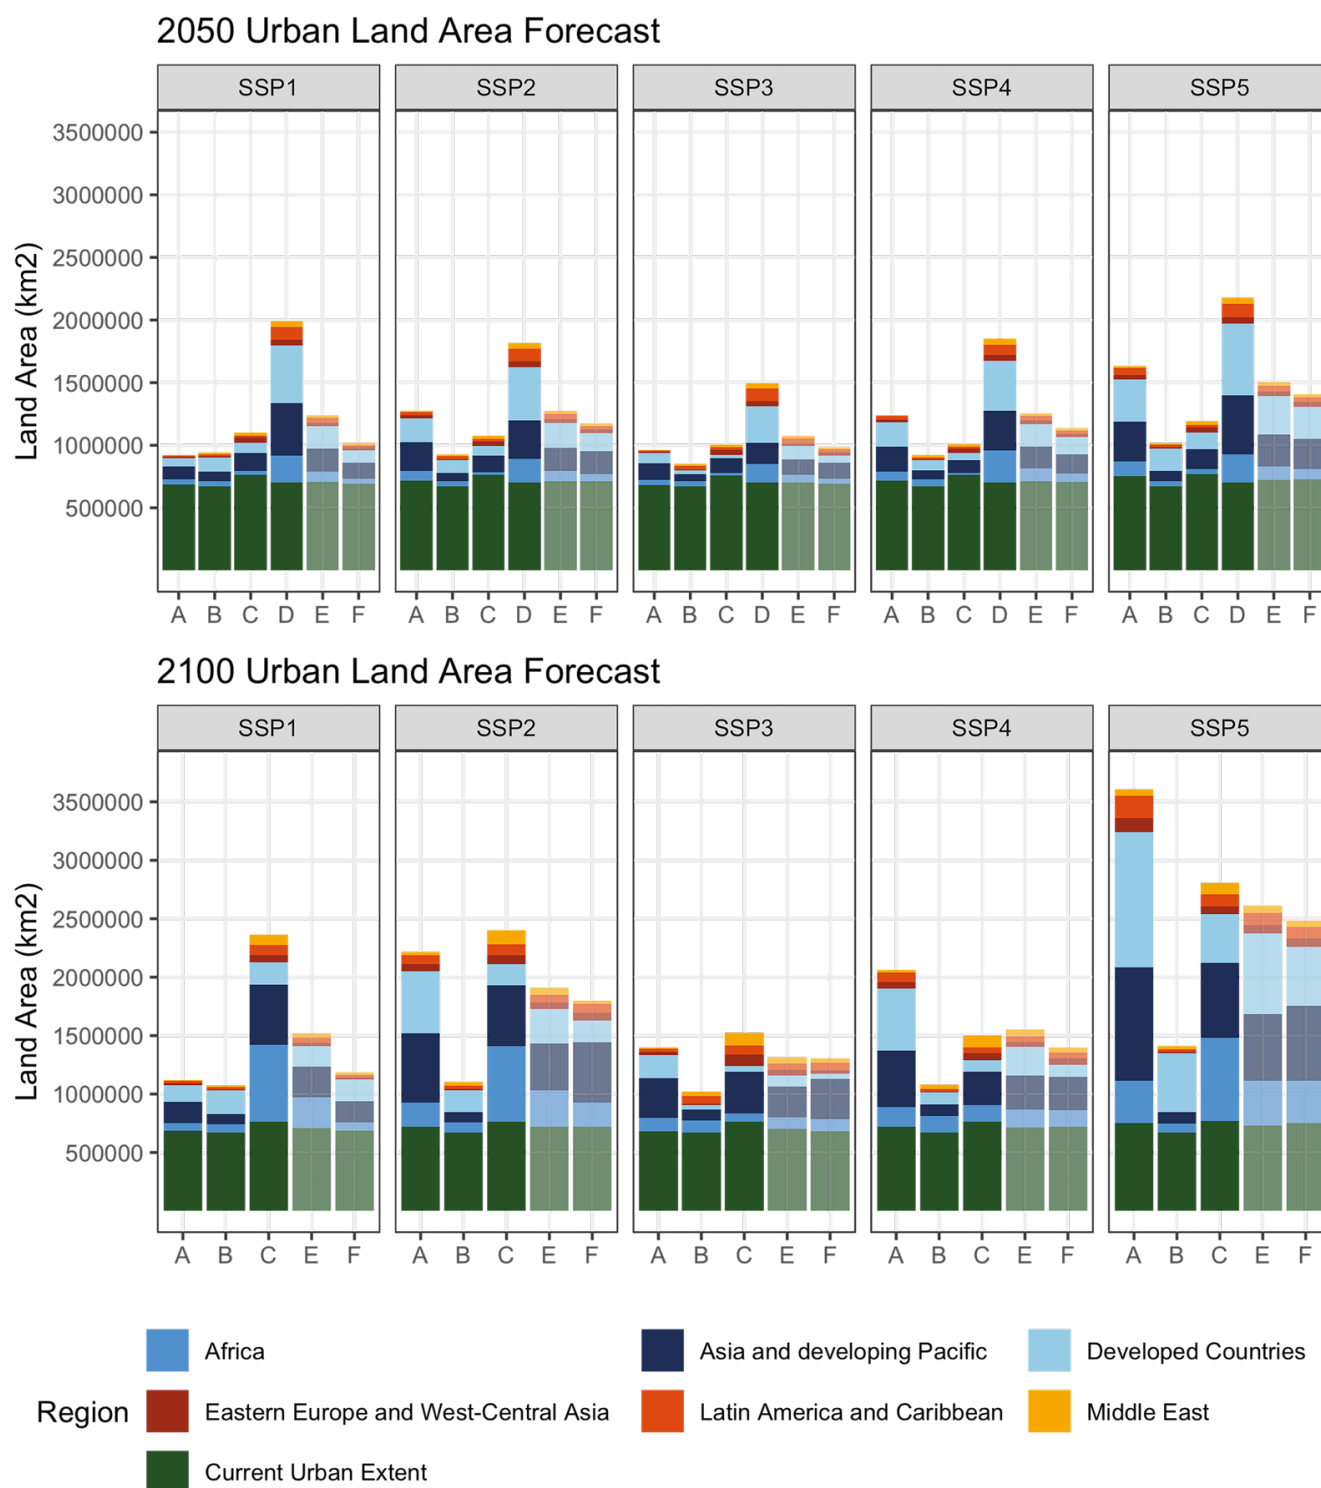

Figure 8.10: Forecasts of urban land expansion in 2050 and 2100 according to each SSP and AR6 WGIII 6-region aggregation, by study, where A: Gao and O'Neill (2020), B: Chen et al. (2020a), C: Li et al. (2019), D: Huang et al. (2019), E: mean across studies, and F: median across all studies. Three studies (Li et al. 2019b; Chen et al. 2020a; Gao and O'Neill 2020) report forecasts of urban land expansion to both 2050 and 2100. One study (Huang et al. 2019) reports the forecast only to 2050. Global current urban extents and the respective initial years vary slightly among the four studies. Years for values of current urban extent range from 2010 to 2020. See Table 8.1 for the range of data across the four studies and across SSPs. Source: data compiled from Huang et al. (2019), Li et al. (2019), Chen et al. (2020), and Gao and O'Neill (2020).

et al. 2019). Furthermore, this urban expansion-induced warming is on average about half – and in certain locations nearly twice – as strong as warming that will be caused by GHG emissions based on the multi-model ensemble average forecasts in RCP4.5. In short, future urban expansion will amplify the background warming caused by GHG emissions, with extreme warming most pronounced during night-time (*very high confidence*) (Huang et al. 2019). These findings corroborate those in the Technical Summary of AR6 WGI (Arias et al. 2021).

The forecasted amounts and patterns of urban expansion presented here bear significant uncertainty due to underlying factors beyond mere methodological differences between the studies. These factors include potential changes in the social, economic, and institutional dynamics that drive urban land development across the world (Güneralp and Seto 2013). Some of these changes may come in the form of sudden shocks such as another global economic crisis or pandemic. The forecasts presented here do not take such factors into account.

8.3.4.2 Scenarios of Future Urban Greenhouse Gas Emissions

There remains little globally comprehensive literature on projections of future baseline GHG emissions from urban areas or scenarios deploying urban mitigation actions on the part of city or regional governments. This dearth of research rests on limited urban emissions data that are consistent and comparable across the globe, making review and synthesis challenging (Creutzig et al. 2016b). Some research has presented urban emissions forecasts and related projections, including estimated urban energy use in 2050 (Creutzig et al. 2015), energy savings for low-carbon development (Creutzig et al. 2016b), emission savings from existing and new infrastructure (Creutzig et al. 2016a) (Figure 8.12), and urban emissions from buildings, transport, industry, and agriculture (IEA 2016a).

In its study of about 700 urban areas with a population of at least 750,000, the Coalition for Urban Transitions (2019), attempts to quantify

Figure 8.11: Reference scenario and mitigation potential for global urban areas in the residential and commercial building, transport, waste, and material production sectors. The top red line indicates the reference scenario where no further emissions reduction efforts are taken, while the bottom dark line indicates the combined potential of reducing emissions across the sectors displayed. Wedges are provided for potential emissions savings associated with decarbonising residential buildings, commercial buildings, transport, waste, and materials as indicated in the legend. The shaded areas that take place among the wedges with lines indicate contributions from decarbonisation of electricity supply. Source: Re-used with permission from Coalition for Urban Transitions (2019).

the urban portion of global GHG emissions, including the residential and commercial building, transport, waste, and material production (focusing on cement, aluminium, and steel) sectors, along with mitigation wedges aimed at staying below a 2°C level of atmospheric warming (Figure 8.11). Starting in 2015 with a global urban emissions total of almost 14 GtCO₂-eq, the study projects an increase to 17.3 GtCO₂-eq by 2050 – but this reduces to 1.8 GtCO₂-eq by 2050 with the inclusion of mitigation wedges: 58% from buildings, 21% from transport, 15% materials efficiency, and 5% waste, with decarbonisation of electricity supply as a cross-cutting strategy across the wedges.

Figure 8.12: Urban infrastructure-based CO₂-eq emission mitigation wedges. Urban infrastructure-based CO₂-eq emission mitigation wedges across categories of existing (yellow/green), new (blue), and construction (grey) of urban infrastructure. The wedges include low-carbon energy systems and infrastructure, modal shift, tolls/tax, or behavioural change, and reductions from construction materials. Source: re-used with permission from Creutzig et al. (2016a).

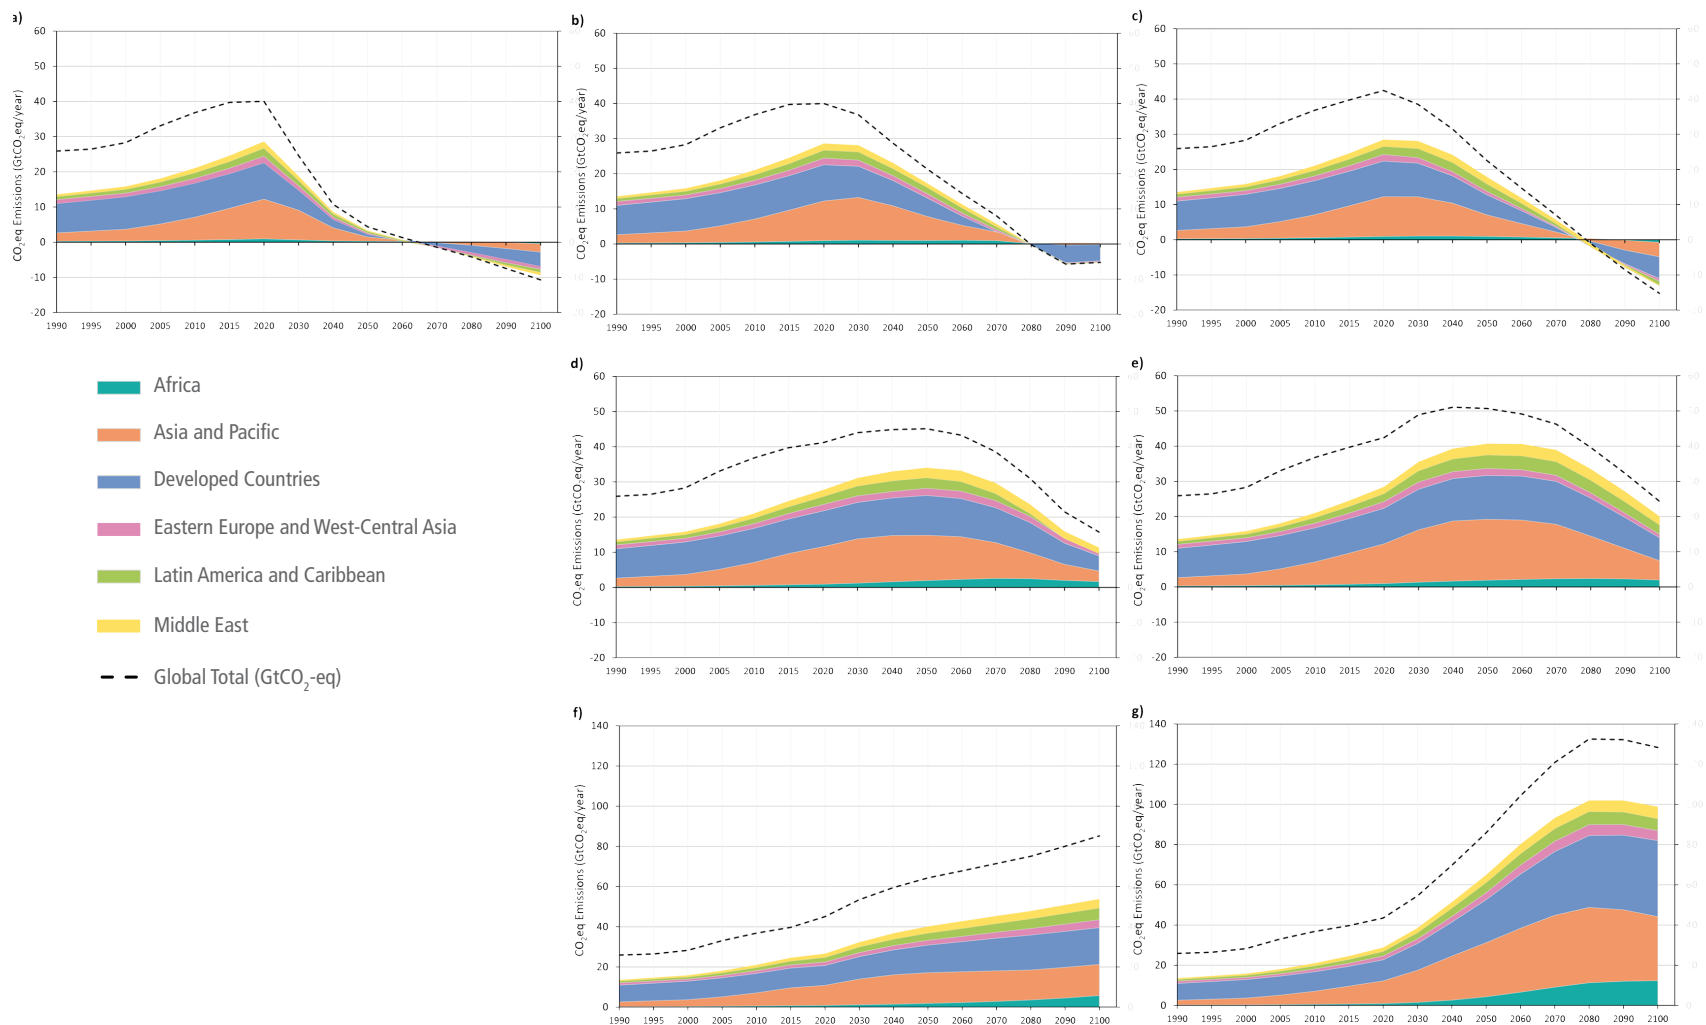

Figure 8.13: Carbon dioxide equivalent (CO₂-eq) emissions from global urban areas in seven SSP-RCP variations spanning the 1990 to 2100 time period. Urban areas are aggregated to six regional domains based on the AR6 WGI 6-region aggregation. Global total CO₂-eq emissions (CO₂ and CH₄ (methane)) are also shown as marked by the dashed line. Future urban emissions in the context of SSP-RCP-Shared Policy Assumption (SPA) variations correspond to (a) SSP1-RCP1.9-SPA1, (b) SSP1-RCP2.6-SPA1, (c) SSP4-RCP3.4-SPA4, (d) SSP2-RCP4.5-SPA2, (e) SSP4-RCP6.0-SPA4, (f) SSP5-RCP7.0-SPA0 and (g) SSP5-RCP8.5 based on the marker scenario implementations.⁶ The first three scenarios (a–c) with more stringent reduction pathways represent contexts where urban per capita emissions decline rapidly against various increases in urban population and are oriented to reach net-zero emissions within this century at different radiative forcing levels. SSP1 scenarios (a, b) represent contexts where urbanisation takes place rapidly while providing resource efficiency based on compact urban form (Jiang and O'Neill 2017), with high levels of electrification (van Vuuren et al. 2017b; Rogelj et al. 2018). The scenario context of SSP1-RCP1.9 represents a pathway in which there can be a transformative shift towards sustainability. Note that the scale of panels (f) and (g) is different from the other panels.⁷ See Table 8.2 detailing the SSP-RCPs. Source: adapted from Gurney et al. (2022).⁸

⁶ These scenarios have been assessed by WGI to correspond to intermediate, high, and very low GHG emissions.

⁷ The SSP1-RCP1.9 scenario is aligned with the C1 category of the Illustrative Mitigation Pathways (IMPs) that include IMP-LD, IMP-Ren and IMP-SP. Implications are provided in Table 8.3.

⁸ Figure adapted from *Global Environmental Change*, Vol 73, Gurney et al., Greenhouse gas emissions from global cities under SSP/RCP scenarios, 1990 to 2100, ©2022 with permission from Elsevier.

Estimated urban emissions changes in two different scenarios (2020–2030)

Figure 8.14: Comparison of urban emissions under different urbanisation scenarios (GtCO₂-eq yr⁻¹) for the AR6 WGIII 6-region aggregation. The panels represent the estimated urban emissions change in two different scenarios for the time period 2020–2030. Panel (a) represents resource efficient and compact urbanisation while panel (b) represents urbanisation with moderate progress. The two scenarios are consistent with estimated urban emissions under the SSP1-RCP1.9-SPA1 and SSP2-RCP4.5-SPA2 scenarios, respectively (Figure 8.13). In both panels, urban emissions estimates for the year 2020 are marked by the lines for each region. In the resource efficient and compact scenario, various reductions in urban emissions that take place by 2030 are represented by the dashed areas within the bars. The remaining solid shaded areas represent the remaining urban emissions in 2030 for each region on the path towards net-zero emissions. The total reductions in urban emissions worldwide that are given by the last dashed grey bar in panel (a) is estimated to be 9.8 GtCO₂-eq yr⁻¹ between 2020 and 2030 in this scenario. In the scenario with moderate progress, there are no regions with reductions in urban emissions. Above the white lines that represent urban emissions in 2020, the grey shaded areas are the estimated increases for each region so that the total urban emissions would increase by 3.4 GtCO₂-eq yr⁻¹ from 2020 levels in 2030 under this scenario. The values are based on urban scenario analyses as given in Gurney et al. (2021, 2022). Source: synthesised based on data from Gurney et al. (2022).⁹

Table 8.2: Synthesis of the urbanisation and scenario contexts of the urban emissions scenarios. Descriptions for urbanisation are adapted based on Jiang and O'Neill (2017) while high, medium, low, or mixed levels in the scenario context are drawn from the marker model implementations of SSP1-SSP5 for IMAGE (van Vuuren et al. 2017b; Rogelj et al. 2018), MESSAGE-GLOBIOM (Fricko et al. 2017), AIM/CGE (Fujimori et al. 2017), GCAM (Calvin et al. 2017), and REMIND-MAGPIE (Kriegler et al. 2017). The letters in parentheses refer to the panels in Figure 8.13. Energy and material efficiency relate to energy efficiency improvement and decrease in the intermediate input of materials, including steel and cement. Dietary responses include less meat-intensive diets. Implications for urban areas relate to the mitigation options in Section 8.4. Source: adapted from Gurney et al. (2022).

SSP/RCP framework	Urbanisation context	Scenario context					
		Electrification	Energy and material efficiency	Technology development/innovation	Renewable energy preferences	Behavioural, lifestyle and dietary responses	Afforestation and re-forestation
SSP1 RCP1.9 (a) RCP2.6 (b)	Resource efficient, walkable and sustainable rapid urbanisation	High	High	High	High	High	High
		Implications for urban climate mitigation include: <ul style="list-style-type: none"> – Electrification across the urban energy system while supporting flexibility in end-use – Resource efficiency from a consumption-based perspective with cross-sector integration – Knowledge and financial resources to promote urban experimentation and innovation – Empowerment of urban inhabitants for reinforcing positive lock-in for decarbonisation – Integration of sectors, strategies and innovations across different typologies and regions 					
SSP2 RCP4.5 (d)	Moderate progress	Medium	Medium	Medium	Medium	Medium	Medium
SSP3 RCP7.0 (f)	Slow urbanisation, inadequate urban planning	Medium	Low	Low	Medium	Low	Low
SSP4 RCP3.4 (c) RCP6.0 (e)	Pace of urbanisation differs with inequalities	Mixed	Mixed	Mixed	Mixed	Mixed	Mixed
SSP5 RCP8.5 (g)	Rapid urbanisation with carbon lock-in	High	Low	High	Low	Low	–

⁹ Figure adapted from *Global Environmental Change*, Vol 73, Gurney et al., Greenhouse gas emissions from global cities under SSP/RCP scenarios, 1990 to 2100, ©2022 with permission from Elsevier.

Similar analysis by the urban networks C40 and GCoM examine current and future GHG emissions on smaller subsets of global cities, offering further insight on the potential emissions impacts of urban mitigation options. However, this analysis is limited to just a sample of the global urban landscape and primarily focused on cities in the Global North (GCoM 2018, 2019; C40 Cities et al. 2019) with methods to project avoided emissions in development (Kovac et al. 2020). Different scopes of analysis between sectors, as well as limited knowledge of the impact of existing and new urban infrastructure, limit the possibility of direct comparisons in emissions. Still, the shares of urban mitigation potential ranges between 77.7% and 78.9% for combined strategies that involve decarbonised buildings and transport in urban infrastructure, and the wedges approach the remaining emissions reductions also considering construction materials and waste. This data supports urban areas pursuing a package of multiple, integrated mitigation strategies in planning for decarbonisation (Sections 8.4 and 8.6, and Figure 8.21).

The most comprehensive approach to-date for quantifying urban emissions within the global context (Gurney et al. 2021, 2022) combines the per capita carbon footprint estimates for 13,000 cities from Moran et al. (2018) with projections of the share of urban population (Jiang and O'Neill 2017) within the IPCC's SSP-RCP framework (van Vuuren et al. 2014, 2017a; Riahi et al. 2017). Urban emissions in seven SSP-RCP scenarios are shown in Figure 8.13 along with an estimate of the global total CO₂-eq for context.

In 2020, total urban emissions (including CO₂ and CH₄) derived from consumption-based accounting were estimated to be 29 GtCO₂-eq,

representing between 67% and 72% of global CO₂ and CH₄ emissions, excluding aviation, shipping, and biogenic sources of emissions. By 2050, with moderate to low urban mitigation efforts, urban emissions are projected to rise to 34.0 GtCO₂-eq (SSP2-RCP4.5) or 40.2 GtCO₂-eq (SSP3-RCP7.0) – driven by growing urban population, infrastructure, and service demands. However, scenarios that involve rapid urbanisation can have different outcomes as seen in SSP1-RCP1.9 based on green growth, versus SSP5-RCP8.5 with the strongest carbon lock-in lacking any decarbonisation. Other scenarios involve mixed and/or low urbanisation, along with other differences, including the implementation of electrification, energy, and material efficiency, technology development and innovation, renewable energy preferences, and behavioural, lifestyle, and dietary responses (Table 8.2). With aggressive and immediate mitigation efforts to limit global warming to 1.5°C (>50%) with no or limited overshoot, urban GHG emissions could approach net-zero and reach a maximum of 3.3 GtCO₂-eq in 2050 (SSP1-RCP1.9). Under aggressive but not immediate urban mitigation efforts to limit global warming to 2°C (>67%), urban emissions could reach 17.2 GtCO₂-eq in 2050 (SSP1-RCP2.6).

When 2020 levels are compared to the values for the year 2030, urban areas that utilise multiple opportunities towards resource-efficient and walkable urbanisation are estimated to represent a savings potential of 9.8 GtCO₂-eq of urban emissions, under SSP1-RCP1.9 scenario conditions, on the path towards net-zero CO₂ and CH₄ emissions. In contrast, urban emissions would increase by 3.4 GtCO₂-eq from 2020 levels in 2030 under SSP2-RCP4.5 scenario conditions with moderate changes lacking ambitious mitigation action (Figure 8.14).

Table 8.3: Cross-cutting implications of the reference scenarios and illustrative Mitigation Pathways (IMPs) for urban areas. The IMPs illustrate key themes of mitigation strategies throughout the WGIII report (Section 3.2.5). The implications of the key themes of the six IMPs (in addition to two pathways illustrative of higher emissions) for mitigation in urban areas are represented based on the main storyline elements that involve energy, land use, food biodiversity and lifestyle, as well as policy and innovation. The cross-cutting implications of these elements for urban areas, where multiple elements interact, are summarised for each reference scenario and the IMPs. IMP-Ren, IMP-LD and IMP-SP represent pathways in the C1 category that also includes SSP1–1.9. Source: adapted from the key themes of the IMPs for urban areas.

Reference scenarios and IMPs	Cross-cutting implications for urban areas
Current Policies (CurPol scenario)	<ul style="list-style-type: none"> – Urban mitigation is challenged by overcoming lock-in to fossil fuel consumption; also with car-based and low-density urban growth prevailing – Consumption patterns have land impacts, supply chains remain the same, urban inhabitants have limited participation in mitigation options – Progress in low-carbon urban development takes place at a relatively slower pace and there is limited policy learning within climate networks
Moderate Action (ModAct scenarios)	<ul style="list-style-type: none"> – Renewable energy continues to increase its share that is supported by urban areas to a more limited extent with ongoing lock-in effects – Changes in land use, consumption patterns, and lifestyles mostly continue as before with negligible changes taking place – if any – The fragmented policy landscape also prevails at the urban level with different levels of ambitions and without integration across the urban system
Gradual Strengthening (IMP-GS)	<ul style="list-style-type: none"> – Urban areas depend upon energy supply from distant power plants or those in rural areas without rapid progress in urban electrification – Afforestation/reforestation is supported with some delay while lower incentives for limiting growth in urban extent provide inconsistencies – The mobilisation of urban actors for GHG emission reductions is strengthened more gradually with stronger coordination taking place after 2030
Net Negative Emissions (IMP-Neg)	<ul style="list-style-type: none"> – Urban areas depend upon energy supply from distant power plants or those in rural areas with more limited electrification in urban energy systems – Afforestation/reforestation is supported to a certain extent while lower incentives for limiting growth in urban extent provide inconsistencies – Urban areas are less prominent in policy and innovation given emphasis on carbon capture and storage (CCS) options. Rural areas are more prominent considering BECCS
Renewable Energy (IMP-Ren)	<ul style="list-style-type: none"> – Urban areas support renewable energy penetration with electrification of urban infrastructure and sector coupling for increasing system flexibility – Consumption patterns and urban planning are able to reduce pressures on land use, demand response is increased to support renewables – Urban climate governance is enabling rapid deployment of renewable energy while fostering innovation for sustainable urban planning
Low Demand (IMP-LD)	<ul style="list-style-type: none"> – Walkable urban form is increased, active and public transport modes are encouraged, low-energy buildings and green-blue infrastructure is integrated – Changes in consumption patterns and urban planning reduce pressures on land use to lower levels while service provisioning is improved – Urban policymaking is used to accelerate solutions that foster innovation and increased efficiencies across all sectors, including material use
Shifting Pathways (IMP-SP)	<ul style="list-style-type: none"> – Urban areas are transformed to be resource efficient, low demand, and renewable energy supportive with an integrated approach in urban planning – Reinforcing measures enable GHG emission reductions from consumption patterns while also avoiding resource impacts across systems – Urban climate mitigation is best aligned with the SDGs to accelerate GHG emission reductions, increasing both scalability and acceptance

Among the 500 urban areas with the highest consumption-based urban emissions footprint in 2015 (Moran et al. 2018), urban-level emission scenarios under SSP1 conditions are constructed for 420 urban areas located across all regions of the world (Kılış 2021a). These scenarios are based on urban-level population projections by SSP (Kii 2021), trends in relevant CMIP6 scenarios (Gidden et al. 2019), and a 100% renewable energy scenario (Bogdanov et al. 2021). In the year 2020, the 420 urban areas are responsible for about 10.7 ± 0.32 GtCO₂-eq, or 27% of the global total CO₂ and CH₄ emissions of about 40 GtCO₂-eq, excluding aviation, shipping, and biogenic sources. Under three SSP1-based scenarios, the urban emissions of the 420 urban areas in 2030 is projected to be about 7.0 GtCO₂-eq in SSP1-RCP1.9, 10.5 GtCO₂-eq in SSP1-RCP2.6, and 5.2 GtCO₂-eq in the SSP1 renewable energy scenario.

The Illustrative Mitigation Pathways (IMPs) represent different strategies for maintaining temperature goals that are compliant with the Paris Agreement, as well as their comparison with the continuation of current policies (Sections 1.5 and 3.2.5, and Table 8.3). The key characteristics that define the IMPs involve aspects of energy, land use, lifestyle, policy, and innovation. Urban areas provide cross-cutting contexts where each of these key characteristics can be enabled and have a particularly important role in the transformation pathways for renewable energy (IMP-Ren), low demand (IMP-LD), and shifting to sustainability (IMP-SP). Pathways that are compliant with the Paris Agreement include such urban implications as a reversal of decreasing land-use efficiency in urban areas to lower energy demand based on spatial planning for compact urban form (Section 8.4.2), changes in urban infrastructure for supporting demand flexibility to handle variable energy supply (Section 8.4.3), as well as policies and governance that are conducive to innovation in urban areas (Section 8.5). Spatial planning for compact urban form can enable reduced energy demand and changes in service provisioning, including through walkable neighbourhoods and mixed land use, providing venues for socio-behavioural change towards active transport (Section 8.4.5). Electrification and sector coupling in urban infrastructure can, for instance, be an important enabler of supporting higher penetrations of renewable energy in the energy system.

8.4 Urban Mitigation Options

Urban mitigation options can be categorised into three broad strategies: (i) reducing or changing urban energy and material use towards more sustainable production and consumption across all sectors, including through spatial planning and infrastructure; (ii) electrification and switching to net-zero-emissions resources; and (iii) enhancing carbon storage in the urban environment through urban green and blue infrastructure, which can also offer multiple co-benefits. A fourth, socio-behavioural aspects, can shift energy demand and emerge as the result of implementing the strategies. Urban mitigation options covered in this section are organised around these three strategies and can facilitate deep decarbonisation through systemic transformation (see Section 8.6 and Figure 8.21 for prioritising mitigation options based on urban form and urban growth typologies).

Urban areas are systems where multiple mitigation options – especially when integrated – have cascading effects across transport, energy, buildings, land use, and behaviour. These cascading effects take place both within and across urban systems (Figure 8.15). Mitigation actions also occur at multiple urban scales, from households and blocks to districts and city regions, and can be implemented as standalone sectoral strategies, such as increasing energy efficiency for appliances, and also as system-wide actions. In reducing emissions locally, urban areas can help lower emissions outside of their administrative boundaries through their use of materials and resources, and by increasing the efficiency of infrastructure and energy use beyond what is possible with individual sectoral strategies. Urban mitigation policies that implement multiple integrated interventions will provide more emissions savings than the sum of individual interventions (Sethi et al. 2020).

Integrated action also has a key role in providing benefits for human well-being. Urban mitigation options and strategies that are effective, efficient, and fair can also support broader sustainability goals (Güneralp et al. 2017; Kona et al. 2018; Pasimeni et al. 2019). Due to the complex and intensive interactions in urban systems and the interlinked nature of the SDGs, cities can be important intervention points to harness synergies and co-benefits for achieving emissions reductions along with other SDGs (Nilsson et al. 2016; Corbett and Mellouli 2017) (Section 8.2 and Figure 8.4).

8.4.1 Avoiding Carbon Lock-in

Carbon lock-in occurs as the result of interactions between different geographic and administrative scales (institutional lock-in) and across sectors (infrastructural and technological lock-in), which create the conditions for behavioural lock-in covering both individual and social structural behaviours (Seto et al. 2016) (see Glossary for a broader definition of 'lock-in'). The way that urban areas are designed, laid out, and built (i.e., urban form) affects and is affected by the interactions across the different forms of carbon lock-in (Figures 8.15 and 8.16). Cities are especially prone to carbon lock-in because of the multiple interactions of technological, institutional, and behavioural systems, which create inertia and path dependency that are difficult to break. For example, the lock-in of gasoline cars is reinforced by highway and energy infrastructures that are further locked-in by social and cultural preferences for individual mobility options. The dominance of cars and their supporting infrastructures in auto-centric urban forms is further reinforced by zoning and urban development patterns, such as dispersed and low-density housing distantly located from jobs, that create obstacles to creating alternative mobility options (Seto et al. 2016; Linton et al. 2021).

Urban infrastructures and the built environment are long-lived assets, embodying triple carbon lock-ins in terms of their construction, operations, and demolition (Creutzig et al. 2016b; Seto et al. 2016; Ürge-Vorsatz et al. 2018). There is much focus in the climate change literature on the operational lifetimes of the energy sector, especially power plants and the electricity grid, which are between 30 and 60 years (Rode et al. 2017). Yet, in reality, the lifespans of urban

(a)

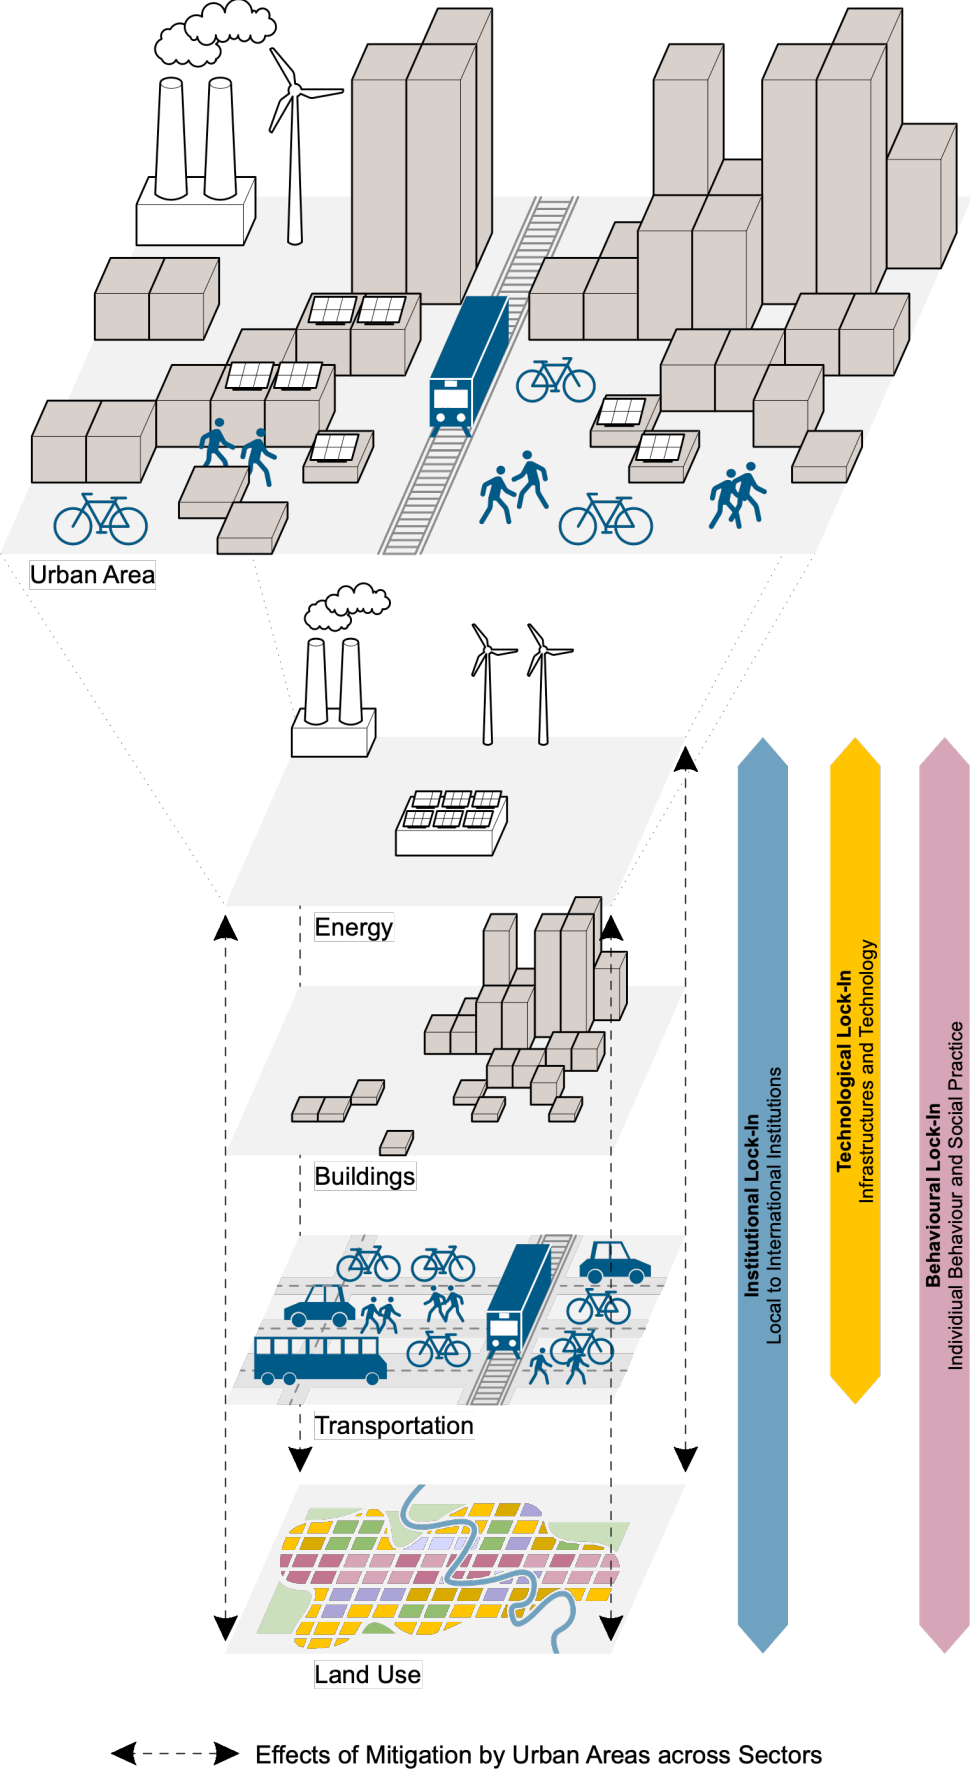

Figure 8.15: Urban systems, lock-in, and cascading effects of mitigation strategies.

(b)

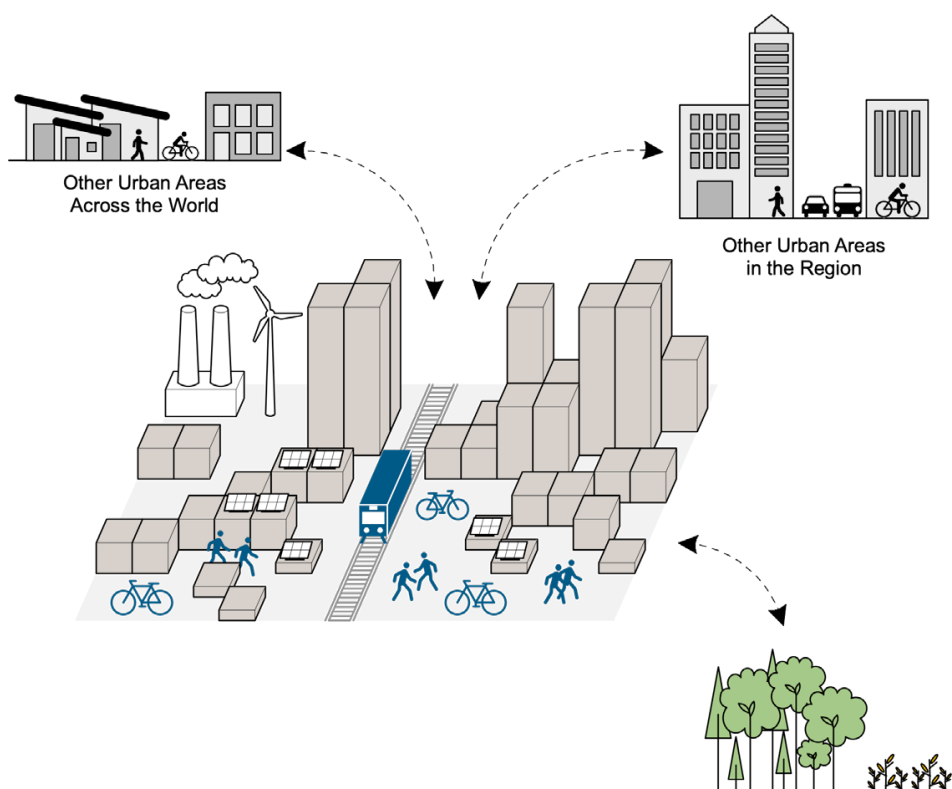

Figure 8.15 (continued): Urban systems, lock-in, and cascading effects of mitigation strategies. Cities are systems of interconnected sectors, activities, and governance structures. Urban-scale mitigation action can have cascading effects across multiple sectors, as shown in panel (a), as well as regional, national, and global impacts through supply chains, resource flows, and institutions, as shown in panel (b). Mitigation efforts implemented at larger scales of governance or in sectors that transcend urban boundaries, like energy and transportation, can also facilitate and amplify mitigation at the urban scale, as shown by the arrows extending in both directions across layers (a). Because urban areas are connected locally and globally, urban mitigation efforts can also impact other cities and surrounding areas (agriculture, forestry and other land use (AFOLU)). Cities are prone to carbon lock-in due to the numerous reinforcing interactions among urban infrastructures and technologies, institutions, and individual and collective behaviours; see the side arrows extending across the layers in panel (a): the yellow arrow represents the infrastructure and technological lock-in involving user technologies and supporting infrastructure, the blue arrow indicates lock-in of local to international institutions, and the pink arrow represents behavioural lock-in for individuals and society. Urban carbon lock-in is strongly determined by urban form, in particular the layout of streets and land-use mix. The different coloured spatial patterns represent varying levels of co-location of housing and jobs, and mobility options (Figure 8.16). Efforts to break urban carbon lock-in require meta-transformations to break inertia in and among infrastructures, institutions, and behaviours. Source: adapted in part from Seto et al. (2016).

infrastructures, especially the basic layout of roadways, are often much longer (Reyna and Chester 2015). A number of detailed case studies on the evolution of urban road networks for cities around the world reveal that the current layout of streets grew out of street networks that were established hundreds of years ago (Strano et al. 2012; Masucci et al. 2013; Mohajeri and Gudmundsson 2014). Furthermore, there is evidence that urban street layout, population growth, urban development, and automobile ownership co-evolve (Li et al. 2019a).

For cities to break out of mutually reinforcing carbon lock-in, it will require systematic transformation and systems-based planning that integrates mitigation strategies across sectors and geopolitical scales. Urban energy demand patterns are locked-in whenever incremental urban design and planning decisions, coupled with investments in long-lasting infrastructure, such as roads and buildings, take place (Seto et al. 2016). The fundamental building blocks of cities are based on the layout of the street network, the size of city blocks, and the density of street intersections. If not significantly altered, these three factors will continue to shape and lock-in energy demand for decades after their initial construction, influencing the mitigation potential of urban areas (Section 8.4.2 and Figure 8.22).

Avoiding carbon lock-in inherently involves decisions that extend beyond the administrative boundaries of cities. This includes pricing of low-emissions technology or materials, such as electric battery or hydrogen vehicles and buses, although cities can support their development and deployment (Cross-Chapter Box 12 in Chapter 16 on Transition Dynamics). In contrast, urban governments in most parts of the world do have powers to set building codes that regulate materials and construction standards for buildings, including heating and cooling technologies, and major appliances. Other examples include zoning that determines the location of buildings, land uses, standards for densities, and the inclusion of energy planning in their building standards and public works, including streets, parks, and open spaces (Blanco et al. 2011; Raven et al. 2018).

8.4.2 Spatial Planning, Urban Form, and Infrastructure

Urban form is the resultant pattern and spatial layout of land use, transportation networks, and urban design elements, including the physical urban extent, configuration of streets and building orientation, and the spatial figuration within and throughout cities

and towns (Lynch 1981; Handy 1996). Infrastructure describes the physical structures, social and ecological systems, and corresponding institutional arrangements that provide services and enable urban activity (Dawson et al. 2018; Chester 2019) and comprises services and built-up structures that support urban functioning, including transportation infrastructure, water and wastewater systems, solid waste systems, telecommunications, and power generation and distribution (Seto et al. 2014).

8.4.2.1 Urban Form

The AR5 concluded that infrastructure and four dimensions of urban form are especially important for driving urban energy use: density, land-use mix, connectivity, and accessibility. Specifically, low-carbon cities have the following characteristics: (i) co-located medium to high densities of housing, jobs, and commerce; (ii) high mix of land uses; (iii) high connectivity of streets; and (iv) high levels of accessibility, distinguished by relatively low travel distances and travel times that are enabled by multiple modes of transportation. Urban areas with these features tend to have smaller dwelling units, smaller parcel sizes, walking opportunities, high density of intersections, and are highly accessible to shopping. For brevity, we will refer to these characteristics collectively as ‘compact and walkable urban form’ (Figure 8.16). Compact and walkable urban form has many co-benefits, including mental and physical health, lower resource demand, and saving land for AFOLU. In contrast, dispersed and auto-centric urban form is correlated with higher GHG emissions, and characterised by separated land uses, low population and job densities, large block size, and low intersection density.

Since AR5, a range of studies have been published on the relationships between urban spatial structures, urban form, and GHG emissions. Multiple lines of evidence reaffirm the key findings from AR5, especially regarding the mitigation benefits associated with reducing vehicle miles or kilometres travelled (VMT/VKT) through

spatial planning. There are important cascading effects not only for transport but also other key sectors and consumption patterns, such as in buildings, households, and energy. However, these benefits can be attained only when the existing spatial structure of an urban area does not limit locational and mobility options, thereby avoiding carbon lock-in through the interaction of infrastructure and the resulting socio-behavioural aspects.

Modifying the layout of emerging urbanisation to be more compact, walkable, and co-located can reduce future urban energy use by 20–25% in 2050 while providing a corresponding mitigation potential of 23–26% (Creutzig et al. 2015, 2016b; Sethi et al. 2020), forming the basis for other urban mitigation options. Cross-Chapter Box 7 in Chapter 10 provides perspectives on simultaneously reducing urban transport emissions, avoiding infrastructure lock-in, and providing accessible services. The systemic nature of compact urban form and integrated spatial planning influences ‘Avoid-Shift-Improve’ (ASI, see Glossary) options across several sectors simultaneously, including for mobility and shelter (for an in-depth discussion on the integration of service provision solutions within the ASI framework, see Section 5.3).

8.4.2.2 Co-located Housing and Jobs, Mixed Land Use, and High Street Connectivity

Integrated spatial planning, co-location of higher residential and job densities, and systemic approaches are widely identified with development that is characterised by the 5Ds of transit-oriented development (TOD) based on density, diversity (mixed land uses), design (street connectivity), destination accessibility, and distance to transit. Spatial strategies that integrate the 5Ds are shown to reduce VMT/VKT, and thereby transport-related GHG emissions through energy savings. The effect of urban form and built environment strategies on VMT per capita varies by a number of factors (Ewing and Cervero 2010; Stevens 2017; Blanco and Wikstrom 2018). Density and destination accessibility have the highest elasticities, followed by design (Stevens 2017). Population-weighted densities for

Compact and Walkable

Dispersed and Auto-Centric

Figure 8.16: Urban form and implications for GHG emissions. Compact and walkable urban form is strongly correlated with low GHG emissions and characterised by co-located medium to high densities of housing and jobs, high street density, small block size, and mixed land use (Seto et al. 2014). Higher population densities at places of origin (e.g., home) and destination (e.g., employment, shopping) concentrate demand and are necessary for achieving the Avoid-Shift-Improve (ASI) approach for sustainable mobility (Chapters 5 and 10). Dispersed and auto-centric urban form is strongly correlated with high GHG emissions, and characterised by separated land uses, especially of housing and jobs, low street density, large block sizes, and low urban densities. Separated and low densities of employment, retail, and housing increase average travel distances for both work and leisure, and make active transport and modal shift a challenge. Since cities are systems, urban form has interacting implications across energy, buildings, transport, land use, and individual behaviour. Compact and walkable urban form enables effective mitigation while dispersed and auto-centric urban form locks-in higher levels of energy use. The colours represent different land uses and indicate varying levels of co-location and mobility options.

121 metropolitan areas have further found that the concentration of population and jobs along mass transit corridors decreases VMT/VKT significantly when compared to more dispersed metropolitan areas. In this sample, elasticity rates were twice as high for dense metropolitan areas located along mass transit lines (Lee and Lee 2020).

Meta-analyses of the reduction in VMT and the resulting GHG emissions consider the existing and still dominant use of emitting transportation technology, transportation fleets, and urban form characteristics. Varied historical legacies of transportation and the built environment, which can be utilised to develop more sustainable cities (Newman et al. 2016, 2017), are often not taken into account directly. Metropolitan policies and spatial planning, as evident in Copenhagen's Finger Plan, as well as strategic spatial planning in Stockholm and Seoul, have been major tools to restructure urban regions and energy patterns (Sung and Choi 2017). Road prices and congestion charges can provide the conditions for urban inhabitants to shift mobility demands and reduce vehicle use (Section 5.6.2). Surprisingly, even cities with higher population densities and a greater range of land uses can show declines in these important attributes, which can lead to emissions increases, such as found in a study of 323 East and South East Asian cities (Chen et al. 2020c). Conversely, the annual CO₂ emissions reduction of passenger cars in compact versus dispersed urban form scenarios can include at least a 10% reduction by 2030 (Matsuhashi and Ariga 2016). When combined with advances in transport technology, this share increases to 64–70% in 2050 based on compact urban form scenarios for 1727 municipalities (Kii 2020).

As a reaffirmation of AR5, population density reduces emissions per capita in the transport, building, and energy sectors (Baur et al. 2015; Gudipudi et al. 2016; Wang et al. 2017; Yi et al. 2017) (see also Sections 8.3.1 and 8.3.4 on past trends and forecasts of urban population density and land expansion). Urban compactness tends to reduce emissions per capita in the transport sector, especially for commuting (Matsuhashi and Ariga 2016; Lee and Lim 2018; Lee and Lee 2020). The relative accessibility of neighbourhoods to the rest of the region, in addition to the density of individual neighbourhoods, is important (Ewing et al. 2018). Creating higher residential and employment densities, developing smaller block sizes, and increasing housing opportunities in an employment area can significantly reduce household car ownership and car driving, and increase the share of transit, walk, and bicycle commuting (Ding et al. 2018). In addition to population density, land-use mix, rail transit accessibility, and street design reduce emissions from transport (Dou et al. 2016; Cao and Yang 2017; Choi 2018). The impact of population density and urban compactness on emissions per capita in the household or energy sector is also associated with socioeconomic characteristics or lifestyle preferences (Baiocchi et al. 2015; Miao 2017). Changes in the attributes of urban form and spatial structure have influences on overall energy demand across spatial scales, particularly street, block, neighbourhood, and city scales, as well as across the building (housing) and transport (mobility) sectors (Silva et al. 2017). Understanding the existing trade-offs (or synergetic links) between urban form variables across major emissions source sectors, and how they impact the size of energy flows within the urban system, is key to prioritising action for energy-efficient spatial planning strategies, which are likely to vary across urban areas.

8.4.2.3 Urban Form, Growth, and Sustainable Development

Spatial planning for compact urban form is a system-wide intervention (Sethi et al. 2020) and has potential to be combined with sustainable development objectives while pursuing climate mitigation for urban systems (Große et al. 2016; Cheshmehzangi and Butters 2017; Facchini et al. 2017; Lwasa 2017; Stokes and Seto 2019). Compact urban form can enable positive impacts on employment and green growth given that the local economy is decoupled from GHG emissions and related parameters while the concentration of people and activity can increase productivity based on both proximity and efficiency (Lee and Erickson 2017; Salat et al. 2017; Gao and Newman 2018; Han et al. 2018; Li and Liu 2018; Lall et al. 2021).

Public acceptance can have a positive impact on integrated spatial planning especially when there is a process of co-design (Grandin et al. 2018; Webb et al. 2018). The quality of spatial planning can also increase co-benefits for health and well-being, including decisions to balance urban green areas with density (Li et al. 2016; Sorkin 2018; Pierer and Creutzig 2019). The distributional effects of spatial planning can depend on the policy tools that shape the influence of urban densification on affordable housing while evidence for transit-induced gentrification is found to be partial and inconclusive (Chava and Newman 2016; Jagarnath and Thambiran 2018; Padeiro et al. 2019; Debrunner and Hartmann 2020) (Sections 8.2 and 8.4.4).

Reducing GHG emissions across different urban growth typologies (Figure 8.20) depends in part on the ability to integrate opportunities for climate mitigation with co-benefits for health and well-being (Grandin et al. 2018). At the same time, requirements for institutional capacity and governance for cross-sector coordination for integrated urban planning is high given the complex relations between urban mobility, buildings, energy systems, water systems, ecosystem services, other urban sectors, and climate adaptation (Große et al. 2016; Castán Broto 2017a; Endo et al. 2017; Geneletti et al. 2017). The capacity for implementing land-use zoning and regulations in a way that is consistent with supporting spatial planning for compact urban form is not equal across urban areas and depends on different contexts as well as institutional capacities (Bakır et al. 2018; Deng et al. 2018; Shen et al. 2019).

Currently, integrating spatial planning, urban form, and infrastructure in urban mitigation strategies remains limited in mainstream practices, including in urban areas targeting an emissions reduction of 36–80% in the next decades (Asarpota and Nadin 2020). Capacity building for integrated spatial planning for urban mitigation includes increasing collaboration among city departments and with civil society to develop robust mitigation strategies, bringing together civil engineers, architects, urban designers, public policy and spatial planners, and enhancing the education of urban professionals (Asarpota and Nadin 2020) (Section 8.5).

Spatial planning for compact urban form is a prerequisite for efficient urban infrastructure, including district heating and/or cooling networks (Swilling et al. 2018; Möller et al. 2019; Persson et al. 2019; UNEP IRP 2020). District heating and cooling networks

benefit from urban design parameters, including density, block area, and elongation that represent the influence of urban density on energy density (Fonseca and Schlueter 2015; Shi et al. 2020). Heat-demand density is a function of both population density and heat demand per capita and can be equally present in urban areas with high population density or high heat demand per capita (Möller et al. 2019; Persson et al. 2019). Low-temperature networks that utilise waste heat or renewable energy can provide an option to avoid carbon lock-in to fossil fuels while layout and eco-design principles can further optimise such networks (Gang et al. 2016; Buffa et al. 2019; Dominković and Krajačić 2019). Replacing gas-based heating and cooling with electrified district heating and cooling networks, for instance, provides 65% emissions reductions also involving carbon-aware scheduling for grid power (De Chalendar et al. 2019). The environmental and ecological benefits increase through the interaction of urban energy and spatial planning (Tuomisto et al. 2015; Bartolozzi et al. 2017; Dénarié et al. 2018; Zhai et al. 2020). These interactions include support for demand-side flexibility, spatial planning using geographic information systems, and access to renewable and urban waste heat sources (Möller et al. 2018; REN21 2020; Sorknæs et al. 2020; Dorotić et al. 2019) (see Table 8.SM.2 for other references).

8.4.3 Electrification and Switching to Net-Zero-Emissions Resources

Pursuing the electrification of mobility, heating, and cooling systems, while decarbonising electricity and energy carriers, and switching to net-zero materials and supply chains, represent important strategies for urban mitigation. Electrification of energy end uses in cities and efficient energy demand for heating, transport, and cooking through multiple options and urban infrastructure, has an estimated mitigation potential of at least 6.9 GtCO₂-eq by 2030 and 15.3 GtCO₂-eq by 2050 (Coalition for Urban Transitions 2019). Energy efficiency measures in urban areas can be enabled by urban form, building codes, retrofitting and renovation, modal shifts, and other options. Decarbonising electricity supply raises the mitigation potential of efficient buildings and transport in urban areas to about 75% of the total estimate (Coalition for Urban Transitions 2019). In addition, relatively higher-density urban areas enable more cost-effective infrastructure investments, including electric public transport and large-scale heat pumps in districts that support electrification. Urban policymakers can play a key role in supporting carbon-neutral energy systems by acting as target setters and planners, demand aggregators, regulators, operators, conveners, and facilitators for coordinated planning and implementation across sectors, urban form, and demand (IEA 2021a; IRENA 2021).

8.4.3.1 Electrification and Decarbonisation of the Urban Energy System

Urban energy infrastructures often operate as part of larger energy systems that can be electrified, decarbonised, and become enablers of urban system flexibility through demand-side options. With multiple end-use sectors (e.g., transport, buildings) and their interactions with land use drawing on the same urban energy system(s), increasing electrification is essential for rapid decarbonisation, renewable

energy penetration, and demand flexibility (Kammen and Sunter 2016) (see IMPs in Sections 3.2.5 and 8.3.4). The mitigation potential of electrification is ultimately dependent on the carbon intensity of the electricity grid (Kennedy 2015; Hofmann et al. 2016; Peng et al. 2018; Zhang and Fujimori 2020) and starts providing lifecycle emission savings for carbon intensities below a threshold of 600 tCO₂-eq GWh⁻¹ (Kennedy et al. 2019). Integrated systems of roof-top photovoltaics (PVs) and all-electric vehicles (EVs) alone could supply affordable carbon-free electricity to cities and reduce CO₂ emissions by 54–95% (Brenna et al. 2014; Kobashi et al. 2021). Furthermore, electrification and decarbonisation of the urban energy system holds widespread importance for climate change mitigation across different urban growth typologies and urban form (Section 8.6 and Figure 8.21) and leads to a multitude of public health co-benefits (see Section 8.2).

Strategies that can bring together electrification with reduced energy demand based on walkable and compact urban form can accelerate and amplify decarbonisation. Taking these considerations – across the energy system, sectors, and land use – contributes to avoiding, or breaking out of, carbon lock-in and allows continued emission savings as the energy supply is decarbonised (Kennedy et al. 2018; Teske et al. 2018; Seto et al. 2021). Indeed, electrification is already transforming urban areas and settlements and has the potential to continue transforming urban areas into net-negative electric cities that may sequester more carbon than emitted (Kennedy et al. 2018; Seto et al. 2021).

In its simplest form, electrification involves the process of replacing fossil fuel-based technologies with electrified innovations such as electric vehicles, buses, streetcars, and trains (Sections 10.3 and 10.4), heat pumps, PVs (Section 6.4.2.1), electric cook-stoves (Section 9.8.2.1), and other technologies (Stewart et al. 2018). Cost-effective decarbonisation of energy use can be supported by electrification in urban areas if there is also demand-side flexibility for power, heat, mobility, and water with sector coupling (Guelpa et al. 2019; Pfeifer et al. 2021). Overall, demand-side flexibility across sectors in urban areas is supported by smart charging, electric mobility, electrified urban rail, power-to-heat, demand side response, and water desalination (Lund et al. 2015; Calvillo et al. 2016; Salpakari et al. 2016; Newman 2017; Meschede 2019).

As an enabler, electrification supports integrating net-zero energy sources in urban infrastructure across sectors, especially when there is more flexible energy demand in mobility, heating, and cooling to absorb greater shares of variable renewable energy. In the transport sector, smart charging can reduce electric vehicle impacts on peak demand by 60% (IEA 2021a). Urban areas that connect efficient building clusters with the operation of smart thermal grids in district heating and cooling networks with large-scale heat pumps can support higher penetrations of variable renewable energy in smart energy systems (Lund et al. 2014, 2017). Higher urban densities provide the advantage of increasing the penetration of renewable power for deep decarbonisation, including mixed-use neighbourhoods for grid balancing and electric public transport (Hsieh et al. 2017; Tong et al. 2017; Fichera et al. 2018; Kobashi et al. 2020). Based on these opportunities, urban areas that provide low-

cost options to energy storage for integrating the power sector with multiple demands reduce investment needs in grid electricity storage capacities (Mathiesen et al. 2015; Lund et al. 2018).

Electrification at the urban scale encompasses strategies to aggregate energy loads for demand response in the urban built environment to reduce the curtailment of variable renewable energy and shifting time-of-use based on smart charging for redistributing energy demands (O'Dwyer et al. 2019). Peak shaving or shifting takes place among frequent interventions at the urban level (Sethi et al. 2020). Business models and utility participation, including municipal level demonstrations, can allow for upscaling (Gjorgievski et al. 2020; Meha et al. 2020). The urban system can support increasing demand-side flexibility in energy systems, including in contexts of 100% renewable energy systems (Drysdales et al. 2019; Thellufsen et al. 2020).

Smart grids in the urban system

Smart electricity grids enable peak demand reductions, energy conservation, and renewable energy penetration, and are a subset of smart energy systems. GHG emission reductions from smart grids range from 10 to 180 gCO₂ kWh⁻¹ (grams of CO₂ per kilowatt-hour) with a median value of 89 gCO₂ kWh⁻¹, depending on the electricity mix, penetration of renewable energy, and the system boundary (Moretti et al. 2017). Smart electricity grids are characterised by bi-directional flows of electricity and information between generators and consumers, although some actors can be both as 'prosumer' (see Glossary). Two-way power flows can be used to establish peer-to-peer trading (P2P) (Hansen et al. 2020). Business models based on local citizen utilities (Green and Newman 2017; Green et al. 2020; Syed et al. 2020) and community batteries (Mey and Hicks 2019; Green et al. 2020) can support the realisation of distributed energy and solar energy cities (Galloway and Newman 2014; Byrne and Taminiau 2016; Stewart et al. 2018; Allan 2020).

Currently, despite power outages that are costly to local economies, the adoption of smart electricity grids or smart energy systems has been slow in many developing regions, including in Sub-Saharan Africa (Westphal et al. 2017; Kennedy et al. 2019). This is due to a number of different factors, such as unreliable existing infrastructure, fractured fiscal authority, lack of electricity access in urban areas, upfront cost, financial barriers, inefficient pricing of electricity, and low consumer education and engagement (Venkatachary et al. 2018; Acakpovi et al. 2019; Cirolia 2020).

Pathways and trade-offs of electrification in urban systems

Urbanisation and population density are one of the key drivers for enabling access to electricity across the world, with benefits for sustainable development (Aklin et al. 2018). Grid-connected PV systems for urban locations that currently lack electricity access can allow urban areas to leapfrog based on green electrification (Abid et al. 2021). In the Global South, the conversion of public transport to electric transport, especially municipal buses (e.g., Bengaluru, India; Jakarta, Indonesia; Medellín, Colombia; Rio de Janeiro, Brazil; Quito, Ecuador) and micro-mobility (e.g., e-trikes in Manila,

Philippines) have been quantified based on reductions in GHG and PM_{2.5} emissions, avoided premature deaths, and increases in life expectancies (IEA 2014; C40 Cities 2018, 2020b,c,d,e). In 22 Latin American cities, converting 100% of buses and taxis in 2030 to electric was estimated to result in a reduction of 300 MtCO₂-eq compared to 2017 (ONU Medio Ambiente 2017). Yet the scaling up of electric vehicles in cities can be examined within a larger set of possible social objectives, such as reducing congestion and the prioritisation of other forms of mobility.

Electrification requires a layering of policies at the national, state, and local levels. Cities have roles as policy architects, including transit planning (e.g., EV targets and low-emission zones, restrictions on the types of energy use in new buildings), implementers (e.g., building codes and compliance checking, financial incentives to encourage consumer uptake of EVs and heat pumps), and complementary partners to national and state policymaking (e.g., permitting or installation of charging infrastructure) (Broekhoff et al. 2015). The number of cities that have instituted e-mobility targets that aim for a certain percentage of EVs sold, in circulation or registered, is increasing (REN21 2021). Realising the mitigation potential of electrification will require fiscal and regulatory policies and public investment (Hall et al. 2017a; Deason and Borgeson 2019; Wappelhorst et al. 2020) (Section 8.5).

EVs are most rapidly deployed when there has been a suite of policies, including deployment targets, regulations and use incentives (e.g., zero-emission zone mandates, fuel economy standards, building codes), financial incentives (e.g., vehicles, chargers), industrial policies (e.g., subsidies), and fleet procurement (IEA 2016b, 2017, 2018, 2020a; Cazzola et al. 2019). The policy mix has included mandates for bus deployment, purchase subsidies, or split ownership of buses and chargers (IEA 2021b) (Chapter 10). Subsidies are often critical to address the often-higher upfront costs of electric devices. In other instances, the uptake of electric induction stoves was increased through government credit and allotment of free electricity (Martínez et al. 2017; Gould et al. 2018).

Bringing multiple stakeholders together in local decision-making for smart energy systems requires effort beyond usual levels while multi-actor settings can be increased to enable institutional conditions (Lammers and Hoppe 2019). Public participation and community involvement in the planning, design and operation of urban energy projects can be an enabler of decarbonising local energy demands (Corsini et al. 2019). Cooperation across institutions is important for municipalities that are engaged in strategic energy planning and implementation for smart energy systems (Krog 2019) (Section 8.5).

Electrification technologies can present potential trade-offs that can be minimised through governance strategies, smart grid technologies, circular economy practices, and international cooperation. One consideration is the increase in electricity demand (Section 5.3.1.1). Across 23 megacities in the world (population greater than 10 million people), electrification of the entire gasoline vehicle fleet could increase electricity demand on average by 18% (Kennedy et al. 2018). How grid capacity will be impacted is dependent on the match between daily

electricity loads and supply (Tarroja et al. 2018). Materials recycling of electrification technologies is also key to minimising potential environmental and social costs (Church and Crawford 2018; Gaustad et al. 2018; Sovacool et al. 2020) and can ensure electrification reaches its complete mitigation potential. Circular economy strategies are particularly valuable to this goal by creating closed-loop supply chains through recycling, material recovery, repair, and reuse. For instance, the PV CYCLE programme in Europe prevented more than 30,000 metric tonnes of renewable technology from reaching the waste stream (Sovacool et al. 2020) (Box 10.6 and 'circular economy' in Glossary).

8.4.3.2 Switching to Net-zero-emissions Materials and Supply Chains

For the carbon embodied in supply chains to become net-zero, all key infrastructure and provisioning systems will need to be decarbonised, including electricity, mobility, food, water supply, and construction (Seto et al. 2021). The growth of global urban populations that is anticipated over the next several decades will create significant demand for buildings and infrastructure. As cities expand in size and density, there is an increase in the production of mineral-based structural materials

Figure 8.17: Relative volume of a given weight, its carbon emissions, and carbon storage capacity of primary structural materials comparing one tonne of concrete, steel, and timber. Concrete and steel have substantial embodied carbon emissions with minimal carbon storage capacities, while timber stores a considerable quantity of carbon with a relatively small ratio of carbon emissions-to-material volume. The displayed carbon storage of concrete is the theoretical maximum value, which may be achieved after hundreds of years. Cement ratios of 10%, 15%, and 20% are assumed to estimate minimum, mean, and maximum carbon storage in concrete. Carbon storage of steel is not displayed as it is negligible (0.004 tonne C per tonne of steel). The middle-stacked bars represent the mean carbon emission or mean carbon storage values displayed in bold font and underlined. The darker and lighter coloured stacked bars depict the minimum and maximum values. Grey tones represent carbon emissions and green tones are given for storage capacity values. Construction materials have radically different volume-to-weight ratios, as well as material intensity (see representations of structural columns in the upper panel. These differences should be accounted for in the estimations of their carbon storage and emissions (see also Figure 8.22). Source: adapted with permission from Churkina et al. (2020).

and enclosure systems that are conventionally associated with mid- and high-rise urban construction morphologies, including concrete, steel, aluminium, and glass. This will create a significant spike in GHG emissions and discharge of CO₂ at the beginning of each building lifecycle, necessitating alternatives (Churkina et al. 2020).

The initial carbon debt incurred in the production stage, even in sustainable buildings, can take decades to offset through operational stage energy efficiencies alone. Increased reduction in the energy demands and GHG emissions associated with the manufacture of mineral-based construction materials will be challenging, as these industries have already optimised their production processes. Among the category of primary structural materials, it is estimated that final energy demand for steel production can be reduced by nearly 30% compared to 2010 levels, with 12% efficiency improvement for cement (Lechtenböhmer et al. 2016). Even when industries are decarbonised, residual CO₂ emissions will remain from associated chemical reactions that take place in calcination and use of coke from coking coal to reduce iron oxide (Davis et al. 2018). Additionally, carbon sequestration by cement occurs over the course of the building lifecycle in quantities that would offset only a fraction of their production stage carbon spike (Xi et al. 2016; Davis et al. 2018). Moreover, there are collateral effects on the carbon cycle related to modern construction and associated resource extraction. The production of cement, asphalt, and glass requires large amounts of sand extracted from beaches, rivers, and seafloors, disturbing aquatic ecosystems and reducing their capacity to absorb atmospheric carbon. The mining of ore can lead to extensive local deforestation and soil degradation (Sonter et al. 2017). Deforestation significantly weakens the converted land as a carbon sink and in severe cases may even create a net emissions source.

A broad-based substitution of monolithic engineered timber systems for steel and concrete in mid-rise urban buildings offers the opportunity to transform cityscapes from their current status as net sources of GHG emissions into large-scale, human-made carbon sinks. The storage of photosynthetic forest carbon through the substitution of biomass-based structural materials for emissions-intensive steel and concrete is an opportunity for urban infrastructure. The construction of timber buildings for 2.3 billion new urban dwellers from 2020 to 2050 could store between 0.01 and 0.68 GtCO₂ per year depending on the scenario and the average floor area per capita. Over 30 years, wood-based construction can accumulate between 0.25 and 20 GtCO₂ and reduce cumulative emissions from 4 GtCO₂ (range of 7–20 GtCO₂) to 2 GtCO₂ (range of 0.3–10 GtCO₂) (*high confidence*) (Churkina et al. 2020).

Figure 8.17 indicates that new and emerging structural assemblies in engineered timber rival the structural capacity of steel and reinforced concrete while offering the benefit of storing significant quantities of atmospheric carbon (see also Figure 8.22). ‘Mass timber’ refers to engineered wood products that are laminated from smaller boards or lamella into larger structural components such as glue-laminated (glulam) beams or cross-laminated timber (CLT) panels. Methods of mass-timber production that include finger-jointing, longitudinal and transverse lamination with both liquid adhesive and mechanical fasteners, have allowed for the reformulation of large structural

timbers. The parallel-to-grain strength of mass (engineered) timber is similar to that of reinforced concrete (Ramage et al. 2017). As much as half the weight of a given volume of wood is carbon, sequestered during forest growth as a by-product of photosynthesis (Martin et al. 2018). Mass timber is inflammable, but in large sections forms a self-protective charring layer when exposed to fire that will protect the remaining ‘cold wood’ core. This property, formed as massive structural sections, is recognised in the fire safety regulations of building codes in several countries, which allow mid- and high-rise buildings in timber. Ongoing studies have addressed associated concerns about the vulnerability of wood to decay and the capacity of structural timber systems to withstand seismic and storm-related stresses.

Transitioning to biomass-based building materials, implemented through the adoption of engineered structural timber products and assemblies, will succeed as a mitigation strategy only if working forests are managed and harvested sustainably (Churkina et al. 2020). Since future urban growth and the construction of timber cities may lead to increased timber demand in regions with low forest cover, it is necessary to systematically analyse timber demand, supply, trade, and potential competition for agricultural land in different regions (Pomponi et al. 2020). The widespread adoption of biomass-based urban construction materials and techniques will demand more robust forest and urban land governance and management policies, as well as internationally standardised carbon accounting methods to properly value and incentivise forest restoration, afforestation, and sustainable silviculture.

Expansion of agroforestry practices may help to reduce land-use conflicts between forestry and agriculture. Harvesting pressures on forests can be reduced through the reuse and recycling of wooden components from dismantled timber buildings. Potential synergies between the carbon sequestration capacity of forests and the associated carbon storage capacity of dense mid-rise cities built from engineered timber offer the opportunity to construct carbon sinks deployed at the scale of landscapes, sinks that are at least as durable as other buildings (Churkina et al. 2020). Policies and practices promoting design for disassembly and material reuse will increase their durability.

8.4.4 Urban Green and Blue Infrastructure

The findings of AR6 WGI and WGII have underscored the importance of urban green and blue infrastructure for reducing the total warming in urban areas due to its local cooling effect on temperature and its benefits for climate adaptation (IPCC 2021; Cross-Working Group Box 2 in this chapter). Urban green and blue infrastructure in the context of nature-based solutions (NBS) involves the protection, sustainable management, and restoration of natural or modified ecosystems while simultaneously providing benefits for human well-being and biodiversity (IUCN 2021) (see Glossary for additional definitions). As an umbrella concept, urban NBS integrates established ecosystem-based approaches that provide multiple ecosystem services and are important in the context of societal challenges related to urbanisation, climate change, and reducing GHG emissions

through the conservation and expansion of carbon sinks (Naumann et al. 2014; Raymond et al. 2017) (Section 8.1.6.1).

Urban green and blue infrastructure includes a wide variety of options, from street trees, parks, and sustainable urban drainage systems (Davis and Naumann 2017), to building-related green roofs or green facades, including green walls and vertical forests (Enzi et al. 2017). Figure 8.18 synthesises urban green and blue infrastructure based on urban forests, street trees, green roofs, green walls, blue

spaces, greenways, and urban agriculture. Key mitigation benefits, adaptation co-benefits, and SDG linkages are represented by types of green and blue infrastructure. Local implementations of urban green and blue infrastructure can pursue these linkages while progressing toward inclusive sustainable urban planning (SDG 11.3) and the provision of safe, inclusive and accessible green and public spaces for all (SDG 11.7) (Butcher-Gollach 2018; Pathak and Mahadevia 2018; Rigolon et al. 2018; Anguelovski et al. 2019; Buyana et al. 2019; Azunre et al. 2021) (Section 8.2).

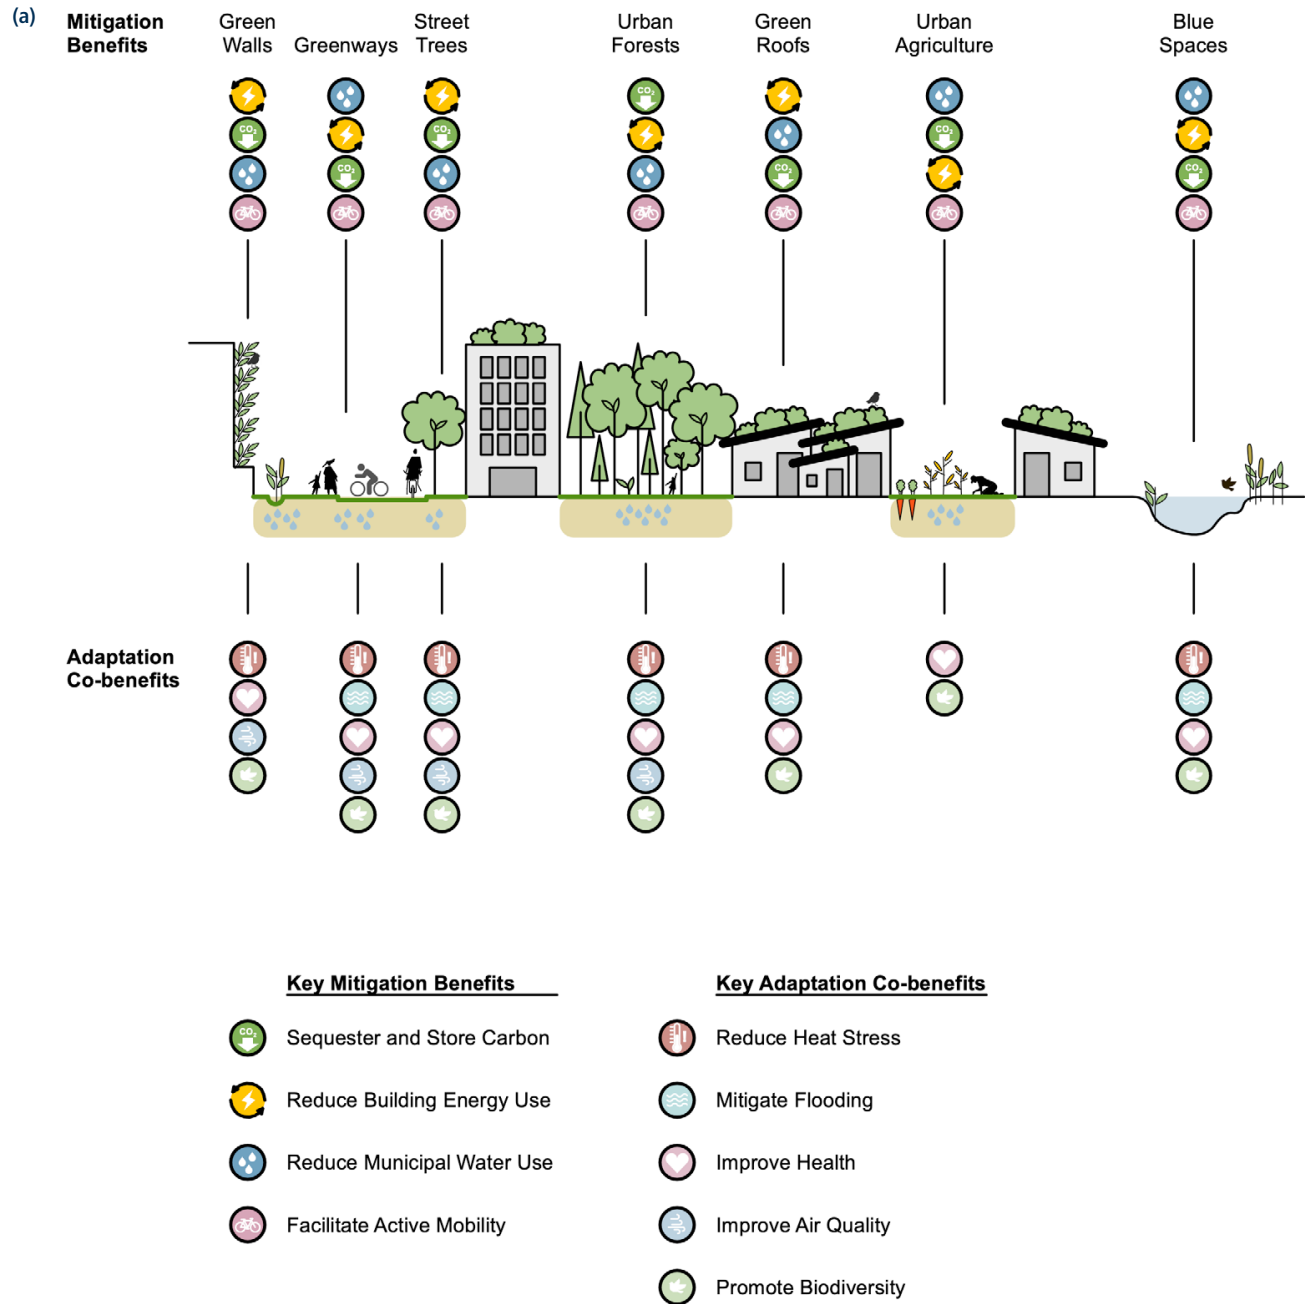

Figure 8.18: Key mitigation benefits, adaptation co-benefits, and SDG linkages of urban green and blue infrastructure. Panel (a) illustrates the potential integration of various green and blue infrastructure strategies within an urban system.

(b)

	Urban Green and Blue Infrastructure	Mitigation Benefits	Adaptation Co-benefits	SDG Linkages
Urban Forests				
Street Trees				
Green Roofs				
Green Walls				
Blue Spaces				
Greenways				
Urban Agriculture				

Figure 8.18: Key mitigation benefits, adaptation co-benefits, and SDG linkages of urban green and blue infrastructure. Panel (b) evaluates those strategies in the context of their mitigation benefits, adaptation co-benefits, and linkages to the SDGs. Urban forests and street trees provide the greatest mitigation benefit because of their ability to sequester and store carbon while simultaneously reducing building energy demand. Moreover, they provide multiple adaptation co-benefits and synergies based on the linkages to the SDGs (Figure 8.4). The assessments of mitigation benefits are dependent on context, scale, and spatial arrangement of each green and blue infrastructure type and their proximity to buildings. Mitigation benefits due to reducing municipal water use are based on reducing wastewater loads that reduce energy use in wastewater treatment plants. The sizes of the bars are illustrative and their relative size is based on the authors' best understanding and assessment of the literature.

8.4.4.1 The Mitigation Potential of Urban Trees and Associated Co-benefits

Due to their potential to store relatively high amounts of carbon compared to other types of urban vegetation, as well as their ability to provide many climate mitigation co-benefits (*high agreement, robust evidence*), natural area protection and natural forest management in urban areas is an important priority for cities looking to mitigate climate change. Globally, urban tree cover averages 26.5%, but varies from an average of 12% in deserts to 30.4% in forested regions (Nowak and Greenfield 2020).

Global urban tree carbon storage is approximately 7.4 billion tonnes (GtC) given 363 million hectares of urban land, 26.5% tree cover, and an average carbon storage density of urban tree cover of 7.69 kgC m^{-2} (kilograms carbon per square metre) (Nowak et al. 2013; World Bank et al. 2013). Estimated global annual carbon sequestration by urban trees is approximately 217 million tonnes (MtC) given an average carbon sequestration density per unit urban tree cover of 0.226 kgC m^{-2} (Nowak et al. 2013). With an average plantable (non-tree and non-imperious) space of 48% globally (Nowak and Greenfield 2020), the carbon storage value could nearly triple if all this space is converted to tree cover. In Europe alone, if 35% of the urban surfaces ($26,450 \text{ km}^2$) were transformed into green surfaces, the mitigation potential based on carbon sequestration would be an estimated $25.9 \text{ MtCO}_2 \text{ yr}^{-1}$ with the total mitigation benefit being $55.8 \text{ MtCO}_2 \text{ yr}^{-1}$, including an energy saving of about 92 TWh yr^{-1} (Quaranta et al. 2021). Other co-benefits include reducing urban runoff by about 17.5% and reducing summer temperatures by 2.5°C – 6°C (Quaranta et al. 2021).

Urban tree carbon storage is highly dependent on biome. For example, carbon sequestered by vegetation in Amazonian forests is two to five

times higher compared to boreal and temperate forests (Blais et al. 2005). At the regional level, the estimated carbon storage density rates of tree cover include a range of 3.14 – 14.1 kgC m^{-2} in the United States, 3.85 – 5.58 kgC m^{-2} in South Korea, 1.53 – 9.67 kgC m^{-2} in Barcelona, Spain, 28.1 – 28.9 kgC m^{-2} in Leicester, England, and an estimated 6.82 kgC m^{-2} in Leipzig, Germany and 4.28 kgC m^{-2} in Hangzhou, China (Nowak et al. 2013). At the local scale, above- and below-ground tree carbon densities can vary substantially, as with carbon in soils and dead woody materials. The conservation of natural mangroves has been shown to provide urban mitigation benefits through carbon sequestration, as demonstrated in the Philippines (Abino et al. 2014). Research on urban carbon densities from the Southern Hemisphere will contribute to better estimates.

On a per-tree basis, urban trees offer the most potential to mitigate climate change through both carbon sequestration and GHG emissions reduction from reduced energy use in buildings (Nowak et al. 2017). Maximum possible street tree planting among 245 world cities could reduce residential electricity use by about 0.9–4.8% annually (McDonald et al. 2016). Urban forests in the United States reduce building energy use by 7.2%, equating to an emissions reduction of 43.8 MtCO_2 annually (Nowak et al. 2017).

Urban trees can also mitigate some of the impacts of climate change by reducing the UHI effect and heat stress, reducing stormwater runoff, improving air quality, and supporting health and well-being in areas where the majority of the world's population resides (Nowak and Dwyer 2007). Urban forest planning and management can maximise these benefits for present and future generations by sustaining optimal tree cover and health (also see SDG linkages in Figure 8.4). Urban and peri-urban agriculture can also have economic benefits from fruit, ornamental, and medicinal trees (Gopal and Nagendra 2014; Lwasa 2017; Lwasa et al. 2018).

Box 8.2: Urban Carbon Storage: An Example from New York City

The structure, composition, extent, and growing conditions of vegetation in cities has an influence on their potential for mitigating climate change (Pregitzer et al. 2021). Urban natural areas, particularly forested natural areas, grow in patches and contain many of the same components as non-urban forests, such as high tree density, down woody material, and regenerating trees (Box 8.2, Figure 1).

Urban forested natural areas have unique benefits as they can provide habitat for native plants and animals, protecting local biodiversity in a fragmented landscape (Di Giulio et al. 2009). Forests can have a greater cooling effect on cities than designed greenspaces, and the bigger the forest the greater the effect (Jaganmohan et al. 2016). In New York City, urban forested natural areas have been found to account for the majority of trees estimated in the city (69%), but are a minority of the total tree canopy (25%, or 5.5% of the total city land area) (Pregitzer et al. 2019a). In New York City, natural areas are estimated to store a mean of $263.5 \text{ MgC ha}^{-1}$ (megagram carbon per hectare), adding up to 1.86 TgC (teragram carbon) across the city, with the majority of carbon (86%) being stored in the trees and soils (Pregitzer et al. 2021). These estimates are similar to per-hectare estimates of carbon storage across different pools in non-urban forest types (Table 1), and 1.5 times greater than estimates for carbon stored in just trees across the entire city (Pregitzer et al. 2021).

Within urban natural areas, the amount of carbon stored varies widely based on vegetation type, tree density, and the species composition (Box 8.2, Figure 1). The oak-hardwood forest type is one of the most abundant in New York City's natural areas and is characterised by large and long-lived native hardwood tree species, with relatively dense wood. These forests store an estimated $311.5 \text{ MgC ha}^{-1}$. However, non-native exotic invasive species can be prevalent in the understory vegetation layer (<1m height), and account for about 50% of cover in New York City (Pregitzer et al. 2019b).

Box 8.2 (continued)

This could lead to a trajectory where exotic understory species, which are often herbaceous, out-compete regenerating trees in the understory layer, alter the soil (Ward et al. 2020), and alter the forest canopy (Matthews et al. 2016). A change in New York City's vegetation structure and composition to a more open vegetation type could reduce the carbon storage by over half (open grassland $120.1 \text{ MgC ha}^{-1}$).

When compared to estimates of carbon storage presented in other studies, the components (pools) of the natural area forests in New York City store carbon in similar proportions to other non-urban forests (see Table 1). This might suggest that in other geographies, similar adjacent non-urban forest types may store similar carbon stocks per unit area (*medium confidence*). However, despite similarities to non-urban forests, the urban context can lead to altered forest function and carbon cycling that should be considered. For example, trees growing in urban areas have been observed to grow at much higher rates due to higher access to light, nutrients, and increased temperatures (Gregg et al. 2003; Reinmann et al. 2020).

Higher growth rates coupled with the UHI effect have also been suggested to yield greater evaporative cooling by urban canopies relative to rural forests (Winbourne et al. 2020). Based on estimates in New York City, it is likely that the majority of tree biomass, and carbon in trees in cities, could be found in urban natural area forest patches (*medium agreement, limited evidence*). More research is needed to map urban natural areas, assess vegetation, and differentiate tree canopy types (natural versus non-natural) at fine scales within many cities and geographies. Accurate maps, as well as greater understanding of definitions of urban canopies and vegetation, could lead to better accounts for carbon stocks and the many other unique benefits they provide (Raciti et al. 2012; Pregitzer et al. 2019a).

Despite this potential, natural areas are inherently a minority land-use type in cities and should be viewed along with other types of urban tree canopy that occur in more designed environments that might out-perform natural areas in other ecosystem services. The mosaic of vegetation characteristics and growing conditions will yield different ecosystem services across cities (Pataki et al. 2011) and should be an important consideration in planning, management, and policy in the future.

Box 8.2, Figure 1: Estimates for carbon storage in natural area forests in New York City. (a) Mean estimated carbon stock per hectare in natural area forests (Pregitzer et al. 2019a, 2021); (b) estimates for carbon stocks vary based on vegetation types; and (c) estimates of the amount of carbon stock in different forest pools per hectare. The proportion of the total estimated carbon stock per pool is out of the total estimated for the entire city (1.86 TgC). Source: adapted from Pregitzer et al. (2021).

Box 8.2 (continued)

Box 8.2, Table 1: A selection of benchmark reference estimates of different carbon pools sampled and the related urban considerations to contextualise the results from New York City (NYC), United States (USA) natural area carbon stocks. The benchmark estimates are intended to provide a point of reference to help contextualise the calculations for carbon pools in NYC's forests. Forest carbon is highly variable and dependent on microclimatic conditions such as moisture, microbial communities, and nutrient availability, all of which can be impacted by human activity in urban or altered environments. Standard errors and 95% confidence intervals can be found in Pregitzer et al. (2021). DBH: diameter at breast height; DWM: down woody material; CWM: coarse woody material and FWM: fine woody material. Source: Pregitzer et al. (2021).

Pool considered in NYC natural area	Published estimates of carbon stock (MgC ha ⁻¹)	NYC estimated carbon stock (MgC ha ⁻¹)	Urban considerations
Live trees: all trees (>2 cm DBH) including above and below ground	87.1: northeastern USA (Smith et al. 2013) 73.3: NYC assuming 100% cover (Nowak et al. 2013)	135.4	Lower ozone levels, higher CO ₂ , warmer temperatures, and higher nutrient deposition could lead to increased growth rates and annual carbon sequestration. However, pollutants in soil (e.g., heavy metals), increased pests, and GHGs in the atmosphere (e.g., NO _x and SO ₂) could decrease annual tree growth and carbon sequestration (Gregg et al. 2003)
Groundcover: all vegetation growing <1 m height	1.8: northeastern USA (Smith et al. 2013)	5.5	Anthropogenic disturbance creates canopy gaps that accelerate herbaceous growth; invasive vines are prevalent in urban forests that can alter tree survival and growth and soils (Matthews et al. 2016; Ward et al. 2020)
Standing dead trees	5.1: northeastern USA (Smith et al. 2013) 2.59: Massachusetts (Liu et al. 2006)	5.8	Removal may occur due to safety considerations
CWM: coarse (>10 cm) and FWM (>0.1 cm)	9.18: CWM – New York state 2.52: CWM – Massachusetts (Liu et al. 2006) 6.37: FWM – New York (Woodall et al. 2013) 3.67: FWM northern hardwood; 0 to 227.94: Northern USA (Domke et al. 2016)	15.25 (added together DWM and FWM)	Removal may occur due to safety considerations
Litter and duff: depth measured	12: NYC (Pouyat et al. 2002) 9.36: northern hardwood; 0.04: northern USA (Domke et al. 2016)	10.95	Decomposition increases with temperature (Hanson et al. 2003); decreased ozone levels facilitate litter decay (Carreiro et al. 2009)
Mineral soil (organic 30 cm)	104: to 30 cm depth, NYC (Cambou et al. 2018) 50: to 10 cm depth, NYC (Pouyat et al. 2002)	105.11(30 cm) and 77.78 (10 cm)	UHI and pollution alter the litter chemistry, decomposer organisms, conditions, and resources, which all influence respiration rates (Carreiro et al. 2009); earthworms, prevalent in urban areas, accelerate decay, but some carbon is sequestered in passive pools (Pouyat et al. 2002). Soil could be compacted.

8.4.4.2 Benefits of Green Roofs, Green Walls, and Greenways

Green roofs and green walls have potential to mitigate air and surface temperature, improve thermal comfort, and mitigate UHI effects (Jamei et al. 2021; Wong et al. 2021), while lowering the energy demand of buildings (Susca 2019) (Figure 8.18). Green roofs have the highest median cooling effect in dry climates (3°C) and the lowest cooling effect in hot, humid climates (1°C) (Jamei et al. 2021). These mitigation potentials depend on numerous factors and the scale of implementation. The temperature reduction potential for green roofs when compared to conventional roofs can be about 4°C in winter and about 12°C during summer conditions (Bevilacqua et al. 2016). Green roofs can reduce building heating demands by about 10–30% compared to conventional roofs (Besir and Cuce 2018), 60–70% compared to black roofs, and 45–60% compared to white roofs (Silva et al. 2016). Green walls or facades can provide

a temperature difference between air temperature outside and behind a green wall of up to 10°C, with an average difference of 5°C in Mediterranean contexts in Europe (Perini et al. 2017). The potential of saving energy for air conditioning by green facades can be around 26% in summer months. Considerations of the spatial context are essential given their dependence on climatic conditions (Susca 2019). Cities are diverse and emissions savings potentials depend on several factors, while the implementation of green roofs or facades may be prevented in heritage structures.

Green roofs have been shown to have beneficial effects in stormwater reduction (Andrés-Doménech et al. 2018). A global meta-analysis of 75 international studies on the potential of green roofs to mitigate runoff indicate that the runoff retention rate was on average 62% but with a wide range (0–100%) depending on a number of interdependent factors (Zheng et al. 2021). These factors relate to the

characteristics of the rainfall event (e.g., intensity) and characteristics of the green roof (e.g., substrate, vegetation type, and size), and of the climate and season type. A hydrologic modelling approach applied to an Italian case demonstrated that implementing green roofs may reduce peak runoff rates and water volumes by up to 35% in a 100% green roof conversion scenario (Masseroni and Cislighi 2016).

Greenways support stormwater management to mitigate water runoff and urban floods by reducing the water volume (e.g., through infiltration) and by an attenuation or temporal shift of water discharge (Fiori and Volpi 2020; Pour et al. 2020). Using green infrastructure delays the time to runoff and reduces water volume but depends on the magnitude of floods (Qin et al. 2013). Measures are most effective for flood mitigation at a local scale; however, as the size of the catchment increases, the effectiveness of reducing peak discharge decreases (Fiori and Volpi 2020). Reduction of water volume through infiltration can be more effective with rainfall events on a lower return rate. Overall, the required capacity for piped engineered systems for water runoff attenuation and mitigation can be reduced while lowering flow rates, controlling pollution transport, and increasing the capacity to store stormwater (Srishantha and Rathnayake 2017). Benefits for flood mitigation require a careful consideration of the spatial context of the urban area, the heterogeneity of the rainfall events, and characteristics of implementation (Qiu et al. 2021). Maintenance costs and stakeholder coordination are other aspects requiring attention (Mguni et al. 2016).

Providing a connected system of greenspace throughout the urban area may promote active transportation (Nieuwenhuijsen and Khreis 2016), thereby reducing GHG emissions. Soft solutions for improving green infrastructure connectivity for cycling is an urban NBS mitigation measure, although there is *low evidence* for emissions reductions. In the city of Lisbon, Portugal, improvements in cycling infrastructure and bike-sharing system resulted in 3.5 times more cyclists within two years (Félix et al. 2020). In Copenhagen, the cost of cycling (0.08 EUR km⁻¹) is declining and is about six times lower than car driving (Euro 0.50/km) (Vedel et al. 2017). In addition, participants were willing to cycle 1.84 km longer if the route has a designated cycle track and 0.8 km more if there are also green surroundings. Changes in urban landscapes, including through the integration of green infrastructure in sustainable urban and transport planning, can support the transition from private motorised transportation to public and physically active transportation in carbon-neutral, more liveable and healthier cities (Nieuwenhuijsen and Khreis 2016; Nieuwenhuijsen 2020). Car infrastructure can be also transferred into public open and green space, such as in the Superblock model in Barcelona's neighbourhoods (Rueda 2019). Health impact assessment models estimated that 681 premature deaths may be prevented annually with this implementation (Mueller et al. 2020) and the creation of greenways in Maanshan, China has stimulated interest in walking or cycling (Zhang et al. 2020).

8.4.5 Socio-behavioural Aspects

Urban systems shape the behaviour and social structures of their residents through urban form, energy systems, and infrastructure – all of which provide a range of options for consumers to make choices about residential location, mobility, energy sources, and the consumption of materials, food, and other resources. The relative availability of options across these sectors has implications on urban emissions through individual behaviour. In turn, urban GHG emissions, as well as emissions from the supply chains of cities, are driven by the behaviour and consumption patterns of residents, with households accounting for over 60% of carbon emissions globally (Ivanova et al. 2016). The exclusion of consumption-based emissions and emissions that occur outside of city boundaries as a result of urban activities, however, will lead to significant undercounting. For example, a study of 79 major cities found that about 41% of consumption-based carbon footprints (1.8 GtCO₂-eq of 4.4 GtCO₂-eq) occurred outside of city boundaries.

Changes in behaviour across all areas (e.g., transport, buildings, food) could reduce an individual's emissions by 5.6–16.2% relative to the accumulated GHG emissions from 2011 to 2050 in a baseline scenario modelled with the Global Change Assessment Model (van de Ven et al. 2018). In other models, behaviour change in transport and residential energy use could reduce emissions by 2 GtCO₂-eq in 2030 compared to 2019 (IEA 2020b) (Chapter 5). Voluntary behaviour change can support emissions reduction, but behaviours that are not convenient to change are unlikely to shift without changes to policy (Sköld et al. 2018). Cities can increase the capability of citizens to make sustainable choices by making these choices less onerous, through avenues such as changing urban form to increase locational and mobility options and providing feedback mechanisms to support socio-behavioural change.

Transport emissions can be reduced by options including telecommuting (0.3%), taking closer holidays (0.5%), avoiding short flights (0.5%), using public transit (0.7%), cycling (0.6%), car sharing (1.1%), and carpool commuting (1.2%); all reduction estimates reflect cumulative per capita emission savings relative to baseline emissions for the period 2011–2050, and assume immediate adoption of behavioural changes (van de Ven et al. 2018). Cities can support voluntary shift to walking, cycling, and transit instead of car use through changes to urban form, such as TOD (Kamruzzaman et al. 2015), increased density of form with co-location of activities (Ma et al. 2015; Ding et al. 2017; Duranton and Turner 2018; Masoumi 2019), and greater intersection density and street integration (Koohsari et al. 2016). Mechanisms such as providing financial incentives or disincentives for car use can also be effective in reducing emissions (Wynes et al. 2018) (Section 8.4.2).

Adopting energy efficient practices in buildings could decrease global building energy demand in 2050 by 33–44% compared to a business-as-usual scenario (Levesque et al. 2019). Reductions in home energy use can be achieved by reducing floor area (0.5–3.0%), utilising more efficient appliances and lighting (2.7–5.0%), optimising thermostat settings (8.3–11%), using efficient heating and cooling technologies (6.7–10%), improving building insulation (2.9–4.0%), optimising

clothes washing (5.0–5.7%), and optimising dishwashing (1–1.1%) (Levesque et al. 2019). Building standards and mandates could work towards making these options required or more readily available and accessible. Residential appliance use, water heating, and thermostat settings can be influenced by feedback on energy use, particularly when paired with real-time feedback and/or instructions on how to reduce energy use (Kastner and Stern 2015; Stern et al. 2016; Wynes et al. 2018; Tiefenbeck et al. 2019). The energy-saving potentials of changing occupant behaviour can range between 10% and 25% for residential buildings, and between 5% and 30% for commercial buildings (Zhang et al. 2018). Households are more likely to invest in energy-related home technologies if they believe it financially benefits (rather than disadvantages) them, increases comfort, or will benefit the natural environment (Kastner and Stern 2015). Social influences and availability of funding for household energy measures also support behaviour change (Kastner and Stern 2015).

8.4.5.1 Increasing Locational and Mobility Options

Spatial planning, urban form, and infrastructure can be utilised to deliberately increase both locational and mobility options for socio-behavioural change in support of urban mitigation. The mitigation impacts of active travel can include a reduction of mobility-related lifecycle CO₂ emissions by about 0.5 tonnes over a year when an average person cycles one trip per day more, and drives one trip per day less, for 200 days a year (Brand et al. 2021). Urban areas that develop and implement effective 15/20-minute city programmes are very likely to reduce urban energy use and multiply emission reductions, representing an important cascading effect.

Accessibility as a criterion widens the focus beyond work trips and VKT/VMT, paying attention to a broader set of destinations beyond workplaces, as well as walking and biking trips or active travel. It holds promise for targeting and obtaining greater reductions in GHG emissions in household travel by providing access through walking, biking, and public transit. Accessibility as a criterion for urban form has been embedded in neighbourhood form models since at least the last century and in more recent decades in the ‘urban village’ concept of the New Urbanism (Duany and Plater-Zyberck 1991) and TODs (Calthorpe 1993). However, accessibility did not gain much traction in urban planning and transportation until the last decade. The experience of cities and metropolitan areas with the COVID-19 pandemic has led to a further resurgence in interest and importance (Handy 2020; Hu et al. 2020), and it is becoming a criterion at the core of the concept of the 15/20-minute city (Moreno et al. 2021; Pozoukidou and Chatziyiannaki 2021). Initially, neighbourhoods have been designed to provide quality, reliable services within 15 or 20 minutes of active transport (i.e., walking or cycling), as well as a variety of housing options and open space (Portland Bureau of Planning and Sustainability 2012; Pozoukidou and Chatziyiannaki 2021; State Government of Victoria 2021). Community life circles strategy for urban areas has also emphasised walking access and health (Weng et al. 2019; Wu et al. 2021). The growing popularity of the 15/20-minute city movement has significant potential for reducing VMT/VKT and associated GHG emissions.

8.4.5.2 Avoiding, Minimising, and Recycling Waste

The waste sector is a significant source of GHG emissions, particularly CH₄ (Gonzalez-Valencia et al. 2016; Nisbet et al. 2019). Currently, the sector remains the largest contributor to urban emissions after the energy sector, even in low-carbon cities (Lu and Li 2019). Since waste management systems are usually under the control of municipal authorities, they are a prime target for city-level mitigation efforts with co-benefits (EC 2015, 2020; Gharfalkar et al. 2015; Herrero and Vilella 2018; Zaman and Ahsan 2019). Despite general agreement on mitigation impacts, quantification remains challenging due to differing assumptions for system boundaries and challenges related to measuring avoided waste (Zaman and Lehmann 2013; Bernstad Saraiva Schott and Cánovas 2015; Matsuda et al. 2018).

The implementation of the waste hierarchy from waste prevention onward, as well as the effectiveness of waste separation at source, involves socio-behavioural options in the context of urban infrastructure (Sun et al. 2018a; Hunter et al. 2019). Managing and treating waste as close to the point of generation as possible, including distributed waste treatment facilities, can minimise transport-related emissions, congestion, and air pollution. Home composting and compact urban form can also reduce waste transport emissions (Oliveira et al. 2017). Decentralised waste management can reinforce source-separation behaviour since the resulting benefits can be more visible (Eisted et al. 2009; Hoornweg and Bhada-Tata 2012; Linzner and Lange 2013). Public acceptance for waste management is greatest when system costs for citizens are reduced, there is greater awareness of primary waste separation at source, and there are positive behavioural spill-overs across environmental policies (Milutinović et al. 2016; Boyer and Ramaswami 2017; Díaz-Villavicencio et al. 2017; Slorach et al. 2020). In addition to the choice of technology, the costs of waste management options depend on the awareness of system users that can represent time-dependent costs (Khan et al. 2016; Chifari et al. 2017; Ranieri et al. 2018; Tomić and Schneider 2020). Waste management systems and the inclusion of materials from multiple urban sectors for alternative by-products can increase scalability (Eriksson et al. 2015; Boyer and Ramaswami 2017; D’Adamo et al. 2021). As a broader concept, circular economy approaches can contribute to managing waste (Box 12.8) with varying emissions impacts (Section 5.3.4).

The generation and composition of waste varies considerably from region to region and city to city. So do the levels of institutional management, infrastructure, and (informal) work in waste disposal activities. Depending on context, policy priorities are directed towards reducing waste generation and transforming waste to energy or other products in a circular economy (Díaz 2017; Ezeudu and Ezeudu 2019; Joshi et al. 2019; Calderón Márquez and Rutkowski 2020; Fatimah et al. 2020). Similarly, waste generation, waste collection coverage, recycling, and composting rates, as well as the means of waste disposal and treatment, differ widely, including the logistics of urban waste management systems. Multiple factors influence waste generation, and regions with similar urbanisation rates can generate different levels of waste per capita (Kaza et al. 2018).

Under conventional practices, municipal solid waste is projected to increase by about 1.4 Gt between 2016 and 2050, reaching 3.4 Gt in 2050 (Kaza et al. 2018). Integrated policymaking can increase the energy, material, and emissions benefits in the waste management sector (Hjalmarsson 2015; Fang et al. 2017; Jiang et al. 2017). Organisational structure and programme administration poses demands for institutional capacity, governance, and cross-sectoral coordination for obtaining the maximum benefit (Hjalmarsson 2015; Kalmykova et al. 2016; Conke 2018; Marino et al. 2018; Yang et al. 2018).

The informal sector plays a critical role in waste management, particularly but not exclusively in developing countries (Linzner and Lange 2013; Dias 2016). Sharing of costs and benefits, and transforming informality of waste recycling activities into programmes, can support distributional effects (Conke 2018; Grové et al. 2018). Balancing centralised and decentralised waste management options along low-carbon objectives can address potential challenges in transforming informality (de Bercegol and Gowda 2019). Overall, the positive impacts of waste management on employment and economic growth can be increased when informality is transformed to stimulate employment opportunities for value-added products with an estimated 45 million jobs in the waste management sector by 2030 (Alzate-Arias et al. 2018; Coalition for Urban Transitions 2020; Soukiazis and Proença 2020).

8.4.6 Urban-Rural Linkages

Urban-rural linkages, especially through waste, food, and water, are prominent elements of the urban system, given that cities are open systems that depend on their hinterlands for imports and exports (Pichler et al. 2017), and include resources, products for industrial production or final use (Section 8.1.6). As supply chains are becoming increasingly global in nature, so are the resource flows with the hinterlands of cities. In addition to measures within the jurisdictional boundaries of cities, cities can influence large upstream emissions through their supply chains, as well as through activities that rely on resources outside city limits. The dual strategy of implementing local actions and taking responsibility for the entire supply chains of imported and exported goods can reduce GHG emissions outside of a city's administrative boundaries (Figure 8.15).

Waste prevention, minimisation, and management provides the potential of alleviating resource usage and upstream emissions from urban settlements (Swilling et al. 2018; Chen et al. 2020a; Harris et al. 2020). Integrated waste management and zero-waste targets can allow urban areas to maximise the mitigation potential while reducing pressures on land use and the environment. This mitigation option reduces emissions due to (i) avoided emissions upstream in the supply chain of materials based on measures for recycling and the reuse of materials; (ii) avoided emissions due to land-use changes as well as emissions that are released into the atmosphere from waste disposal; and (iii) avoided primary energy (see Glossary) spending and emissions. Socio-behavioural change that reduces waste generation, combined with technology and infrastructure according to the waste hierarchy, can be especially effective. The mitigation potential

of waste-to-energy depends on the technological choices that are undertaken (e.g., anaerobic digestion of the organic fraction), the emissions factor of the energy mix that it replaces, and its broader role within integrated municipal solid management practices (Eriksson et al. 2015; Potdar et al. 2016; Yu and Zhang 2016; Soares and Martins 2017; Alzate-Arias et al. 2018; Islam 2018). The climate mitigation potential of anaerobic digestion plants can increase when power, heat and/or cold is co-produced (Thanopoulos et al. 2020).

Urban food systems, as well as city-regional production and distribution of food, factors into supply chains. Reducing food demand from urban hinterlands can have a positive impact on energy and water demand for food production (Eigenbrod and Gruda 2015) (see 'food system' in Glossary). Managing food waste in urban areas through recycling or reduction of food waste at source of consumption would require behavioural change (Gu et al. 2019). Urban governments could also support shifts towards more climate-friendly diets, including through procurement policies. These strategies have created economic opportunities or have enhanced food security while reducing the emissions that are associated with waste and the transportation of food. Strategies for managing food demand in urban areas would depend on the integration of food systems in urban planning.

Urban and peri-urban agriculture and forestry is pursued by both developing and some developed country cities. There is increasing evidence for economically feasible, socially acceptable, and environmentally supportive urban and peri-urban agricultural enterprises although these differ between cities (Brown 2015; Eigenbrod and Gruda 2015; Blay-Palmer et al. 2019; De la Sota et al. 2019). The pathways include integrated crop-livestock systems, urban agroforestry systems, aquaculture-livestock-crop systems, and crop systems (Lwasa et al. 2015), while the mitigation potential of urban and peri-urban agriculture has *medium agreement* and *low evidence*. Strategies for urban food production in cities have also relied on recycling nutrients from urban waste and utilisation of harvested rainwater or wastewater.

Systems for water reallocation between rural areas and urban areas will require change by leveraging technological innovations for water capture, water purification, and reducing water wastage either by plugging leakages or changing behaviour in regard to water use (Eigenbrod and Gruda 2015; Prior et al. 2018). Reducing energy use for urban water systems involves reducing energy requirements for water supply, purification, distribution, and drainage (Ahmad et al. 2020). Various levels of rainwater harvesting in urban settings for supplying end-use water demands or supporting urban food production can reduce municipal water demands, including by up to 20% or more in Cape Town (Fisher-Jeffes et al. 2017).

8.4.7 Cross-sectoral Integration

There are two broad categories of urban mitigation strategies. One is from the perspective of key sectors, including clean energy, sustainable transport, and construction (Rocha et al. 2017; Álvarez Fernández 2018; Magueta et al. 2018; Seo et al. 2018; Waheed

et al. 2018); the coupling of these sectors can be enabled through electrification (Section 8.4.3.1). The other looks at the needs for emissions through a more systematic or fundamental understanding of urban design, urban form, and urban spatial planning (Wang et al. 2017; Privitera et al. 2018), and proposes synergistic scenarios for their integration for carbon neutrality (Ravetz et al. 2020).

Single-sector analysis in low-carbon urban planning examines solutions in supply, demand, operations, and assets management either from technological efficiency or from a system approach. For example, the deployment of renewable energy technologies for urban mitigation can be evaluated in detail and the transition to zero-carbon energy in energy systems and EVs in the transport sector can bring about a broad picture for harvesting substantial low-carbon potentials through urban planning (*high agreement, robust evidence*) (Álvarez Fernández 2018; Tarigan and Sagala 2018).

The effects of urban carbon lock-in on land use, energy demand, and emissions vary depending on national circumstances (Wang et al. 2017; Pan 2020). Systematic consideration of urban spatial planning and urban forms, such as polycentric urban regions and rational urban population density, is essential not only for liveability but also for achieving net-zero GHG emissions as it aims to shorten commuting distances and is able to make use of NBS for energy and resilience (*high agreement, medium evidence*). However, crucial knowledge gaps remain in this field. There is a shortage of consistent and comparable GHG emissions data at the city level and a lack of in-depth understanding of how urban renewal and design can contribute to carbon neutrality (Mi et al. 2019).

An assessment of opportunities suggests that strategies for material efficiency that cross-cut sectors will have greater impact than those that focus one-dimensionally on a single sector (UNEP IRP 2020). In the urban context, this implies using less material by the design of physical infrastructure based on light-weighting and down-sizing, material substitution, prolonged use, as well as enhanced recycling, recovery, remanufacturing, and reuse of materials and related components. For example, light-weight design in residential buildings and passenger vehicles can enable about 20% reductions in lifecycle material-related GHG emissions (UNEP IRP 2020).

The context of urban areas as the nexus of both sectors (i.e., energy, and urban form and planning) underlines the role of urban planning and policies in contributing to reductions in material-related GHG emissions while enabling housing and mobility services for the benefit of inhabitants. In addition, combining resource efficiency measures with strategic densification can increase the GHG reduction potential and lower resource impacts. While resource efficiency measures are estimated to reduce GHG emissions, land use, water consumption, and metal use impacts from a lifecycle assessment perspective by 24–47% over a baseline, combining resource efficiency with strategic densification can increase this range to about 36–54% over the baseline for a sample of 84 urban settlements worldwide (Swilling et al. 2018).

Evidence from a systematic scoping of urban solutions further indicates that the GHG abatement potential of integrating measures

across urban sectors is greater than the net sum of individual interventions due to the potential of realising synergies when realised in tandem, such as urban energy infrastructure and renewable energy (Sethi et al. 2020). Similarly, system-wide interventions, such as sustainable urban form, are important for increasing the GHG abatement potential of interventions based on individual sectoral projects (Sethi et al. 2020). Overall, the pursuit of inter-linkages among urban interventions is important for accelerating GHG reductions in urban areas (Sethi et al. 2020); this is also important for reducing reliance on carbon capture and storage technologies (CCS) at the global scale (Figures 8.15 and 8.21).

Currently, cross-sectoral integration is one of the main thematic areas of climate policy strategies among the actions that are adopted by signatories to an urban climate and energy network (Hsu et al. 2020c). Although not as prevalent as those for efficiency, municipal administration, and urban planning measures (Hsu et al. 2020c), strategies that are cross-cutting in nature across sectors can provide important emission-saving opportunities for accelerating the pace of climate mitigation in urban areas. Cross-sectoral integration also involves mobilising urban actors to increase innovation in energy services and markets beyond individual energy efficiency actions (Hsu et al. 2020c). Indeed, single-sector versus cross-sector strategies for 637 cities from a developing country can enable an additional 15–36% contribution to the national climate mitigation reduction potential (Ramaswami et al. 2017a). The strategies at the urban level involved those for energy cascading and exchange of materials that connected waste, heat, and electricity strategies (Section 8.5 and Box 8.4).

The feasibility of upscaling multiple response options depends on the urban context as well as the stage of urban development, with certain stages providing additional opportunities over others (Dienst et al. 2015; Maier 2016; Affolderbach and Schulz 2017; Roldán-Fontana et al. 2017; Zhao et al. 2017a; Beygo and Yüzer 2017; Lwasa 2017; Pacheco-Torres et al. 2017; Alhamwi et al. 2018; Kang and Cho 2018; Lin et al. 2018; Collaço et al. 2019) (Figures 8.19 and 8.21, and Section 8.SM.2).

8.5 Governance, Institutions, and Finance

Governance and other institutions act as core components to urban systems by facilitating and managing linkages between different sectors, geographic regions, and stakeholders. This position renders subnational governments and institutions key enablers of climate change mitigation (Seto et al. 2016, 2021; Hsu et al. 2018, 2020c; Vedeld et al. 2021) (Section 8.4.1). Indeed, since AR5 more research has emerged identifying these actors as vehicles through which to accelerate local-to-global efforts to decarbonise (IPCC 2018a; Hsu et al. 2020b; Salvia et al. 2021; Seto et al. 2021) (Chapter 13, Sections 4.2.3, 14.5.5, 15.6.5 and 16.4.7, and ‘subnational actors’ in Glossary). The current extent (Section 8.3.3) and projected rise (Section 8.3.4.2) in the urban share of global emissions underscores the transformative global impact of supporting urban climate governance and institutions (Section 8.5.2). Further, the multisector approach to mitigation emphasised in this chapter (Sections 8.4

and 8.6, and Figure 8.21) highlights the need for facilitation across sectors (Figure 8.19).

8.5.1 Multi-level Governance

IPCC SR1.5 identified multi-level governance (see Glossary for full definition) as an enabling condition that facilitates systemic transformation consistent with keeping global temperatures below 1.5°C (IPCC 2018a, pp. 18–19). The involvement of governance at multiple levels is necessary to enable cities to plan and implement emissions reductions targets (*high confidence*) (Seto et al. 2021) (Boxes 8.3 and 8.4). Further, regional, national, and international climate goals are most impactful when local governments are involved alongside higher levels, rendering urban areas key foci of climate governance more broadly (*high confidence*) (Fuhr et al. 2018; Kern 2019; Hsu et al. 2020b).

Since AR5, multi-level governance has grown in influence within the literature and has been defined as a framework for understanding the complex interaction of the many players involved in GHG generation and mitigation across geographic scales – the ‘vertical’ levels of governance from neighbourhoods to the national and international levels, and those ‘horizontal’ networks of non-state and subnational actors at various scales (Corfee-Morlot et al. 2009; Seto et al. 2014; Castán Broto 2017b; Fuhr et al. 2018; Peng and Bai 2018; Kern 2019), as well as the complex linkages between them (Vedeld et al. 2021). This more inclusive understanding of climate governance provides multiple pathways through which urban actors can engage in climate policy to reduce emissions.

8.5.1.1 Multi-level, Multi-player Climate Governance in Practice

A multi-level, multi-player framework highlights both the opportunities and constraints on local autonomy to engage in urban mitigation efforts (Castán Broto 2017b; Fuhr et al. 2018; Vedeld et al. 2021). When multiple actors – national, regional, and urban policymakers, as well as non-state actors and civil society – work together to exploit the opportunities, it leads to the most impactful mitigation gains (Melica et al. 2018). This framework also highlights the multiple paths and potential synergies available to actors who wish to pursue mitigation policies despite not having a full slate of enabling conditions (Castán Broto 2017b; Keller 2017; Fuhr et al. 2018; Hsu et al. 2020b,a; Seto et al. 2021).

For example, Sections 8.4.3. and 8.4.5 highlight how instigating the electrification of urban energy systems requires a ‘layered’ approach to policy implementation across different levels of governance (see Section 8.4.3.1 for specific policy mechanisms associated with electrification), with cities playing a key role in setting standards, particularly through mechanisms like building codes (Hsu et al. 2020c; Salvia et al. 2021), as well as through facilitation between stakeholders (e.g., consumers, government, utilities) to advocate for zero-emissions targets (Linton et al. 2021; Seto et al. 2021). Local governments can minimise trade-offs associated with electrification technologies by enabling circular economy practices and

opportunities (Pan et al. 2015; Gaustad et al. 2018; Sovacool et al. 2020). These include public-private partnerships between consumers and producers, financial and institutional support, and networking for stakeholders like entrepreneurs, so as to increase accessibility and efficiency of recycling for consumers by providing a clear path from consumer waste back to the producers (Pan et al. 2015; Prendeville et al. 2018; Fratini et al. 2019). Box 8.3 discusses the mitigation benefits of coordination between local and central government in the context of Shanghai’s GHG emissions reduction goals.

Still, there are constraints on urban autonomy that might limit urban mitigation influence. The capacity of subnational governments to autonomously pursue emissions reductions on their own depends on different political systems and other aspects of multi-level governance, such as innovation, legitimacy, and institutional fit, as well as the resources, capacity, and knowledge available to subnational technicians and other officials (Widerberg and Pattberg 2015; Valente de Macedo et al. 2016; Green 2017; Roger et al. 2017). Financing is considered one of the most crucial facets of urban climate change mitigation. It is also considered one of the biggest barriers, given the limited financial capacities of local and regional governments (Sections 8.5.4 and 8.5.5).

When sufficient local autonomy is present, local policies have the ability to upscale to higher levels of authority, imparting influence at higher geographic scales. Established urban climate leaders with large institutional capacity can influence small and mid-sized cities, or other urban areas with less institutional capacity, to enact effective climate policies, by engaging with those cities through transnational networks and by adopting a public presence of climate leadership (Chan et al. 2015; Kern 2019; Seto et al. 2021) (Section 8.5.3). Increasingly, subnational actors are also influencing their national and international governments through lobbying efforts that call on them to adopt more ambitious climate goals and provide more support for subnational GHG mitigation efforts (Linton et al. 2021; Seto et al. 2021). These dynamics underscore the importance of relative local autonomy in urban GHG mitigation policy. They also highlight the growing recognition of subnational authorities’ role in climate change mitigation by national and international authorities.

The confluence of political will and policy action at the local level, and growing resources offered through municipal and regional networks and agreements, have provided a platform for urban actors to engage in international climate policy (Section 8.5.3). This phenomenon is recognised in the Paris Agreement, which, for the first time in a multilateral climate treaty, referenced the crucial role subnational and non-state actors like local communities have in meeting the goals set forth in the agreement (UNFCCC 2015). The Durban Platform for Enhanced Action (Widerberg and Pattberg 2015), as well as UN-Habitat’s NUA and the 2030 Development Agenda, are other examples of the international sphere elevating the local level to global influence (Fuhr et al. 2018). Another facet of local-to-global action is the emergence of International Cooperative Initiatives (ICIs) (Widerberg and Pattberg 2015). One such ICI, the City Hall Declaration, was signed alongside the Paris Agreement during the first Climate Summit for Local Leaders. Signatories included hundreds of local government leaders, in partnership with private sector

representatives and NGOs, who pledged to enact the goals of the Paris Agreement through their own spheres of influence (Cities for Climate 2015). Similar Summits have been held at each subsequent UNFCCC COP (Hsu et al. 2018). Like transnational climate networks,

these platforms provide key opportunities to local governments to further their own mitigation goals, engage in knowledge transfer with other cities and regions, and shape policies at higher levels of authority (Cities for Climate 2015; Castán Broto 2017b).

Box 8.3: Coordination of Fragmented Policymaking for Low-carbon Urban Development: Example from Shanghai, China

As a growing megacity in the Global South, Shanghai represents the challenge of becoming low carbon despite its economic growth and population size (Chen et al. 2017). Shanghai was designated as one of the pilot low-carbon cities by the central government. The city utilised a coordination mechanism for joining fragmented policymaking across the city's economy, energy, and environment. The coordination mechanism was supported by a direct fund that enabled implementation of cross-sector policies beyond a single-sector focus across multiple institutions while increasing capacity for enabling a low-carbon transition for urban sustainability (Peng and Bai 2020).

Implementation and governance process

In Shanghai, coordination between the central and local governments had an instrumental role for encouraging low-carbon policy experimentation. Using a nested governance framework, the central government provided target setting and performance evaluation while the local government initiated pilot projects for low-carbon development. The policy practices in Shanghai surpassed the top-down targets and annual reporting of GHG emissions, including carbon labelling standards at the local level, pilot programme for transitioning sub-urban areas, and the engagement of public utilities (Peng and Bai 2018).

Towards low-carbon urban development

New policy measures in Shanghai were built upon a series of related policies from earlier, ranging from general energy saving measures to air pollution reduction. This provided a continuum of policy learning for implementing low-carbon policy measures. An earlier policy was a green electricity scheme based on the Jade Electricity Program while the need for greater public awareness was one aspect requiring further attention in policy design (Baeumler et al. 2012), supporting policy-learning for policies later on. The key point here is that low-carbon policies were built on and learned from earlier policies with similar goals.

Outcomes and impacts of the policy mix

Trends during 1998 and 2015 indicate that energy intensity decreased from about 130 tonnes per million RMB to about 45 tonnes per million RMB and carbon intensity decreased from about 0.35 Mt per billion RMB to 0.10 Mt per billion RMB (Peng and Bai 2018). These impacts on energy and carbon intensities represent progress, while challenges remain. Among the challenges are the need for investment in low-carbon technology and increases in urban carbon sinks (Yang and Li 2018) while cross-sector interaction and complexity are increasing.

8.5.2 Mitigation Potential of Urban Subnational Actors

A significant research question that has been paid more attention in both the scientific and policy communities is related to subnational actors' role in and contribution to global climate mitigation. The 2018 UN Environment Programme's (UNEP) annual Emissions Gap report in 2018 included for the first time a special chapter on subnational and non-state (i.e., businesses and private) actors and assessed the landscape of studies aiming to quantify their contributions to global climate mitigation. Non-state action on net-zero GHG or CO₂ emissions continues to be emphasised (UNEP 2021) (Box 8.4). There has been an increase in the number of studies aiming to quantify the overall aggregate mitigation impact of subnational climate action globally. Estimates for the significance of their impact vary widely, from up to 30 MtCO₂-eq from 25 cities in the United States in 2030 (Roelfsema 2017), to a 2.3 GtCO₂-eq reduction in 2030 compared to a current policy scenario from over 10,239 cities participating in GCoM (Hsu et al. 2018; GCoM 2019). For regional governments, the Under 2 Coalition, which

includes 260 governments pledging goals to keep global temperature rise below 2°C, is estimated to reduce emissions by 4.2 GtCO₂-eq in 2030, compared to a current policy scenario (Kuramochi et al. 2020).

Some studies suggest that subnational mitigation actions (Roelfsema 2017; Kuramochi et al. 2020) are in addition to national government mitigation efforts and can therefore reduce emissions even beyond current national policies, helping to 'bridge the gap' between emissions trajectories consistent with least-cost scenarios for limiting temperature rise below 1.5°C or 2°C (Blok et al. 2012). In some countries, such as the United States, where national climate policies have been curtailed, the potential for cities' and regions' emissions reduction pledges to make up the country's Nationally Determined Contribution under the Paris Agreement is assessed to be significant (Kuramochi et al. 2020).

These estimates are also often contingent on assumptions that subnational actors fulfil their pledges and that these actions do not result in rollbacks in climate action (i.e., weakening of national

climate legislation) from other actors or rebound in emissions growth elsewhere, but data tracking or quantifying the likelihood of their implementation remains rare (Chan et al. 2018; Hsu et al. 2019; Hale et al. 2020; Kuramochi et al. 2020). Reporting networks may attract high-performing cities, suggesting an artificially high level of cities interested in taking climate action or piloting solutions that may not be effective elsewhere (van der Heijden 2018). These studies could also present a conservative view of potential mitigation impact because they draw upon publicly reported mitigation actions and inventory data, excluding subnational actors that may be taking actions but not reporting them (Kuramochi et al. 2020). The nuances of likelihood, and the drivers and obstacles of climate action across different contexts is a key source of uncertainty around subnational actors' mitigation impacts.

8.5.3 Urban Climate Networks and Transnational Governance

As of 2019, more than 10,000 cities and regions (Hsu et al. 2020a) have recorded participation in a transnational or cooperative climate action network, which are voluntary membership networks of a range of subnational governments such as cities, as well as regional governments like states and provinces (Hsu et al. 2020a). These organisations, often operating across and between national boundaries, entail some type of action on climate change. Among the most prominent climate networks are GCoM, ICLEI, and C40, all of which ask their members to adopt emission reduction commitments, develop climate action plans, and regularly report on emissions inventories.

Municipal and regional networks and agreements have provided a platform for urban actors to engage in international climate policy (Fraundorfer 2017; Keller 2017; Fuhr et al. 2018; Hsu et al. 2018, 2020b; Westman and Broto 2018; Kern 2019; Seto et al. 2021). Their impact comes through (i) providing resources for cities and regions

to reduce their GHG emissions and improve environmental quality more generally, independent of national policy; (ii) encouraging knowledge transfer between member cities and regions; and (iii) acting as platforms of national and international policy influence (Castán Broto 2017b; Fuhr et al. 2018).

Subnational governments that participate in transnational climate networks, however, are primarily located in developed countries, particularly Europe and North America, with far less representation in developing countries. In one of the largest studies of subnational climate mitigation action, more than 93% of just over 6000 quantifiable subnational climate commitments come from cities and regions based in the European Union (NewClimate Institute et al. 2019). Such gaps in geographic coverage have been attributed to factors such as the dominating role of Global North actors in the convening and diffusion of 'best practices' related to climate action (Bouteligier 2013), or the more limited autonomy or ability of subnational or non-state actors in Global South countries to define boundaries and interests separately from national governments, particularly those that exercise top-down decision-making or have vertically integrated governance structures (Bulkeley et al. 2012). Many of the participating subnational actors from under-represented regions are large megacities (of 10 million people or more) that will play a pivotal role in shaping emissions trajectories (Data Driven Yale et al. 2018; NewClimate Institute et al. 2019).

While these networks have proven to be an important resource in local-level mitigation, their long-term effects and impact at larger scales is less certain (Valente de Macedo et al. 2016; Fuhr et al. 2018). Their influence is most effective when multiple levels of governance are aligned in mitigation policy. Nevertheless, these groups have become essential resources to cities and regions with limited institutional capacity and support (for more on transnational climate networks and transnational governance more broadly, see Sections 13.5 and 14.5).

Box 8.4: Net-zero Targets and Urban Settlements

Around the world, net-zero-emissions targets, whether economy-wide or targeting a specific sector (e.g., transport, buildings) or emissions scope (e.g., direct scope 1, or both scope 1 and 2), have been adopted by at least 826 cities and 103 regions that represent 11% of the global population with 846 million people across six continents (NewClimate Institute and Data-Driven EnviroLab 2020). In some countries, the share of such cities and regions has reached a critical mass by representing more than 70% of their total populations with or without net-zero-emissions targets at the national level.

In some cases, the scope of these targets extends beyond net-zero emissions from any given sector based on direct emissions (see Glossary) and encompass downstream emissions from a consumption-based perspective with 195 targets that are found to represent economy-wide targets. These commitments range from 'carbon neutrality' (see Glossary) or net-zero GHG emissions targets, which entail near elimination of cities' own direct or electricity-based emissions but could involve some type of carbon offsetting, to more stringent net-zero-emissions goals (Data-Driven EnviroLab and NewClimate Institute 2020) (for related definitions, such as 'carbon neutrality', 'net-zero CO₂ emissions', 'net-zero GHG emissions', and 'offset', see Glossary).

Currently, 43% of the urban areas with net-zero-emissions targets have also put into place related action plans while about 24% have integrated net-zero-emissions targets into formal policies and legislation (Data-Driven EnviroLab and NewClimate Institute 2020). Moreover, thousands of urban areas have adopted renewable energy-specific targets for power, heating/cooling and transport and about 600 cities are pursuing 100% renewable energy targets (REN21 2019, 2021) with some cities already achieving it.

Box 8.4 (continued)

The extent of realising and implementing these targets with the collective contribution of urban areas to net-zero-emissions scenarios with sufficient timing and pace of emission reductions will require a coordinated integration of sectors, strategies, and innovations (Swilling et al. 2018; Hsu et al. 2020c; Sethi et al. 2020; UNEP IRP 2020). In turn, the transformation of urban systems can significantly impact net-zero-emissions trajectories within mitigation pathways. Institutional capacity, governance, financing, and cross-sector coordination is crucial for enabling and accelerating urban actions for rapid decarbonisation.

8.5.4 Financing Urban Mitigation

Meeting the goals of the Paris Agreement will require fundamental changes that will be most successful when cities work together with provincial and national leadership and legislation, third-sector leadership, transformative action, and supportive financing. Urban governments often obtain their powers from provincial, state and/or national governments, and are subjected to laws and regulations to regulate development and implement infrastructure. In addition, the sources of revenue are often set at these levels so that many urban governments rely on state/provincial and national government funds for improving infrastructure, especially transit infrastructure. The increasing financialisation of urban infrastructures is another factor that can make it more difficult for local governments to determine infrastructure choices (O'Brien et al. 2019). Urban transit system operations, in particular, are heavily subsidised in many countries, both locally and by higher levels of government. As a result of this interplay of policy and legal powers among various levels of government, the lock-in nature of urban infrastructures and built environments will require multi-level governance responses to ensure meeting decarbonisation targets. The reliance on state and national policy and/or funding can accelerate or impede the decarbonisation of urban environments (McCarney et al. 2011; McCarney 2019).

The world's infrastructure spending is expected to more than double from 2015 to 2030 under a low-carbon and climate-resilient scenario. More than 70% of the infrastructure will concentrate in urban areas by requiring USD4.5–5.4 trillion per year (CCFLA 2015). However, today's climate finance flows for cities or 'urban climate finance', estimated at USD384 billion annually on average in 2017/18, are insufficient to meet the USD4.5–5.4 trillion annual investment needs for urban mitigation actions across key sectors (CCFLA 2015; CPI and World Bank 2021; Negreiros et al. 2021). Low-carbon urban form (e.g., compact, high-density, and mixed-use characteristics) is likely to economise spending in infrastructure along with the application of new technologies and renewable energies that would be able to recover the increasing upfront cost of low-carbon infrastructure from more efficient operating and energy savings (*medium evidence, high agreement*) (Global Commission on the Economy and Climate 2014; Foxon et al. 2015; Bhattacharya et al. 2016; Floater et al. 2017; Colenbrander et al. 2018b).

Governments have traditionally financed a large proportion of infrastructure investment. When budget powers remain largely centralised, intergovernmental transfers will be needed to fund low-carbon infrastructure in cities. During the COVID-19 pandemic,

cities tend to rely more on intergovernmental transfers in the form of stimulus packages for economic recovery. Nonetheless, the risk of high carbon lock-ins is likely to increase in rapidly growing cities if long-term urban mitigation strategies are not incorporated into short-term economic recovery actions (Granoff et al. 2016; Floater et al. 2017; Colenbrander et al. 2018b; CPI and World Bank 2021; Negreiros et al. 2021). Indeed, large and complex infrastructure projects for urban mitigation are often beyond the capacity of both national government and local municipality budgets. Additionally, the COVID-19 pandemic necessitates large government expenditures for public health programme and decimates municipal revenue sources for urban infrastructure projects in cities.

To meet the multi-trillion-dollar annual investment needs in urban areas, cities in partnership with international institutions, national governments, and local stakeholders increasingly play a pivotal role in mobilising global climate finance resources for a range of low-carbon infrastructure projects and related urban land use and spatial planning programmes across key sectors (*high confidence*). In particular, national governments are expected to set up enabling conditions for the mobilisation of urban climate finance resource by articulating various goals and strategies, improving pricing, regulation and standards, and developing investment vehicles and risk sharing instruments (Qureshi 2015; Bielenberg et al. 2016; Granoff et al. 2016; Floater et al. 2017; Sudmant et al. 2017; Colenbrander et al. 2018b; Zhan and de Jong 2018; Hadfield and Cook 2019; CPI and World Bank 2021; Negreiros et al. 2021).

Indeed, 75% of the global climate finance for both mitigation and adaptation in 2017 and 2018 took the form of commercial financing (e.g., balance sheets, commercial-rate loans, equity), while 25% came in the form of concessionary financing (e.g., grants, below-market-rate loans). However, cities in developing countries are facing difficulty making use of commercial financing and gaining access to international credit markets. Cities without international creditworthiness currently rely on local sources, including domestic commercial banks (*medium evidence, high agreement*) (Global Commission on the Economy and Climate 2014; CCFLA 2015; Floater et al. 2017; Buchner et al. 2019).

Cities with creditworthiness have rapidly become issuers of 'green bonds' eligible for renewable energy, energy efficiency, low-carbon transport, sustainable water, waste, and pollution, and other various climate mitigation projects across the global regions since 2013. The world's green bond market reached USD1 trillion in cumulative issuance, with issuance of USD280 billion in 2020, during the

COVID-19 pandemic. While green municipal bonds still account for a small share of the whole green bond market in 2020, scale is predicted to grow further in emerging markets over the coming years. Green municipal bonds have great potential for cities to expand and diversify their investor base. In addition, the process of issuing green municipal bonds is expected to promote cross-sector cooperation within a city by bringing together various agencies responsible for finance, climate change, infrastructure, planning and design, and operation. Indeed, the demand for green bonds presently outstrips supply as being constantly over-subscribed (*robust evidence, high agreement*) (Global Commission on the Economy and Climate 2014; Saha and D'Almeida 2017; Amundi and IFC 2021).

On the other hand, cities without creditworthiness face difficulty making use of commercial financing and getting access to international credit markets (Global Commission on the Economy and Climate 2014; CCFLA 2015; Floater et al. 2017). The lack of creditworthiness is one of the main problems preventing cities from issuing green municipal bonds in developing countries. As a prerequisite for the application of municipal debt-financing, it is an essential condition for cities to ensure sufficient own revenues from low-carbon urbanisation, or the default risk becomes too high for potential investors. Indeed, many cities in developed countries and emerging economies have already accumulated substantial amounts of debts through bond insurances, and ongoing debt payments prevent new investments in low-carbon infrastructure projects.

National governments and multilateral development banks might be able to provide support for debt financing by developing municipal creditworthiness programme and issuing sovereign bonds or providing national guarantees for investors (Floater et al. 2017). Another problem with green municipal bonds is the lack of aggregation mechanisms to support various small-scale projects in cities. Asset-backed securities are likely to reduce the default risk for investors through portfolio diversification and create robust pipelines for a bundle of small-scale projects (Granoff et al. 2016; Floater et al. 2017; Saha and D'Almeida 2017).

In principle, the upfront capital costs of various low-carbon infrastructure projects, including the costs of urban climate finance (dividend and interest payments), are eventually transferred to users and other stakeholders in the forms of taxes, charges, fees, and other revenue sources. Nevertheless, small cities in developing countries are likely to have a small revenue base, most of which is committed to recurring operating costs, associated with weak revenue collection and management systems. In recent years, there has been scope to apply not only user-based but also land-based funding instruments for the recovery of upfront capital costs (Braun and Hazelroth 2015; Kościelniak and Górka 2016; Floater et al. 2017; Colenbrander et al. 2018b; Zhan and de Jong 2018; Zhan et al. 2018a).

In practice, however, the application of land-based or 'land value capture' funding requires cities to arrange various instruments, including property (both land and building taxes), betterment levies/special assessments, impact fees (exactions), tax increment financing, land readjustment/land pooling, sales of public land/development rights, recurring lease payments, and transfer taxes/stamp duties,

across sectors in different urban contexts (Suzuki et al. 2015; Chapman 2017; Walters and Gaunter 2017; Berrisford et al. 2018). Land value capture is expected not only for cities to generate additional revenue streams but also to prevent low-density urban expansion around city-fringe locations. Inversely, land value capture is supposed to perform well when accompanied by low-carbon urban form and private real estate investments along with the application of green building technologies (*robust evidence, high agreement*) (Suzuki et al. 2015; Floater et al. 2017; Colenbrander et al. 2018b).

For the implementation of land-based funding, property rights are essential. However, weak urban-rural governance leads to corruption in land occupancy and administration, especially in developing countries with no land information system or less reliable paper-based land records under a centralised registration system. The lack of adequate property rights seriously discourages low-carbon infrastructure and real estate investments in growing cities.

The emerging application of blockchain technology for land registry and real estate investment is expected to change the governance framework, administrative feasibility, allocative efficiency, public accountability, and political acceptability of land-based funding in cities across developed countries, emerging economies, and developing countries (Graglia and Mellon 2018; Kshetri and Voas 2018). Particularly, the concept of a transparent, decentralised public ledger is adapted to facilitate value-added property transactions on a P2P basis without centralised intermediate parties and produce land-based funding opportunities for low-carbon infrastructure and real estate development district-wide and city-wide in unconventional ways (Veuger 2017; Nasarre-Aznar 2018).

The consolidation of local transaction records into national or supranational registries is likely to support large-scale land formalisation, but most pilot programmes are not yet at the scale (Graglia and Mellon 2018). Moreover, the potential application of blockchain for land-based funding instruments is possibly associated with urban form attributes, such as density, compactness, and land-use mixture, to disincentivise urban expansion and emissions growth around city-fringe locations (*medium confidence*) (Allam and Jones 2019).

8.5.5 Barriers and Enablers for Implementation

Irrespective of geography or development level, many cities face similar climate governance challenges such as lacking institutional, financial, and technical capacities (Gouldson et al. 2015; Hickmann and Stehle 2017; Sharifi et al. 2017; Fuhr et al. 2018). Large-scale system transformations are also deeply influenced by factors outside governance and institutions, such as private interests and power dynamics (Jaglin 2014; Tyfield 2014). In some cases, these private interests are tied up with international flows of capital. At the local level, a lack of empowerment, high upfront costs, inadequate and uncertain funding for mitigation, diverse and conflicting policy objectives, multiple agencies and actors with diverse interests, high levels of informality, and a siloed approach to climate action are constraining factors to mainstreaming climate action (Beermann

et al. 2016; Gouldson et al. 2016; Pathak and Mahadevia 2018; Khosla and Bhardwaj 2019).

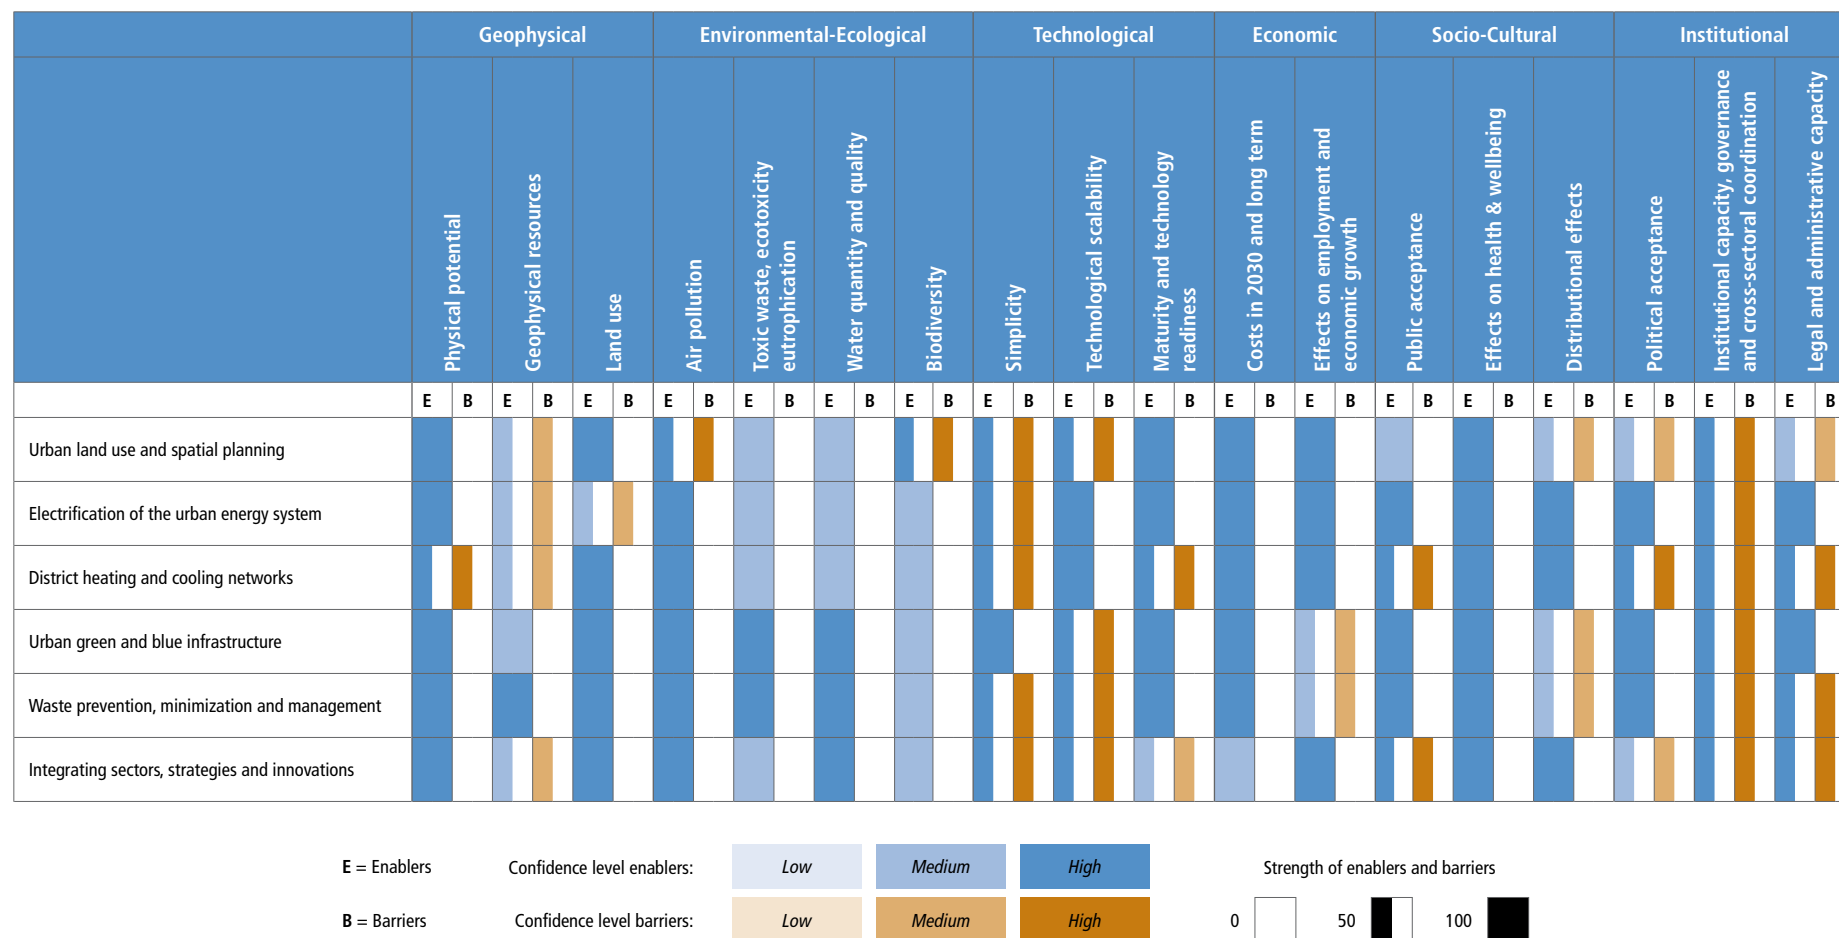

Yet urban mitigation options that can be implemented to transform urban systems involve the interplay of multiple enablers and barriers. Based on a framework for assessing feasibility from a multi-dimensional perspective, feasibility is malleable and various enablers can be brought into play to increase the implementation of mitigation options. The scope of this assessment enables an approach for considering multiple aspects that have an impact on feasibility as a tool for policy support (Singh et al. 2020). In Figure 8.19, the assessment framework that is based on geophysical, environmental-ecological, technological, economic, socio-cultural, and institutional dimensions is applied to identify the enablers and/or barriers in implementing mitigation options in urban systems. The feasibility of options may differ across context, time, and scale (Section 8.SM.2). The line of sight upon which the assessment is based includes urban case studies (Lamb et al. 2019) and assessments of land use and spatial planning in IPCC SR1.5 (IPCC 2018a).

Across the enablers and barriers of different mitigation options, urban land use and spatial planning for increasing co-located densities in urban areas has positive impacts in multiple indicators, particularly reducing land use and preserving carbon sinks when the growth in urban extent is reduced and avoided, which if brought into interplay in decision-making, can support the enablers for its implementation. Improvements in air quality are possible when higher urban densities are combined with modes of active transport, electrified mobility as well as urban green and blue infrastructure (Sections 8.3.4, 8.4 and 8.6). The demands on geophysical resources, including materials for urban development, will depend on whether additional strategies are in place with largely negative impacts under conventional practices. The technological scalability of multiple urban mitigation options is favourable while varying according to the level of existing urban development and scale of implementation (Tables 8.SM.3 and 8.SM.4).

Similarly, multiple mitigation options have positive impacts on employment and economic growth, especially when urban densities enable productivity. Possible distributional effects, including availability of affordable accommodation and access to greenspace, are best addressed when urban policy packages combine more than one policy objective. Such an approach can provide greater support to urban mitigation efforts with progress towards shifting urban development to sustainability. The electrification of the urban energy system involves multiple enablers that support the feasibility of this mitigation option, including positive impacts on health and well-being. In addition, increases in urban densities can support the planning of district heating and cooling networks that can decarbonize the built environment at scale with technology readiness levels increasing for lower temperature supply options. Preventing, minimising, and managing waste as an urban mitigation option can be enabled when informality in the sector is transformed to secure employment effects and value-addition based on the more circular use of resources (Sections 8.4.3 and 8.4.5, and Tables 8.SM.3 and 8.SM.4 in Supplementary Material 8.2).

As a combined evaluation, integrating multiple mitigation options in urban systems involves the greatest requirement for strengthening institutional capacity and governance through cross-sectoral coordination. Notably, integrated action requires significant effort to coordinate sectors and strategies across urban growth typologies (Sections 8.4 and 8.6, and Figure 8.21). Institutional capacity, if not strengthened to a suitable level to handle this process – especially to break out of carbon lock-in – can fall short of the efforts this entails. These conditions can pose barriers for realising cross-sectoral coordination while the formation of partnerships and stakeholder engagement take place as important enablers. Overcoming institutional challenges for cross-sectoral coordination can support realising synergies among the benefits that each mitigation option can offer within and across urban systems, including for the SDGs. These include those that can be involved in co-located and walkable urban form together with decarbonising and electrifying the urban energy system as well as urban green and blue infrastructure, providing the basis for more liveable, resource efficient and compact urban development with benefits for urban inhabitants (Section 8.2).

Figure 8.19: Feasibility assessment based on the enablers and barriers of implementing mitigation options for urban systems across multiple dimensions. The figure summarises the extent to which different factors would enable or inhibit the deployment of mitigation options in urban systems. These factors are assessed systematically based on 18 indicators in 6 dimensions (geophysical, environmental-ecological, technological, economic, socio-cultural, and institutional dimensions). Blue bars indicate the extent to which the indicator enables the implementation of the option (E) and orange bars indicate the extent to which an indicator is a barrier (B) to the deployment of the option, relative to the maximum possible barriers and enablers assessed. The shading indicates the level of confidence, with darker shading signifying higher levels of confidence. Supplementary Material 8.SM.2 provides an overview of the extent to which the feasibility of options may differ across context, time and scale of implementation (Table 8.SM.3) and includes line of sight upon which the assessment is based (Table 8.SM.4). The line of sight builds upon urban case studies in (Lamb et al. 2019) and assessments for land use and urban planning (IPCC 2018a) involving 414 references. The assessment method is further explained in Annex II, Section 11.

8.6 A Roadmap for Integrating Mitigation Strategies for Different Urbanisation Typologies

The most effective and appropriate packages of mitigation strategies will vary depending on several dimensions of a city. This section brings together the urban mitigation options described in Section 8.4 and assesses the range of mitigation potentials for different types of cities. There is consensus in the literature that mitigation strategies are most effective when multiple interventions are coupled together. Urban-scale interventions that implement multiple strategies concurrently through policy packages are more effective and have greater emissions savings than when single interventions are implemented separately. This is because a city-wide strategy can have cascading effects across sectors, that have multiplicative effects on GHG emissions reduction within and outside a city's administrative boundaries. Therefore, city-scale strategies can reduce more emissions than the net sum of individual interventions, particularly if multiple scales of governance are included (Sections 8.4 and 8.5). Furthermore, cities have the ability to implement policy packages across sectors using an urban systems approach, such as through planning, particularly those that affect key infrastructures (Figures 8.15, 8.17 and 8.22).

The way that cities are laid out and built will shape the entry points for realising systemic transformation across urban form and infrastructure, energy systems, and supply chains. Section 8.3.1 discusses the ongoing trend of rapid urbanisation – and how it

varies through different forms of urban development or 'typologies' (Figure 8.6). Below, Figure 8.20 distils the typologies of urban growth across three categories: emerging, rapidly growing, and established. Urban growth is relatively stabilised in established urban areas with mature urban form while newly taking shape in emerging urban areas. In contrast, rapidly growing urban areas experience pronounced changes in outward and/or upward growth. These typologies are not mutually exclusive, and can co-exist within an urban system; cities typically encompass a spectrum of development, with multiple types of urban form and various typologies (Mahtta et al. 2019).

Taken together, urban form (Figure 8.16) and growth typology (Figure 8.20) can act as a roadmap for cities or sub-city communities looking to identify their urban context and, by extension, the mitigation opportunities with the greatest potential to reduce GHG emissions. Specifically, this considers whether a city is established with existing and managed infrastructure; rapidly growing with new and actively developing infrastructure; or emerging with large amounts of infrastructure build-up. The long lifespan of urban infrastructure locks in behaviour and committed emissions. Therefore, the sequencing of mitigation strategies is important for determining emissions savings in the short and long term. Hence, different types of cities will have different mitigation pathways, depending upon a city's urban form and state of that city's urban development and infrastructure; the policy packages and implementation plan that provide the highest mitigation potential for rapidly growing cities with new infrastructures will differ from those for established cities with existing infrastructure.

Figure 8.20: Urban growth typologies define the main patterns of urban development. Emerging urban areas are undergoing the buildup of new infrastructure. These are new urban areas that are budding out. Rapidly growing urban areas are undergoing significant changes in either outward and/or upward growth, accompanied by large-scale development of new urban infrastructure. Established urban areas are relatively stable with mature urban form and existing urban infrastructures. Each of these typologies represents different levels of economic development and state of urbanisation. Rapidly growing urban areas that are building up through vertical development are often those with higher levels of economic development. Rapidly growing urban areas that are building outward through horizontal expansion are found at lower levels of economic development and are land intensive. Like with urban form, different areas of a single city can undergo different growth typologies. Therefore a city will be comprised of multiple urban growth typologies. Source: synthesized from Mahtta et al. (2019) and Lall et al. (2021).

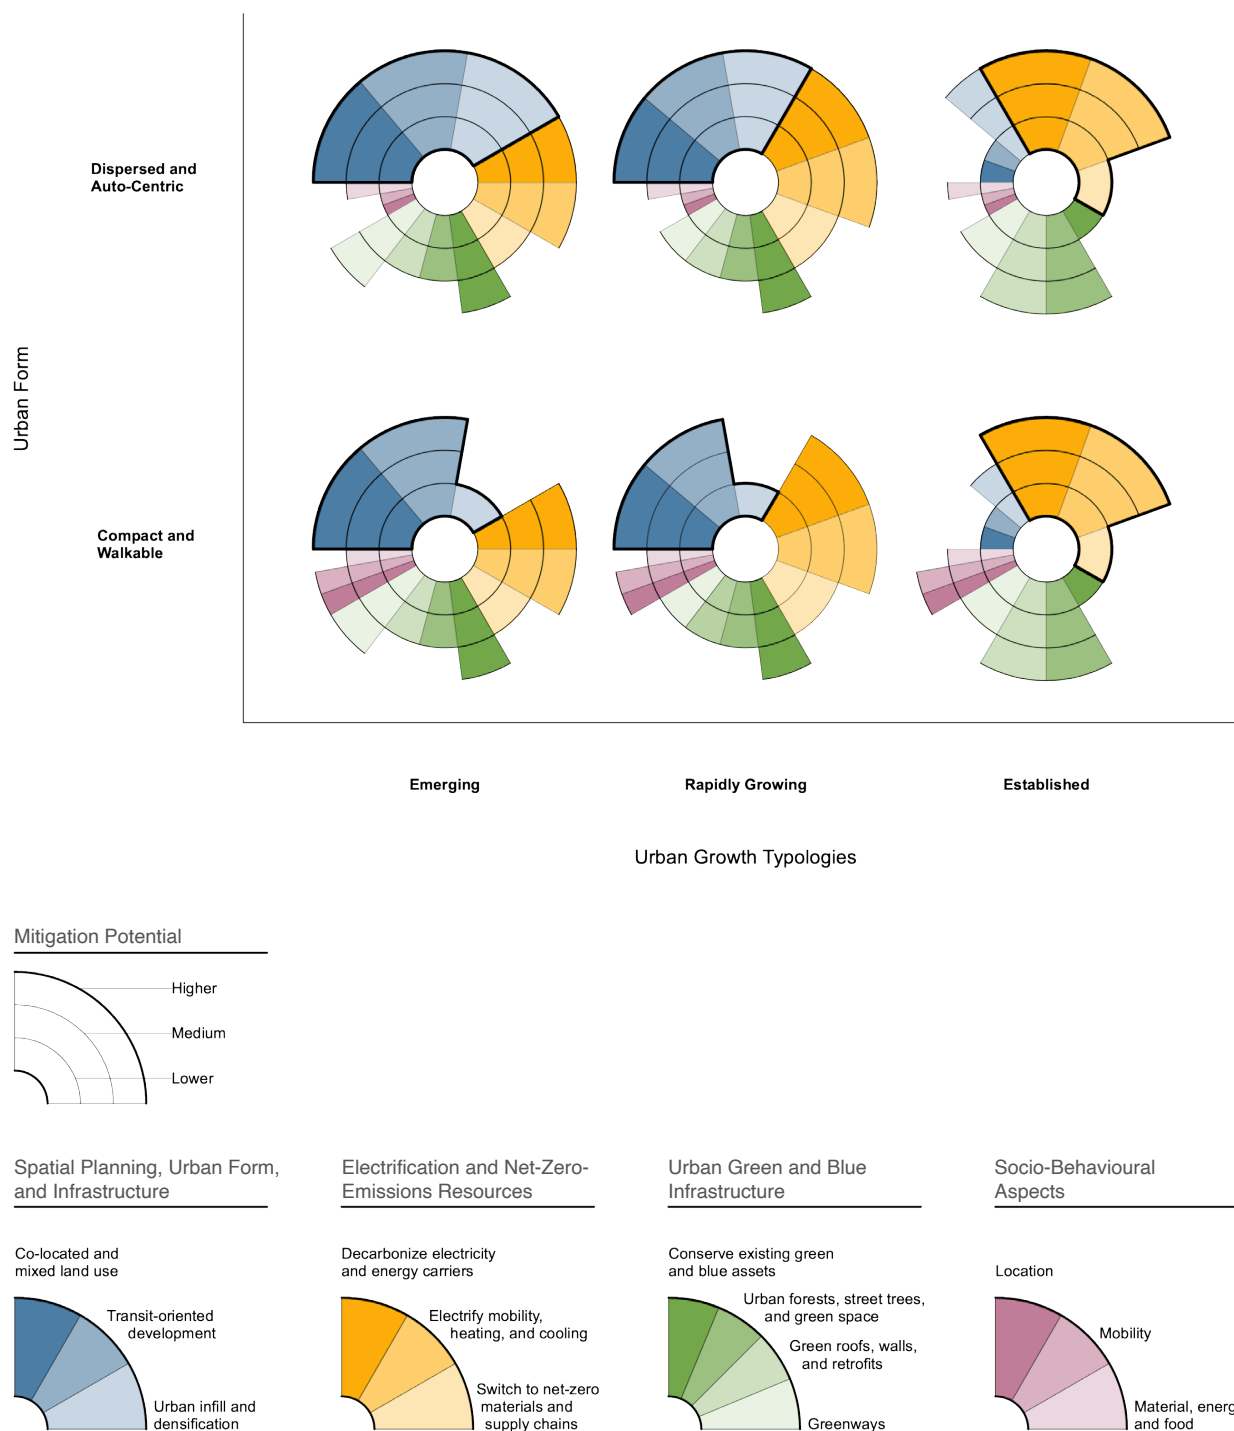

Figure 8.21: Priorities and potentials for packages of urban mitigation strategies across typologies of urban growth (Figure 8.20) and urban form (Figure 8.16). The horizontal axis represents urban growth typologies based on emerging, rapidly growing, and established urban areas. The vertical axis shows the continuum of urban form, from compact and walkable, to dispersed and auto-centric. Urban areas can first locate their relative positioning in this space according to their predominant style of urban growth and urban form. The urban mitigation options are bundled across four broad sectors of mitigation strategies: (i) spatial planning, urban form, and infrastructure (blue); (ii) electrification and net-zero-emissions resources (yellow); (iii) urban green and blue infrastructure (green); and (iv) socio-behavioural aspects (purple). The concentric circles indicate lower, medium, and higher mitigation potential considering the context of the urban area. For each city type (circular graphic) the illustrative urban mitigation strategy that is considered to provide the greatest cascading effects across mitigation opportunities is represented by a section that is larger relative to others; those strategy sections outlined in black are 'entry points' for sequencing of strategies. Within each of the larger strategy sections (i.e., spatial planning, urban green and blue infrastructure, etc.), the size of the sub-strategy sections are equal and do not suggest any priority or sequencing. The relative sizes of the strategies and extent of mitigation potential are illustrative and based on the authors' best understanding and assessment of the literature.

Mitigation options that involve spatial planning, urban form, and infrastructure – particularly co-located and mixed land use, as well as TOD – provide the greatest opportunities when urban areas are rapidly growing or emerging (Section 8.4.2). Established urban areas that are already compact and walkable have captured mitigation benefits from these illustrative strategies to various extents. Conversely, established urban areas that are dispersed and auto-centric have foregone these opportunities, with the exception of urban infill and densification that can be used to transform or continue to transform the existing urban form. Figure 8.21 underscores that urban mitigation options and illustrative strategies differ by urban growth typologies and urban form. Cities can identify their entry points for sequencing mitigation strategies.

The emissions reduction potential of urban mitigation options further varies based on governance contexts, institutional capacity, and economic structure, as well as human and physical geography. According to the development level, for instance, urban form can remain mostly planned or unplanned, taking place spontaneously, with persistent urban infrastructure gaps remaining (Lwasa et al. 2018; Kareem et al. 2020). Measures for closing the urban infrastructure gap while addressing ‘leapfrogging’ opportunities (see Glossary) for mitigation and providing co-benefits represent possibilities for shifting development paths for sustainability (Cross-Chapter Box 5 in Chapter 4).

8.6.1 Mitigation Opportunities for *Established Cities*

Established cities will achieve the largest GHG emissions savings by replacing, repurposing, or retrofitting the building stock, encouraging modal shift, electrifying the urban energy system, as well as infilling and densifying urban areas.

Shifting pathways to low-carbon development for established cities with existing infrastructures and locked-in behaviours and lifestyles is admittedly challenging. Urban infrastructures such as buildings, roads, and pipelines often have long lifetimes that lock-in emissions, as well as institutional and individual behaviour. Although the expected lifetime of buildings varies considerably by geography, design, and materials, typical lifespans are at minimum 30 years to more than 100 years.

Cities where urban infrastructure has already been built have opportunities to increase energy efficiency measures, prioritise compact and mixed-use neighbourhoods through urban regeneration, advance the urban energy system through electrification, undertake cross-sector synergies, integrate urban green and blue infrastructure, encourage behavioural and lifestyle change to reinforce climate mitigation, and put into place a wide range of enabling conditions as necessary to guide and coordinate actions in the urban system and its impacts in the global system. Retrofitting buildings with state of the art deep-energy retrofit measures could reduce emissions of the existing stock by about 30–60% (Creutzig et al. 2016a) and in some cases up to 80% (Ürge-Vorsatz et al. 2020) (Section 8.4.3).

Established cities that are compact and walkable are likely to have low per capita emissions, and thus can keep emissions low by focusing on electrification of all urban energy services and using urban green and blue infrastructure to sequester and store carbon while reducing urban heat stress. Illustrative mitigation strategies with the highest mitigation potential are decarbonising electricity and energy carriers while electrifying mobility, heating, and cooling (Table 8.3 and Figure 8.19). Within integrated strategies, the importance of urban forests, street trees, and green space as well as green roofs, walls, and retrofits, also have high mitigation potential (Section 8.4.4 and Figure 8.18).

Established cities that are dispersed and auto-centric are likely to have higher per capita emissions and thus can reduce emissions by focusing on creating modal shift and improving public transit systems in order to reduce urban transport emissions, as well as focusing on infilling and densifying. Only then can the urban form constraints on locational and mobility options be effective at reducing transport-based emissions. Among mitigation options based on spatial planning, urban form, and infrastructure, urban infill and densification has priority. For these cities, the use of urban green and blue infrastructure will be essential to offset residual emissions that cannot be reduced because their urban form is already established and difficult to change.

System-wide energy savings and emissions reductions for low-carbon urban development are widely recognised to require both behavioural and structural changes (Zhang and Li 2017). Synergies between social and ecological innovation can reinforce the sustainability of urban systems while decoupling energy usage and economic growth (Hu et al. 2018; Ma et al. 2018). In addition, an integrated sustainable development approach that enables cross-sector energy efficiency, sustainable transport, renewable energy, and local development in urban neighbourhoods can address issues of energy poverty (Pukšec et al. 2018). In this context, cross-sectoral, multi-scale, and public-private collaborative action is crucial to steer societies and cities closer to low-carbon futures (Hölscher et al. 2019). Such actions include guiding residential living area per capita, limiting private vehicle growth, expanding public transport, improving the efficiency of urban infrastructure, enhancing urban carbon pools, and minimising waste through sustainable, ideally circular, waste management (Lin et al. 2018). Through a coordinated approach, urban areas can be transformed into hubs for renewable and distributed energy, sustainable mobility, as well as inclusivity and health (Newman et al. 2017; Newman 2020).

Urban design for existing urban areas includes strategies for urban energy transitions for carbon neutrality based on renewable energy, district heating for the city centre and suburbs, as well as green and blue interfaces (Pulselli et al. 2021). Integrated modelling approaches for urban energy system planning, including land use and transport and flexible demand-side options, is increased when municipal actors are also recognised as energy planners (Yazdanie and Orehounig 2021) (Section 8.4.3). Enablers for action can include the co-design of infill residential development through an inclusive and participatory process with citizen utilities and disruptive innovation that can support net-zero-carbon power while contributing to 1.5°C pathways,

the SDGs, and affordable housing simultaneously (Wiktorowicz et al. 2018). Cross-sectoral strategies for established cities, including those taking place among 120 urban areas, also involve opportunities for sustainable development (Kilkis 2019, 2021b).

A shared understanding for urban transformation through a participatory approach can largely avoid maladaptation and contribute to equity (Moglia et al. 2018). Transformative urban futures that are radically different from the existing trajectories of urbanisation, including in developing countries, can remain within planetary boundaries while being inclusive of the urban poor (Friend et al. 2016). At the urban policy level, an analysis of 12,000 measures in urban-level monitoring emissions inventories based on the mode of governance further suggests that local authorities with lower population have primarily relied on municipal self-governing while local authorities with higher population more frequently adopted regulatory measures as well as financing and provision (Palermo et al. 2020b). Policies that relate to education and enabling were uniformly adopted regardless of population size (Palermo et al. 2020b). Multi-disciplinary teams, including urban planners, engineers, architects, and environmental institutions, can support local decision-making capacities, including for increasing energy efficiency and renewable energy considering building intensity and energy use (Mrówczyńska et al. 2021) (Section 8.5).

8.6.2 Mitigation Opportunities for Rapidly Growing Cities

Rapidly growing cities with new and actively developing infrastructures can avoid higher future emissions through using urban planning to co-locate jobs and housing, and achieve compact urban form; leapfrogging to low-carbon technologies; electrifying all urban services, including transportation, cooling, heating, cooking, recycling, water extraction, wastewater recycling, and so on; and preserving and managing existing green and blue assets.

Rapidly growing cities have significant opportunities for integrating climate mitigation response options in earlier stages of urban development, which can provide even greater opportunities for avoiding carbon lock-in and shifting pathways towards net-zero GHG emissions. In growing cities that are expected to experience large increases in population, a significant share of urban development remains to be planned and built. The ability to shift these investments towards low-carbon development earlier in the process represents an important opportunity for contributing to net-zero GHG emissions at the global scale. In particular, evidence suggests that investment in low-carbon development measures and reinvestment based on the returns of the measures, even without considering substantial co-benefits, can provide tipping points for climate mitigation action and reaching peak emissions at lower levels while decoupling emissions from economic growth, even in fast-growing megacity contexts with well-established infrastructure (Colenbrander et al. 2017).

At the same time, some of the rapidly growing cities in developing countries can have existing walkable urban design that can be maintained and supported with electrified urban rail plus renewable-energy-based solutions to avoid a shift to private vehicles (Sharma 2018). In addition, community-based distributed renewable electricity can be applicable for the regeneration of informal settlements rather than more expensive informal settlement clearance (Teferi and Newman 2018). Scalable options for decentralised energy, water, and wastewater systems, as well as spatial planning and urban agriculture and forestry, are applicable to urban settlements across multiple regions simultaneously (Lwasa 2017).

Rapidly urbanising areas can experience pressure for rapid growth in urban infrastructure to address growth in population. This challenge can be addressed with coordinated urban planning and support from enabling conditions for pursuing effective climate mitigation (Section 8.5 and Box 8.3). The ability to mobilise low-carbon development will also increase opportunities for capturing co-benefits for urban inhabitants while reducing embodied and operational emissions. Transforming urban growth, including its impacts on energy and materials, can be carefully addressed with the integration of cross-sectoral strategies and policies.

Rapidly growing cities have entry points into an integrated strategy based on spatial planning, urban form and infrastructure (Figure 8.21). For rapidly growing cities that may be co-located and walkable at present, remaining compact is better ensured when co-location and mixed land use, as well as TOD, continues to be prioritised (Section 8.4.2). Concurrently, ensuring that electricity and energy carriers are decarbonised while electrifying mobility, heating and cooling will support the mitigation potential of these cities. Along with an integrated approach across other illustrative strategies, switching to net-zero materials and supply chains holds importance (Section 8.4.3). Cities that remain compact and walkable can provide a greater array of locational and mobility options to the inhabitants that can be adopted for mitigation benefits. Rapidly growing cities that may currently be dispersed and auto-centric can capture high mitigation potential through urban infill and densification. Conserving existing green and blue assets, thereby protecting sources of carbon storage and sequestration, as well as biodiversity, have high potential for both kinds of existing urban form, especially when the rapid growth can be controlled.

8.6.3 Mitigation Opportunities for New and Emerging Cities

New and emerging cities have unparalleled potential to become low- or net-zero-emissions urban areas while achieving high quality of life by creating compact, co-located, and walkable urban areas with mixed land use and TOD, that also preserve existing green and blue assets.

The fundamental building blocks that make up the physical attributes of cities, such as the layout of streets, the size of the city blocks, the location of where people live versus where they work, can affect and lock in energy demand for long time periods (Seto et al. 2016)

(Section 8.4.1). A large share of urban infrastructures that will be in place by 2050 has yet to be constructed and their design and implementation will determine both future GHG emissions as well as the ability to meet mitigation goals (Creutzig et al. 2016a) (Figure 8.10 and Table 8.1). Thus, there are tremendous opportunities for new and emerging cities to be designed and constructed to be low-emissions while providing high quality of life for their populations.

The UN International Resource Panel (IRP) estimates that building future cities under conventional practices will require a more than doubling of material consumption, from 40 billion tonnes annually in 2010 to about 90 billion tonnes annually by 2050 (Swilling et al. 2018). Thus, the demand that new and emerging cities will place on natural resource use, materials, and emissions can be minimised and avoided only if urban settlements are planned and built much differently than today, including minimised impacts on land use based on compact urban form, lowered use of materials, and related cross-sector integration, including energy-driven urban design for sustainable urbanisation.

Minimising and avoiding raw material demands depends on alternative options while accommodating the urban population. In addition, operational emissions that can be committed by new urban infrastructure can range between 8.5 GtCO₂ and 14 GtCO₂ annually up to 2030 (Erickson and Tempest 2015). Buildings and road networks are strongly influenced by urban layouts, densities, and specific uses. Cities that are planned and built much differently than today through light-weighting, material substitution, resource efficiency, renewable energy, and compact urban form, have the potential to support more sustainable urbanisation and provide co-benefits for inhabitants (Figures 8.17 and 8.22).

In this context, illustrative mitigation strategies that can serve as a roadmap for emerging cities includes priorities for co-located and mixed land use, as well as TOD, within an integrated approach (Table 8.3 and Figure 8.19). This has cascading effects, including conserving existing green and blue assets (e.g., forests, grasslands, wetlands), many of which sequester and store carbon. Priorities for decarbonising electricity and energy carriers while electrifying mobility, heating, and cooling take place within the integrated approach (Section 8.4.3). Increasing greenways and permeable surfaces, especially from the design of emerging urban areas onward, can be pursued, also for adaptation co-benefits and linkages with the SDGs (Section 8.4.4 and Figure 8.18).

In low-energy-driven urban design, parameters are evaluated based on the energy performance of the urban area in the early design phase of future urban development (Shi et al. 2017b). Energy-driven urban design generates and optimises urban form according to the energy performance outcome (Shi et al. 2017b). Beyond the impact of urban form on building energy performance, the approach focuses on the interdependencies between urban form and energy infrastructure in urban energy systems. The process can provide opportunities for both passive options for energy-driven urban design, such as the use of solar gain for space heating, or of thermal mass to moderate indoor temperatures, as well as active options that involve the use of energy infrastructure and technologies while recognising interrelations of the system. Future urban settlements can also be planned and built with net-zero CO₂ or net-zero GHG emissions, as well as renewable energy targets, in mind. Energy master planning of urban areas that initially target net-zero operational GHG emissions can be supported with energy master planning from conceptual design to operation, including district-scale energy strategies (Charani Shandiz et al. 2021).

Figure 8.22: Raw material demands and committed emissions from building urban areas. The horizontal bars represent the projected increase in raw material demands in the year 2050. The vertical bars represent the possible range of committed CO₂ emissions in 2030. The importance of alternative solutions to reduce raw material demands and committed emissions while increasing co-benefits is represented by the circular process on the right-hand side. Ranges for committed emissions from new urban infrastructure are based on Erickson and Tempest (2015) SEI WP 11. Source: drawn using data from Erickson and Tempest (2015) and Swilling et al. (2018).

Integrated scenarios across sectors at the local level can decouple resource usage from economic growth (Hu et al. 2018) and enable 100% renewable energy scenarios (Zhao et al. 2017a; Bačekočić and Østergaard 2018). Relative decoupling is obtained (Kalmykova et al. 2015) with increasing evidence for turning points in per capita emissions, total emissions, or urban metabolism (Chen et al. 2018b; Shen et al. 2018). The importance of integrating energy and resource efficiency in sustainable and low-carbon city planning (Dienst et al. 2015), structural changes, as well as forms of disruptive social innovation, such as the 'sharing economy' (see Glossary), is also evident based on analyses for multiple cities, including those that can be used to lower the carbon footprints of urban areas relative to sub-urban areas (Chen et al. 2018a).

To minimise carbon footprints, new cities can utilise new intelligence functions as well as changes in energy sources and material processes. Core design strategies of a compact city can be facilitated by data-driven decision-making so that new urban intelligence functions are holistic and proactive rather than reactive (Bibri 2020). In mainstream practices, for example, many cities use environmental impact reviews to identify potentially negative consequences of individual development projects on environmental conditions on a piecemeal project basis.

New cities can utilise: system-wide analyses of construction materials, or renewable power sources, that minimise ecosystem disruption and energy use, through the use of lifecycle assessments for building types permitted in the new city (Ingrao et al. 2019); urban-scale metabolic impact assessments for neighbourhoods in the city (Pinho and Fernandes 2019); strategic environmental assessments (SEAs) that go beyond the individual project and assess plans for neighbourhoods (Noble and Nwanekezie 2017); or modelling of the type and location of building masses, tree canopies and parks, and temperature (surface conditions) and prevailing winds profiles to reduce the combined effects of climate change and UHI phenomena, thus minimising the need for air conditioning (Matsuo and Tanaka 2019).

Resource-efficient, compact, sustainable, and liveable urban areas can be enabled with an integrated approach across sectors, strategies, and innovations. From a geophysical perspective, the use of materials with lower lifecycle GHG impacts, including the use of timber in urban infrastructure and the selection of urban development plans with lower material and land demand can lower the emission impacts of existing and future cities (Müller et al. 2013; Carpio et al. 2016; Liu et al. 2016a; Ramage et al. 2017; Shi et al. 2017a; Stocchero et al. 2017; Bai et al. 2018; Zhan et al. 2018b; Swilling et al. 2018; Xu et al. 2018b; UNEP IRP 2020) (Figure 8.17). The capacity to implement relevant policy instruments in an integrated and coordinated manner within a policy mix while leveraging multi-level support as relevant can increase the enabling conditions for urban system transformation (Agyepong and Nhamo 2017; Roppongi et al. 2017).

The integration of urban land use and spatial planning, electrification of urban energy systems, renewable energy district heating and cooling networks, urban green and blue infrastructure, and circular

economy can also have positive impacts on improving air and environmental quality with related co-benefits for health and well-being (Diallo et al. 2016; Nieuwenhuijsen and Khreis 2016; Shakya 2016; Liu et al. 2017; Ramaswami et al. 2017a; Sun et al. 2018b; Tayarani et al. 2018; Park and Sener 2019; González-García et al. 2021). Low-carbon development options can be implemented in ways that reduce impacts on water use, including water use efficiency, demand management, and water recycling, while increasing water quality (Koop and van Leeuwen 2015; Topi et al. 2016; Drangert and Sharatchandra 2017; Lam et al. 2017, 2018; Vanham et al. 2017; Kim and Chen 2018). The ability to enhance biodiversity while addressing climate change depends on improving urban metabolism and biophilic urbanism towards urban areas that are able to regenerate natural capital (Thomson and Newman 2018; IPBES 2019b).

There are readily available solutions for low-carbon urban development that can be further supported by new and emerging ones, such as tools for optimising the impact of urban form on energy infrastructure (Hu et al. 2015; Shi et al. 2017b; Xue et al. 2017; Dobler et al. 2018; Egusquiza et al. 2018; Pedro et al. 2018; Soilán et al. 2018). The costs of low-carbon urban development are manageable, and enhanced with a portfolio approach for cost-effective, cost-neutral, and reinvestment options with evidence across different urban typologies (Colenbrander et al. 2015, 2017; Gouldson et al. 2015; Nieuwenhuijsen and Khreis 2016; Saujot and Lefèvre 2016; Sudmant et al. 2016; Brozynski and Leibowicz 2018).

Low-carbon urban development that triggers economic decoupling can have a positive impact on employment and local competitiveness (Kalmykova et al. 2015; Chen et al. 2018b; García-Gusano et al. 2018; Hu et al. 2018; Shen et al. 2018). In addition, sustainable urban transformation can be supported with participatory approaches that provide a shared understanding of future opportunities and challenges where public acceptance increases with citizen engagement and citizen empowerment as well as an awareness of co-benefits (Blanchet 2015; Bjørkelund et al. 2016; Flacke and de Boer 2017; Gao et al. 2017; Neuvonen and Ache 2017; Sharp and Salter 2017; Wiktorowicz et al. 2018; Fastenrath and Braun 2018; Gorissen et al. 2018; Herrmann et al. 2018; Moglia et al. 2018). Sustainable and low-carbon urban development that integrates issues of equity, inclusivity, and affordability, while safeguarding urban livelihoods, providing access to basic services, lowering energy bills, addressing energy poverty, and improving public health can also improve the distributional effects of existing and future urbanisation (Friend et al. 2016; Claude et al. 2017; Colenbrander et al. 2017; Ma et al. 2018; Mrówczyńska et al. 2018; Pukšec et al. 2018; Wiktorowicz et al. 2018) (Section 8.2).

Information and communications technologies can play an important role for integrating mitigation options at the urban systems level for achieving zero-carbon cities. Planning for decarbonisation at the urban systems level involves integrated considerations of the interaction among sectors, including synergies and trade-offs among households, businesses, transport, land use, and lifestyles. The utilisation of big data, artificial intelligence and internet of things (IoT) technologies can be used to plan, evaluate and integrate rapidly progressing transport and building technologies, such as

autonomous EVs, zero-energy buildings, and districts as an urban system, including energy-driven urban design (Creutzig et al. 2020; Yamagata et al. 2020). Community-level energy sharing systems will contribute to realising the decarbonisation potential of urban systems at community scale, including in smart cities (Section 4.2.5.9, Box 10.1, and Cross-Chapter Box 11 in Chapter 16).

8.7 Knowledge Gaps

While there is growing literature on urban NBS, which encompasses urban green and blue infrastructure in cities, there is still a knowledge gap regarding how these climate mitigation actions can be integrated in urban planning and design, as well as their mitigation potential, especially for cities that have yet to be built. In moving forward with the research agenda on cities and climate change science, transformation of urban systems will be critical; however, understanding this transformation and how best to assess mitigation action remain key knowledge gaps (Butcher-Gollach 2018; Pathak and Mahadevia 2018; Rigolon et al. 2018; Anguelovski et al. 2019; Buyana et al. 2019; Trundle 2020; Azunre et al. 2021).

There is a key knowledge gap in respect to the potential of the informal sector in developing country cities. Informality extends beyond illegality of economic activities to include housing, locally developed off-grid infrastructure, and alternative waste management strategies. Limited literature and understanding of the mitigation potential of enhanced informal sector is highlighted in the key research agenda on cities from the Cities and Climate Change Science Conference (Prieur-Richard et al. 2018).

City-level models and data for understanding of urban systems is another knowledge gap. With increased availability of open data systems, big data and computing capacities, there is an opportunity for analysis of urban systems (Frantzeskaki et al. 2019).

While there is much literature on urban climate governance, there is still limited understanding of the governance models and regimes that support multi-level decision-making for mitigation and climate action in general. Transformative climate action will require changing relationships between actors to utilise the knowledge from data and models and deepen understanding of the urban system to support decision-making.

8.7.1 COVID-19 and Cities

The COVID-19 pandemic has disrupted many aspects of urban life while raising questions about urban densities, transportation, public space, and other urban issues. The impact of COVID-19 on urban activity and urban GHG emissions may offer insights into urban emissions and their behavioural drivers and may include structural shifts in emissions that last into the future. The science is unclear as to the links between urban characteristics and COVID-19, and involves multiple aspects. For example, some research shows higher COVID-19 infection rates with city size (e.g., Dalziel et al. 2018; Stier et al. 2021), as well as challenges to epidemic preparedness due to high population

density and high volume of public transportation (Layne et al. 2020; Lee et al. 2020). Other research from 913 metropolitan areas shows that density is unrelated to COVID-19 infection rates and, in fact, has been inversely related to COVID-19 mortality rates when controlled for metropolitan population.

Densely populated counties are found to have significantly lower mortality rates, possibly due to such advantages as better health care systems, as well as greater adherence to social-distancing measures (Hamidi et al. 2020). Sustainable urbanisation and urban infrastructure that address the SDGs can also improve preparedness and resilience against future pandemics. For example, long-term exposure to air pollution has been found to exacerbate the impacts of COVID-19 infections (Wu et al. 2020b), while urban areas with cleaner air from clean energy and greenspace, can provide advantages.

Some studies indicate that socio-economic factors, such as poverty, racial and ethnic disparities, and crowding are more significant than density in COVID-19 spread and associated mortality rate (Borjas 2020; Maroko et al. 2020; Lamb et al. 2021). The evidence for the connection between household crowding and the risk of contagion from infectious diseases is also strong. A 2018 World Health Organization (WHO) systematic review of the effect of household crowding on health concluded that a majority of studies of the risk of non-tuberculosis infectious diseases, including flu-related illnesses, were associated with household crowding (Shannon et al. 2018).

Though preliminary, some studies suggest that urban areas saw larger overall declines in emissions because of lower commuter activity and associated emissions. For example, researchers have explored the COVID-19 impact in the cities of Los Angeles, Baltimore, Washington, DC, and San Francisco Bay Area in the United States. In the San Francisco region, a decline of 30% in anthropogenic CO₂ was observed, which was primarily due to changes in on-road traffic (Turner et al. 2020). Declines in the Washington, DC/Baltimore region and in the Los Angeles urban area were 33% and 34%, respectively, in the month of April 2020 compared to previous years (Yadav et al. 2021).

At the global scale COVID-related lockdown and travel restrictions reduced daily CO₂ emissions by –17% in early April 2020 compared to 2019 values (Le Quéré et al. 2020; Liu et al. 2020b), though subsequent studies have questioned the accuracy of the indirect proxy data used (Oda et al. 2021). Research at the national scale in the United States found that daily CO₂ emissions declined –15% during the late March to early June time period (Gillingham et al. 2020). Research in China estimated that the first quarter of 2020 saw an 11.5% decline in CO₂ emissions relative to 2019 (Zheng et al. 2020; Han et al. 2021). In Europe, estimates indicated a –12.5% decline in the first half of 2020 compared to 2019 (Andreoni 2021). Rebound to pre-COVID trajectories has been evidenced following the ease of travel restrictions (Le Quéré et al. 2021). It remains unclear to what extent COVID resulted in any structural change in the underlying drivers of urban emissions.

Changes in local air pollution emissions, particularly due to altered transportation patterns, have caused temporary air quality

improvements in many cities around the world (see critical review by Adam et al. 2021). Many outdoor air pollutants, such as particulates, nitrogen dioxide, carbon monoxide, and volatile organic compounds declined during national lockdowns. Levels of tropospheric ozone, however, remained constant or increased. A promising transformation that has been observed in many cities is an increase in the share of active travel modes such as cycling and walking (Sharifi and Khavarian-Garmsir 2020). While this may be temporary, other trends, such as increased rates of teleworking and/or increased reliance on smart solutions that allow remote provision of services provide an unprecedented opportunity to transform urban travel patterns (Belzunegui-Eraso and Erro-Garcés 2020; Sharifi and Khavarian-Garmsir 2020).

Related to the transport sector, the pandemic has resulted in concerns regarding the safety of public transport modes, which has resulted in significant reductions in public transport ridership in some cities (Bucsky 2020; de Haas et al. 2020) while providing opportunities for urban transitions in others (Newman AO 2020). Considering the significance of public transportation for achieving low-carbon and inclusive urban development, appropriate response measures could enhance health safety of public transport modes and regain public trust (Sharifi and Khavarian-Garmsir 2020). Similarly, there is a perceived correlation between the higher densities of urban living and the risk of increased virus transmission (Hamidi et al. 2020; Khavarian-Garmsir et al. 2021).

While city size could be a risk factor with higher transmission in larger cities (Hamidi et al. 2020; Stier et al. 2021), there is also evidence showing that density is not a major risk factor and indeed cities that are more compact have more capacity to respond to and control the pandemic (Hamidi et al. 2020). Considering the spatial pattern of density, even distribution of density can reduce the possibility of crowding that is found to contribute to the scale and length of virus outbreak in cities. Overall, more research is needed to better understand the impacts of density on outbreak dynamics and address public health concerns for resilient cities.

Cities could seize this opportunity to provide better infrastructure to further foster active transportation. This could, for example, involve measures, such as expanding cycling networks and restricting existing streets to make them more pedestrian- and cycling-friendly contributing to health and adaptation co-benefits, as discussed in Section 8.2 (Sharifi 2021). Strengthening the science–policy interface is another consideration that could support urban transformation (Cross-Chapter Box 1 in Chapter 1).

8.7.2 Future Urban Emissions Scenarios

The urban share of global emissions is significant and is expected to increase in the coming decades. This places emphasis on the need to expand development of urban emissions scenarios within climate mitigation scenarios (Gurney et al. 2021, 2022). The literature on globally comprehensive analysis of urban emissions within the existing IPCC scenario framework remains very limited, curtailing understanding of urban emissions tipping points, mitigation opportunities and overall climate policy complexity. A review of the applications of the SSP-RCP scenario framework also recommended downscaling global SSPs to improve the applicability of this framework to regional and local scales (O'Neill et al. 2020). This remains an urgent need and will require multidisciplinary research efforts, particularly as net-zero-emissions targets are emphasised.

8.7.3 Urban Emissions Data

Though there has been a rapid rise in quantification and analysis of urban emissions, gaps remain in comprehensive global coverage, particularly in the Global South, and reliance on standardised frameworks and systematic data are lacking (Gurney and Shepson 2021; Mueller et al. 2021). The development of protocols by (BSI 2013; Fong et al. 2014; ICLEI 2019b) that urban areas can use to organise emissions accounts has been an important step forward, but no single agreed-upon reporting framework exists (Lombardi et al. 2017; Chen et al. 2019b; Ramaswami et al. 2021). Additionally, there is no standardisation of emissions data and limited independent validation procedures (Gurney and Shepson 2021). This is partly driven by the recognition that urban emissions can be conceptualised using different frameworks, each of which has a different meaning for different urban communities (Section 8.1.6.2). Equally important is the recognition that acquisition and analysis of complex data used to populate urban GHG inventory protocols remains a barrier for local practitioners (Creutzig et al. 2019). The limited standardisation has also led to incomparability of the many individual or city cluster analyses that have been accomplished since AR5. Finally, comprehensive, global quantification of urban emissions remains incomplete in spite of recent efforts (Moran et al. 2018; Zheng et al. 2018; Harris et al. 2020; Jiang et al. 2020; Wei et al. 2021; Wiedmann et al. 2021).

Similarly, independent verification or evaluation of urban GHG emissions has seen a large number of research studies (e.g., Wu et al. 2016; Sargent et al. 2018; Whetstone 2018; Lauvaux et al. 2020). This has been driven by the recognition that self-reported approaches may not provide adequate accuracy to track emissions changes and provide confidence for mitigation investment (Gurney and Shepson 2021).

The most promising approach to independent verification of urban emissions has been the use of urban atmospheric monitoring (direct flux and/or concentration) as a means to assess and track urban GHG emissions (Davis et al. 2017). However, like the basic accounting approach itself, standardisation and practical deployment and scaling is an essential near-term need.

FAQ 8.1 | Why are urban areas important to global climate change mitigation?

Over half of the world's population currently resides in urban areas – a number forecasted to increase to nearly 70% by 2050. Urban areas also account for a growing proportion of national and global emissions, depending on emissions scope and geographic boundary. These trends are projected to grow in the coming decades; in 2100, some scenarios show the urban share of global emissions above 80%, with 63% being the minimum for any scenario (with the shares being in different contexts of emissions reduction or increase) (Sections 8.3.3 and 8.3.4). As such, urban climate change mitigation considers the majority of the world's population, as well as some of the key drivers of global emissions. In general, emissions scenarios with limited outward urban land expansion are also associated with a smaller rise in global temperature (Section 8.3.4).

The urban share of global emissions and its projected growth stem in part from urban carbon lock-in – that is, the path dependency and inertia of committed emissions through the long lifespan of urban layout, infrastructures, and behaviour. As such, urban mitigation efforts that address lock-in can significantly reduce emissions (Section 8.4.1). Electrification of urban energy systems, in tandem with implementing multiple urban-scale mitigation strategies, could reduce urban emissions by 90% by 2050 – thereby significantly reducing global emissions (Section 8.3.4). Urban areas can also act as points of intervention to amplify synergies and co-benefits for accomplishing the Sustainable Development Goals (Section 8.2).

FAQ 8.2 | What are the most impactful options cities can take to mitigate urban emissions, and how can these be best implemented?

The most impactful urban mitigation plans reduce urban GHG emissions by considering the long lifespan of urban layout and urban infrastructures (Sections 8.4.1 and 8.6). Chapter 8 identifies three overarching mitigation strategies with the largest potential to decrease current, and avoid future, urban emissions: (i) reducing or changing urban energy and material use towards more sustainable production and consumption across all sectors including through spatial planning and infrastructure that supports compact, walkable urban form (Section 8.4.2); (ii) decarbonise through electrification of the urban energy system, and switch to net-zero-emissions resources (i.e., low-carbon infrastructure) (Section 8.4.3); and (iii) enhance carbon sequestration through urban green and blue infrastructure (e.g., green roofs, urban forests and street trees), which can also offer multiple co-benefits like reducing ground temperatures and supporting public health and well-being (Section 8.4.4). Integrating these mitigation strategies across sectors, geographic scales, and levels of governance will yield the greatest emissions savings (Sections 8.4 and 8.5).

A city's layout, patterns, and spatial arrangements of land use, transportation systems, and built environment (urban form), as well as its state and form(s) of development (urban growth typology), can inform the most impactful emissions savings 'entry points' and priorities for urban mitigation strategies (Sections 8.4.2 and 8.6). For rapidly growing and emerging urban areas, there is the opportunity to avoid carbon lock-in by focusing on urban form that promotes low-carbon infrastructure and enables low-impact behaviour facilitated by co-located medium to high densities of jobs and housing, walkability, and transit-oriented development (Sections 8.6.2 and 8.6.3). For established cities, strategies include electrification of the grid and transport, and implementing energy efficiency across sectors (Section 8.6.1).

FAQ 8.3 | How do we estimate global emissions from cities, and how reliable are the estimates?

There are two different emissions estimation techniques applied, individually or in combination, to the four frameworks outlined in Section 8.1.6.2 to estimate urban GHG emissions: 'top-down' and 'bottom-up'. The top-down technique uses atmospheric GHG concentrations and atmospheric modelling to estimate direct (scope 1) emissions (see Glossary). The bottom-up technique estimates emissions using local activity data or direct measurements such as in smokestacks, traffic data, energy consumption information, and building use. Bottom-up techniques will often include indirect emissions (see Glossary) from purchased electricity (scope 2) and the urban supply chain (scope 3). Inclusion of supply-chain emissions often requires additional data such as consumer purchasing data and supply chain emission factors. Some researchers also take a hybrid approach combining top-down and bottom-up estimation techniques to quantify territorial emissions. Individual self-reported urban inventories from cities have shown chronic underestimation when compared to estimates using combined top-down/bottom-up atmospherically calibrated estimation techniques.

No approach has been systematically applied to all cities worldwide. Rather, they have been applied individually or in combination to subsets of global cities. Considerable uncertainty remains in estimating urban emissions. However, top-down approaches have somewhat more objective techniques for uncertainty estimation in comparison to bottom-up approaches. Furthermore, supply chain estimation typically has more uncertainty than direct or territorial emission frameworks.

8.SM.1 Supplementary Material to Section 8.2
on SDG Linkages 3

References 8

8.SM.2 Supplementary Material to Section 8.5
on the Feasibility Assessment 10

References 20

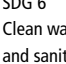

In Chapter 8, Figure 8.4 on co-benefits of urban mitigation actions in Section 8.2, and Figure 8.18 on the feasibility assessment based on the enablers and barriers of implementing mitigation options for urban systems in Section 8.5 refer to supplementary materials 8.SM.1 and 8.SM.2, respectively. These two materials for the SDG linkages and the feasibility assessment are contained in this contribution.

8.SM.1 Supplementary Material to Section 8.2 on SDG Linkages

Co-benefits and trade-offs in the scope of urban mitigation are focused in Section 8.2.1. Based on the urban mitigation options that are synthesised in Section 8.4, SDG linkages are further considered per urban mitigation option, including the integration of urban mitigation options through integrated approaches. The evaluations are based on the linkages with the SDGs considering synergies (+) and trade-offs (-). These linkages are context specific and the possible synergies and/or trade-offs with the SDGs will change

according to the specific urban area. Synergies and/or trade-offs may be more significant in certain contexts than others. **Table 8.SM.1** includes the evaluation of the SDG linkages of the mitigation options for urban systems and indicates the levels of confidence as high (H), medium (M) and low (L). **Table 8.SM.2** includes the references/line of sight for these SDG linkages with 64 references that involve the urban context and extends the mappings that are provided in Thacker et al. (2019) and Fuso Nerini et al. (2018) in addition to the synthesis that is provided in the main chapter text. The evaluations further support Chapter 17 on 'Accelerating the transition in the context of sustainable development'. Urban mitigation with a view of the SDGs can support shifting pathways of urbanisation towards sustainability (also see Cross-Chapter Box 5 on 'Shifting development pathways to increase sustainability and broaden mitigation options' in Chapter 4). Moreover, the multi-dimensional feasibility assessment of mitigation options for urban systems indicates that feasibility is malleable and can increase when more enablers come into play. Strengthened institutional capacity that supports scale and coordination can increase the synergies of the urban mitigation options with the SDGs.

Table 8.SM.1 | Evaluation of the SDG linkages of the mitigation options for urban systems.

Urban mitigation options/SDGs	Urban land use and spatial planning	Electrification of the urban energy system	District heating and cooling networks
SDGs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs
 SDG 1 End poverty	(+) Provides employment density and supports productivity (H) (+) Can reduce exposure and vulnerability to climate change given policy integration (H)	(+) Can address energy poverty that is linked to poverty; eradicating poverty is supported by access to modern energy services for all (M)	(+) Can address energy poverty that is linked to poverty; eradicating poverty is supported by access to modern energy services for all (M)
 SDG 2 Zero hunger	(+) Better spatial planning will reduce pressures on land-use change, including croplands (H) (-) Growth in urban extent can still reduce cropland if not sufficiently managed (H)	(+) Electrification can support welfare; electric stoves can support nutritional food intake (M) (-) Can have trade-offs if food systems are coupled with electricity and bioenergy (M)	(-) Can have trade-offs if food systems are coupled with bioenergy and heat (M)
 SDG 3 Good health and wellbeing	(+) Improves access to health infrastructure; improves air quality when coupled to shifting energy use, improves well-being with green and blue infrastructure (H)	(+) Improves air quality when coupled to shifting energy use as included in the option; avoids air pollution from energy and transport infrastructure; supports energy services for quality health services in hospitals (H)	(+) Improves air quality when coupled to shifting energy use as included in the option; supports energy services for quality health services in hospitals (M)
 SDG 4 Quality education	(+) Better spatial planning increases educational opportunities (M)	(+) Electrification and access to electricity supports quality education and educational attainment (H)	
 SDG 5 Gender equality	(+) Can increase equal opportunities and effective participation of women, including urban governance (M)	(+) Supports equal opportunities, also through electricity for internet access if previously lacking (M)	
 SDG 6 Clean water and sanitation	(+) Can improve water quality, water-use efficiency, water harvesting and wastewater treatment; efficient urbanization can also reduce GHG emissions from water infrastructure (H)	(+) Renewable-energy-powered water treatment facilities can support clean water and sanitation (M)	
 SDG 7 Affordable and clean energy	(+) Can reduce energy use and enable access to modern energy infrastructure while urban infrastructure for energy services varies (H)	(+) Supports renewable energy, energy efficiency and access to affordable, reliable and modern energy; renewable-energy generation technologies can enhance infrastructure resilience (H)	(+) Supports renewable energy, energy efficiency and access to affordable, reliable and modern energy (M)

Urban mitigation options/SDGs	Urban land use and spatial planning	Electrification of the urban energy system	District heating and cooling networks
SDGs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs
 SDG 8 Decent work and economic growth	(+) Provides employment density and supports productivity (H)	(+) Supports technological upgrading, innovation and decent job creation (H)	(+) Supports technological upgrading, innovation and decent job creation (M)
 SDG 9 Industry, innovation and infrastructure	(+) Sustainable urbanisation and settlement planning requires development across all infrastructure sectors (H)	(+) Supports sustainable and resilient infrastructure and can support domestic technology development; renewable-energy generation technologies can enhance infrastructure resilience (H)	(+) Is being used to support sustainable and resilient infrastructure, including adaptation and mitigation (M)
 SDG 10 Reduced inequalities	(+) Spatial inequalities within cities can be reduced; urban infrastructure gap between cities can be reduced (H) (-) Unintended gentrification and spatial inequalities are still possible (M)	(+) Supports equal opportunities, e.g., through internet access if previously lacking (H)	
 SDG 11 Sustainable cities and communities	(+) Supports capacity for participatory, integrated and sustainable human settlement planning (Target 11.3) and protecting the poor and vulnerable (Target 11.5) (H)	(+) Supports adequate, safe and affordable housing as well as safe, affordable, accessible and sustainable transport (Targets 11.1 and 11.2) (H)	(+) Supports capacity for participatory, integrated and sustainable human settlement planning (Target 11.3) (H)
 SDG 12 Responsible consumption and production	(+) Urbanisation with lower material demands will support responsible consumption and production (H) (-) Urban population growth contributes to increased demand for resources with differences in scenarios; increase in urban water demand can increase pressures on water scarcity; over-exploitation of groundwater needs to be avoided (M)	(+) Allows leapfrogging to more resource-efficient urban development (H) (-) Material demands of electrification technologies will increase; policies are important (M)	(+) Allows leapfrogging to more resource-efficient urban development (M)
 SDG 13 Climate action	(+) Contributes to both climate mitigation and adaptation given integration in urban planning (H)	(+) Energy infrastructure can also strengthen climate resilience and adaptive capacity if addressed together (M)	(+) Energy infrastructure can also strengthen climate resilience and adaptive capacity if addressed together (M)
 SDG 14 Life below water	(+) Can reduce growth in urban expansion that can help protect coastal and marine ecosystems (M) (-) Urban development can still impact coastal and marine ecosystems (M)	(+) Energy systems can be designed to minimise impacts on water ecosystems (M)	
 SDG 15 Life on land	(+) Can reduce growth in urban expansion that can help protect biodiversity on land and terrestrial and inland freshwaters (H) (-) Urban development can still impact biodiversity (M)	(+) Clean energy will reduce the impacts of climate change on biodiversity and terrestrial ecosystems (H) (-) Hydropower development and biofuel cultivation may impact ecosystems while there are multiple alternatives, e.g., use of degraded lands for solar energy farms (M)	(+) Clean energy will reduce the impacts of climate change on biodiversity and terrestrial ecosystems (H)
 SDG 16 Peace, justice and strong institutions	(+) Has synergies with responsive, inclusive and participatory decision-making at all levels, and transparent institutions (M)	(+) Improvement in governance through inclusive decision-making improves ability for energy systems to contribute to sustainable development (M)	(+) Improvement in governance through inclusive decision-making improves ability for energy systems to contribute to sustainable development (M)
 SDG 17 Partnerships for the goals			

Urban mitigation options/SDGs	Urban green and blue infrastructure	Waste prevention, minimisation and management	Integrating sectors, strategies and innovations
SDGs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs
 SDG 1 End poverty	(+) Can increase employment and food security, e.g., urban agriculture (H)	(+) Can reduce informality in the waste sector and support poverty alleviation (H)	(+) Increases employment density, reduces poverty and exposure and vulnerability to climate change (H)
 SDG 2 Zero hunger	(+) Can increase employment and food security, e.g., urban agriculture (M)	(+) Can support reducing food waste in municipalities and urban centres (M)	(+) Supports livelihoods, reduces pressures on croplands and consumption-related land-use impacts (H)
 SDG 3 Good health and well-being	(+) Better ecosystem services improve health and well-being, can improve air quality (H)	(+) Better waste management improves air quality (H) (–) Can depend on air pollution control techniques if waste incineration is involved (M)	(+) Improves access to health infrastructure; improves air quality when coupled to shifting energy use, improves well-being with green and blue infrastructure (H)
 SDG 4 Quality education	(+) Urban green and blue infrastructure can increase opportunities and sites for environmental education (M)		(+) Can increase education opportunities, access to electricity and environmental education (H)
 SDG 5 Gender equality			(+) Can increase equal opportunities and effective participation of women, including urban governance (M)
 SDG 6 Clean water and sanitation	(+) Also supports water-sensitive urban planning and protection of water-related ecosystems (H)	(+) Improved water and wastewater infrastructure will reduce water pollution (H)	(+) Can improve water quality, water-use efficiency, water harvesting and wastewater treatment; efficient urbanisation can also reduce GHG emissions from water infrastructure (H)
 SDG 7 Affordable and clean energy	(+) Produces a cooling effect, lowering energy use when in relative proximity (M)		(+) Supports renewable energy, energy efficiency and access to affordable, reliable and modern energy (H)
 SDG 8 Decent work and economic growth	(+) Can stimulate new green economies and green jobs (M)	(+) Can stimulate employment for value added products (M) (–) Transforming informality of waste recycling activities into programmes is important (M)	(+) Supports technological upgrading, innovation and decent job creation (H)
 SDG 9 Industry, innovation and infrastructure	(+) Supports sustainable and resilient infrastructure (H)	(+) Supports sustainable and resilient infrastructure (H)	(+) Supports sustainable and resilient infrastructure (H)
 SDG 10 Reduced inequalities	(+) Can support equity given policy design (M) (–) Can push out low-income residents from main city areas without inclusive policy design (M)		(+) Can reduce the urban infrastructure gap; sustainable urbanisation can support reducing inequality within and among cities; inclusivity of inhabitants in the informal sector is important (H)

Urban mitigation options/SDGs	Urban green and blue infrastructure	Waste prevention, minimisation and management	Integrating sectors, strategies and innovations
SDGs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs	Evaluation of synergies and trade-offs
 SDG 11 Sustainable cities and communities	(+) Supports air quality and universal access to safe, inclusive and accessible green and public spaces (Target 11.7) (H)	(+) Directly related to waste management; supports links between urban, peri-urban and rural areas (Target 11.a) (H)	(+) Supports integrated policies and plans for inclusion, resource efficiency, mitigation and adaptation (Target 11.b) (H)
 SDG 12 Responsible consumption and production	(+) Supports sustainable development and lifestyles also 'in harmony with nature' as emphasised (Target 12.8) (H)	(+) Reduces waste generation through prevention, reduction, recycling and reuse (Target 12.5) (H) (–) Waste segregation at source and waste processing facilities differs across context (H)	(+) Allows leapfrogging to more resource-efficient urban development (H)
 SDG 13 Climate action	(+) Contributes to both climate mitigation and adaptation given integration in urban planning (H)	(+) Reduces emissions through better management of urban waste in different contexts and is important for resilience, including coastal areas (M)	(+) Contributes to both climate mitigation and adaptation given integration in urban planning (H)
 SDG 14 Life below water	(+) Blue infrastructure can contribute to protecting coastal and marine ecosystems (H)	(+) Better waste management and wastewater treatment will protect coastal and marine ecosystems, reduce marine debris and nutrient pollution (H)	(+) Can reduce growth in urban expansion that can help protect coastal and marine ecosystems (M)
 SDG 15 Life on land	(+) Enhances biodiversity within urban areas and ecosystem services (H)	(+) Better waste management and wastewater treatment will protect terrestrial and inland freshwaters (H)	(+) Can reduce growth in urban expansion that can help protect biodiversity on land and terrestrial and inland freshwaters (H)
 SDG 16 Peace, justice and strong institutions	(+) Has synergies with responsive, inclusive and participatory decision-making at all levels and transparent institutions (M)	(+) Has synergies with responsive, inclusive and participatory decision-making at all levels and transparent institutions (M)	(+) Has synergies with responsive, inclusive and participatory decision-making at all levels and transparent institutions (M)
 SDG 17 Partnerships for the goals			(+) Partnerships support sustainable infrastructure for urban areas; supports policy coherence for sustainable development (Target 17.14) (H)

Table 8.SM.2. | References/line of sight for the SDG linkages of the mitigation options for urban systems.

Urban mitigation options/SDGs	Urban land use and spatial planning	Electrification of the urban energy system	District heating and cooling networks
SDGs	References/line of sight	References/line of sight	References/line of sight

8.SM.2 Supplementary Material to Section 8.5 on the Feasibility Assessment

This Supplementary Material to Chapter 8 provides an overview of the extent to which different factors affect the feasibility of mitigation options in urban systems that may differ across context, time and scale of implementation and the line of sight upon which the feasibility assessment in Figure 8.19 in Section 8.5 is based. The multi-dimensional feasibility assessment is based on 18 indicators in the 6 dimensions of geophysical, environmental-ecological, technological, economic, socio-cultural and institutional feasibility. An indicator in this assessment framework can pose positive and/or negative impacts as enablers or barriers of the mitigation option. Indicators that provide positive impacts as enablers (E) are marked in blue while those that can have negative impacts as barriers (B) are marked in orange in **Table 8.SM.3**. Levels of confidence (LoC) are evaluated as *low*, *medium* or *high* based on the robustness and agreement of the evidence and shaded in light to dark tones. Lines of sight that are used per indicator of the feasibility assessment are contained in **Table 8.SM.4**, including 414 references across urban mitigation options. Lines of sight utilise the systematic assessment of urban case studies considering 1373 scientific references during the timeframe of the AR6 cycle based on Lamb et al. (2019) and additional systematic searches according to the indicators of the feasibility assessment. The lines of sight further build upon the feasibility assessment for land use and urban planning that was initiated by SR1.5 (IPCC 2018). The feasibility assessment for integrating sectors, strategies and innovations is based on multiple urban mitigation options implemented concurrently, such as co-located densities and electrification of the urban energy system whenever relevant (Figure 8.21). The feasibility assessment method is explained in detail in Annex II.11 and Annex II.12.

Table 8.SM.3 | Feasibility assessment of mitigation options in urban systems.

Mitigation options	Urban land-use and spatial planning		Electrification of the urban energy system		District heating and cooling networks	
Dimensions/ indicators	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation
1. Geophysical						
Physical potential	(E) LoC = 3	Reduces pressures on land, e.g. a total of 125,000 km ² of land could be saved between the years 1970 and 2020 if population density remained the same as 1970 levels while cities have had different dynamics of stable, outward and/or upward growth	(E) LoC = 3	The realisation of the available physical potential depends on the ability to electrify the urban energy system while supporting flexibility and sector coupling options for deep decarbonisation	(E/B) LoC = 3	Depends on district heating and cooling demands in comparison to the spatial characteristics of urban areas, e.g., heat demand density is a function of both population density and heat demand per capita where physical suitability can be equally present in urban areas with high population density or high heat demand per capita
Geophysical resources	(E/B) LoC = 2	Depends on the ability of the mitigation option to limit demands on materials for urban construction needs, thereby avoiding and shifting pressures on geophysical resources, including scarce resources	(E/B) LoC = 2	Depends on the demands on geophysical resources in comparison to other energy technologies, recycling of relevant energy technologies and energy storage needs at suitable levels	(E/B) LoC = 2	Depends on optimization of the piping layout with metal use and the implementation of eco-design principles for resource efficiency
Land use	(E) LoC = 3	Land-use efficiency reduces pressures on growth in urban extent while urban land use changes according to the drivers in SSP scenarios. Scenarios that involve sustainability involve lower urban land use, e.g., 1.1 million km ² in 2100 in SSP1 versus 3.6 million km ² in SSP5	(E/B) LoC = 2	Depends on the energy supply to support electrification and the ability to use urban density to increase the penetration of renewable power and electric public transport, e.g., mixed-use neighbourhoods for grid balancing	(E) LoC = 3	Improves based on urban design parameters, including density, block area, and elongation with close impact of urban density on energy density. Walkable and higher density urban form can further enable its implementation
2. Environmental-ecological						

Levels of Confidence (LoC)	Low	Medium	High
Enablers (E)			
Barriers (B)			

Mitigation options	Urban land-use and spatial planning		Electrification of the urban energy system		District heating and cooling networks	
Dimensions/indicators	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation
Air pollution	(E/B) LoC = 3	Depends on the energy mix that is involved in the urban infrastructure (energy use in buildings, private vehicles and public transport) while energy use due to vehicle transport is reduced with walkable urban form	(E) LoC = 3	Level of improvement depends on the shift to non-polluting energy sources, e.g., shifting to 100% renewable energy can save about 408,270 lives per year due to better air quality in 74 metropolitan areas around the world, enabling its implementation	(E) LoC = 3	Level of improvement depends on the energy resource that is replaced and air quality regulations when applicable
Toxic waste, ecotoxicity, eutrophication	(E) LoC = 2	Better urban land-use and spatial planning will limit negative impacts depending on urban land use, urban surface (permeable versus impermeable), ability to limit urban stormwater runoff and discharge	(E) LoC = 2	Depends on the source of the electrification of urban energy systems while favourable. It is also possible to displace water and soil pollution from conventional fuels	(E) LoC = 2	The energy resource that is replaced can provide additional environmental benefits, e.g., replacing coal use improves air and water pollution
Water quantity and quality	(E) LoC = 2	Improves based on the urban water system (supply, purification, distribution, drainage, the magnitude, source and location of water supply), and the level of integration between urban land-use and water planning that requires both policy integration and innovation (<i>see last option on integrating sectors, strategies and innovations</i>)	(E) LoC = 2	Depends on the source of the electrification of urban energy systems while favourable. It is also possible to displace water and soil pollution from conventional fuels	(E) LoC = 2	Resource-efficient and strategic densification for 84 cities indicate lifecycle assessment benefits for water that can also increase when integrated with other options, e.g., urban metabolism
Biodiversity	(E/B) LoC = 3	Depends on the context, including the ability to limit urban growth, governance capacity, and integrating ecosystem service information into spatial planning. Land-use change for urban areas can threaten biodiversity	(E) LoC = 2	Deep decarbonisation pathways involve electrification, including urban vehicle kilometres and reduction in land use, including for urban areas. These pathways have a positive impact on biodiversity considering reduced land and climate impacts	(E) LoC = 2	Increases with the interaction of urban energy planning with urban land-use and spatial planning, e.g., limiting the growth in urban extent together with this option can avoid impacts on biodiversity

Levels of Confidence (LoC)	Low	Medium	High
Enablers (E)			
Barriers (B)			

Mitigation options	Urban land-use and spatial planning		Electrification of the urban energy system		District heating and cooling networks	
Dimensions/indicators	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation
3. Technological						
Simplicity	(E/B) LoC = 3	Urban land-use and spatial planning supports other mitigation options as a fundamental necessity for climate mitigation while complex in many ways. The geographical coverage of harmonised algorithms to monitor land-use change also remains one of the current gaps in knowledge	(E/B) LoC = 3	Simplicity varies according to the scale of electrification, energy system interactions and system integration to support flexibility in energy systems with high renewable energy penetration	(E/B) LoC = 3	Depends on economies of scope in urban areas with access to already existing excess heat, system integration, level of climate ambition for climate neutrality, urban infrastructure and support from geographic information systems (GIS) for planning district heating and cooling networks that also provide an entry point for decarbonising thermal needs
Technological scalability	(E/B) LoC = 3	Depends on the stage of urban development with more opportunities at earlier stages and/or differences in opportunities, e.g., strategic intensification. Scalability also depends on combining urban land-use and spatial planning practices with climate mitigation as well as sustainable development objectives	(E) LoC = 3	Holds advantages for rapid pace of decarbonisation despite carbon lock-in across urban typologies. Also depends on support from flexibility options, e.g., demand response, power-to-heat and electric mobility to increase the penetration of renewable energy in the urban system. The choice of options, e.g., electrified urban rail, can integrate with existing urban design based on walkable neighbourhoods in rapidly growing cities	(E) LoC = 3	Is technologically scalable in different regions that increases with the geographic heat/cold demand density of the urban area. There are relatively more opportunities with urban energy planning processes. District heating and/or cooling networks are able to also support flexibility in the energy system and act as low-cost storage options
Maturity and technology readiness	(E) LoC = 3	Is favourable, while further depending on the level of integration, e.g., energy-driven urban design for optimising the impact of urban form on energy infrastructure	(E) LoC = 3	Maturity is favourable, including demand response based on power-to-heat in support of electrification and other options that have technical feasibility for providing flexibility in the energy system, particularly based on municipal level demonstrations	(E/B) LoC = 3	Depends on the generation with a role for low-temperature, fourth-generation district heating and cooling networks in emerging and future energy networks with high renewable energy penetration
4. Economic						
Costs in 2030 and long term	(E) LoC = 3	Provides cost benefits that increase with characteristics of urban development. Beyond costs, limiting the growth in urban extent has multiple benefits for climate mitigation	(E) LoC = 3	Costs are favourable. Renewable electricity is also relevant for decarbonising the heating sector through power-to-heat that can be a cost-effective option, including large-scale heat pumps in district heating and cooling networks	(E) LoC = 3	Can already provide total annual cost savings over building-level solutions. Future improvements depend on system optimisation, the ability to integrate low-temperature renewable energy sources and excess electricity from renewables in upgrading existing or implementing new district heating and cooling networks, and modular approach across suitable urban areas
Employment effects and economic growth	(E) LoC = 3	The concentration of people and activity in walkable, higher density urban areas increases productivity based on proximity and efficiency while providing employment density. The ability to decouple urban economic growth from emissions and other parameters, e.g., vehicle kilometres travelled, can further increase sustainable growth	(E) LoC = 3	Is positive and increases with the ability to establish local jobs and use revenues locally. Access to renewable electricity reduces the operational GHG emissions of the local economy, thereby increasing competitiveness, while providing a net status of long-term, full-time jobs	(E) LoC = 3	Is positive and increases with the ability to stimulate a green economy, e.g., access to renewable-energy-based district heating and cooling networks reduces the operational GHG emissions of the local economy, increases competitiveness and supports jobs in design and implementation, equipment manufacturing, operation and maintenance

Levels of Confidence (LoC)	Low	Medium	High
Enablers (E)			
Barriers (B)			

Mitigation options	Urban land-use and spatial planning		Electrification of the urban energy system		District heating and cooling networks	
Dimensions/ indicators	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation
5. Socio-cultural						
Public acceptance	(E) LoC = 2	Increases with processes that are involved in the planning and implementation of the urban mitigation option, i.e., co-design	(E) LoC = 3	Depends on the provision of clean and affordable energy services through electrification of the urban energy system and socially-accepted potential for load shifting	(E/B) LoC =3	Depends on role in climate neutrality targets, co-benefits for air quality, addressing energy poverty, citizen and consumer ownership models, technology perception as well as public and consumer awareness
Effects on health and well-being	(E) LoC = 3	Increases with the quality of spatial planning to increase co-benefits for health and well-being, e.g., balancing urban green areas with density	(E) LoC = 3	Increases with the energy resource that is displaced through electrification of the urban energy system. Residential electricity access also provides a positive influence on health and well-being, as well as life expectancy	(E) LoC = 3	Provides improvement in both indoor and outdoor air quality, provision of thermal comfort, alleviation of the urban heat island effect, and improved safety with gas supply outside accommodation as an enabler of the mitigation option
Distributional effects	(E/B) LoC = 2	Depends on the policy tools that shape the impacts or benefits of urban densification on affordable housing while evidence for transit-induced gentrification is partial and inconclusive	(E) LoC = 3	Increases with the ability of addressing aspects of energy poverty as well as increasing energy access in informal settlements based on urban planning. Urbanisation is also a driver of access to electricity, which if combined with renewable energy, can further support sustainable development. Business models and nature of ownership can increase intra-generational equity while shifting to inter-generational equity	(E) LoC = 3	Increases based on the business model with local ownership of district heating and cooling networks having the most positive impact on local benefits. Also contributes to addressing energy poverty based on the provision of affordable energy for satisfying thermal comfort in urban areas
6. Institutional						
Political acceptance	(E/B) LoC = 2	Depends on context, increasing with the ability to integrate opportunities for climate mitigation with co-benefits for health and wellbeing	(E) LoC = 3	Depends on the coordination ability of local authorities and the local level renewable energy target setting and implementation with close to 1000 cities having adopted climate neutrality targets, including some that further extend into urban climate positive targets	(E/B) LoC =3	Depends on the ability to plan and implement structural policies for climate neutrality as well as the population size of municipalities
Institutional capacity and governance, cross-sectoral coordination	(E/B) LoC =3	Depends on the ability to implement integrated urban planning as well as relations between urban mobility, buildings, energy systems, water systems, ecosystem services, other urban sectors and climate adaptation	(E/B) LoC =3	Depends on policy coherence to avoid policy fragmentation and electrification at scale. High renewable energy targets, high climate ambition as well as high fuel and CO ₂ prices support the diffusion of related options	(E/B) LoC =3	Depends on coordination with urban planning, the scope of urban energy planning, forming of partnerships and local ownership
Legal and administrative feasibility	(E/B) LoC = 2	Depends on the capacity for implementing land-use zoning and regulations consistently with urban land-use and spatial planning	(E) LoC = 3	Enabled by the policy and financing instruments that are used to support and increase electrification of the urban energy system, including green bonds and green procurement strategies	(E/B) LoC =3	Depends on the ability to implement policy instruments to exploit and integrate local resources for supplying thermal energy cost-effectively to urban areas while implementing climate targets. Bottom-up and interactive regulatory frameworks based on multi-level policies are suggested for facilitating coordination among energy sectors as an enabler

Levels of Confidence (LoC)	Low	Medium	High
Enablers (E)			
Barriers (B)			

Mitigation options	Urban green and blue infrastructure		Waste prevention, minimisation and management		Integrating sectors, strategies and innovations	
Dimensions/indicators	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation
1. Geophysical						
Physical potential	(E) LoC = 3	Is favourable, increasing with the physical space that is available for urban green/blue space and infrastructure to an extent that will support climate mitigation strategies	(E) LoC = 3	Is favourable, also depending on alleviating resource usage and upstream emissions from urban settlements based on the mitigation option	(E) LoC = 3	The ability to reduce pressures on physical land resources for urban areas is a feasibility enabler
Geophysical resources	(E) LoC = 2	Urban green and blue infrastructure are based on ecomimicry and sustainability innovations and do not represent pressures on geophysical resource demands	(E) LoC = 3	Resource benefits increase with the scale of waste prevention, minimisation and material recovery, e.g., reducing demands for new virgin raw resources	(E/B) LoC = 2	Depends on lowering the material demands for urban development with opportunities for considering materials with lower GHG impacts and selection of urban development plans with lower material demands
Land use	(E) LoC = 3	Depends on the scope of green and blue infrastructure while restoration-based nature-based solutions can also restore degraded urban land area	(E) LoC = 3	Is favourable, also depending on reducing ecological footprint due to integrated waste management and possibly biochar to improve soil quality. Walkable urban form can also reduce distances for waste collection	(E) LoC = 3	Increases with the role of urban land-use and spatial planning in the low-carbon development (see <i>first mitigation option on urban land-use and spatial planning</i>) and the relevance of brownfield urban development for the project
2. Environmental-ecological						
Air pollution	(E) LoC = 3	The indicator is an enabler while the highest benefits depend on the design of urban ecological infrastructure and related parameters that influence better air quality, including leaf area index, foliage density and the impact on reducing urban energy usage	(E) LoC = 3	Better waste management enables better air quality, further depending on the adopted waste hierarchy principles and the energy use of facilities for material and/or energy recovery in the urban vicinity, if any	(E) LoC = 3	Integrating across urban land-use and spatial planning, electrification of urban energy systems, district heating and cooling networks, urban green and blue infrastructure and waste management has positive impacts on improving air quality
Toxic waste, ecotoxicity, eutrophication	(E) LoC = 3	Urban green and blue infrastructure can be used for also remediating brownfield sites, e.g., phytoremediation and bioremediation, and limiting urban runoff	(E) LoC = 3	Is favourable, also considering the avoided environmental burden of local strategies for waste and wastewater management and avoided resource use	(E) LoC = 2	Level of improvement depends on the demands of low-carbon development on materials and urban metabolism performance
Water quantity and quality	(E) LoC = 3	Is an enabler based on the ability to reduce water runoff, increase permeable surfaces and increase the quality of waterways and wetlands	(E) LoC = 3	Increases with the ability of integrated waste management to avoid environmental contamination, including micropollutants, groundwater and marine pollution, and stringency of municipal wastewater treatment systems	(E) LoC = 3	Level of improvement depends on the interaction and inclusion of low-carbon development options that reduce impacts on water use and increase quality, including water-use efficiency, demand management and recycling
Biodiversity	(E) LoC = 2	Benefits for biodiversity increase depending on the location, ecosystem and context of intervention as well as connectivity of natural habitats	(E) LoC = 2	Level of improvement depends on avoiding waste to landfill and landfill leachate as well as activities for land reclamation for biodiversity preservation	(E) LoC = 2	Level of improvement depends on urban metabolism and biophilic urbanism towards urban areas that regenerate natural capital

Levels of Confidence (LoC)	Low	Medium	High
Enablers (E)			
Barriers (B)			

Mitigation options	Urban green and blue infrastructure		Waste prevention, minimisation and management		Integrating sectors, strategies and innovations	
Dimensions/ indicators	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation	Feasibility barriers or enablers (LoC)	Role of context, time and scale of implementation
3. Technological						
Simplicity	(E) LoC = 3	Is favourable and increases with the ability to harness local resources and available technologies in multi-actor and cross-scalar processes	(E/B) LoC = 3	Depends on the context of implementing the waste hierarchy from prevention onward and the effectiveness of practices for waste separation at source	(E/B) LoC = 3	Depends on the ability to initiate and learn from experimentation and the ability to support GHG emission reductions based on both structural, behavioural and lifestyle changes
Technological scalability	(E/B) LoC = 3	Depends on the ability to up-scale interventions, including for urban regeneration and restoration, and the utilisation of available urban areas for multifunctional, place- and location-based ecological solutions	(E/B) LoC = 3	Depends on the waste management system as well as the stage of urban development, including material use and waste from urban construction	(E/B) LoC = 3	Depends on the mitigation options integrated, the stage of urban development and typology of the urban area with certain contexts providing additional opportunities over others
Maturity and technology readiness	(E) LoC = 3	Maturity is favourable while further depending on the ability to up-scale interventions and the role of nature-based solutions in urban sustainability, resilience and transformations	(E) LoC = 3	Maturity is favourable that further depends on the choices for waste management. There are also opportunities for reducing the embodied energy that is used during material recovery	(E/B) LoC = 2	Multiple technologies are available for integration while further depending on context and the level of integration, e.g., energy-driven urban design for optimising the impact of urban form on energy infrastructure
4. Economic						
Costs in 2030 and long term	(E) LoC = 3	The benefit-to-cost ratio is already favourable based on monetary costs excluding co-benefits while the exact values depend on context and scale	(E) LoC = 3	Is favourable with changes according to the choice of technology, strategy and awareness of system users that can represent time-dependent costs and revenue changes	(E) LoC = 2	Provides cost benefits that increase with a portfolio approach for cost-effective, cost-neutral and re-investment options with evidence across different urban typologies as well as cost reduction options with urban form
Employment effects and economic growth	(E/B) LoC = 2	Depends on the upscaling of interventions to support local employment opportunities and sustainable growth, including employment for urban forestry	(E/B) LoC = 2	Depends on labour efficiency, ability to stimulate employment for value added products through circular economy and innovation activities with an estimated 45 million jobs in the waste management sector by 2030	(E) LoC = 3	Increases based on the speed that the mitigation option triggers economic decoupling with a positive impact on employment and local competitiveness
5. Socio-cultural						
Public acceptance	(E) LoC = 3	Public acceptance is commonly high and represents a positive lock-in with awareness and recreational use also given that potential concerns for green gentrification are addressed	(E) LoC = 3	Is favourable and increases with reduced system costs for citizens, greater awareness of primary waste separation and possible positive behavioural spillover across environmental policies	(E/B) LoC = 3	Contexts that involve a participatory approach towards urban transformation with a shared understanding of future opportunities and challenges are enablers. Public acceptance increases with citizen engagement and citizen empowerment as well as an awareness of the co-benefits
Effects on health and well-being	(E) LoC = 3	Urban green/blue infrastructure can provide reductions in the urban heat island effect, provide cleaner air as well as cardiovascular and mental health benefits that are related to availability and accessibility	(E) LoC = 3	Contributes to health and well-being through liveable cities, reducing human toxicity, particulate matter, photochemical oxidant and similar with possibilities of increasing the nutrition status of urban diets also considering food systems with less waste, less water, GHG emissions and land impacts	(E) LoC = 3	The scope of low-carbon urban development measures provides significant potential for co-benefits for public health and well-being

Levels of Confidence (LoC)	Low	Medium	High
Enablers (E)			
Barriers (B)			

Mitigation options	Urban green and blue infrastructure		Waste prevention, minimisation and management		Integrating sectors, strategies and innovations

Distributional effects	(E/B) LoC = 2	Depends on the availability (percentage of total area), accessibility (proportion of the urban population living within an accessible distance) of urban green areas and public versus private ownership. Distributional effects for urban green and blue infrastructure are important and may or may not represent inequalities that depends on inclusive policy design and empowerment	(E/B) LoC = 2	Depends on the sharing of costs and benefits and the ability to transform informality of waste recycling activities into programmes	(E) LoC = 3	Level of improvement depends on integrating issues of equity, inclusivity and affordability, safeguarding urban livelihoods, access to basic services, lowering energy bills, addressing energy poverty, and improving public health
6. Institutional						
Political acceptance	(E) LoC = 3	Political acceptance is commonly high with potential additional support from collaborative planning, co-creating solutions and mandate for urban greening in development	(E) LoC = 3	Efficient waste management infrastructure is the most widely adopted strategy, including among 210 circular economy strategies in urban areas	(E/B) LoC = 2	Depends on the GHG reduction or climate neutrality target that is set, as well as support from participatory processes
Institutional capacity and governance, cross-sectoral coordination	(E/B) LoC = 3	Depends on transdisciplinary coordination for urban ecological infrastructure that encompasses terrestrial and/or aquatic ecosystems, as well as institutional and community capacity for holistic design that is better connected with the ecological constraints of Earth systems	(E/B) LoC = 3	Depends on the organisational structure for promoting integrated waste management and capabilities related to programme administration	(E/B) LoC = 3	Depends on the ability to form partnerships to overcome barriers, including technology development, rule-setting and demonstration, capacity to manage transitions, establishing integrated departments and funding schemes for low-carbon urban development, implementing system innovations and aligning system actors, engaging in policy learning among cities and implementing supportive policy mixes
Legal and administrative feasibility	(E) LoC = 3	Favourable while further depending on the governance content as well as new targets for restoring degraded ecosystems	(E/B) LoC = 3	Depends on local legislation and policies, choices within municipal waste management strategies to reduce investment costs, and compliance with targets for circular economy	(E/B) LoC = 3	Depends on the capacity to implement relevant policy instruments in an integrated way and leverage multi-level policies as relevant
