Foreword and Preface

Foreword

Climate Change 2022: Mitigation of Climate Change is the third part of the Sixth Assessment Report (AR6) of the Intergovernmental Panel on Climate Change (IPCC) and was prepared by its Working Group III. The volume provides an updated global assessment of current and projected emissions from all sources and sectors, mitigation options that reduce emissions or remove greenhouse gases from the atmosphere, and progress towards meeting climate ambitions. It assesses what is required to achieve net zero emissions as pledged by many countries.

This report shows that greenhouse gas emissions over the last decade are at the highest levels in human history. It shows that urgent action is needed. Unless there are immediate and deep emissions reductions across all sectors, limiting global warming to 1.5°C will be beyond reach. Global greenhouse gas emissions implied by Nationally Determined Contributions announced prior to COP26 make it likely that warming will exceed 1.5°C and will also make it harder to limit warming to below 2°C.

But there are positive signs and increased evidence of climate action. Options are available now in every sector that can at least halve emissions by 2030. Some countries have already achieved a steady decrease in emissions consistent with limiting warming to 2°C. Costs for some forms of renewable energy have fallen, use of renewables continues to rise and, in some countries and regions, electricity systems are already predominantly powered by renewables.

This IPCC report highlights for the first time the social and demand-side aspects of climate mitigation. As long as the necessary policies, infrastructure and technologies are in place, changes to lifestyles and behaviour have the potential for large reductions in global greenhouse gas emissions and, at the same time, lead to improved wellbeing.

The report calls attention to the deep links between climate mitigation and sustainable development. It draws attention to the way that climate action is intimately connected to addressing the nature crisis. Attention to equity and just transitions can support deeper ambition for accelerated climate action.

The findings in this report have considerably enhanced our understanding of available mitigation pathways. The timing of this report is critical. It provides crucial information that informs the first Global Stocktake under the Paris Agreement. It demands the urgent attention of policymakers and the general public.

Petteri Taalas
Secretary-General
World Meteorological Organization

As an intergovernmental body jointly established in 1988 by the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP), the IPCC has successfully provided policymakers with the most authoritative and objective scientific and technical assessments, which are policy relevant without being policy prescriptive. Beginning in 1990, this series of IPCC Assessment Reports, Special Reports, Technical Papers, Methodology Reports and other products have become standard works of reference.

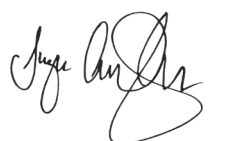

This Working Group III assessment was made possible thanks to the commitment and dedication of many hundreds of experts, representing a wide range of regions and scientific disciplines. WMO and UNEP are proud that so many of the experts belong to their communities and networks.

We express our deep gratitude to all authors, review editors and expert reviewers for devoting their knowledge, expertise and time. We note the particular challenges presented by the COVID-19 pandemic and the burdens placed on experts. We would like to thank the staff of the Working Group III Technical Support Unit and the IPCC Secretariat for their dedication.

We are also thankful to the governments that supported their scientists' participation in developing this report and that contributed to the IPCC Trust Fund to provide for the essential participation of experts from developing countries and countries with economies in transition.

We would like to express our appreciation to the government of Ethiopia for hosting the scoping meeting for the IPCC's Sixth Assessment Report, to the governments of the United Kingdom of Great Britain and Northern Ireland, India, Ecuador and Italy for hosting drafting sessions for the Working Group III contribution. The latter two meetings were held in a virtual format due to the COVID-19 pandemic. We also express our thanks to the government of the United Kingdom for hosting the Fourteenth Session of Working Group III for approval of the Working Group III Report. The generous financial support by the government of the United Kingdom, and the hosting of the Working Group III Technical Support Unit by Imperial College London (United Kingdom) and Ahmedabad University (India), is gratefully acknowledged.

We would particularly like to thank Dr. Hoesung Lee, Chairman of the IPCC, for his direction and guidance of the IPCC and we express our deep gratitude to Professor Priyadarshi R. Shukla and Professor Jim Skea, the Co-Chairs of Working Group III, for their tireless leadership throughout the development and production of this report.

Inger Andersen
Executive Director
United Nations Environment Programme

Preface

The Working Group III (WG III) contribution to the Sixth Assessment Report (AR6) of the Intergovernmental Panel on Climate Change (IPCC) provides a comprehensive and transparent assessment of the scientific literature on climate change mitigation. It builds upon the WG III contribution to the IPCC's Fifth Assessment Report (AR5) in 2014, the WG I and WG II contributions to the AR6, and the three AR6 Special Reports: *Global Warming of 1.5°C*; *Climate Change and Land*; and *The Ocean and Cryosphere in a Changing Climate*.

The report assesses progress in climate change mitigation and options for reducing emissions and enhancing sinks. It evaluates the societal implications of mitigation actions, without recommending any specific options.

Scope of the Report

The scoping of the WG III contribution to AR6 was driven by three guiding principles: to achieve a better synthesis between higher-level whole system and grounded bottom-up insights into technologies and other approaches for reducing emissions; to make wider use of social science disciplines, especially for gaining insight into issues related to lifestyle, behaviour, consumption and socio-technical transitions; and to link climate change mitigation better to other agreed policy goals both nationally and internationally.

The core of the report remains, as in AR5, a set of chapters devoted to different sectors, broadly aligned with the categorisation used in the IPCC Guidelines for National Greenhouse Gas Inventories. These chapters cover emission trends and drivers, mitigation costs and potentials, regional specificities, and sector specific barriers, policies, financing and enabling conditions. A systems level perspective was followed where appropriate. A cross-sectoral perspectives chapter integrates findings from the sectoral chapters and assesses approaches falling outside the scope of individual sectors.

As in the AR5, there is a chapter on recent trends and drivers, with the scope expanded to cover historic emissions and recent policy developments. Following the pattern established in the WG III AR5 report, and the Special Report on Global Warming of 1.5°C, this report assesses published emission scenarios with a 21st century perspective. Modelled emission scenarios are categorised according to climate outcomes, allowing a handshake with the WG I assessment. To meet the goal of linking top-down and bottom-up insights, the report includes an additional pathways chapter that provides a mid-century perspective, focussing on national and regional scales and the alignment between development pathways and mitigation actions.

As in the AR5, this report addresses mitigation enablers such as international cooperation, finance and investment, and policies and institutions, with a greater emphasis placed on the role of institutions than in the AR5. A new chapter is dedicated to the assessment of innovation systems, technology development and technology

transfer. A further novelty is a chapter that assesses the literature on human behaviour, lifestyle and culture, and its implications for mitigation action. This chapter touches on patterns of development and human well-being, and circular and sharing economy concepts. It brings a wide range of disciplines, notably from the social sciences, within the scope of the WG III assessment.

Linkages with development and specifically the Sustainable Development Goals (SDGs) permeate the WG III report. This framing is set up in Chapter 1, and the threads are drawn together in the final chapter where linkages between mitigation and the SDGs are systematically assessed.

The AR6 has benefited from close and unprecedented collaboration between the three IPCC WGs: with WG I on scenarios and with WG II on urban systems, land use and development pathways. This collaboration is manifested in a number of Cross-Working Group boxes covering topics such as the economic benefits from avoided impacts along mitigation pathways, climate change and urban areas, mitigation and adaptation through the bioeconomy, and solar radiation modification.

Structure of the Report

This report consists of a Summary for Policymakers, a Technical Summary, 17 Chapters, six Annexes, and Index, as well as online Supplementary Material to chapters.

Chapters 1 (Introduction and framing) and 17 (Accelerating the transition in the context of sustainable development), the first and final chapters of the report, set climate change mitigation in the context of sustainable development. Chapter 1 sets out the evolving policy landscape for climate mitigation, provides the reader with the framing of, and context for, the report, and highlights key concepts. Chapter 17 adopts an integrative perspective on sustainable development and climate change responses, identifying synergies and trade-offs, and explores joint responses to climate change and sustainable development challenges.

Chapters 2–4 take a high-level view of trends and future pathways using three different time frames. Chapter 2 (Emissions trends and drivers) covers historic and current emission trends and socio-economic and demographic drivers of emissions. It also maps developments in technologies and policies since the AR5. Chapter 3 (Mitigation pathways compatible with long-term goals) assesses modelled emission pathways compatible with the Paris Agreement and higher warming levels. It addresses socio-cultural-techno-economic assumptions, technological and behavioural aspects of mitigation pathways, and links to adaptation and sustainable development. Chapter 4 (Mitigation and development pathways in the near- to mid-term) takes a mid-century perspective, considering national, regional and international scales and the implications

of mitigation for national development objectives including employment, competitiveness, poverty eradication and the SDGs. Annex III (Scenarios and modelling methods) provides methodological background to Chapters 3 and 4.

Chapter 5 (Demand, services and social aspects of mitigation), a new chapter in AR6, explores how mitigation interacts with meeting human needs and access to services. It explores, *inter alia*: sustainable production and consumption; patterns of development and indicators of wellbeing; the role of culture, social norms, practices and behaviour changes; the sharing economy and circular economy; and policies facilitating behavioural and lifestyle change.

Chapters 6–12 (Energy systems; Agriculture, Forestry, and Other Land Uses (AFOLU); Urban systems and other settlements; Buildings; Transport; Industry; Cross-sectoral perspectives) assess the potential for emissions reductions in specific systems and sectors, taking into account trends in emissions and their key drivers, global and regional costs and potentials, links to climate adaptation and associated risks and co-benefits, and sector specific barriers, policies, financing and enabling conditions. Specificities include fugitive emissions and carbon capture and storage (Energy), provision of food, feed, fibre, wood, biomass for energy and other ecosystem services (AFOLU), demographic changes and urban form (Urban systems and other settlements), mitigation strategies including efficiency, sufficiency and renewables (Buildings), access to mobility (Transport), and resource efficiency (Industry). Chapter 12 (Cross-sectoral perspectives) synthesises costs and potentials, and co-benefits and trade-offs, across sectors; it also addresses cross-cutting approaches such as carbon dioxide removal and mitigation opportunities in the food system.

Chapters 13–16 address enabling conditions for mitigation action. Chapter 13 (National and sub-national policies and institutions) provides insights from national and subnational plans and strategies, including trends in legislation and institutions. Chapter 14 (International cooperation) assesses international cooperation and institutions, including linkages with non-climate organisations and processes, international sectoral agreements, and institutions for finance and investment and capacity building. Chapter 15 (Investment and finance) assesses scenarios of, and needs for, mitigation investment and financial flows, and the means of mobilising climate finance at the national and sub-national levels. Chapter 16 (Innovation, technology development and transfer) examines the role of innovation, technology development, diffusion and transfer in contributing to sustainable development and the aims of the Paris Agreement. It addresses specific challenges in emerging economies and least developed countries.

The Assessment Process

This WG III contribution to the AR6 has been prepared in accordance with IPCC rules and procedures. A scoping meeting was held in May 2017 and the outlines for the contributions of the three WGs were approved at the 46th Session of the Panel in September 2017.

Governments and IPCC observer organisations nominated experts for the author teams. The team of 199 Coordinating Lead Authors and Lead Authors, plus 38 Review Editors, selected by the WG III Bureau, was accepted at the 55th Session of the IPCC Bureau in January 2018. More than 350 Contributing Authors provided text for the author teams.

Drafts were subject to two rounds of formal review and revision followed by a final round of government comments on the Summary for Policymakers. More than 59,000 written comments were submitted by more than 1,600 expert reviewers and 42 governments. For each chapter, the review process was monitored by Review Editors to ensure that all comments received appropriate consideration.

During the review periods and in the run-up to the approval session, webinars were held with governments and two of the UNFCCC non-governmental organisation (NGO) constituencies, the Business and Industry NGOs (BINGOs), and the Environmental NGOs (ENGOS). These informal webinars offered an opportunity for authors to present draft material to IPCC audiences and to receive additional feedback.

The Report was accepted by the Panel at its 56th Session. The Summary for Policymakers was approved line-by-line and the underlying chapters were accepted at the 14th Session of IPCC WG III from 21 March – 4 April 2022, hosted virtually by the United Kingdom of Great Britain and Northern Ireland (UK).

Acknowledgements

The report was made possible thanks to the expertise, hard work and commitment to excellence shown by Coordinating Lead Authors and Lead Authors, with inputs from many Contributing Authors. Their efforts and stamina are particularly commendable given the additional demands and stresses imposed by virtual working as a consequence of the COVID pandemic.

We gratefully acknowledge the support of the Chapter Scientists, who worked tirelessly alongside the authors to deliver their chapters to the highest possible standards. Their time, dedication and hard work is greatly appreciated.

We would like to express our appreciation to the Government and Expert Reviewers for the time and energy they invested to provide constructive and useful comments on the draft reports. Our Review Editors were also critical in the AR6 process, helping author teams to process comments, and assuring an objective discussion of relevant issues.

We wish to thank the governments and other institutions for generous support which enabled the authors, Review Editors and Government and Expert Reviewers to participate.

We would like to thank the Vice-Chairs of the WG III Bureau, who provided invaluable scientific input and thoughtful advice throughout the AR6 process: Amjad Abdulla, Carlo Carraro, Diriba Korecha Dadi, Ramón Pichs-Madruga, Nagmeldin G.E. Mahmoud, Andy Reisinger and Diana Ürge-Vorsatz. Specific thanks are due to Andy Reisinger, who together with the Co-Chairs acted as an editor of the Summary for Policymakers, and to Ramón Pichs-Madruga and Diana Ürge-Vorsatz, who took on roles of editors of the Technical Summary.

We thank the Integrated Assessment Modelling Consortium (IAMC) and the International Institute for Applied Systems Analysis (IIASA) for facilitating the development, and hosting, of the AR6 Scenario Explorer and Database. Particular thanks are due to Edward Byers and Keywan Riahi of IIASA who led this initiative. We thank the International Energy Agency (IEA), in particular Roberta Quadrelli and her team, for providing us with access to their data products. We also thank Monica Crippa and her team at the Joint Research Centre of the European Commission for access to the EDGAR (Emissions Database for Global Atmospheric Research), and William Lamb and Jan Minx who led the assessment of emissions data across the report.

We acknowledge support from countries hosting WG III Lead Author Meetings (LAMs): the UK for hosting the first LAM in Edinburgh (March 2019); India for hosting the second LAM in New Delhi (September 2019); Ecuador for hosting the third LAM virtually (April 2020); and Italy for hosting the fourth LAM, also held virtually (April 2021). We thank the government of Ethiopia for hosting the Scoping Meeting for the report in Addis Ababa (May 2017).

We are especially grateful for the support of the UK government, in particular the Department of Business, Energy and Industrial Strategy (BEIS) and the Engineering and Physical Sciences Research Council (EPSRC), for funding the WG III Technical Support Unit (TSU). Jolene Cook, Eleanor Webster, Rhian Rees-Owen, Sarah Honour, Cathy Johnson, Julie Maclean, Alice Montgomery, Caroline Prescott, and Andrew Russell at BEIS, and Jim Fleming, Kathryn Magnay, Strachan McCormick, Kate Bowman and Jasmine Cain at EPSRC were always ready to dedicate time and energy to the needs of the team. BEIS also organised the venue hosting the core team for the 14th Session of IPCC WG III.

We are grateful for the close collaboration with authors, Bureau members and members of the Technical Support Units from WGs I and II, and Task Force on National Greenhouse Gas Inventories (TFI). We especially thank WG I Co-Chairs Valérie Masson-Delmotte and Panmao Zhai, WG II Co-Chairs Hans-Otto Portner and Debra Roberts, and the Co-Chairs of the Task Force on Greenhouse Gas Inventories, Eduardo

Calvo Buendía and Kiyoto Tanabe, for their collegial spirit and mutual support during the assessment. We extend our gratitude to the IPCC leadership. The Executive Committee, notably Vice-Chairs Ko Barrett, Thelma Krug, Youba Sokona, strengthened the work of all three WGs. We thank IPCC Chair, Hoesung Lee, for his leadership.

We would like to thank the Secretary of the IPCC, Abdalah Mokssit, and Deputy Secretaries, Ermira Fida and Kerstin Stendahl, and their colleagues Mudathir Abdallah, Jesbin Baidya, Laura Biagioni, Annie Courtin, Oksana Ekzarkho, Judith Ewa, Joelle Fernandez, Emelie Larrode, Jennifer Lew Schneider, Jonathan Lynn, Andrej Mahecic, Nina Peeva, Sophie Schlingemann, Mxolisi Shongwe, Melissa Walsh, and Werani Zabula, for their guidance in implementing IPCC processes, their logistical support, their close collaboration on communications, and for enabling the participation of experts from developing countries through the IPCC Trust Fund.

We wish to thank Sue Escott of Escott-Hunt and staff at the UN Foundation for their insight and hard work to ensure the effective communication of the messages in the report. Thanks are expressed to John Schwartz and his team at Soapbox Communications Ltd for graphics design support and for typesetting the final report, in particular Ian Blenkinsop, Margherita Cardoso, Autumn Forecast, Žiga Kropivšek, Sharon Mah, Jenny McCarten, Polly O'Hara, Francesca Romano and Alice Woodward, to Georgie Bowden for her careful compilation of the report index, and to Matt Lloyd, Jenny van der Meijden, and the team at Cambridge University Press for final publication of the report.

We are grateful to the members of the core team at the 14th Session of WG III, especially the IPCC Vice Chairs, WG I and II Vice-Chairs Greg Flato, Jan Fuglestad and Mark Howden, WG I, II and SYR TSU members, in particular Nada Caud, Sarah Connors, Melissa Gomis, Tijana Kerscher, Katherine Leitzell, Noémie Leprince-Ringuet, Sina Löschke, Tom Maycock, Katja Mintenbeck, Komila Nabiyeveva, Clotilde Péan, Anna Pirani, Elvira Poloczanska, Jussi Savolainen, and Melinda Tignor, as well as Sophie Berger, Kiane de Kleijne, and Chloe Ludden.

It is a pleasure to acknowledge the tireless work, resilience and good humour of the staff of the WG III TSU throughout the many challenges faced during the assessment cycle. Our thanks go to Raphael Slade, Roger Fradera, Minal Pathak, Alaa Al Khourdajie, Malek Belkacemi, Renée van Diemen, Apoorva Hasija, Géninha Lisboa, Sigourney Luz, Juliette Malley, David McCollum, Shreya Some, and Purvi Vyas, and also to past team members: Elizabeth Huntley, Katie Kissick, Suvadip Neogi and Joanna Portugal-Pereira. Your professionalism, creativity and indomitable spirit has been exemplary and continually inspiring. Finally, on behalf of all participants, we thank colleagues, family and friends for their understanding and support throughout the production of this report, which has taken place during unprecedented times.

Sincerely,

Jim Skea
Co-Chair Working Group III

Priyadarshi R. Shukla
Co-Chair Working Group III

In memoriam

Cristóbal Díaz Morejón
(1949–2021)

Lead Author of Chapter 17 on Accelerating the transition in the context of sustainable development

Cristóbal Díaz Morejón was an internationally renowned expert across a range of environmental disciplines. Over the course of a busy and successful career he led projects on the salinity of soils, water resource management, environmental strategy, desertification and droughts, and energy efficiency, amongst others. He represented Cuba in many international meetings on water resources and sustainable development. In 1994 he was awarded a Medal by the Academy of Sciences of Cuba on its 30th Anniversary, and in 2004, the “Juan Tomas Roig” Medal for 25 years dedicated to research. A contributor to IPCC reports since 2004, he was an intelligent, knowledgeable, dedicated and kind colleague, and will be sorely missed.

IPCC, 2022: Summary for Policymakers. In: *Climate Change 2022: Mitigation of Climate Change. Contribution of Working Group III to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change* [P.R. Shukla, J. Skea, R. Slade, A. Al Khourdajie, R. van Diemen, D. McCollum, M. Pathak, S. Some, P. Vyas, R. Fradera, M. Belkacemi, A. Hasija, G. Lisboa, S. Luz, J. Malley, (eds.)]. Cambridge University Press, Cambridge, UK and New York, NY, USA. doi: 10.1017/9781009157926.001.

A. Introduction and Framing

The Working Group III (WGIII) contribution to the IPCC's Sixth Assessment Report (AR6) assesses literature on the scientific, technological, environmental, economic and social aspects of mitigation of climate change.¹ Levels of confidence² are given in () brackets. Numerical ranges are presented in square [] brackets. References to Chapters, Sections, Figures and Boxes in the underlying report and Technical Summary (TS) are given in {} brackets.

The report reflects new findings in the relevant literature and builds on previous IPCC reports, including the WGIII contribution to the IPCC's Fifth Assessment Report (AR5), the WGI and WGII contributions to AR6 and the three Special Reports in the Sixth Assessment cycle,³ as well as other UN assessments. Some of the main developments relevant for this report include {TS.1, TS.2}:

- **An evolving international landscape.** The literature reflects, among other factors: developments in the UN Framework Convention on Climate Change (UNFCCC) process, including the outcomes of the Kyoto Protocol and the adoption of the Paris Agreement {13, 14, 15, 16}; the UN 2030 Agenda for Sustainable Development including the Sustainable Development Goals (SDGs) {1, 3, 4, 17}; and the evolving roles of international cooperation {14}, finance {15} and innovation {16}.
- **Increasing diversity of actors and approaches to mitigation.** Recent literature highlights the growing role of non-state and sub-national actors including cities, businesses, Indigenous Peoples, citizens including local communities and youth, transnational initiatives, and public-private entities in the global effort to address climate change {5, 13, 14, 15, 16, 17}. Literature documents the global spread of climate policies and cost declines of existing and emerging low emission technologies, along with varied types and levels of mitigation efforts, and sustained reductions in greenhouse gas (GHG) emissions in some countries {2, 5, 6, 8, 12, 13, 16}, and the impacts of, and some lessons from, the COVID-19 pandemic. {1, 2, 3, 5, 13, 15, Box TS.1, Cross-Chapter Box 1 in Chapter 1}
- **Close linkages between climate change mitigation, adaptation and development pathways.** The development pathways taken by countries at all stages of economic development impact GHG emissions and hence shape mitigation challenges and opportunities, which vary across countries and regions. Literature explores how development choices and the establishment of enabling conditions for action and support influence the feasibility and the cost of limiting emissions {1, 3, 4, 5, 13, 15, 16}. Literature highlights that climate change mitigation action designed and conducted in the context of sustainable development, equity, and poverty eradication, and rooted in the development aspirations of the societies within which they take place, will be more acceptable, durable and effective {1, 3, 4, 5}. This report covers mitigation from both targeted measures, and from policies and governance with other primary objectives.
- **New approaches in the assessment.** In addition to the sectoral and systems chapters {3, 6, 7, 8, 9, 10, 11, 12}, the report includes, for the first time in a WGIII report, chapters dedicated to demand for services, and social aspects of mitigation {5, Box TS.11}, and to innovation, technology development and transfer {16}. The assessment of future pathways in this report covers near term (to 2030), medium term (up to 2050), and long term (to 2100) time scales, combining assessment of existing pledges and actions {4, 5}, with an assessment of emissions reductions, and their implications, associated with long-term temperature outcomes up to the year 2100 {3}.⁴ The assessment of modelled global pathways addresses ways of shifting development pathways towards sustainability. Strengthened collaboration between IPCC Working Groups is reflected in Cross-Working Group Boxes that integrate physical science, climate risks and adaptation, and the mitigation of climate change.⁵

¹ The Report covers literature accepted for publication by 11 October 2021.

² Each finding is grounded in an evaluation of underlying evidence and agreement. A level of confidence is expressed using five qualifiers, typeset in italics: *very low*, *low*, *medium*, *high* and *very high*. The assessed likelihood of an outcome or a result is described as: *virtually certain* 99–100% probability; *very likely* 90–100%; *likely* 66–100%; *more likely than not* 50–100%; *about as likely as not* 33–66%; *unlikely* 0–33%; *very unlikely* 0–10%; *exceptionally unlikely* 0–1%. Additional terms may also be used when appropriate, consistent with the IPCC uncertainty guidance: <https://www.ipcc.ch/site/assets/uploads/2018/05/uncertainty-guidance-note.pdf>.

³ The three Special Reports are: Global Warming of 1.5°C: an IPCC Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty (2018); Climate Change and Land: an IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems (2019); IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (2019).

⁴ The term 'temperature' is used in reference to 'global surface temperatures' throughout this SPM as defined in footnote 8 of the AR6 WGI SPM (see note 14 of Table SPM.2). Emission pathways and associated temperature changes are calculated using various forms of models, as summarised in Box SPM.1 and Chapter 3, and discussed in Annex III.

⁵ Namely: Economic Benefits from Avoided Climate Impacts along Long-Term Mitigation Pathways {Cross-Working Group Box 1 in Chapter 3}; Urban: Cities and Climate Change {Cross-Working Group Box 2 in Chapter 8}; and Mitigation and Adaptation via the Bioeconomy {Cross-Working Group Box 3 in Chapter 12}.

- **Increasing diversity of analytic frameworks from multiple disciplines including social sciences.** This report identifies multiple analytic frameworks to assess the drivers of, barriers to and options for, mitigation action. These include: economic efficiency, including the benefits of avoided impacts; ethics and equity; interlinked technological and social transition processes; and socio-political frameworks, including institutions and governance {1, 3, 13, Cross-Chapter Box 12 in Chapter 16}. These help to identify risks and opportunities for action, including co-benefits and just and equitable transitions at local, national and global scales. {1, 3, 4, 5, 13, 14, 16, 17}

Section B of this Summary for Policymakers (SPM) assesses *Recent developments and current trends*, including data uncertainties and gaps. Section C, *System transformations to limit global warming*, identifies emission pathways and alternative mitigation portfolios consistent with limiting global warming to different levels, and assesses specific mitigation options at the sectoral and system level. Section D addresses *Linkages between mitigation, adaptation, and sustainable development*. Section E, *Strengthening the response*, assesses knowledge of how enabling conditions of institutional design, policy, finance, innovation and governance arrangements can contribute to climate change mitigation in the context of sustainable development.

B. Recent Developments and Current Trends

- B.1** Total net anthropogenic GHG emissions⁶ have continued to rise during the period 2010–2019, as have cumulative net CO₂ emissions since 1850. Average annual GHG emissions during 2010–2019 were higher than in any previous decade, but the rate of growth between 2010 and 2019 was lower than that between 2000 and 2009. (*high confidence*) (Figure SPM.1) {Figure 2.2, Figure 2.5, Table 2.1, 2.2, Figure TS.2}
- B.1.1** Global net anthropogenic GHG emissions were 59 ± 6.6 GtCO₂-eq^{7,8} in 2019, about 12% (6.5 GtCO₂-eq) higher than in 2010 and 54% (21 GtCO₂-eq) higher than in 1990. The annual average during the decade 2010–2019 was 56 ± 6.0 GtCO₂-eq, 9.1 GtCO₂-eq yr⁻¹ higher than in 2000–2009. This is the highest increase in average decadal emissions on record. The average annual rate of growth slowed from 2.1% yr⁻¹ between 2000 and 2009 to 1.3% yr⁻¹ between 2010 and 2019. (*high confidence*) (Figure SPM.1) {Figure 2.2, Figure 2.5, Table 2.1, 2.2, Figure TS.2}
- B.1.2** Growth in anthropogenic emissions has persisted across all major groups of GHGs since 1990, albeit at different rates. By 2019, the largest growth in absolute emissions occurred in CO₂ from fossil fuels and industry followed by CH₄, whereas the highest relative growth occurred in fluorinated gases, starting from low levels in 1990 (*high confidence*). Net anthropogenic CO₂ emissions from land use, land-use change and forestry (CO₂-LULUCF) are subject to large uncertainties and high annual variability, with *low confidence* even in the direction of the long-term trend.⁹ (Figure SPM.1) {Figure 2.2, Figure 2.5, 2.2, Figure TS.2}
- B.1.3** Historical cumulative net CO₂ emissions from 1850 to 2019 were 2400 ± 240 GtCO₂ (*high confidence*). Of these, more than half (58%) occurred between 1850 and 1989 [1400 ± 195 GtCO₂], and about 42% between 1990 and 2019 [1000 ± 90 GtCO₂]. About 17% of historical cumulative net CO₂ emissions since 1850 occurred between 2010 and 2019 [410 ± 30 GtCO₂].¹⁰ By comparison, the current central estimate of the remaining carbon budget from 2020 onwards for limiting warming to 1.5°C with a probability of 50% has been assessed as 500 GtCO₂, and as 1150 GtCO₂ for a probability of 67% for limiting warming to 2°C. Remaining carbon budgets depend on the amount of non-CO₂ mitigation (± 220 GtCO₂) and are further subject to geophysical uncertainties. Based on central estimates only, cumulative net CO₂ emissions between 2010 and 2019 compare to about four-fifths of the size of the remaining carbon budget from 2020 onwards for a 50% probability of limiting global warming to 1.5°C, and about one-third of the remaining carbon budget for a 67% probability to limit global warming to 2°C. Even when taking uncertainties into account, historical emissions between 1850 and 2019 constitute a large share of total carbon budgets for these global

⁶ Net GHG emissions in this report refer to releases of greenhouse gases from anthropogenic sources minus removals by anthropogenic sinks, for those species of gases that are reported under the common reporting format of the United Nations Framework Convention on Climate Change (UNFCCC): CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI); net CO₂ emissions from land use, land-use change and forestry (CO₂-LULUCF); methane (CH₄); nitrous oxide (N₂O); and fluorinated gases (F-gases) comprising hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆), as well as nitrogen trifluoride (NF₃). Different datasets for GHG emissions exist, with varying time horizons and coverage of sectors and gases, including some that go back to 1850. In this report, GHG emissions are assessed from 1990, and CO₂ sometimes also from 1850. Reasons for this include data availability and robustness, scope of the assessed literature, and the differing warming impacts of non-CO₂ gases over time.

⁷ GHG emission metrics are used to express emissions of different greenhouse gases in a common unit. Aggregated GHG emissions in this report are stated in CO₂-equivalent (CO₂-eq) using the Global Warming Potential with a time horizon of 100 years (GWP100) with values based on the contribution of Working Group I to the AR6. The choice of metric depends on the purpose of the analysis, and all GHG emission metrics have limitations and uncertainties, given that they simplify the complexity of the physical climate system and its response to past and future GHG emissions. [Cross-Chapter Box 2 in Chapter 2, Supplementary Material 2.SM.3, Box TS.2; AR6 WGI Chapter 7 Supplementary Material]

⁸ In this SPM, uncertainty in historic GHG emissions is reported using 90% uncertainty intervals unless stated otherwise. GHG emission levels are rounded to two significant digits; as a consequence, small differences in sums due to rounding may occur.

⁹ Global databases make different choices about which emissions and removals occurring on land are considered anthropogenic. Currently, net CO₂ fluxes from land reported by global bookkeeping models used here are estimated to be about 5.5 GtCO₂ yr⁻¹ higher than the aggregate global net emissions based on national GHG inventories. This difference, which has been considered in the literature, mainly reflects differences in how anthropogenic forest sinks and areas of managed land are defined. Other reasons for this difference, which are more difficult to quantify, can arise from the limited representation of land management in global models and varying levels of accuracy and completeness of estimated LULUCF fluxes in national GHG inventories. Neither method is inherently preferable. Even when the same methodological approach is applied, the large uncertainty of CO₂-LULUCF emissions can lead to substantial revisions to estimated emissions. [Cross-Chapter Box 3 in Chapter 3, 7.2, SRCL SPM A.3.3]

¹⁰ For consistency with WGI, historical cumulative CO₂ emissions from 1850 to 2019 are reported using 68% confidence intervals.

warming levels.^{11,12} Based on central estimates only, historical cumulative net CO₂ emissions between 1850 and 2019 amount to about four-fifths¹² of the total carbon budget for a 50% probability of limiting global warming to 1.5°C (central estimate about 2900 GtCO₂), and to about two thirds¹² of the total carbon budget for a 67% probability to limit global warming to 2°C (central estimate about 3550 GtCO₂). {Figure 2.7, 2.2, Figure TS.3, WGI Table SPM.2}

- B.1.4** Emissions of CO₂-FFI dropped temporarily in the first half of 2020 due to responses to the COVID-19 pandemic (*high confidence*), but rebounded by the end of the year (*medium confidence*). The annual average CO₂-FFI emissions reduction in 2020 relative to 2019 was about 5.8% [5.1–6.3%], or 2.2 [1.9–2.4] GtCO₂ (*high confidence*). The full GHG emissions impact of the COVID-19 pandemic could not be assessed due to a lack of data regarding non-CO₂ GHG emissions in 2020. {Cross-Chapter Box 1 in Chapter 1, Figure 2.6, 2.2, Box TS.1, Box TS.1 Figure 1}

Global net anthropogenic emissions have continued to rise across all major groups of greenhouse gases.

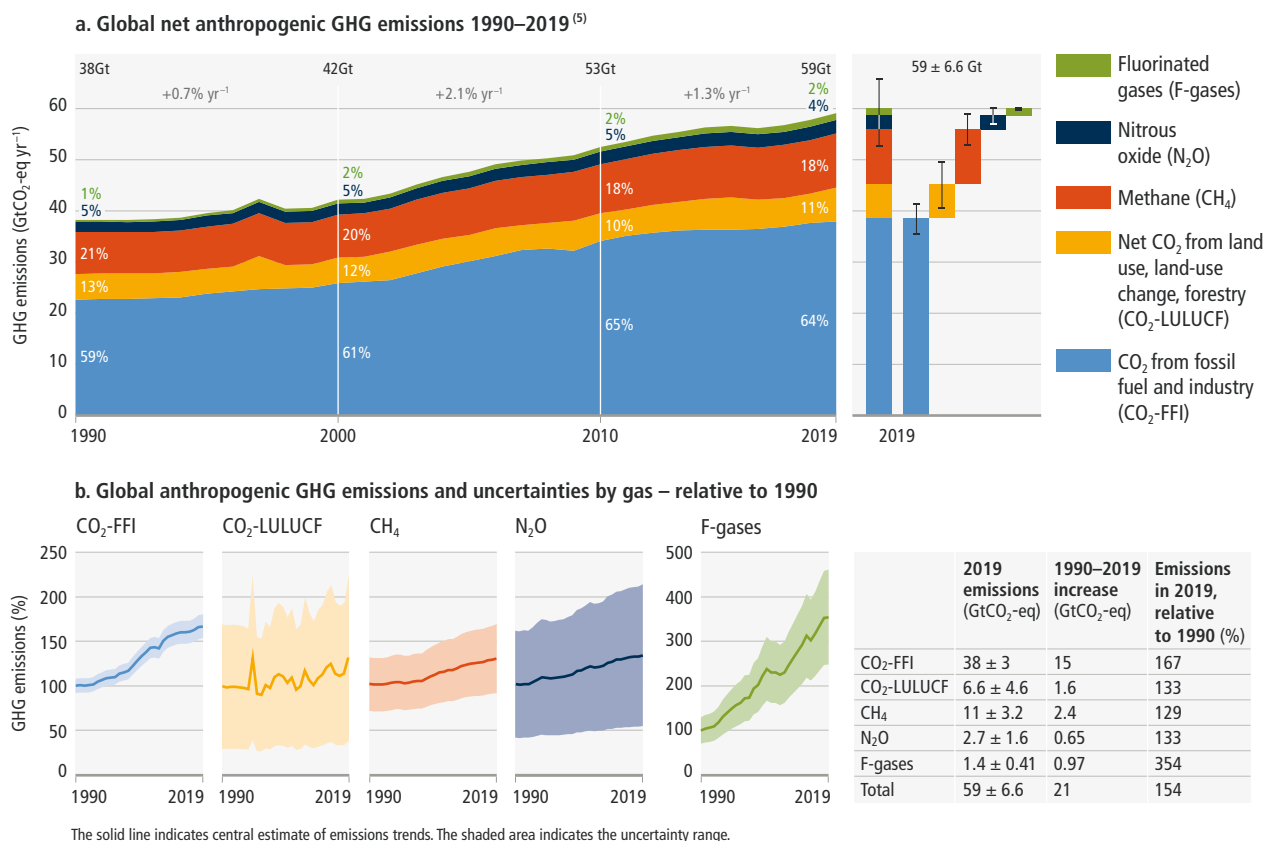

Figure SPM.1 | Global net anthropogenic GHG emissions (GtCO₂-eq yr⁻¹) 1990–2019. Global net anthropogenic GHG emissions include CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI); net CO₂ from land use, land-use change and forestry (CO₂-LULUCF)⁹; methane (CH₄); nitrous oxide (N₂O); and fluorinated gases (HFCs, PFCs, SF₆, NF₃).⁶ **Panel a** shows aggregate annual global net anthropogenic GHG emissions by groups of gases from 1990 to 2019 reported in GtCO₂-eq converted based on global warming potentials with a 100-year time horizon (GWP100-AR6) from the IPCC Sixth Assessment Report Working Group I (Chapter 7). The fraction of global emissions for each gas is shown for 1990, 2000, 2010 and 2019; as well as the aggregate average annual growth rate between these decades. At the right side of Panel a, GHG emissions in 2019 are broken down into individual components with the associated uncertainties (90% confidence interval) indicated by the error bars: CO₂-FFI ±8%; CO₂-LULUCF ±70%; CH₄ ±30%; N₂O ±60%; F-gases ±30%; GHG ±11%. Uncertainties in GHG emissions are assessed in Supplementary Material 2.2. The single-year peak of emissions in 1997 was due to higher CO₂-LULUCF emissions from a forest and peat fire event in South East Asia. **Panel b** shows global anthropogenic CO₂-FFI, net CO₂-LULUCF, CH₄, N₂O and F-gas emissions individually for the period 1990–2019, normalised relative to 100 in 1990. Note the different scale for the included F-gas emissions compared to other gases, highlighting its rapid growth from a low base. Shaded areas indicate the uncertainty range. Uncertainty ranges as shown here are specific for individual groups of greenhouse gases and cannot be compared. The table shows the central estimate for: absolute emissions in 2019; the absolute change in emissions between 1990 and 2019; and emissions in 2019 expressed as a percentage of 1990 emissions. {2.2, Figure 2.5, Supplementary Material 2.2, Figure TS.2}

¹¹ The carbon budget is the maximum amount of cumulative net global anthropogenic CO₂ emissions that would result in limiting global warming to a given level with a given likelihood, taking into account the effect of other anthropogenic climate forcers. This is referred to as the 'total carbon budget' when expressed starting from the pre-industrial period, and as the 'remaining carbon budget' when expressed from a recent specified date. The total carbon budgets reported here are the sum of historical emissions from 1850 to 2019 and the remaining carbon budgets from 2020 onwards, which extend until global net zero CO₂ emissions are reached. {Annex I: Glossary; WGI SPM}

¹² Uncertainties for total carbon budgets have not been assessed and could affect the specific calculated fractions.

- B.2** Net anthropogenic GHG emissions have increased since 2010 across all major sectors globally. An increasing share of emissions can be attributed to urban areas. Emissions reductions in CO₂ from fossil fuels and industrial processes (CO₂-FFI), due to improvements in energy intensity of GDP and carbon intensity of energy, have been less than emissions increases from rising global activity levels in industry, energy supply, transport, agriculture and buildings. (*high confidence*) {2.2, 2.4, 6.3, 7.2, 8.3, 9.3, 10.1, 11.2}
- B.2.1** In 2019, approximately 34% (20 GtCO₂-eq) of total net anthropogenic GHG emissions came from the energy supply sector, 24% (14 GtCO₂-eq) from industry, 22% (13 GtCO₂-eq) from agriculture, forestry and other land use (AFOLU), 15% (8.7 GtCO₂-eq) from transport and 6% (3.3 GtCO₂-eq) from buildings.¹³ If emissions from electricity and heat production are attributed to the sectors that use the final energy, 90% of these indirect emissions are allocated to the industry and buildings sectors, increasing their relative GHG emissions shares from 24% to 34%, and from 6% to 16%, respectively. After reallocating emissions from electricity and heat production, the energy supply sector accounts for 12% of global net anthropogenic GHG emissions. (*high confidence*) {Figure 2.12, 2.2, 6.3, 7.2, 9.3, 10.1, 11.2, Figure TS.6}
- B.2.2** Average annual GHG emissions growth between 2010 and 2019 slowed compared to the previous decade in energy supply (from 2.3% to 1.0%) and industry (from 3.4% to 1.4%), but remained roughly constant at about 2% yr⁻¹ in the transport sector (*high confidence*). Emissions growth in AFOLU, comprising emissions from agriculture (mainly CH₄ and N₂O) and forestry and other land use (mainly CO₂) is more uncertain than in other sectors due to the high share and uncertainty of CO₂-LULUCF emissions (*medium confidence*). About half of total net AFOLU emissions are from CO₂-LULUCF, predominantly from deforestation¹⁴ (*medium confidence*). {Figure 2.13, 2.2, 6.3, 7.2, Figure 7.3, 9.3, 10.1, 11.2, TS.3}
- B.2.3** The global share of emissions that can be attributed to urban areas is increasing. In 2015, urban emissions were estimated to be 25 GtCO₂-eq (about 62% of the global share) and in 2020, 29 GtCO₂-eq (67–72% of the global share).¹⁵ The drivers of urban GHG emission are complex and include population size, income, state of urbanisation and urban form. (*high confidence*) {8.1, 8.3}
- B.2.4** Global energy intensity (total primary energy per unit GDP) decreased by 2% yr⁻¹ between 2010 and 2019. Carbon intensity (CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI) per unit primary energy) decreased by 0.3% yr⁻¹, with large regional variations, over the same period mainly due to fuel switching from coal to gas, reduced expansion of coal capacity, and increased use of renewables. This reversed the trend observed for 2000–2009. For comparison, the carbon intensity of primary energy is projected to decrease globally by about 3.5% yr⁻¹ between 2020 and 2050 in modelled scenarios that limit warming to 2°C (>67%), and by about 7.7% yr⁻¹ globally in scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot.¹⁶ (*high confidence*) {Figure 2.16, 2.2, 2.4, Table 3.4, 3.4, 6.3}

¹³ Sector definitions can be found in Annex II.9.1.

¹⁴ Land overall constituted a net sink of –6.6 (±4.6) GtCO₂ yr⁻¹ for the period 2010–2019, comprising a gross sink of –12.5 (±3.2) GtCO₂ yr⁻¹ resulting from responses of all land to both anthropogenic environmental change and natural climate variability, and net anthropogenic CO₂-LULUCF emissions +5.7 (±4.0) GtCO₂ yr⁻¹ based on bookkeeping models. {Table 2.1, 7.2, Table 7.1}

¹⁵ This estimate is based on consumption-based accounting, including both direct emissions from within urban areas, and indirect emissions from outside urban areas related to the production of electricity, goods and services consumed in cities. These estimates include all CO₂ and CH₄ emission categories except for aviation and marine bunker fuels, land-use change, forestry and agriculture. {8.1, Annex I: Glossary}

¹⁶ See Box SPM.1 for the categorisation of modelled long-term emission scenarios based on projected temperature outcomes and associated probabilities adopted in this report.

- B.3 Regional contributions¹⁷ to global GHG emissions continue to differ widely. Variations in regional, and national per capita emissions partly reflect different development stages, but they also vary widely at similar income levels. The 10% of households with the highest per capita emissions contribute a disproportionately large share of global household GHG emissions. At least 18 countries have sustained GHG emission reductions for longer than 10 years. (*high confidence*) (Figure SPM.2) {Figure 1.1, Figure 2.9, Figure 2.10, Figure 2.25, 2.2, 2.3, 2.4, 2.5, 2.6, Figure TS.4, Figure TS.5}**
- B.3.1** GHG emissions trends over 1990–2019 vary widely across regions and over time, and across different stages of development, as shown in Figure SPM.2. Average global per capita net anthropogenic GHG emissions increased from 7.7 to 7.8 tCO₂-eq, ranging from 2.6 tCO₂-eq to 19 tCO₂-eq across regions. Least developed countries (LDCs) and Small Island Developing States (SIDS) have much lower per capita emissions (1.7 tCO₂-eq and 4.6 tCO₂-eq, respectively) than the global average (6.9 tCO₂-eq), excluding CO₂-LULUCF.¹⁸ (*high confidence*) (Figure SPM.2) {Figure 1.2, Figure 2.9, Figure 2.10, 2.2, Figure TS.4}
- B.3.2** Historical contributions to cumulative net anthropogenic CO₂ emissions between 1850 and 2019 vary substantially across regions in terms of total magnitude, but also in terms of contributions to CO₂-FFI (1650 ± 73 GtCO₂-eq) and net CO₂-LULUCF (760 ± 220 GtCO₂-eq) emissions.¹⁰ Globally, the major share of cumulative CO₂-FFI emissions is concentrated in a few regions, while cumulative CO₂-LULUCF⁹ emissions are concentrated in other regions. LDCs contributed less than 0.4% of historical cumulative CO₂-FFI emissions between 1850 and 2019, while SIDS contributed 0.5%. (*high confidence*) (Figure SPM.2) {Figure 2.10, 2.2, TS.3, Figure 2.7}
- B.3.3** In 2019, around 48% of the global population lives in countries emitting on average more than 6 tCO₂-eq per capita, excluding CO₂-LULUCF. 35% live in countries emitting more than 9 tCO₂-eq per capita. Another 41% live in countries emitting less than 3 tCO₂-eq per capita. A substantial share of the population in these low-emitting countries lack access to modern energy services.¹⁹ Eradicating extreme poverty, energy poverty, and providing decent living standards²⁰ to all in these regions in the context of achieving sustainable development objectives, in the near-term, can be achieved without significant global emissions growth. (*high confidence*) (Figure SPM.2) {Figure 1.2, 2.2, 2.4, 2.6, 3.7, 4.2, 6.7, Figure TS.4, Figure TS.5}
- B.3.4** Globally, the 10% of households with the highest per capita emissions contribute 34–45% of global consumption-based household GHG emissions,²¹ while the middle 40% contribute 40–53%, and the bottom 50% contribute 13–15%. (*high confidence*) {2.6, Figure 2.25}
- B.3.5** At least 18 countries have sustained production-based GHG and consumption-based CO₂ emission reductions for longer than 10 years. Reductions were linked to energy supply decarbonisation, energy efficiency gains, and energy demand reduction, which resulted from both policies and changes in economic structure. Some countries have reduced production-based GHG emissions by a third or more since peaking, and some have achieved several years of consecutive reduction rates of around 4% yr⁻¹, comparable to global reductions in scenarios limiting warming to 2°C (>67%) or lower. These reductions have only partly offset global emissions growth. (*high confidence*) (Figure SPM.2) {Figure TS.4, 2.2, 1.3.2}

¹⁷ See Annex II, Part 1 for regional groupings adopted in this report.

¹⁸ In 2019, LDCs are estimated to have emitted 3.3% of global GHG emissions, and SIDS are estimated to have emitted 0.6% of global GHG emissions, excluding CO₂-LULUCF. These country groupings cut across geographic regions and are not depicted separately in Figure SPM.2. {Figure 2.10}

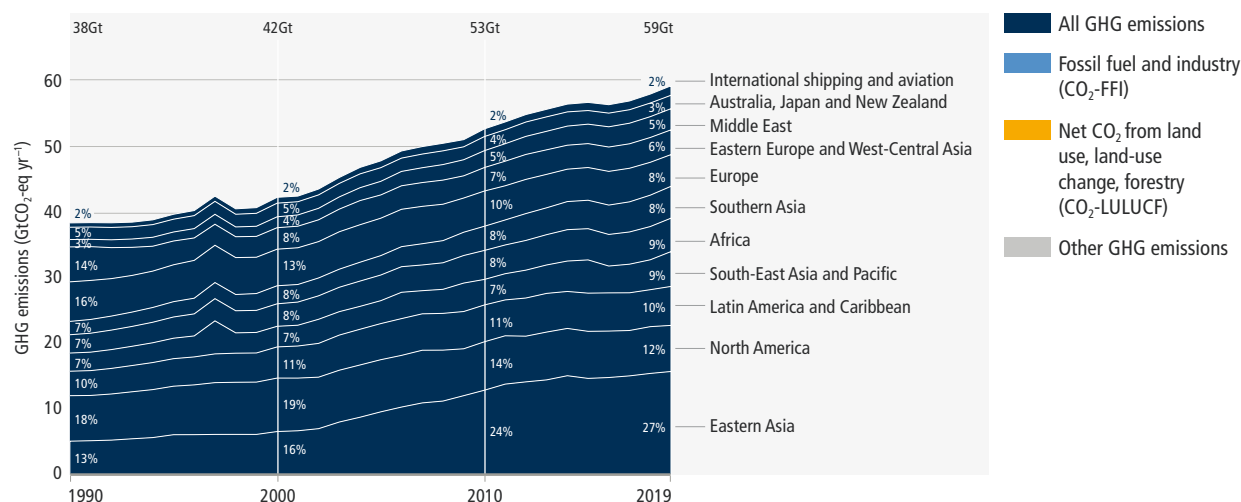

¹⁹ In this report, access to modern energy services is defined as access to clean, reliable and affordable energy services for cooking and heating, lighting, communications, and productive uses. {Annex I: Glossary}

²⁰ In this report, decent living standards are defined as a set of minimum material requirements essential for achieving basic human well-being, including nutrition, shelter, basic living conditions, clothing, health care, education, and mobility. {5.1}

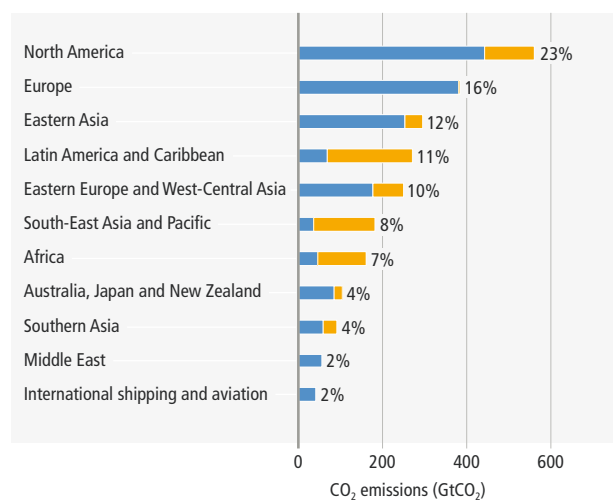

²¹ Consumption-based emissions refer to emissions released to the atmosphere to generate the goods and services consumed by a certain entity (e.g., a person, firm, country, or region). The bottom 50% of emitters spend less than USD3 PPP (purchasing power parity) per capita per day. The top 10% of emitters (an open-ended category) spend more than USD23 PPP per capita per day. The wide range of estimates for the contribution of the top 10% results from the wide range of spending in this category and differing methods in the assessed literature. {2.6, Annex I: Glossary}

Emissions have grown in most regions but are distributed unevenly, both in the present day and cumulatively since 1850.

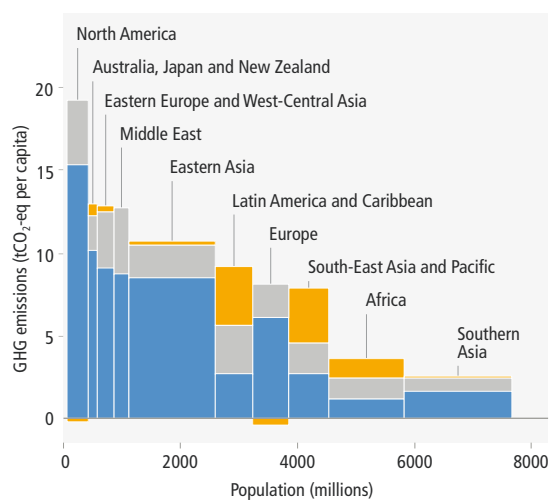

a. Global net anthropogenic GHG emissions by region (1990–2019)

b. Historical cumulative net anthropogenic CO₂ emissions per region (1850–2019)

c. Net anthropogenic GHG emissions per capita and for total population, per region (2019)

d. Regional indicators (2019) and regional production vs consumption accounting (2018)

	Africa	Australia, Japan, New Zealand	Eastern Asia	Eastern Europe, West-Central Asia	Europe	Latin America and Caribbean	Middle East	North America	South-East Asia and Pacific	Southern Asia
Population (million persons, 2019)	1292	157	1471	291	620	646	252	366	674	1836
GDP per capita (USD1000 _{ppp} 2017 per person) ¹	5.0	43	17	20	43	15	20	61	12	6.2

¹ GDP per capita in 2019 in USD2017 currency purchasing power basis.

² Includes CO₂-FFI, CO₂-LULUCF and Other GHGs, excluding international aviation and shipping.

The regional groupings used in this figure are for statistical purposes only and are described in Annex II, Part I.

Figure SPM.2 | Regional GHG emissions, and the regional proportion of total cumulative production-based CO₂ emissions from 1850 to 2019.

Figure SPM.2 (continued): Regional GHG emissions, and the regional proportion of total cumulative production-based CO₂ emissions from 1850 to 2019. **Panel a** shows global net anthropogenic GHG emissions by region (in GtCO₂-eq yr⁻¹ (GWP100-AR6)) for the time period 1990–2019.⁶ Percentage values refer to the contribution of each region to total GHG emissions in each respective time period. The single-year peak of emissions in 1997 was due to higher CO₂-LULUCF emissions from a forest and peat fire event in South East Asia. Regions are as grouped in Annex II. **Panel b** shows the share of historical cumulative net anthropogenic CO₂ emissions per region from 1850 to 2019 in GtCO₂. This includes CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI) and net CO₂ emissions from land use, land-use change, forestry (CO₂-LULUCF). Other GHG emissions are not included.⁶ CO₂-LULUCF emissions are subject to high uncertainties, reflected by a global uncertainty estimate of ±70% (90% confidence interval). **Panel c** shows the distribution of regional GHG emissions in tonnes CO₂-eq per capita by region in 2019. GHG emissions are categorised into: CO₂-FFI; net CO₂-LULUCF; and other GHG emissions (methane, nitrous oxide, fluorinated gases, expressed in CO₂-eq using GWP100-AR6). The height of each rectangle shows per capita emissions, the width shows the population of the region, so that the area of the rectangles refers to the total emissions for each region. Emissions from international aviation and shipping are not included. In the case of two regions, the area for CO₂-LULUCF is below the axis, indicating net CO₂ removals rather than emissions. CO₂-LULUCF emissions are subject to high uncertainties, reflected by a global uncertainty estimate of ±70% (90% confidence interval). **Panel d** shows population, GDP per person, emission indicators by region in 2019 for percentage GHG contributions, total GHG per person, and total GHG emissions intensity, together with production-based and consumption-based CO₂-FFI data, which is assessed in this report up to 2018. Consumption-based emissions are emissions released to the atmosphere in order to generate the goods and services consumed by a certain entity (e.g., region). Emissions from international aviation and shipping are not included. {1.3, Figure 1.2, 2.2, Figure 2.9, Figure 2.10, Figure 2.11, Annex II}

B.4 The unit costs of several low-emission technologies have fallen continuously since 2010. Innovation policy packages have enabled these cost reductions and supported global adoption. Both tailored policies and comprehensive policies addressing innovation systems have helped overcome the distributional, environmental and social impacts potentially associated with global diffusion of low-emission technologies. Innovation has lagged in developing countries due to weaker enabling conditions. Digitalisation can enable emission reductions, but can have adverse side effects unless appropriately governed. (*high confidence*) (Figure SPM.3) {2.2, 6.3, 6.4, 7.2, 12.2, 16.2, 16.4, 16.5, Cross-Chapter Box 11 in Chapter 16}

B.4.1 From 2010 to 2019, there have been sustained decreases in the unit costs of solar energy (85%), wind energy (55%), and lithium-ion batteries (85%), and large increases in their deployment, e.g., >10× for solar and >100× for electric vehicles (EVs), varying widely across regions (Figure SPM.3). The mix of policy instruments which reduced costs and stimulated adoption includes public R&D, funding for demonstration and pilot projects, and demand pull instruments such as deployment subsidies to attain scale. In comparison to modular small-unit size technologies, the empirical record shows that multiple large-scale mitigation technologies, with fewer opportunities for learning, have seen minimal cost reductions and their adoption has grown slowly. (*high confidence*) {1.3, 1.5, Figure 2.5, 2.5, 6.3, 6.4, 7.2, 11.3, 12.2, 12.3, 12.6, 13.6, 16.3, 16.4, 16.6}

B.4.2 Policy packages tailored to national contexts and technological characteristics have been effective in supporting low-emission innovation and technology diffusion. Appropriately designed policies and governance have helped address distributional impacts and rebound effects. Innovation has provided opportunities to lower emissions and reduce emission growth and created social and environmental co-benefits (*high confidence*). Adoption of low-emission technologies lags in most developing countries, particularly least developed ones, due in part to weaker enabling conditions, including limited finance, technology development and transfer, and capacity. In many countries, especially those with limited institutional capacities, several adverse side effects have been observed as a result of diffusion of low-emission technology, for example, low-value employment, and dependency on foreign knowledge and suppliers. Low-emission innovation along with strengthened enabling conditions can reinforce development benefits, which can, in turn, create feedbacks towards greater public support for policy. (*medium confidence*) {9.9, 13.6, 13.7, 16.3, 16.4, 16.5, 16.6, Cross-Chapter Box 12 in Chapter 16, TS.3}

B.4.3 Digital technologies can contribute to mitigation of climate change and the achievement of several SDGs (*high confidence*). For example, sensors, internet of things, robotics, and artificial intelligence can improve energy management in all sectors, increase energy efficiency, and promote the adoption of many low-emission technologies, including decentralised renewable energy, while creating economic opportunities (*high confidence*). However, some of these climate change mitigation gains can be reduced or counterbalanced by growth in demand for goods and services due to the use of digital devices (*high confidence*). Digitalisation can involve trade-offs across several SDGs, for example, increasing electronic waste, negative impacts on labour markets, and exacerbating the existing digital divide. Digital technology supports decarbonisation only if appropriately governed (*high confidence*). {5.3, 10, 12.6, 16.2, Cross-Chapter Box 11 in Chapter 16, TS.5, Box TS.14}

The unit costs of some forms of renewable energy and of batteries for passenger EVs have fallen, and their use continues to rise.

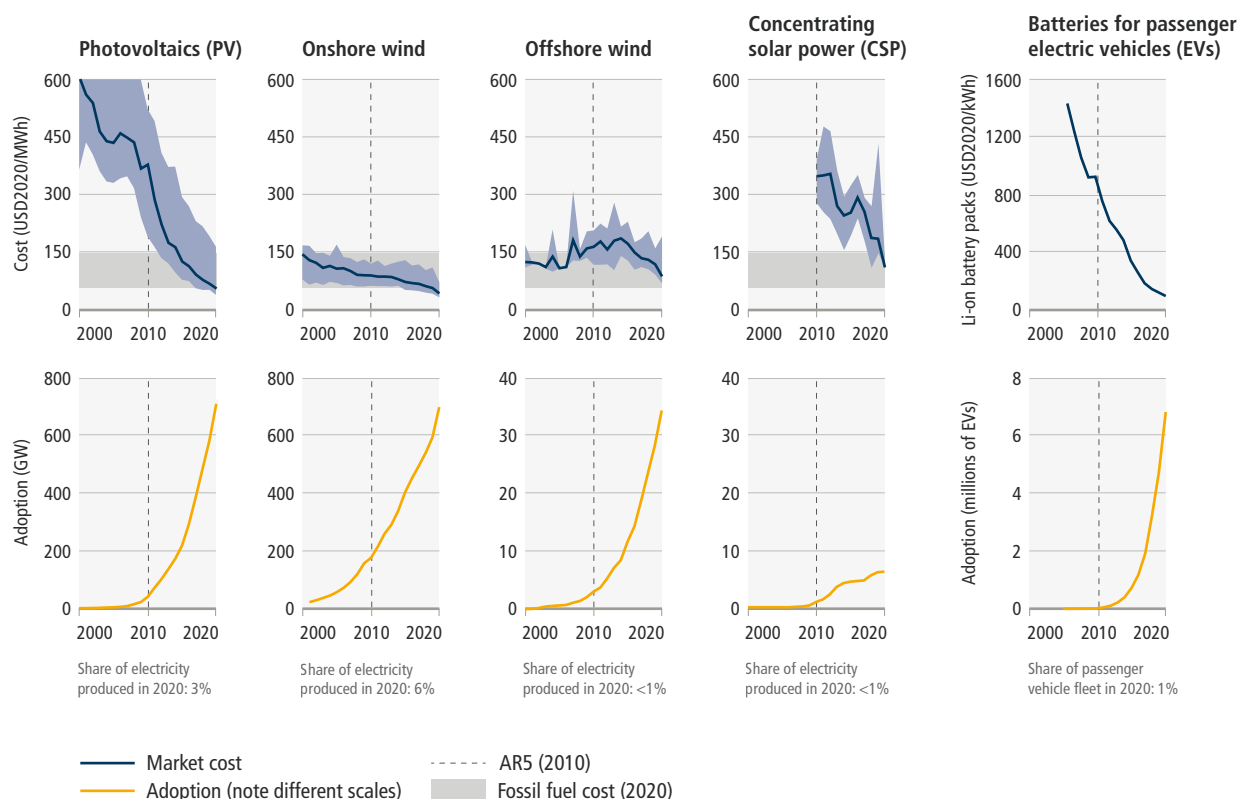

Figure SPM.3 | Unit cost reductions and use in some rapidly changing mitigation technologies. The **top panel** shows global costs per unit of energy (USD per MWh) for some rapidly changing mitigation technologies. Solid blue lines indicate average unit cost in each year. Light blue shaded areas show the range between the 5th and 95th percentiles in each year. Grey shading indicates the range of unit costs for new fossil fuel (coal and gas) power in 2020 (corresponding to USD55–148 per MWh). In 2020, the levelised costs of energy (LCOE) of the four renewable energy technologies could compete with fossil fuels in many places. For batteries, costs shown are for 1 kWh of battery storage capacity; for the others, costs are LCOE, which includes installation, capital, operations, and maintenance costs per MWh of electricity produced. The literature uses LCOE because it allows consistent comparisons of cost trends across a diverse set of energy technologies to be made. However, it does not include the costs of grid integration or climate impacts. Further, LCOE does not take into account other environmental and social externalities that may modify the overall (monetary and non-monetary) costs of technologies and alter their deployment. The **bottom panel** shows cumulative global adoption for each technology, in GW of installed capacity for renewable energy and in millions of vehicles for battery-electric vehicles. A vertical dashed line is placed in 2010 to indicate the change since AR5. Shares of electricity produced and share of passenger vehicle fleet are indicated in text for 2020 based on provisional data, i.e., percentage of total electricity production (for PV, onshore wind, offshore wind, CSP) and of total stock of passenger vehicles (for EVs). The electricity production share reflects different capacity factors; for example, for the same amount of installed capacity, wind produces about twice as much electricity as solar PV. [2.5, 6.4] Renewable energy and battery technologies were selected as illustrative examples because they have recently shown rapid changes in costs and adoption, and because consistent data are available. Other mitigation options assessed in the report are not included as they do not meet these criteria.

- B.5** There has been a consistent expansion of policies and laws addressing mitigation since AR5. This has led to the avoidance of emissions that would otherwise have occurred and increased investment in low-GHG technologies and infrastructure. Policy coverage of emissions is uneven across sectors. Progress on the alignment of financial flows towards the goals of the Paris Agreement remains slow and tracked climate finance flows are distributed unevenly across regions and sectors. (*high confidence*) {5.6, 13.2, 13.4, 13.5, 13.6, 13.9, 14.3, 14.4, 14.5, Cross-Chapter Box 10 in Chapter 14, 15.3, 15.5}
- B.5.1** The Kyoto Protocol led to reduced emissions in some countries and was instrumental in building national and international capacity for GHG reporting, accounting and emissions markets (*high confidence*). At least 18 countries that had Kyoto targets for the first commitment period have had sustained absolute emission reductions for at least a decade from 2005, of which two were countries with economies in transition (*very high confidence*). The Paris Agreement, with near universal participation, has led to policy development and target-setting at national and sub-national levels, in particular in relation to mitigation, as well as enhanced transparency of climate action and support (*medium confidence*). {14.3, 14.6}
- B.5.2** The application of diverse policy instruments for mitigation at the national and sub-national levels has grown consistently across a range of sectors (*high confidence*). By 2020, over 20% of global GHG emissions were covered by carbon taxes or emissions trading systems, although coverage and prices have been insufficient to achieve deep reductions (*medium confidence*). By 2020, there were 'direct' climate laws focused primarily on GHG reductions in 56 countries covering 53% of global emissions (*medium confidence*). Policy coverage remains limited for emissions from agriculture and the production of industrial materials and feedstocks (*high confidence*). {5.6, 7.6, 11.5, 11.6, 13.2, 13.6}
- B.5.3** In many countries, policies have enhanced energy efficiency, reduced rates of deforestation and accelerated technology deployment, leading to avoided and in some cases reduced or removed emissions (*high confidence*). Multiple lines of evidence suggest that mitigation policies have led to avoided global emissions of several GtCO₂-eq yr⁻¹ (*medium confidence*). At least 1.8 GtCO₂-eq yr⁻¹ can be accounted for by aggregating separate estimates for the effects of economic and regulatory instruments. Growing numbers of laws and executive orders have impacted global emissions and were estimated to result in 5.9 GtCO₂-eq yr⁻¹ less emissions in 2016 than they otherwise would have been. (*medium confidence*) (Figure SPM.3) {2.2, 2.8, 6.7, 7.6, 9.9, 10.8, 13.6, Cross-chapter Box 10 in Chapter 14}
- B.5.4** Annual tracked total financial flows for climate mitigation and adaptation increased by up to 60% between 2013/14 and 2019/20 (in USD2015), but average growth has slowed since 2018²² (*medium confidence*). These financial flows remained heavily focused on mitigation, are uneven, and have developed heterogeneously across regions and sectors (*high confidence*). In 2018, public and publicly mobilised private climate finance flows from developed to developing countries were below the collective goal under the UNFCCC and Paris Agreement to mobilise USD100 billion per year by 2020 in the context of meaningful mitigation action and transparency on implementation (*medium confidence*). Public and private finance flows for fossil fuels are still greater than those for climate adaptation and mitigation (*high confidence*). Markets for green bonds, ESG (environmental, social and governance) and sustainable finance products have expanded significantly since AR5. Challenges remain, in particular around integrity and additionality, as well as the limited applicability of these markets to many developing countries. (*high confidence*) {Box 15.4, 15.3, 15.5, 15.6, Box 15.7}

²² Estimates of financial flows (comprising both private and public, domestic and international flows) are based on a single report which assembles data from multiple sources and which has applied various changes to their methodology over the past years. Such data can suggest broad trends but is subject to uncertainties.

B.6 Global GHG emissions in 2030 associated with the implementation of Nationally Determined Contributions (NDCs) announced prior to COP26²³ would make it *likely* that warming will exceed 1.5°C during the 21st century.²⁴ *Likely* limiting warming to below 2°C would then rely on a rapid acceleration of mitigation efforts after 2030. Policies implemented by the end of 2020²⁵ are projected to result in higher global GHG emissions than those implied by NDCs. (*high confidence*) (Figure SPM.4) {3.3, 3.5, 4.2, Cross-Chapter Box 4 in Chapter 4}

B.6.1 Policies implemented by the end of 2020 are projected to result in higher global GHG emissions than those implied by NDCs, indicating an implementation gap. A gap remains between global GHG emissions in 2030 associated with the implementation of NDCs announced prior to COP26 and those associated with modelled mitigation pathways assuming immediate action (for quantification see Table SPM.1).²⁶ The magnitude of the emissions gap depends on the global warming level considered and whether only unconditional or also conditional elements of NDCs²⁷ are considered.²⁸ (*high confidence*) {3.5, 4.2, Cross-Chapter Box 4 in Chapter 4}

B.6.2 Global emissions in 2030 associated with the implementation of NDCs announced prior to COP26 are lower than the emissions implied by the original NDCs²⁹ (*high confidence*). The original emissions gap has fallen by about 20% to one-third relative to pathways that limit warming to 2°C (>67%) with immediate action (category C3a in Table SPM.2), and by about 15–20% relative to pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (category C1 in Table SPM.2) (*medium confidence*). (Figure SPM.4) {3.5, 4.2, Cross-Chapter Box 4 in Chapter 4}

Table SPM.1 | Projected global emissions in 2030 associated with policies implemented by the end of 2020 and NDCs announced prior to COP26, and associated emissions gaps. *Emissions projections for 2030 and absolute differences in emissions are based on emissions of 52–56 GtCO₂-eq yr⁻¹ in 2019 as assumed in underlying model studies. (*medium confidence*) {4.2, Table 4.3, Cross-Chapter Box 4 in Chapter 4}

	Implied by policies implemented by the end of 2020 (GtCO ₂ -eq yr ⁻¹)	Implied by NDCs announced prior to COP26	
		Unconditional elements (GtCO ₂ -eq yr ⁻¹)	Including conditional elements (GtCO ₂ -eq yr ⁻¹)
Median projected global emissions (min–max)*	57 [52–60]	53 [50–57]	50 [47–55]
Implementation gap between implemented policies and NDCs (median)		4	7
Emissions gap between NDCs and pathways that limit warming to 2°C (>67%) with immediate action		10–16	6–14
Emissions gap between NDCs and pathways that limit warming to 1.5°C (>50%) with no or limited overshoot with immediate action		19–26	16–23

²³ NDCs announced prior to COP26 refer to the most recent Nationally Determined Contributions submitted to the UNFCCC up to the literature cut-off date of this report, 11 October 2021, and revised NDCs announced by China, Japan and the Republic of Korea prior to October 2021 but only submitted thereafter. 25 NDC updates were submitted between 12 October 2021 and the start of COP26.

²⁴ This implies that mitigation after 2030 can no longer establish a pathway with less than 67% probability to exceed 1.5°C during the 21st century, a defining feature of the class of pathways that limit warming to 1.5°C (>50%) with no or limited overshoot assessed in this report (category C1 in Table SPM.2). These pathways limit warming to 1.6°C or lower throughout the 21st century with a 50% likelihood.

²⁵ The policy cut-off date in studies used to project GHG emissions of ‘policies implemented by the end of 2020’ varies between July 2019 and November 2020. (Table 4.2)

²⁶ Immediate action in modelled global pathways refers to the adoption between 2020 and at latest before 2025 of climate policies intended to limit global warming to a given level. Modelled pathways that limit warming to 2°C (>67%) based on immediate action are summarised in category C3a in Table SPM.2. All assessed modelled global pathways that limit warming to 1.5°C (>50%) with no or limited overshoot assume immediate action as defined here (Category C1 in Table SPM.2).

²⁷ In this report, ‘unconditional’ elements of NDCs refer to mitigation efforts put forward without any conditions. ‘Conditional’ elements refer to mitigation efforts that are contingent on international cooperation, for example bilateral and multilateral agreements, financing or monetary and/or technological transfers. This terminology is used in the literature and the UNFCCC’s NDC Synthesis Reports, not by the Paris Agreement. {4.2.1, 14.3.2}

²⁸ Two types of gaps are assessed: the implementation gap is calculated as the difference between the median of global emissions in 2030 implied by policies implemented by the end of 2020 and those implied by NDCs announced prior to COP26. The emissions gap is calculated as the difference between GHG emissions implied by the NDCs (minimum/maximum emissions in 2030) and the median of global GHG emissions in modelled pathways limiting warming to specific levels based on immediate action and with stated likelihoods as indicated (Table SPM.2).

²⁹ Original NDCs refer to those submitted to the UNFCCC in 2015 and 2016. Unconditional elements of NDCs announced prior to COP26 imply global GHG emissions in 2030 that are 3.8 [3.0–5.3] GtCO₂-eq yr⁻¹ lower than those from the original NDCs, and 4.5 [2.7–6.3] GtCO₂-eq yr⁻¹ lower when conditional elements of NDCs are included. NDC updates at or after COP26 could further change the implied emissions.

- B.6.3** Modelled global emission pathways consistent with NDCs announced prior to COP26 that limit warming to 2°C (>67%) (category C3b in Table SPM.2) imply annual average global GHG emissions reduction rates of 0–0.7 GtCO₂-eq yr⁻¹ during the decade 2020–2030, with an unprecedented acceleration to 1.4–2.0 GtCO₂-eq yr⁻¹ during 2030–2050 (*medium confidence*). Continued investments in unabated high-emitting infrastructure and limited development and deployment of low-emitting alternatives prior to 2030 would act as barriers to this acceleration and increase feasibility risks (*high confidence*). {3.3, 3.5, 3.8, Cross-Chapter Box 5 in Chapter 4}
- B.6.4** Modelled global emission pathways consistent with NDCs announced prior to COP26 will *likely* exceed 1.5°C during the 21st century. Those pathways that then return warming to 1.5°C by 2100 with a likelihood of 50% or greater imply a temperature overshoot of 0.15°C–0.3°C (42 pathways in category C2 in Table SPM.2). In such pathways, global cumulative net-negative CO₂ emissions are –380 [–860 to –200] GtCO₂³⁰ in the second half of the century, and there is a rapid acceleration of other mitigation efforts across all sectors after 2030. Such overshoot pathways imply increased climate-related risk, and are subject to increased feasibility concerns,³¹ and greater social and environmental risks, compared to pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. (*high confidence*) (Figure SPM.4, Table SPM.2) {3.3, 3.5, 3.8, 12.3; AR6 WGII SPM B.6}

Projected global GHG emissions from NDCs announced prior to COP26 would make it *likely* that warming will exceed 1.5°C and also make it harder after 2030 to limit warming to below 2°C.

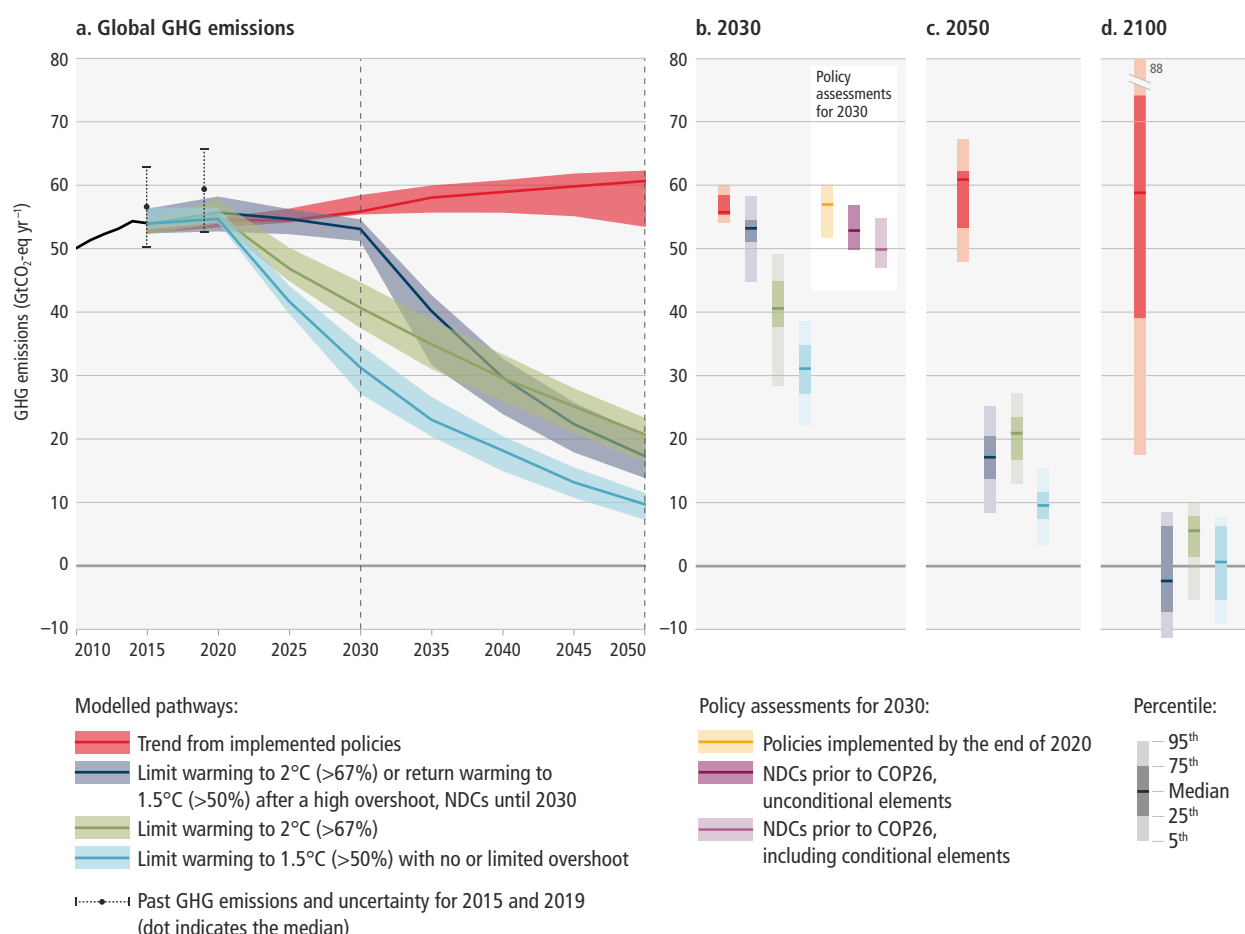

Figure SPM.4 | Global GHG emissions of modelled pathways (funnels in Panel a, and associated bars in Panels b, c, d) and projected emission outcomes from near-term policy assessments for 2030 (Panel b).

³⁰ Median and very likely range [5th to 95th percentile].

³¹ Returning to below 1.5°C in 2100 from GHG emissions levels in 2030 associated with the implementation of NDCs is infeasible for some models due to model-specific constraints on the deployment of mitigation technologies and the availability of net negative CO₂ emissions.

Figure SPM.4 (continued): Global GHG emissions of modelled pathways (funnels in Panel a, and associated bars in Panels b, c, d) and projected emission outcomes from near-term policy assessments for 2030 (Panel b). Panel a shows global GHG emissions over 2015–2050 for four types of assessed modelled global pathways:

- Trend from implemented policies: Pathways with projected near-term GHG emissions in line with policies implemented until the end of 2020 and extended with comparable ambition levels beyond 2030 (29 scenarios across categories C5–C7, Table SPM.2).
- Limit to 2°C (>67%) or return warming to 1.5°C (>50%) after a high overshoot, NDCs until 2030: Pathways with GHG emissions until 2030 associated with the implementation of NDCs announced prior to COP26, followed by accelerated emissions reductions *likely* to limit warming to 2°C (C3b, Table SPM.2) or to return warming to 1.5°C with a probability of 50% or greater after high overshoot (subset of 42 scenarios from C2, Table SPM.2).
- Limit to 2°C (>67%) with immediate action: Pathways that limit warming to 2°C (>67%) with immediate action after 2020²⁶ (C3a, Table SPM.2).
- Limit to 1.5°C (>50%) with no or limited overshoot: Pathways limiting warming to 1.5°C with no or limited overshoot (C1, Table SPM.2 C1). All these pathways assume immediate action after 2020.

Past GHG emissions for 2010–2015 used to project global warming outcomes of the modelled pathways are shown by a black line³² and past global GHG emissions in 2015 and 2019 as assessed in Chapter 2 are shown by whiskers. **Panels b, c and d** show snapshots of the GHG emission ranges of the modelled pathways in 2030, 2050, and 2100, respectively. Panel b also shows projected emissions outcomes from near-term policy assessments in 2030 from Chapter 4.2 (Tables 4.2 and 4.3; median and full range). GHG emissions are in CO₂-equivalent using GWP100 from AR6 WGI. {3.5, 4.2, Table 4.2, Table 4.3, Cross-Chapter Box 4 in Chapter 4}

B.7 Projected cumulative future CO₂ emissions over the lifetime of existing and currently planned fossil fuel infrastructure without additional abatement exceed the total cumulative net CO₂ emissions in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. They are approximately equal to total cumulative net CO₂ emissions in pathways that limit warming to 2°C (>67%). (*high confidence*) {2.7, 3.3}

- B.7.1** If historical operating patterns are maintained,³³ and without additional abatement,³⁴ estimated cumulative future CO₂ emissions from existing fossil fuel infrastructure, the majority of which is in the power sector, would, from 2018 until the end of its lifetime, amount to 660 [460–890] GtCO₂. They would amount to 850 [600–1100] GtCO₂ when unabated emissions from currently planned infrastructure in the power sector is included. These estimates compare with cumulative global net CO₂ emissions from all sectors of 510 [330–710] GtCO₂ until the time of reaching net zero CO₂ emissions³⁵ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and 890 [640–1160] GtCO₂ in pathways that limit warming to 2°C (>67%). (*high confidence*) (Table SPM.2) {2.7, Figure 2.26, Figure TS.8}
- B.7.2** In modelled global pathways that limit warming to 2°C (>67%) or lower, most remaining fossil fuel CO₂ emissions until the time of global net zero CO₂ emissions are projected to occur outside the power sector, mainly in industry and transport. Decommissioning and reduced utilisation of existing fossil fuel-based power sector infrastructure, retrofitting existing installations with CCS,³⁶ switches to low-carbon fuels, and cancellation of new coal installations without CCS are major options that can contribute to aligning future CO₂ emissions from the power sector with emissions in the assessed global modelled least-cost pathways. The most appropriate strategies will depend on national and regional circumstances, including enabling conditions and technology availability. (*high confidence*) (Box SPM.1) {Table 2.7, 2.7, 3.4, 6.3, 6.5, 6.7}

³² See Box SPM.1 for a description of the approach to project global warming outcomes of modelled pathways and its consistency with the climate assessment in AR6 WGI.

³³ Historical operating patterns are described by load factors and lifetimes of fossil fuel installations as observed in the past (average and range).

³⁴ Abatement here refers to human interventions that reduce the amount of greenhouse gases that are released from fossil fuel infrastructure to the atmosphere.

³⁵ Total cumulative CO₂ emissions up to the time of global net zero CO₂ emissions are similar but not identical to the remaining carbon budget for a given temperature limit assessed by Working Group I. This is because the modelled emission scenarios assessed by Working Group III cover a range of temperature levels up to a specific limit, and exhibit a variety of reductions in non-CO₂ emissions that also contribute to overall warming. {Box 3.4}

³⁶ In this context, capture rates of new installations with CCS are assumed to be 90–95%+ {11.3.5}. Capture rates for retrofit installations can be comparable, if plants are specifically designed for CCS retrofits {11.3.6}.

C. System Transformations to Limit Global Warming

- C.1** Global GHG emissions are projected to peak between 2020 and at the latest before 2025 in global modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot and in those that limit warming to 2°C (>67%) and assume immediate action (see Table SPM.2 footnote i).³⁷ In both types of modelled pathways, rapid and deep GHG emissions reductions follow throughout 2030, 2040 and 2050 (*high confidence*). Without a strengthening of policies beyond those that are implemented by the end of 2020, GHG emissions are projected to rise beyond 2025, leading to a median global warming of 3.2 [2.2 to 3.5] °C by 2100^{38,39} (*medium confidence*). (Table SPM.2, Figure SPM.4, Figure SPM.5) {3.3, 3.4}
- C.1.1** Net global GHG emissions are projected to fall from 2019 levels by 27% [13–45%] by 2030 and 63% [52–76%]⁴⁰ by 2050 in global modelled pathways that limit warming to 2°C (>67%) and assuming immediate action (category C3a, Table SPM.2). This compares with reductions of 43% [34–60%] by 2030 and 84% [73–98%] by 2050 in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot (C1, Table SPM.2) (*high confidence*).⁴¹ In modelled pathways that return warming to 1.5°C (>50%) after a high overshoot,⁴² GHG emissions are reduced by 23% [0–44%] in 2030 and by 75% [62–91%] in 2050 (C2, Table SPM.2) (*high confidence*). Modelled pathways that are consistent with NDCs announced prior to COP26 until 2030 and assume no increase in ambition thereafter have higher emissions, leading to a median global warming of 2.8 [2.1–3.4] °C by 2100 (*medium confidence*).²³ (Figure SPM.4) {3.3}
- C.1.2** In modelled pathways that limit warming to 2°C (>67%) assuming immediate action, global net CO₂ emissions are reduced compared to modelled 2019 emissions by 27% [11–46%] in 2030 and by 52% [36–70%] in 2040; and global CH₄ emissions are reduced by 24% [9–53%] in 2030 and by 37% [20–60%] in 2040. In pathways that limit warming to 1.5°C (>50%) with no or limited overshoot global net CO₂ emissions are reduced compared to modelled 2019 emissions by 48% [36–69%] in 2030 and by 80% [61–109%] in 2040; and global CH₄ emissions are reduced by 34% [21–57%] in 2030 and 44% [31–63%] in 2040. There are similar reductions of non-CO₂ emissions by 2050 in both types of pathways: CH₄ is reduced by 45% [25–70%]; N₂O is reduced by 20% [–5 to +55%]; and F-gases are reduced by 85% [20–90%].⁴³ Across most modelled pathways, this is the maximum technical potential for anthropogenic CH₄ reductions in the underlying models (*high confidence*). Further emissions reductions, as illustrated by the IMP-SP pathway, may be achieved through changes in activity levels and/or technological innovations beyond those represented in the majority of the pathways (*medium confidence*). Higher emissions reductions of CH₄ could further reduce peak warming. (*high confidence*) (Figure SPM.5) {3.3}
- C.1.3** In modelled pathways consistent with the continuation of policies implemented by the end of 2020, GHG emissions continue to rise, leading to global warming of 3.2 [2.2–3.5] °C by 2100 (within C5–C7, Table SPM.2) (*medium confidence*). Pathways that exceed warming of >4°C (≥50%) (C8, SSP5-8.5, Table SPM.2) would imply a reversal of current technology and/or mitigation policy trends (*medium confidence*). Such warming could occur in emission pathways consistent with policies implemented by the end of 2020 if climate sensitivity is higher than central estimates (*high confidence*). (Table SPM.2, Figure SPM.4) {3.3, Box 3.3}

³⁷ All reported warming levels are relative to the period 1850–1900. If not otherwise specified, ‘pathways’ always refer to pathways computed with a model. Immediate action in the pathways refers to the adoption of climate policies between 2020 and at latest 2025 intended to limit global warming at a given level.

³⁸ Long-term warming is calculated from all modelled pathways assuming mitigation efforts consistent with national policies that were implemented by the end of 2020 (scenarios that fall into policy category P1b of Chapter 3) and that pass through the 2030 GHG emissions ranges of such pathways assessed in Chapter 4 (see footnote 25). {3.2, Table 4.2}

³⁹ Warming estimates refer to the 50th and [5th–95th] percentile across the modelled pathways and the median temperature change estimate of the probabilistic WGI climate model emulators (see Table SPM.2 footnote a).

⁴⁰ In this report, emissions reductions are reported relative to 2019 modelled emission levels, while in SR1.5 emissions reductions were calculated relative to 2010. Between 2010 and 2019 global GHG and global CO₂ emissions have grown by 12% (6.5 GtCO₂-eq) and 13% (5.0 GtCO₂) respectively. In global modelled pathways assessed in this report that limit warming to 1.5°C (>50%) with no or limited overshoot, GHG emissions are projected to be reduced by 37% [28–57%] in 2030 relative to 2010. In the same type of pathways assessed in SR1.5, reported GHG emissions reductions in 2030 were 39–51% (interquartile range) relative to 2010. In absolute terms, the 2030 GHG emissions levels of pathways that limit warming to 1.5°C (>50%) with no or limited overshoot are higher in AR6 (31 [21–36] GtCO₂-eq) than in SR1.5 (28 [26–31] interquartile range) GtCO₂-eq. (Figure SPM.1, Table SPM.2) {3.3, SR1.5 Figure SPM.3b}

⁴¹ Scenarios in this category limit peak warming to 2°C throughout the 21st century with close to, or more than, 90% likelihood.

⁴² This category contains 91 scenarios with immediate action and 42 scenarios that are consistent with the NDCs until 2030.

⁴³ These numbers for CH₄, N₂O, and F-gases are rounded to the nearest 5% except numbers below 5%.

Table SPM.2 | Key characteristics of the modelled global emissions pathways. Summary of projected CO₂ and GHG emissions, projected net zero timings and the resulting global warming outcomes. Pathways are categorised (rows), according to their likelihood of limiting warming to different peak warming levels (if peak temperature occurs before 2100) and 2100 warming levels. Values shown are for the median [p50] and 5th–95th percentiles [p5–p95], noting that not all pathways achieve net zero CO₂ or GHGs.

p50 [p5–p95] ^a			GHG emissions (GtCO ₂ -eq yr ⁻¹) ^g			GHG emissions reductions from 2019 (%) ^h			Emissions milestones ^{i,j}				Cumulative CO ₂ emissions (GtCO ₂) ^m		Cumulative net-negative CO ₂ emissions (GtCO ₂)	Global mean temperature changes 50% probability (°C) ⁿ		Likelihood of peak global warming staying below (%) ^o		
Category ^{b,c,d} [# pathways]	Category/subset label	WGI SSP & WGIII IPs/IMPs alignment ^{e,f}	2030	2040	2050	2030	2040	2050	Peak CO ₂ emissions (% peak before 2100)	Peak GHG emissions (% peak before 2100)	Net zero CO ₂ (% net zero pathways)	Net zero GHGs (% net zero pathways) ^{k,l}	2020 to net zero CO ₂	2020–2100	Year of net zero CO ₂ to 2100	at peak warming	2100	<1.5°C	<2.0°C	<3.0°C
Modelled global emissions pathways categorised by projected global warming levels (GWL). Detailed likelihood definitions are provided in SPM Box 1. The five illustrative scenarios (SSPx-yy) considered by AR6 WGI and the Illustrative (Mitigation) Pathways assessed in WGIII are aligned with the temperature categories and are indicated in a separate column. Global emission pathways contain regionally differentiated information. This assessment focuses on their global characteristics.			Projected median annual GHG emissions in the year across the scenarios, with the 5th–95th percentile in brackets. Modelled GHG emissions in 2019: 55 [53–58] GtCO ₂ -eq.			Projected median GHG emissions reductions of pathways in the year across the scenarios compared to modelled 2019, with the 5th–95th percentile in brackets. Negative numbers indicate increase in emissions compared to 2019.			Median 5-year intervals at which projected CO ₂ & GHG emissions peak, with the 5th–95th percentile interval in square brackets. Percentage of peaking pathways is denoted in round brackets. Three dots (...) denotes emissions peak in 2100 or beyond for that percentile.		Median 5-year intervals at which projected CO ₂ & GHG emissions of pathways in this category reach net zero, with the 5th–95th percentile interval in square brackets. Percentage of net zero pathways is denoted in round brackets. Three dots (...) denotes net zero not reached for that percentile.		Median cumulative net CO ₂ emissions across the projected scenarios in this category until reaching net zero or until 2100, with the 5th–95th percentile interval in square brackets.		Median cumulative net-negative CO ₂ emissions between the year of net zero CO ₂ and 2100. More net-negative results in greater temperature declines after peak.	Projected temperature change of pathways in this category (50% probability across the range of climate uncertainties), relative to 1850–1900, at peak warming and in 2100, for the median value across the scenarios and the 5th–95th percentile interval in square brackets.		Median likelihood that the projected pathways in this category stay below a given global warming level, with the 5th–95th percentile interval in square brackets.

Modelled global emissions pathways categorised by projected global warming levels (GWL). Detailed likelihood definitions are provided in SPM Box 1. The five illustrative scenarios (SSPx-yy) considered by AR6 WGI and the Illustrative (Mitigation) Pathways assessed in WGIII are aligned with the temperature categories and are indicated in a separate column. Global emission pathways contain regionally differentiated information. This assessment focuses on their global characteristics.			Projected median annual GHG emissions in the year across the scenarios, with the 5th–95th percentile in brackets. Modelled GHG emissions in 2019: 55 [53–58] GtCO ₂ -eq.			Projected median GHG emissions reductions of pathways in the year across the scenarios compared to modelled 2019, with the 5th–95th percentile in brackets. Negative numbers indicate increase in emissions compared to 2019.			Median 5-year intervals at which projected CO ₂ & GHG emissions peak, with the 5th–95th percentile interval in square brackets. Percentage of peaking pathways is denoted in round brackets. Three dots (...) denotes emissions peak in 2100 or beyond for that percentile.		Median 5-year intervals at which projected CO ₂ & GHG emissions of pathways in this category reach net zero, with the 5th–95th percentile interval in square brackets. Percentage of net zero pathways is denoted in round brackets. Three dots (...) denotes net zero not reached for that percentile.		Median cumulative net CO ₂ emissions across the projected scenarios in this category until reaching net zero or until 2100, with the 5th–95th percentile interval in square brackets.		Median cumulative net-negative CO ₂ emissions between the year of net zero CO ₂ and 2100. More net-negative results in greater temperature declines after peak.	Projected temperature change of pathways in this category (50% probability across the range of climate uncertainties), relative to 1850–1900, at peak warming and in 2100, for the median value across the scenarios and the 5th–95th percentile interval in square brackets.		Median likelihood that the projected pathways in this category stay below a given global warming level, with the 5th–95th percentile interval in square brackets.		
C3b [97]	... NDCs until 2030	GS	52 [47–56]	29 [20–36]	18 [10–25]	5 [0–14]	46 [34–63]	68 [56–82]					910 [720–1150]	800 [560–1050]	–60 [–300 to 0]	1.8 [1.6–1.8]	1.6 [1.5–1.7]	17 [12–35]	73 [67–87]	99 [98–99]

Table SPM.2 (continued):

^a Values in the table refer to the 50th and [5th–95th] percentile values across the pathways falling within a given category as defined in Box SPM.1. For emissions-related columns these values relate to the distribution of all the pathways in that category. Harmonised emissions values are given for consistency with projected global warming outcomes using climate emulators. Based on the assessment of climate emulators in AR6 WGI (WG1 Chapter 7, Box 7.1), two climate emulators are used for the probabilistic assessment of the resulting warming of the pathways. For the 'Temperature change' and 'Likelihood' columns, the single upper-row values represent the 50th percentile across the pathways in that category and the median [50th percentile] across the warming estimates of the probabilistic MAGICC climate model emulator. For the bracketed ranges, the median warming for every pathway in that category is calculated for each of the two climate model emulators (MAGICC and FaIR). Subsequently, the 5th and 95th percentile values across all pathways for each emulator are calculated. The coolest and warmest outcomes (i.e., the lowest p5 of two emulators, and the highest p95, respectively) are shown in square brackets. These ranges therefore cover both the uncertainty of the emissions pathways as well as the climate emulators' uncertainty.

^b For a description of pathways categories see Box SPM.1.

^c All global warming levels are relative to 1850–1900. (See footnote n below and Box SPM.1⁴⁵ for more details.)

^d C3 pathways are sub-categorised according to the timing of policy action to match the emissions pathways in Figure SPM.4. Two pathways derived from a cost-benefit analysis have been added to C3a, whilst 10 pathways with specifically designed near-term action until 2030, whose emissions fall below those implied by NDCs announced prior to COP26, are not included in either of the two subsets.

^e Alignment with the categories of the illustrative SSP scenarios considered in AR6 WGI, and the Illustrative (Mitigation) Pathways (IPs/IMPs) of WGIII. The IMPs have common features such as deep and rapid emissions reductions, but also different combinations of sectoral mitigation strategies. See Box SPM.1 for an introduction of the IPs and IMPs, and Chapter 3 for full descriptions. {3.2, 3.3, Annex III.II.4}

^f The Illustrative Mitigation Pathway 'Neg' has extensive use of carbon dioxide removal (CDR) in the AFOLU, energy and the industry sectors to achieve net negative emissions. Warming peaks around 2060 and declines to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as C3, it strongly exhibits the characteristics of C2 high-overshoot pathways, hence it has been placed in the C2 category. See Box SPM.1 for an introduction of the IPs and IMPs.

^g The 2019 range of harmonised GHG emissions across the pathways [53–58 GtCO₂-eq] is within the uncertainty ranges of 2019 emissions assessed in Chapter 2 [53–66 GtCO₂-eq].⁴⁹ (Figure SPM.1, Figure SPM.2, Box SPM.1)

^h Rates of global emission reduction in mitigation pathways are reported on a pathway-by-pathway basis relative to harmonised modelled global emissions in 2019 rather than the global emissions reported in SPM Section B and Chapter 2; this ensures internal consistency in assumptions about emission sources and activities, as well as consistency with temperature projections based on the physical climate science assessment by WGI.⁴⁹ {Annex III.II.2.5}. Negative values (e.g., in C7, C8) represent an increase in emissions.

ⁱ Emissions milestones are provided for five-year intervals in order to be consistent with the underlying five-year time-step data of the modelled pathways. Peak emissions (CO₂ and GHGs) are assessed for five-year reporting intervals starting in 2020. The interval 2020–2025 signifies that projected emissions peak as soon as possible between 2020 and at latest before 2025. The upper five-year interval refers to the median interval within which the emissions peak or reach net zero. Ranges in square brackets underneath refer to the range across the pathways, comprising the lower bound of the 5th percentile five-year interval and the upper bound of the 95th percentile five-year interval. Numbers in round brackets signify the fraction of pathways that reach specific milestones.

^j Percentiles reported across all pathways in that category include those that do not reach net zero before 2100 (fraction of pathways reaching net zero is given in round brackets). If the fraction of pathways that reach net zero before 2100 is lower than the fraction of pathways covered by a percentile (e.g., 0.95 for the 95th percentile), the percentile is not defined and denoted with '...'. The fraction of pathways reaching net zero includes all with reported non-harmonised, and/or harmonised emissions profiles that reach net zero. Pathways were counted when at least one of the two profiles fell below 100 MtCO₂ yr⁻¹ until 2100.

^k The timing of net zero is further discussed in SPM C2.4 and Cross-Chapter Box 3 in Chapter 3 on net zero CO₂ and net zero GHG emissions.

^l For cases where models do not report all GHGs, missing GHG species are infilled and aggregated into a Kyoto basket of GHG emissions in CO₂-eq defined by the 100-year global warming potential. For each pathway, reporting of CO₂, CH₄, and N₂O emissions was the minimum required for the assessment of the climate response and the assignment to a climate category. Emissions pathways without climate assessment are not included in the ranges presented here. {See Annex III.II.5}

^m Cumulative emissions are calculated from the start of 2020 to the time of net zero and 2100, respectively. They are based on harmonised net CO₂ emissions, ensuring consistency with the WGI assessment of the remaining carbon budget.⁵⁰ {Box 3.4}

ⁿ Global mean temperature change for category (at peak, if peak temperature occurs before 2100, and in 2100) relative to 1850–1900, based on the median global warming for each pathway assessed using the probabilistic climate model emulators calibrated to the AR6 WGI assessment.¹² (See also Box SPM.1) {Annex III.II.2.5; WGI Cross-Chapter Box 7.1}

^o Probability of staying below the temperature thresholds for the pathways in each category, taking into consideration the range of uncertainty from the climate model emulators consistent with the AR6 WGI assessment. The probabilities refer to the probability at peak temperature. Note that in the case of temperature overshoot (e.g., category C2 and some pathways in C1), the probabilities of staying below at the end of the century are higher than the probabilities at peak temperature.

- C.1.4** Global modelled pathways falling into the lowest temperature category of the assessed literature (C1, Table SPM.2) are on average associated with a higher median peak warming in AR6 compared to pathways in the same category in SR1.5. In the modelled pathways in AR6, the likelihood of limiting warming to 1.5°C has on average declined compared to SR1.5. This is because GHG emissions have risen since 2017, and many recent pathways have higher projected emissions by 2030, higher cumulative net CO₂ emissions and slightly later dates for reaching net zero CO₂ or net zero GHG emissions. High mitigation challenges, for example, due to assumptions of slow technological change, high levels of global population growth, and high fragmentation as in the Shared Socio-economic Pathway SSP3, may render modelled pathways that limit warming to 2°C (>67%) or lower infeasible. (*medium confidence*) (Table SPM.2, Box SPM.1) {3.3, 3.8, Annex III Figure II.1, Annex III Figure II.3}

Box SPM.1 | Assessment of Modelled Global Emission Scenarios

A wide range of modelled global emission pathways and scenarios from the literature is assessed in this report, including pathways and scenarios with and without mitigation.⁴⁴ Emissions pathways and scenarios project the evolution of GHG emissions based on a set of internally consistent assumptions about future socio-economic conditions and related mitigation measures.⁴⁵ These are quantitative projections and are neither predictions nor forecasts. Around half of all modelled global emission scenarios assume cost-effective approaches that rely on least-cost emission abatement options globally. The other half look at existing policies and regionally and sectorally differentiated actions. Most do not make explicit assumptions about global equity, environmental justice or intra-regional income distribution. Global emission pathways, including those based on cost-effective approaches, contain regionally differentiated assumptions and outcomes, and have to be assessed with the careful recognition of these assumptions. This assessment focuses on their global characteristics. The majority of the assessed scenarios (about 80%) have become available since the SR1.5, but some were assessed in that report. Scenarios with and without mitigation were categorised based on their projected global warming over the 21st century, following the same scheme as in the SR1.5 for warming up to and including 2°C. {1.5, 3.2, 3.3, Annex III.II.2, Annex III.II.3}

Scenario categories are defined by their likelihood of exceeding global warming levels (at peak and in 2100) and referred to in this report as follows:^{46,47}

- Category C1 comprises modelled scenarios that limit warming to 1.5°C in 2100 with a likelihood of greater than 50%, and reach or exceed warming of 1.5°C during the 21st century with a likelihood of 67% or less. In this report, these scenarios are referred to as scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot. Limited overshoot refers to exceeding 1.5°C global warming by up to about 0.1°C and for up to several decades.⁴⁸
- Category C2 comprises modelled scenarios that limit warming to 1.5°C in 2100 with a likelihood of greater than 50%, and exceed warming of 1.5°C during the 21st century with a likelihood of greater than 67%. In this report, these scenarios are also referred to as scenarios that return warming to 1.5°C (>50%) after a high overshoot. High overshoot refers to temporarily exceeding 1.5°C global warming by 0.1°C–0.3°C for up to several decades.
- Category C3 comprises modelled scenarios that limit peak warming to 2°C throughout the 21st century with a likelihood of greater than 67%. In this report, these scenarios are also referred to as scenarios that limit warming to 2°C (>67%).
- Categories C4, C5, C6 and C7 comprise modelled scenarios that limit warming to 2°C, 2.5°C, 3°C, 4°C, respectively, throughout the 21st century with a likelihood of greater than 50%. In some scenarios in C4 and many scenarios in C5–C7, warming continues beyond the 21st century.

⁴⁴ In the literature, the terms ‘pathways’ and ‘scenarios’ are used interchangeably, with the former more frequently used in relation to climate goals. For this reason, this SPM uses mostly the term (emissions and mitigation) pathways. {Annex III.II.1.1}

⁴⁵ Key assumptions relate to technology development in agriculture and energy systems and socio-economic development, including demographic and economic projections. IPCC is neutral with regard to the assumptions underlying the scenarios in the literature assessed in this report, which do not cover all possible futures. Additional scenarios may be developed. The underlying population assumptions range from 8.5 to 9.7 billion in 2050 and 7.4 to 10.9 billion in 2100 (5–95th percentile) starting from 7.6 billion in 2019. The underlying assumptions on global GDP growth (ppp) range from 2.5 to 3.5% per year in the 2019–2050 period and 1.3 to 2.1% per year in the 2050–2100 (5–95th percentile). Many underlying assumptions are regionally differentiated. {1.5; 3.2; 3.3; Figure 3.9; Annex III.II.1.4; Annex III.II.3}

⁴⁶ The future scenario projections presented here are consistent with the total observed increase in global surface temperature between 1850–1900 and 1995–2014 as well as to 2011–2020 (with best estimates of 0.85°C and 1.09°C, respectively) assessed in WGI. The largest contributor to historical human-induced warming is CO₂, with historical cumulative CO₂ emissions from 1850 to 2019 being 2400 ± 240 GtCO₂. {WGI SPM A.1.2, WGI Table SPM.2, WGI Table 5.1, WGIII SPM Section B}.

⁴⁷ In case no explicit likelihood is provided, the reported warming levels are associated with a likelihood of >50%.

⁴⁸ Scenarios in this category are found to have simultaneous likelihood to limit peak global warming to 2°C throughout the 21st century of close to and more than 90%.

Box SPM.1 (continued)

- Category C8 comprises modelled scenarios that exceed warming of 4°C during the 21st century with a likelihood of 50% or greater. In these scenarios warming continues to rise beyond the 21st century.

Categories of modelled scenarios are distinct and do not overlap; they do not contain categories consistent with lower levels of global warming, for example, the category of C3 scenarios that limit warming to 2°C (>67%) does not include the C1 and C2 scenarios that limit or return warming to 1.5°C (>50%). Where relevant, scenarios belonging to the group of categories C1–C3 are referred to in this report as scenarios that limit warming to 2°C (>67%) or lower.

Methods to project global warming associated with the scenarios were updated to ensure consistency with the AR6 WGI assessment of physical climate science.⁴⁹ {3.2, Annex III.II.2.5; AR6 WGI Cross-Chapter Box 7.1}

The range of assessed scenarios results in a range of 21st century projected global warming.

Box SPM.1, Figure 1 | Projected global mean warming of the ensemble of modelled scenarios included in the climate categories C1–C8 and IMPs (based on emulators calibrated to the WGI assessment), as well as five illustrative scenarios (SSPx-y) as considered by AR6 WGI. Panel a shows the p5–p95 range of projected median warming across global modelled pathways within a category, with the category medians (line). **Panel b** shows the peak and 2100 emulated temperature outcomes for the categories C1 to C8 and for IMPs, and the five illustrative scenarios (SSPx-y) as considered by AR6 WGI. The boxes show the p5–p95 range within each scenario category, as in panel a. The combined p5–p95 range across scenarios and the climate uncertainty for each category C1–C8 is also shown for 2100 warming (thin vertical lines). (Table SPM.2) {Figure 3.11; AR6 WGI Figure SPM.8}

⁴⁹ This involved improved methodologies to use climate emulators (MAGICC7 and FAIR v1.6), which were evaluated and calibrated to closely match the global warming response to emissions as assessed in AR6 WGI. It included harmonisation of global GHG emissions in 2015 in modelled scenarios (51–56 GtCO₂-eq; 5th to 95th percentiles) with the corresponding emission value underlying the CMIP6 projected climate response assessed by WGI (54 GtCO₂-eq), based on similar data sources of historical emissions that are updated over time. The assessment of past GHG emissions in Chapter 2 of the report is based on a more recent dataset providing emissions of 57 [±6.3] GtCO₂-eq in 2015 (B.1). Differences are well within the assessed uncertainty range, and arise mainly from differences in estimated CO₂-LULUCF emissions, which are subject to large uncertainties, high annual variability and revisions over time. Projected rates of global emission reduction in mitigation scenarios are reported relative to modelled global emissions in 2019 rather than the global emissions reported in Chapter 2; this ensures internal consistency in assumptions about emission sources and activities, as well as consistency with temperature projections based on the physical climate science assessment by WG I. {Annex III.II.2.5}

Box SPM.1 (continued)

These updated methods affect the categorisation of some scenarios. On average across scenarios, peak global warming is projected to be lower by up to about 0.05 [± 0.1] °C than if the same scenarios were evaluated using the SR1.5 methodology, and global warming in 2100 is projected to be lower by about 0.1 [± 0.1] °C. {Annex III.II.2.5.1, Annex III Figure II.3}

Resulting changes to the emission characteristics of scenario categories described in Table SPM.2 interact with changes in the characteristics of the wider range of emission scenarios published since the SR1.5. Proportionally more scenarios assessed in AR6 are designed to limit temperature overshoot and more scenarios limit large-scale net negative CO₂ emissions than in SR1.5. As a result, AR6 scenarios in the lowest temperature category (C1) generally reach net zero GHG emissions later in the 21st century than scenarios in the same category assessed in SR1.5, and about half do not reach net zero GHG by 2100. The rate of decline of GHG emissions in the near term by 2030 in category C1 scenarios is very similar to the assessed rate in SR1.5, but absolute GHG emissions of category C1 scenarios in AR6 are slightly higher in 2030 than in SR1.5, since the reductions start from a higher emissions level in 2020. (Table SPM.2) {Annex III, 2.5, 3.2, 3.3}

The large number of global emissions scenarios assessed, including 1202 scenarios with projected global warming outcomes using climate emulators, come from a wide range of modelling approaches. They include the five illustrative scenarios (Shared Socio-economic Pathways; SSPs) assessed by WGI for their climate outcomes but cover a wider and more varied set in terms of assumptions and modelled outcomes. For this assessment, Illustrative Mitigation Pathways (IMPs) were selected from this larger set to illustrate a range of different mitigation strategies that would be consistent with different warming levels. The IMPs illustrate pathways that achieve deep and rapid emissions reductions through different combinations of mitigation strategies. The IMPs are not intended to be comprehensive and do not address all possible themes in the underlying report. They differ in terms of their focus, for example, placing greater emphasis on renewables (IMP-Ren), deployment of carbon dioxide removal that results in net negative global GHG emissions (IMP-Neg), and efficient resource use as well as shifts in consumption patterns globally, leading to low demand for resources, while ensuring a high level of services and satisfying basic needs (IMP-LD) (Figure SPM.5). Other IMPs illustrate the implications of a less rapid introduction of mitigation measures followed by a subsequent gradual strengthening (IMP-GS), and how shifting global pathways towards sustainable development, including by reducing inequality, can lead to mitigation (IMP-SP). The IMPs reach different climate goals as indicated in Table SPM.2 and Box SPM.1, Figure 1. {1.5, 3.1, 3.2, 3.3, 3.6, Figure 3.7, Figure 3.8, Box 3.4, Annex III.II.2.4}

- C.2 Global net zero CO₂ emissions are reached in the early 2050s in modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and around the early 2070s in modelled pathways that limit warming to 2°C (>67%). Many of these pathways continue to net negative CO₂ emissions after the point of net zero. These pathways also include deep reductions in other GHG emissions. The level of peak warming depends on cumulative CO₂ emissions until the time of net zero CO₂ and the change in non-CO₂ climate forcings by the time of peaking. Deep GHG emissions reductions by 2030 and 2040, particularly reductions of methane emissions, lower peak warming, reduce the likelihood of overshooting warming limits and lead to less reliance on net negative CO₂ emissions that reverse warming in the latter half of the century. Reaching and sustaining global net zero GHG emissions results in a gradual decline in warming. (*high confidence*) (Table SPM.2) {3.3, 3.5, Box 3.4, Cross-Chapter Box 3 in Chapter 3, AR6 WGI SPM D1.8}**
- C.2.1** Modelled global pathways limiting warming to 1.5°C (>50%) with no or limited overshoot are associated with projected cumulative net CO₂ emissions⁵⁰ until the time of net zero CO₂ of 510 [330–710] GtCO₂. Pathways limiting warming to 2°C (>67%) are associated with 890 [640–1160] GtCO₂ (Table SPM.2). (*high confidence*) {3.3, Box 3.4}
- C.2.2** Modelled global pathways that limit warming to 1.5°C (>50%) with no or limited overshoot involve more rapid and deeper near-term GHG emissions reductions through to 2030, and are projected to have less net negative CO₂ emissions and less carbon dioxide removal (CDR) in the longer term, than pathways that return warming to 1.5°C (>50%) after a high overshoot (C2 category). Modelled pathways that limit warming to 2°C (>67%) have on average lower net negative CO₂ emissions compared to pathways that limit warming to 1.5°C (>50%) with no or limited overshoot and pathways that return warming

⁵⁰ Cumulative net CO₂ emissions from the beginning of the year 2020 until the time of net zero CO₂ in assessed pathways are consistent with the remaining carbon budgets assessed by WGI, taking account of the ranges in the WGIII temperature categories and warming from non-CO₂ gases. {Box 3.4}

to 1.5°C (>50%) after a high overshoot (C1 and C2 categories respectively). Modelled pathways that return warming to 1.5°C (>50%) after a high overshoot (C2 category) show near-term GHG emissions reductions similar to pathways that limit warming to 2°C (>67%) (C3 category). For a given peak global warming level, greater and more rapid near-term GHG emissions reductions are associated with later net zero CO₂ dates. (*high confidence*) (Table SPM.2) {3.3, Table 3.5, Cross-Chapter Box 3 in Chapter 3, Annex I: Glossary}

- SPM**
- C.2.3** Future non-CO₂ warming depends on reductions in non-CO₂ GHGs, aerosols and their precursors, and ozone precursor emissions. In modelled global low-emission pathways, the projected reduction of cooling and warming aerosol emissions over time leads to net warming in the near- to mid-term. In these mitigation pathways, the projected reductions of cooling aerosols are mostly due to reduced fossil fuel combustion that was not equipped with effective air pollution controls. Non-CO₂ GHG emissions at the time of net zero CO₂ are projected to be of similar magnitude in modelled pathways that limit warming to 2°C (>67%) or lower. These non-CO₂ GHG emissions are about 8 [5–11] GtCO₂-eq yr⁻¹, with the largest fraction from CH₄ (60% [55–80%]), followed by N₂O (30% [20–35%]) and F-gases (3% [2–20%]).⁵¹ Due to the short lifetime of CH₄ in the atmosphere, projected deep reduction of CH₄ emissions up until the time of net zero CO₂ in modelled mitigation pathways effectively reduces peak global warming. (*high confidence*) {3.3; AR6 WGI SPM D1.7}
- C.2.4** At the time of global net zero GHG emissions, net negative CO₂ emissions counterbalance metric-weighted non-CO₂ GHG emissions. Typical emissions pathways that reach and sustain global net zero GHG emissions based on the 100-year global warming potential (GWP-100)⁷ are projected to result in a gradual decline of global warming. About half of the assessed pathways that limit warming to 1.5°C (>50%) with no or limited overshoot (C1 category) reach net zero GHG emissions during the second half of the 21st century. These pathways show greater reduction in global warming after the peak to 1.2 [1.1–1.4] °C by 2100 than modelled pathways in the same category that do not reach net zero GHG emissions before 2100 and that result in warming of 1.4 [1.3–1.5] °C by 2100. In modelled pathways that limit warming to 2°C (>67%) (C3 category), there is no significant difference in warming by 2100 between those pathways that reach net zero GHGs (around 30%) and those that do not (*high confidence*). In pathways that limit warming to 2°C (>67%) or lower and that do reach net zero GHG, net zero GHG occurs around 10–40 years later than net zero CO₂ emissions (*medium confidence*). {Cross-Chapter Box 2 in Chapter 2, 3.3, Cross-Chapter Box 3 in Chapter 3; AR6 WGI SPM D1.8}
- C.3** **All global modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and those that limit warming to 2°C (>67%), involve rapid and deep and in most cases immediate GHG emission reductions in all sectors. Modelled mitigation strategies to achieve these reductions include transitioning from fossil fuels without CCS to very low- or zero-carbon energy sources, such as renewables or fossil fuels with CCS, demand side measures and improving efficiency, reducing non-CO₂ emissions, and deploying carbon dioxide removal (CDR) methods to counterbalance residual GHG emissions. Illustrative Mitigation Pathways (IMPs) show different combinations of sectoral mitigation strategies consistent with a given warming level. (*high confidence*) (Figure SPM.5) {3.2, 3.3, 3.4, 6.4, 6.6}**
- C.3.1** There is a variation in the contributions of different sectors in modelled mitigation pathways, as illustrated by the Illustrative Mitigation Pathways (IMPs). However, modelled pathways that limit warming to 2°C (>67%) or lower share common characteristics, including rapid and deep GHG emission reductions. Doing less in one sector needs to be compensated by further reductions in other sectors if warming is to be limited. (*high confidence*) (Figure SPM.5) {3.2, 3.3, 3.4}
- C.3.2** In modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, the global use of coal, oil and gas in 2050 is projected to decline with median values of about 95%, 60% and 45% respectively, compared to 2019. The interquartile ranges are (80 to 100%), (40 to 75%) and (20 to 60%) and the p5–p95 ranges are [60 to 100%], [25 to 90%] and [–30 to +85%], respectively. In modelled pathways that limit warming to 2°C (>67%), these projected declines have a median value and interquartile range of 85% (65 to 95%), 30% (15 to 50%) and 15% (–10 to +40%) respectively by 2050. The use of coal, oil and gas without CCS in modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot is projected to be reduced to a greater degree, with median values of about 100%, 60% and 70% in 2050 compared to 2019. The interquartile ranges are (95 to 100%), (45 to 75%) and (60 to 80%) and the p5–p95 ranges about [85 to 100%], [25 to 90%] and [35 to 90%] for coal, oil and gas respectively. In these global modelled pathways, in 2050 almost all electricity is supplied from zero- or low-carbon sources, such as renewables or fossil fuels with CCS, combined with increased

⁵¹ All numbers here rounded to the closest 5%, except values below 5% (for F-gases).

electrification of energy demand. As indicated by the ranges, choices in one sector can be compensated for by choices in another while being consistent with assessed warming levels.⁵² (*high confidence*) {3.4, 3.5, Table 3.6, Figure 3.22, Figure 6.35}

- C.3.3** In modelled pathways that reach global net zero CO₂ emissions: at the point they reach net zero, 5–16 GtCO₂ of emissions from some sectors are compensated for by net negative CO₂ emissions in other sectors. In most global modelled pathways that limit warming to 2°C (>67%) or lower, the AFOLU sector, via reforestation and reduced deforestation, and the energy supply sector reach net zero CO₂ emissions earlier than the buildings, industry and transport sectors. (*high confidence*) (Figure SPM.5e,f) {3.4}
- C.3.4** In modelled pathways that reach global net zero GHG emissions, at the point they reach net zero GHG, around 74% [54 to 90%] of global emissions reductions are achieved by CO₂ reductions in energy supply and demand, 13% [4 to 20%] by CO₂ mitigation options in the AFOLU sector, and 13% [10 to 18%] through the reduction of non-CO₂ emissions from land-use, energy and industry (*medium confidence*). (Figure SPM.5f) {3.3, 3.4}
- C.3.5** Methods and levels of CDR deployment in global modelled mitigation pathways vary depending on assumptions about costs, availability and constraints.⁵³ In modelled pathways that report CDR and that limit warming to 1.5°C (>50%) with no or limited overshoot, global cumulative CDR during 2020–2100 from bioenergy with carbon dioxide capture and storage (BECCS) and direct air carbon dioxide capture and storage (DACCS) is 30–780 GtCO₂ and 0–310 GtCO₂, respectively. In these modelled pathways, the AFOLU sector contributes 20–400 GtCO₂ net negative emissions. Total cumulative net negative CO₂ emissions including CDR deployment across all options represented in these modelled pathways are 20–660 GtCO₂. In modelled pathways that limit warming to 2°C (>67%), global cumulative CDR during 2020–2100 from BECCS and DACCS is 170–650 GtCO₂ and 0–250 GtCO₂ respectively, the AFOLU sector contributes 10–250 GtCO₂ net negative emissions, and total cumulative net negative CO₂ emissions are around 40 [0–290] GtCO₂. (Table SPM.2) (*high confidence*) {Table 3.2, 3.3, 3.4}
- C.3.6** All mitigation strategies face implementation challenges, including technology risks, scaling, and costs. Many challenges, such as dependence on CDR, pressure on land and biodiversity (e.g., bioenergy) and reliance on technologies with high upfront investments (e.g., nuclear), are significantly reduced in modelled pathways that assume using resources more efficiently (e.g., IMP-LD) or that shift global development towards sustainability (e.g., IMP-SP). (*high confidence*) (Figure SPM.5) {3.2, 3.4, 3.7, 3.8, 4.3, 5.1}

⁵² Most but not all models include the use of fossil fuels for feedstock with varying underlying standards.

⁵³ Aggregate levels of CDR deployment are higher than total net negative CO₂ emissions given that some of the deployed CDR is used to counterbalance remaining gross emissions. Total net negative CO₂ emissions in modelled pathways might not match the aggregated net negative CO₂ emissions attributed to individual CDR methods. Ranges refer to the 5–95th percentile across modelled pathways that include the specific CDR method. Cumulative levels of CDR from AFOLU cannot be quantified precisely given that: (i) some pathways assess CDR deployment relative to a baseline; and (ii) different models use different reporting methodologies that in some cases combine gross emissions and removals in AFOLU. Total CDR from AFOLU equals or exceeds the net negative emissions mentioned.

Modelled mitigation pathways that limit warming to 1.5°C, and 2°C, involve deep, rapid and sustained emissions reductions.

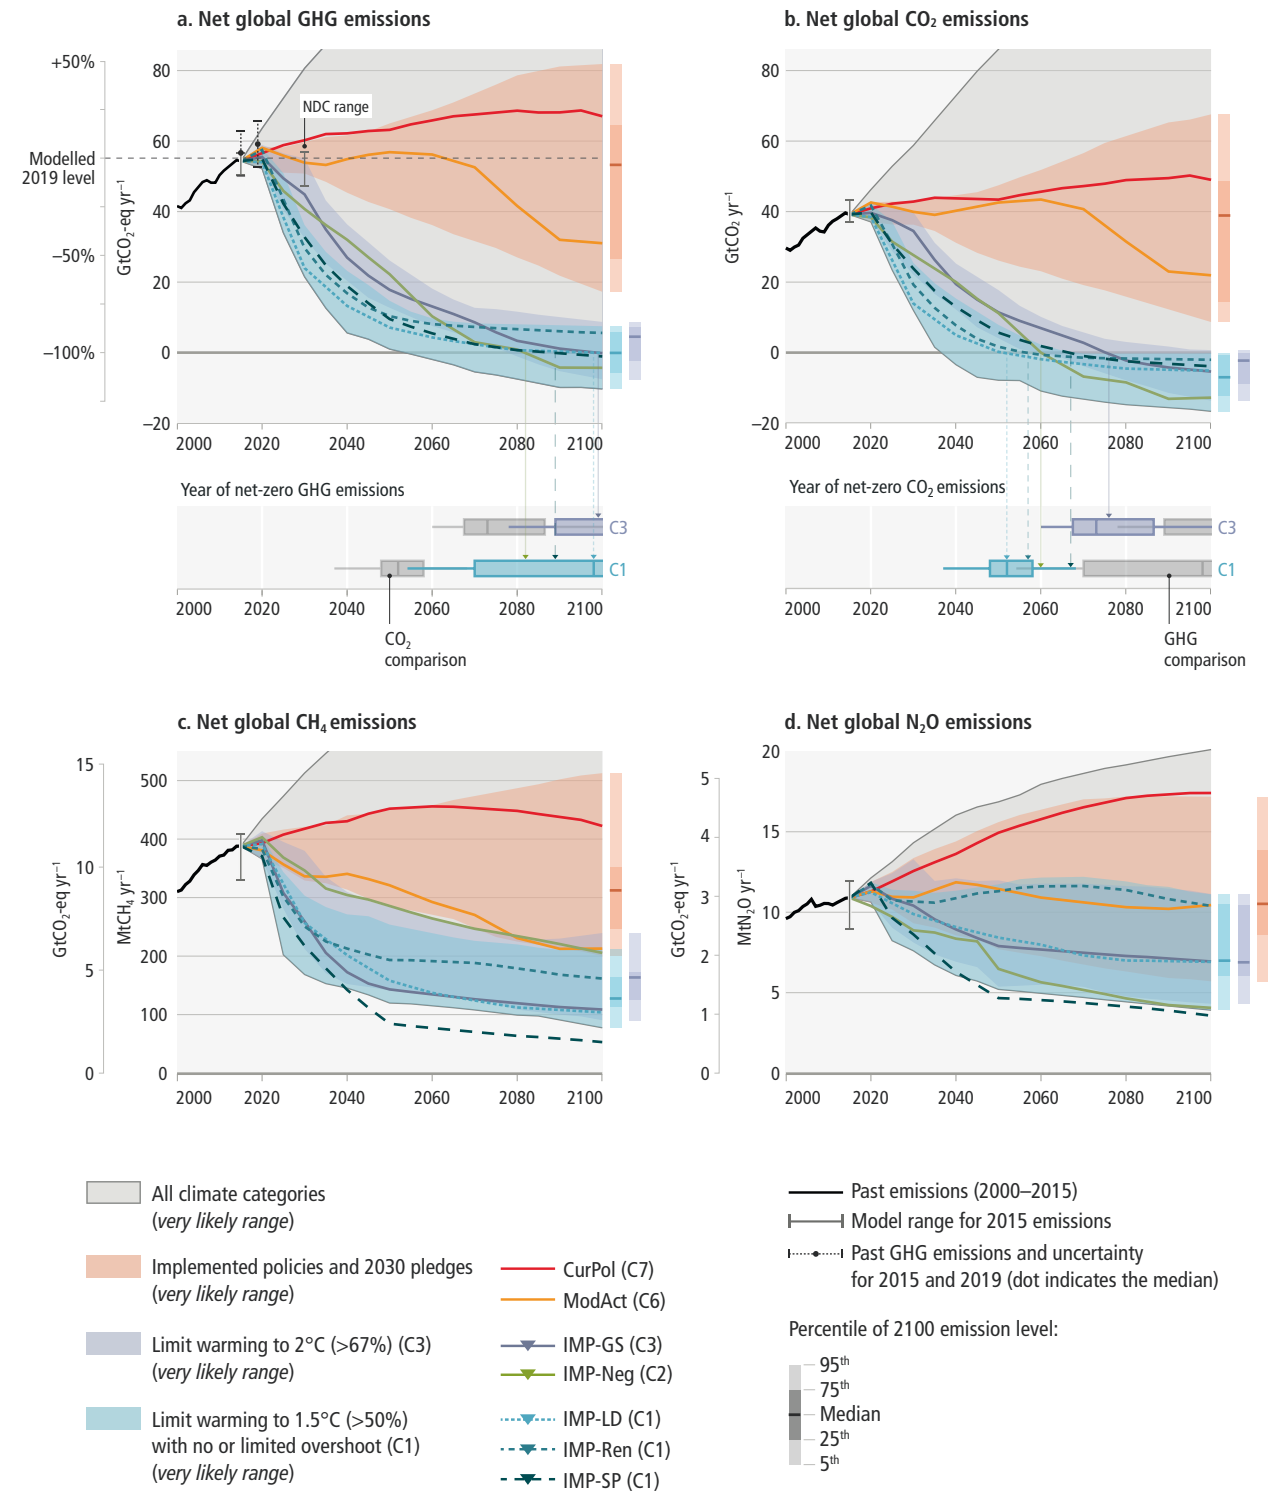

Figure SPM.5 | Illustrative Mitigation Pathways (IMPs) and net zero CO₂ and GHG emissions strategies.

Net zero CO₂ and net zero GHG emissions are possible through different modelled mitigation pathways.

Figure SPM.5 (continued): Illustrative Mitigation Pathways (IMPs) and net zero CO₂ and GHG emissions strategies. Panels a and b show the development of global GHG and CO₂ emissions in modelled global pathways (upper sub-panels) and the associated timing of when GHG and CO₂ emissions reach net zero (lower sub-panels). Panels c and d show the development of global CH₄ and N₂O emissions, respectively. Coloured ranges denote the 5th to 95th percentile across pathways. The red ranges depict emissions pathways assuming policies that were implemented by the end of 2020 and pathways assuming implementation of NDCs (announced prior to COP26). Ranges of modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot are shown in light blue (category C1) and pathways that limit warming to 2°C (>67%) are shown in light purple (category C3). The grey range comprises all assessed pathways (C1–C8) from the 5th percentile of the lowest warming category (C1) to the 95th percentile of the highest warming category (C8). The modelled pathway ranges are compared to the emissions from two pathways illustrative of high emissions (CurPol and ModAct) and five IMPs: IMP-LD, IMP-Ren, IMP-SP, IMP-Neg and IMP-GS. Emissions are harmonised to the same 2015 base year. The vertical error bars in 2015 show the 5–95th percentile uncertainty range of the non-harmonised emissions across the pathways, and the uncertainty range, and median value, in emission estimates for 2015 and 2019. The vertical error bars in 2030 (panel a) depict the assessed range of the NDCs, as announced prior to COP26 (Figure SPM.4).²³ Panel e shows the sectoral contributions of CO₂ and non-CO₂ emissions sources and sinks at the time when net zero CO₂ emissions are reached in the IMPs. Positive and negative emissions for different IMPs are compared to the GHG emissions from the year 2019. Energy supply (neg.) includes BECCS and DACCS. DACCS features in only two of the five IMPs (IMP-REN and IMP-GS) and contributes <1% and 64%, respectively, to the net negative emissions in Energy Supply (neg.). Panel f shows the contribution of different sectors and sources to the emissions reductions from a 2019 baseline for reaching net zero GHG emissions. Bars denote the median emissions reductions for all pathways that reach net zero GHG emissions. The whiskers indicate the p5–p95 range. The contributions of the service sectors (transport, buildings, industry) are split into direct (demand-side) as well as indirect (supply-side) CO₂ emissions reductions. Direct emissions represent demand-side emissions due to the fuel use in the respective demand sector. Indirect emissions represent upstream emissions due to industrial processes and energy conversion, transmission and distribution. In addition, the contributions from the LULUCF sector and reductions from non-CO₂ emissions sources (green and grey bars) are displayed. [3.3, 3.4]

- C.4 Reducing GHG emissions across the full energy sector requires major transitions, including a substantial reduction in overall fossil fuel use, the deployment of low-emission energy sources, switching to alternative energy carriers, and energy efficiency and conservation. The continued installation of unabated fossil fuel⁵⁴ infrastructure will ‘lock-in’ GHG emissions. (*high confidence*) {2.7, 6.6, 6.7, 16.4}**
- C.4.1** Net-zero CO₂ energy systems entail: a substantial reduction in overall fossil fuel use, minimal use of unabated fossil fuels, and use of CCS in the remaining fossil fuel system;⁵⁴ electricity systems that emit no net CO₂; widespread electrification of the energy system including end uses; energy carriers such as sustainable biofuels, low-emissions hydrogen, and derivatives in applications less amenable to electrification; energy conservation and efficiency; and greater physical, institutional, and operational integration across the energy system. CDR will be needed to counterbalance residual emissions in the energy sector. The most appropriate strategies depend on national and regional circumstances, including enabling conditions and technology availability. (*high confidence*) {3.4, 6.6, 11.3, 16.4}
- C.4.2** Unit cost reductions in key technologies, notably wind power, solar power, and storage, have increased the economic attractiveness of low-emission energy sector transitions through 2030. Maintaining emission-intensive systems may, in some regions and sectors, be more expensive than transitioning to low emission systems. Low-emission energy sector transitions will have multiple co-benefits, including improvements in air quality and health. The long-term economic attractiveness of deploying energy system mitigation options depends, *inter alia*, on policy design and implementation, technology availability and performance, institutional capacity, equity, access to finance, and public and political support. (*high confidence*) (Figure SPM.3) {3.4, 6.4, 6.6, 6.7, 13.7}
- C.4.3** Electricity systems powered predominantly by renewables are becoming increasingly viable. Electricity systems in some countries and regions are already predominantly powered by renewables. It will be more challenging to supply the entire energy system with renewable energy. Even though operational, technological, economic, regulatory, and social challenges remain, a variety of systemic solutions to accommodate large shares of renewables in the energy system have emerged. A broad portfolio of options, such as integrating systems, coupling sectors, energy storage, smart grids, demand-side management, sustainable biofuels, electrolytic hydrogen and derivatives, and others will ultimately be needed to accommodate large shares of renewables in energy systems. (*high confidence*) {Box 6.8, 6.4, 6.6}
- C.4.4** Limiting global warming to 2°C or below will leave a substantial amount of fossil fuels unburned and could strand considerable fossil fuel infrastructure (*high confidence*). Depending on its availability, CCS could allow fossil fuels to be used longer, reducing stranded assets (*high confidence*). The combined global discounted value of the unburned fossil fuels and stranded fossil fuel infrastructure has been projected to be around USD1–4 trillion from 2015 to 2050 to limit global warming to approximately 2°C, and it will be higher if global warming is limited to approximately 1.5°C (*medium confidence*). In this context, coal assets are projected to be at risk of being stranded before 2030, while oil and gas assets are projected to be more at risk of being stranded towards mid-century. A low-emission energy sector transition is projected to reduce international trade in fossil fuels. (*high confidence*) {6.7, Figure 6.35}
- C.4.5** Global methane emissions from energy supply, primarily fugitive emissions from production and transport of fossil fuels, accounted for about 18% [13–23%] of global GHG emissions from energy supply, 32% [22–42%] of global CH₄ emissions, and 6% [4–8%] of global GHG emissions in 2019 (*high confidence*). About 50–80% of CH₄ emissions from these fossil fuels could be avoided with currently available technologies at less than USD50 tCO₂-eq⁻¹ (*medium confidence*). {6.3, 6.4.2, Box 6.5, 11.3, 2.2.2, Table 2.1, Figure 2.5, Annex1: Glossary}
- C.4.6** CCS is an option to reduce emissions from large-scale fossil-based energy and industry sources, provided geological storage is available. When CO₂ is captured directly from the atmosphere (DACCS), or from biomass (BECCS), CCS provides the storage component of these CDR methods. CO₂ capture and subsurface injection is a mature technology for gas processing and enhanced oil recovery. In contrast to the oil and gas sector, CCS is less mature in the power sector, as well as in cement and chemicals production, where it is a critical mitigation option. The technical geological CO₂ storage capacity is estimated to be on the order of 1000 GtCO₂, which is more than the CO₂ storage requirements through 2100 to limit global warming to 1.5°C, although the regional availability of geological storage could be a limiting factor. If the geological storage site is appropriately selected and managed, it is estimated that the CO₂ can be permanently isolated from the atmosphere. Implementation of CCS currently faces technological, economic, institutional, ecological-environmental and socio-cultural barriers. Currently, global rates of CCS deployment are far below those in modelled pathways limiting global warming to 1.5°C or 2°C. Enabling

⁵⁴ In this context, ‘unabated fossil fuels’ refers to fossil fuels produced and used without interventions that substantially reduce the amount of GHG emitted throughout the life cycle; for example, capturing 90% or more CO₂ from power plants, or 50–80% of fugitive methane emissions from energy supply. {Box 6.5, 11.3}

conditions such as policy instruments, greater public support and technological innovation could reduce these barriers. (*high confidence*) {2.5, 6.3, 6.4, 6.7, 11.3, 11.4, Cross-Chapter Box 8 in Chapter 12, Figure TS.31; SRCCL Chapter 5}

- C.5 Net zero CO₂ emissions from the industrial sector are challenging but possible. Reducing industry emissions will entail coordinated action throughout value chains to promote all mitigation options, including demand management, energy and materials efficiency, circular material flows, as well as abatement technologies and transformational changes in production processes. Progressing towards net zero GHG emissions from industry will be enabled by the adoption of new production processes using low- and zero-GHG electricity, hydrogen, fuels, and carbon management. (*high confidence*) {11.2, 11.3, 11.4, Box TS.4}**
- C.5.1** The use of steel, cement, plastics, and other materials is increasing globally, and in most regions. There are many sustainable options for demand management, materials efficiency, and circular material flows that can contribute to reduced emissions, but how these can be applied will vary across regions and different materials. These options have a potential for being more used in industrial practice and would need more attention from industrial policy. These options, as well as new production technologies, are generally not considered in recent global scenarios nor in national economy-wide scenarios due to relative newness. As a consequence, the mitigation potential in some scenarios is underestimated compared to bottom-up industry-specific models. (*high confidence*) {3.4, 5.3, Figure 5.7, 11.2, Box 11.2, 11.3, 11.4, 11.5.2, 11.6}
- C.5.2** For almost all basic materials – primary metals,⁵⁵ building materials and chemicals – many low- to zero-GHG intensity production processes are at the *pilot* to *near-commercial* and in some cases *commercial* stage but they are not yet established industrial practice. Introducing new sustainable production processes for basic materials could increase production costs but, given that only a small fraction of consumer costs are based on materials, such new processes are expected to translate into minimal cost increases for final consumers. Hydrogen direct reduction for primary steelmaking is *near-commercial* in some regions. Until new chemistries are mastered, deep reduction of cement process emissions will rely on already commercialised cementitious material substitution and the availability of CCS. Reducing emissions from the production and use of chemicals would need to rely on a life cycle approach, including increased plastics recycling, fuel and feedstock switching, and carbon sourced through biogenic sources, and, depending on availability, carbon capture and use (CCU), direct air CO₂ capture, as well as CCS. Light industry, mining and manufacturing have the potential to be decarbonised through available abatement technologies (e.g., material efficiency, circularity), electrification (e.g., electrothermal heating, heat pumps) and low- or zero-GHG emitting fuels (e.g., hydrogen, ammonia, and bio-based and other synthetic fuels). (*high confidence*) {Table 11.4, Box 11.2, 11.3, 11.4}
- C.5.3** Action to reduce industry sector emissions may change the location of GHG-intensive industries and the organisation of value chains. Regions with abundant low-GHG energy and feedstocks have the potential to become exporters of hydrogen-based chemicals and materials processed using low-carbon electricity and hydrogen. Such reallocation will have global distributional effects on employment and economic structure. (*medium confidence*) {Box 11.1}
- C.5.4** Emissions-intensive and highly traded basic materials industries are exposed to international competition, and international cooperation and coordination may be particularly important in enabling change. For sustainable industrial transitions, broad and sequential national and sub-national policy strategies reflecting regional contexts will be required. These may combine policy packages including: transparent GHG accounting and standards; demand management; materials and energy efficiency policies; R&D and niche markets for commercialisation of low-emission materials and products; economic and regulatory instruments to drive market uptake; high quality recycling, low-emissions energy and other abatement infrastructure (e.g., for CCS); and socially inclusive phase-out plans of emissions-intensive facilities within the context of just transitions. The coverage of mitigation policies could be expanded nationally and sub-nationally to include all industrial emission sources, and both available and emerging mitigation options. (*high confidence*) {11.6}

⁵⁵ Primary metals refers to virgin metals produced from ore.

C.6 Urban areas can create opportunities to increase resource efficiency and significantly reduce GHG emissions through the systemic transition of infrastructure and urban form through low-emission development pathways towards net-zero emissions. Ambitious mitigation efforts for established, rapidly growing and emerging cities will encompass (i) reducing or changing energy and material consumption, (ii) electrification, and (iii) enhancing carbon uptake and storage in the urban environment. Cities can achieve net-zero emissions, but only if emissions are reduced within and outside of their administrative boundaries through supply chains, which will have beneficial cascading effects across other sectors. (*very high confidence*) {8.2, 8.3, 8.4, 8.5, 8.6, Figure 8.21, 13.2}

C.6.1 In modelled scenarios, global consumption-based urban CO₂ and CH₄ emissions¹⁵ are projected to rise from 29 GtCO₂-eq in 2020 to 34 GtCO₂-eq in 2050 with moderate mitigation efforts (intermediate GHG emissions, SSP2-4.5), and up to 40 GtCO₂-eq in 2050 with low mitigation efforts (high GHG emissions, SSP3-7.0). With ambitious and immediate mitigation efforts, including high levels of electrification and improved energy and material efficiency, global consumption-based urban CO₂ and CH₄ emissions could be reduced to 3 GtCO₂-eq in 2050 in the modelled scenario with very low GHG emissions (SSP1-1.9).⁵⁶ (*medium confidence*) {8.3}

C.6.2 The potential and sequencing of mitigation strategies to reduce GHG emissions will vary depending on a city's land use, spatial form, development level, and state of urbanisation (*high confidence*). Strategies for established cities to achieve large GHG emissions savings include efficiently improving, repurposing or retrofitting the building stock, targeted infilling, and supporting non-motorised (e.g., walking, bicycling) and public transport. Rapidly growing cities can avoid future emissions by co-locating jobs and housing to achieve compact urban form, and by leapfrogging or transitioning to low-emissions technologies. New and emerging cities will have significant infrastructure development needs to achieve high quality of life, which can be met through energy efficient infrastructures and services, and people-centred urban design (*high confidence*). For cities, three broad mitigation strategies have been found to be effective when implemented concurrently: (i) reducing or changing energy and material use towards more sustainable production and consumption; (ii) electrification in combination with switching to low-emission energy sources; and (iii) enhancing carbon uptake and storage in the urban environment, for example through bio-based building materials, permeable surfaces, green roofs, trees, green spaces, rivers, ponds and lakes.⁵⁷ (*very high confidence*) {5.3, Figure 5.7, Supplementary Material Table 5.SM.2, 8.2, 8.4, 8.6, Figure 8.21, 9.4, 9.6, 10.2}

C.6.3 The implementation of packages of multiple city-scale mitigation strategies can have cascading effects across sectors and reduce GHG emissions both within and outside a city's administrative boundaries. The capacity of cities to develop and implement mitigation strategies varies with the broader regulatory and institutional settings, as well as enabling conditions, including access to financial and technological resources, local governance capacity, engagement of civil society, and municipal budgetary powers. (*very high confidence*) {Figure 5.7, Supplementary Material Table 5.SM.2, 8.4, 8.5, 8.6, 13.2, 13.3, 13.5, 13.7, Cross-Chapter Box 9 in Chapter 13}

C.6.4 A growing number of cities are setting climate targets, including net-zero GHG targets. Given the regional and global reach of urban consumption patterns and supply chains, the full potential for reducing consumption-based urban emissions to net zero GHG can be met only when emissions beyond cities' administrative boundaries are also addressed. The effectiveness of these strategies depends on cooperation and coordination with national and sub-national governments, industry, and civil society, and whether cities have adequate capacity to plan and implement mitigation strategies. Cities can play a positive role in reducing emissions across supply chains that extend beyond cities' administrative boundaries, for example through building codes and the choice of construction materials. (*very high confidence*) {8.4, Box 8.4, 8.5, 9.6, 9.9, 13.5, 13.9}

⁵⁶ These scenarios have been assessed by WGI to correspond to intermediate, high and very low GHG emissions.

⁵⁷ These examples are considered to be a subset of nature-based solutions or ecosystem-based approaches.

- C.7.** In modelled global scenarios, existing buildings, if retrofitted, and buildings yet to be built, are projected to approach net zero GHG emissions in 2050 if policy packages, which combine ambitious sufficiency, efficiency, and renewable energy measures, are effectively implemented and barriers to decarbonisation are removed. Low ambition policies increase the risk of locking-in buildings' carbon for decades, while well-designed and effectively implemented mitigation interventions (in both new buildings and existing ones if retrofitted), have significant potential to contribute to achieving SDGs in all regions while adapting buildings to future climate. (*high confidence*) {9.1, 9.3, 9.4, 9.5, 9.6, 9.9}
- C.7.1** In 2019, global direct and indirect GHG emissions from buildings and emissions from cement and steel use for building construction and renovation were 12 GtCO₂-eq. These emissions include indirect emissions from offsite generation of electricity and heat, direct emissions produced onsite and emissions from cement and steel used for building construction and renovation. In 2019, global direct and indirect emissions from non-residential buildings increased by about 55% and those from residential buildings increased by about 50% compared to 1990. The latter increase, according to the decomposition analysis, was mainly driven by the increase of the floor area per capita, population growth and the increased use of emission-intensive electricity and heat while efficiency improvements have partly decreased emissions. There are great differences in the contribution of each of these drivers to regional emissions. (*high confidence*) {9.3}
- C.7.2** Integrated design approaches to the construction and retrofit of buildings have led to increasing examples of zero energy or zero carbon buildings in several regions. However, the low renovation rates and low ambition of retrofitted buildings have hindered the decrease of emissions. Mitigation interventions at the design stage include buildings typology, form, and multi-functionality to allow for adjusting the size of buildings to the evolving needs of their users and repurposing unused existing buildings to avoid using GHG-intensive materials and additional land. Mitigation interventions include: at the construction phase, low-emission construction materials, highly efficient building envelope and the integration of renewable energy solutions;⁵⁸ at the use phase, highly efficient appliances/equipment, the optimisation of the use of buildings and their supply with low-emission energy sources; and at the disposal phase, recycling and re-using construction materials. (*high confidence*) {9.4, 9.5, 9.6, 9.7}
- C.7.3** By 2050, bottom-up studies show that up to 61% (8.2 GtCO₂) of global building emissions could be mitigated. Sufficiency policies⁵⁹ that avoid the demand for energy and materials contribute 10% to this potential, energy efficiency policies contribute 42%, and renewable energy policies 9%. The largest share of the mitigation potential of new buildings is available in developing countries while in developed countries the highest mitigation potential is within the retrofit of existing buildings. The 2020–2030 decade is critical for accelerating the learning of know-how, building the technical and institutional capacity, setting the appropriate governance structures, ensuring the flow of finance, and in developing the skills needed to fully capture the mitigation potential of buildings. (*high confidence*) {9.3, 9.4, 9.5, 9.6, 9.7, 9.9}

⁵⁸ Integration of renewable energy solutions refers to the integration of solutions such as solar photovoltaics, small wind turbines, solar thermal collectors, and biomass boilers.

⁵⁹ Sufficiency policies are a set of measures and daily practices that avoid demand for energy, materials, land and water while delivering human well-being for all within planetary boundaries.

- C.8** Demand-side options and low-GHG emissions technologies can reduce transport sector emissions in developed countries and limit emissions growth in developing countries (*high confidence*). Demand-focused interventions can reduce demand for all transport services and support the shift to more energy efficient transport modes (*medium confidence*). Electric vehicles powered by low-emissions electricity offer the largest decarbonisation potential for land-based transport, on a life cycle basis (*high confidence*). Sustainable biofuels can offer additional mitigation benefits in land-based transport in the short and medium term (*medium confidence*). Sustainable biofuels, low-emissions hydrogen, and derivatives (including synthetic fuels) can support mitigation of CO₂ emissions from shipping, aviation, and heavy-duty land transport but require production process improvements and cost reductions (*medium confidence*). Many mitigation strategies in the transport sector would have various co-benefits, including air quality improvements, health benefits, equitable access to transportation services, reduced congestion, and reduced material demand (*high confidence*). {10.2, 10.4, 10.5, 10.6, 10.7}
- C.8.1** In scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot, global transport-related CO₂ emissions fall by 59% (42–68% interquartile range) by 2050 relative to modelled 2020 emissions, but with regionally differentiated trends (*high confidence*). In global modelled scenarios that limit warming to 2°C (>67%), transport-related CO₂ emissions are projected to decrease by 29% [14–44% interquartile range] by 2050 compared to modelled 2020 emissions. In both categories of scenarios, the transport sector likely does not reach zero CO₂ emissions by 2100 so negative emissions are likely needed to counterbalance residual CO₂ emissions from the sector (*high confidence*). {3.4, 10.7}
- C.8.2** Changes in urban form (e.g., density, land-use mix, connectivity, and accessibility) in combination with programmes that encourage changes in consumer behaviour (e.g., transport pricing) could reduce transport-related greenhouse gas emissions in developed countries and slow growth in emissions in developing countries (*high confidence*). Investments in public inter- and intra-city transport and active transport infrastructure (e.g., bicycle and pedestrian pathways) can further support the shift to less GHG-intensive transport modes (*high confidence*). Combinations of systemic changes, including teleworking, digitalisation, dematerialisation, supply chain management, and smart and shared mobility may reduce demand for passenger and freight services across land, air, and sea (*high confidence*). Some of these changes could lead to induced demand for transport and energy services, which may decrease their GHG emissions reduction potential (*medium confidence*). {5.3, 10.2, 10.8}
- C.8.3** Electric vehicles powered by low-GHG emissions electricity have large potential to reduce land-based transport GHG emissions, on a life cycle basis (*high confidence*). Costs of electrified vehicles, including automobiles, two- and three-wheelers, and buses, are decreasing and their adoption is accelerating, but they require continued investments in supporting infrastructure to increase scale of deployment (*high confidence*). Advances in battery technologies could facilitate the electrification of heavy-duty trucks and complement conventional electric rail systems (*medium confidence*). There are growing concerns about critical minerals needed for batteries. Material and supply diversification strategies, energy and material efficiency improvements, and circular material flows can reduce the environmental footprint and material supply risks for battery production (*medium confidence*). Sourced sustainably and with low-GHG emissions feedstocks, bio-based fuels, blended or unblended with fossil fuels, can provide mitigation benefits, particularly in the short and medium term (*medium confidence*). Low-GHG emissions hydrogen and hydrogen derivatives, including synthetic fuels, can offer mitigation potential in some contexts and land-based transport segments (*medium confidence*). {3.4, 6.3, 10.3, 10.4, 10.7, 10.8, Box 10.6}
- C.8.4** While efficiency improvements (e.g., optimised aircraft and vessel designs, mass reduction, and propulsion system improvements) can provide some mitigation potential, additional CO₂ emissions mitigation technologies for aviation and shipping will be required (*high confidence*). For aviation, such technologies include high energy density biofuels (*high confidence*), and low-emission hydrogen and synthetic fuels (*medium confidence*). Alternative fuels for shipping include low-emission hydrogen, ammonia, biofuels, and other synthetic fuels (*medium confidence*). Electrification could play a niche role for aviation and shipping for short trips (*medium confidence*) and can reduce emissions from port and airport operations (*high confidence*). Improvements to national and international governance structures would further enable the decarbonisation of shipping and aviation (*medium confidence*). Such improvements could include, for example, the implementation of stricter efficiency and carbon intensity standards for the sectors (*medium confidence*). {10.3, 10.5, 10.6, 10.7, 10.8, Box 10.5}
- C.8.5** The substantial potential for GHG emissions reductions, both direct and indirect, in the transport sector largely depends on power sector decarbonisation, and low-emissions feedstocks and production chains (*high confidence*). Integrated transport and energy infrastructure planning and operations can enable sectoral synergies and reduce the environmental, social, and economic impacts of decarbonising the transport and energy sectors (*high confidence*). Technology transfer and financing can support developing countries leapfrogging or transitioning to low-emissions transport systems thereby providing multiple co-benefits (*high confidence*). {10.2, 10.3, 10.4, 10.5, 10.6, 10.7, 10.8}

- C.9** AFOLU mitigation options, when sustainably implemented, can deliver large-scale GHG emission reductions and enhanced removals, but cannot fully compensate for delayed action in other sectors. In addition, sustainably sourced agricultural and forest products can be used instead of more GHG-intensive products in other sectors. Barriers to implementation and trade-offs may result from the impacts of climate change, competing demands on land, conflicts with food security and livelihoods, the complexity of land ownership and management systems, and cultural aspects. There are many country-specific opportunities to provide co-benefits (such as biodiversity conservation, ecosystem services, and livelihoods) and avoid risks (for example, through adaptation to climate change). (*high confidence*) {7.4, 7.6, 7.7, 12.5, 12.6}
- C.9.1** The projected economic mitigation potential of AFOLU options between 2020 and 2050, at costs below USD100 tCO₂-eq⁻¹, is 8–14 GtCO₂-eq yr⁻¹ ⁶⁰ (*high confidence*). 30–50% of this potential is available at less than USD20 tCO₂-eq and could be upscaled in the near term across most regions (*high confidence*). The largest share of this economic potential [4.2–7.4 GtCO₂-eq yr⁻¹] comes from the conservation, improved management, and restoration of forests and other ecosystems (coastal wetlands, peatlands, savannas and grasslands), with reduced deforestation in tropical regions having the highest total mitigation. Improved and sustainable crop and livestock management, and carbon sequestration in agriculture (the latter including soil carbon management in croplands and grasslands, agroforestry and biochar), can contribute 1.8–4.1 GtCO₂-eq yr⁻¹ reduction. Demand-side and material substitution measures, such as shifting to balanced, sustainable healthy diets,⁶¹ reducing food loss and waste, and using bio-materials, can contribute 2.1 [1.1–3.6] GtCO₂-eq yr⁻¹ reduction. In addition, demand-side measures together with the sustainable intensification of agriculture can reduce ecosystem conversion and CH₄ and N₂O emissions, and free up land for reforestation and restoration, and the production of renewable energy. The improved and expanded use of wood products sourced from sustainably managed forests also has potential through the allocation of harvested wood to longer-lived products, increasing recycling or material substitution. AFOLU mitigation measures cannot compensate for delayed emission reductions in other sectors. Persistent and region-specific barriers continue to hamper the economic and political feasibility of deploying AFOLU mitigation options. Assisting countries to overcome barriers will help to achieve significant mitigation (*medium confidence*). (Figure SPM.6) {7.1, 7.4, 7.5, 7.6}
- C.9.2** AFOLU carbon sequestration and GHG emission reduction options have both co-benefits and risks in terms of biodiversity and ecosystem conservation, food and water security, wood supply, livelihoods and land tenure and land-use rights of Indigenous Peoples, local communities and small land owners. Many options have co-benefits but those that compete for land and land-based resources can pose risks. The scale of benefit or risk largely depends on the type of activity undertaken, deployment strategy (e.g., scale, method), and context (e.g., soil, biome, climate, food system, land ownership) that vary geographically and over time. Risks can be avoided when AFOLU mitigation is pursued in response to the needs and perspectives of multiple stakeholders to achieve outcomes that maximize co-benefits while limiting trade-offs. (*high confidence*) {7.4, 7.6, 12.3}
- C.9.3** Realising the AFOLU mitigation potential entails overcoming institutional, economic and policy constraints and managing potential trade-offs (*high confidence*). Land-use decisions are often spread across a wide range of land owners; demand-side measures depend on billions of consumers in diverse contexts. Barriers to the implementation of AFOLU mitigation include insufficient institutional and financial support, uncertainty over long-term additionality and trade-offs, weak governance, insecure land ownership, low incomes and the lack of access to alternative sources of income, and the risk of reversal. Limited access to technology, data, and know-how is a barrier to implementation. Research and development are key for all measures. For example, measures for the mitigation of agricultural CH₄ and N₂O emissions with emerging technologies show promising results. However, the mitigation of agricultural CH₄ and N₂O emissions is still constrained by cost, the diversity and complexity of agricultural systems, and by increasing demands to raise agricultural yields, and increasing demand for livestock products. (*high confidence*) {7.4, 7.6}
- C.9.4** Net costs of delivering 5–6 GtCO₂ yr⁻¹ of forest-related carbon sequestration and emission reduction as assessed with sectoral models are estimated to reach to about USD400 billion yr⁻¹ by 2050. The costs of other AFOLU mitigation measures are highly context specific. Financing needs in AFOLU, and in particular in forestry, include both the direct effects of any changes in

⁶⁰ The global top-down estimates and sectoral bottom-up estimates described here do not include the substitution of emissions from fossil fuels and GHG-intensive materials. 8–14 GtCO₂-eq yr⁻¹ represents the mean of the AFOLU economic mitigation potential estimates from top-down estimates (lower bound of range) and global sectoral bottom-up estimates (upper bound of range). The full range from top-down estimates is 4.1–17.3 GtCO₂-eq yr⁻¹ using a ‘no policy’ baseline. The full range from global sectoral studies is 6.7–23.4 GtCO₂-eq yr⁻¹ using a variety of baselines. (*high confidence*)

⁶¹ ‘Sustainable healthy diets’ promote all dimensions of individuals’ health and well-being; have low environmental pressure and impact; are accessible, affordable, safe and equitable; and are culturally acceptable, as described in FAO and WHO. The related concept of ‘balanced diets’ refers to diets that feature plant-based foods, such as those based on coarse grains, legumes, fruits and vegetables, nuts and seeds, and animal-sourced food produced in resilient, sustainable and low-GHG emission systems, as described in SRCCL.

activities as well as the opportunity costs associated with land-use change. Enhanced monitoring, reporting and verification capacity, and the rule of law, are crucial for land-based mitigation in combination with policies also recognising interactions with wider ecosystem services, could enable engagement by a wider array of actors, including private businesses, NGOs, and Indigenous Peoples and local communities. (*medium confidence*) {7.6, 7.7}

C.9.5 Context specific policies and measures have been effective in demonstrating the delivery of AFOLU carbon sequestration and GHG emission reduction options but the above-mentioned constraints hinder large scale implementation (*medium confidence*). Deploying land-based mitigation can draw on lessons from experience with regulations, policies, economic incentives, payments (e.g., for biofuels, control of nutrient pollution, water regulations, conservation and forest carbon, ecosystem services, and rural livelihoods), and from diverse forms of knowledge such as Indigenous knowledge, local knowledge and scientific knowledge. Indigenous Peoples, private forest owners, local farmers and communities manage a significant share of global forests and agricultural land and play a central role in land-based mitigation options. Scaling successful policies and measures relies on governance that emphasises integrated land-use planning and management framed by SDGs, with support for implementation. (*high confidence*) {7.4, Box 7.2, 7.6}

C.10 Demand-side mitigation encompasses changes in infrastructure use, end-use technology adoption, and socio-cultural and behavioural change. Demand-side measures and new ways of end-use service provision can reduce global GHG emissions in end-use sectors by 40–70% by 2050 compared to baseline scenarios, while some regions and socioeconomic groups require additional energy and resources. Demand-side mitigation response options are consistent with improving basic well-being for all. (*high confidence*) (Figure SPM.6) {5.3, 5.4, Figure 5.6, Figure 5.14, 8.2, 9.4, 10.2, 11.3, 11.4, 12.4, Figure TS.22}

C.10.1 Infrastructure design and access, and technology access and adoption, including information and communication technologies, influence patterns of demand and ways of providing services, such as mobility, shelter, water, sanitation, and nutrition. Illustrative global low-demand scenarios, accounting for regional differences, indicate that more efficient end-use energy conversion can improve services while reducing the need for upstream energy by 45% by 2050 compared to 2020. Demand-side mitigation potential differs between and within regions, and some regions and populations require additional energy, capacity, and resources for human well-being. The lowest population quartile by income worldwide faces shortfalls in shelter, mobility, and nutrition. (*high confidence*) {5.2, 5.3, 5.4, 5.5, Figure 5.6, Figure 5.10, Table 5.2, Figure TS.20, Figure TS.22}

C.10.2 By 2050, comprehensive demand-side strategies could reduce direct and indirect CO₂ and non-CO₂ GHG emissions in three end-use sectors (buildings, land transport, and food) globally by 40%–70% compared to the 2050 emissions projection of two scenarios consistent with policies announced by national governments until 2020. With policy support, socio-cultural options and behavioural change can reduce global GHG emissions of end-use sectors by at least 5% rapidly, with most of the potential in developed countries, and more until 2050, if combined with improved infrastructure design and access. Individuals with high socio-economic status contribute disproportionately to emissions and have the highest potential for emissions reductions, e.g., as citizens, investors, consumers, role models, and professionals. (*high confidence*) (Figure SPM.6) {5.2, 5.3, 5.4, 5.5, 5.6, Supplementary Material Table 5.SM.2, 8.4, 9.9, 13.2, 13.5, 13.8, Figure TS.20}

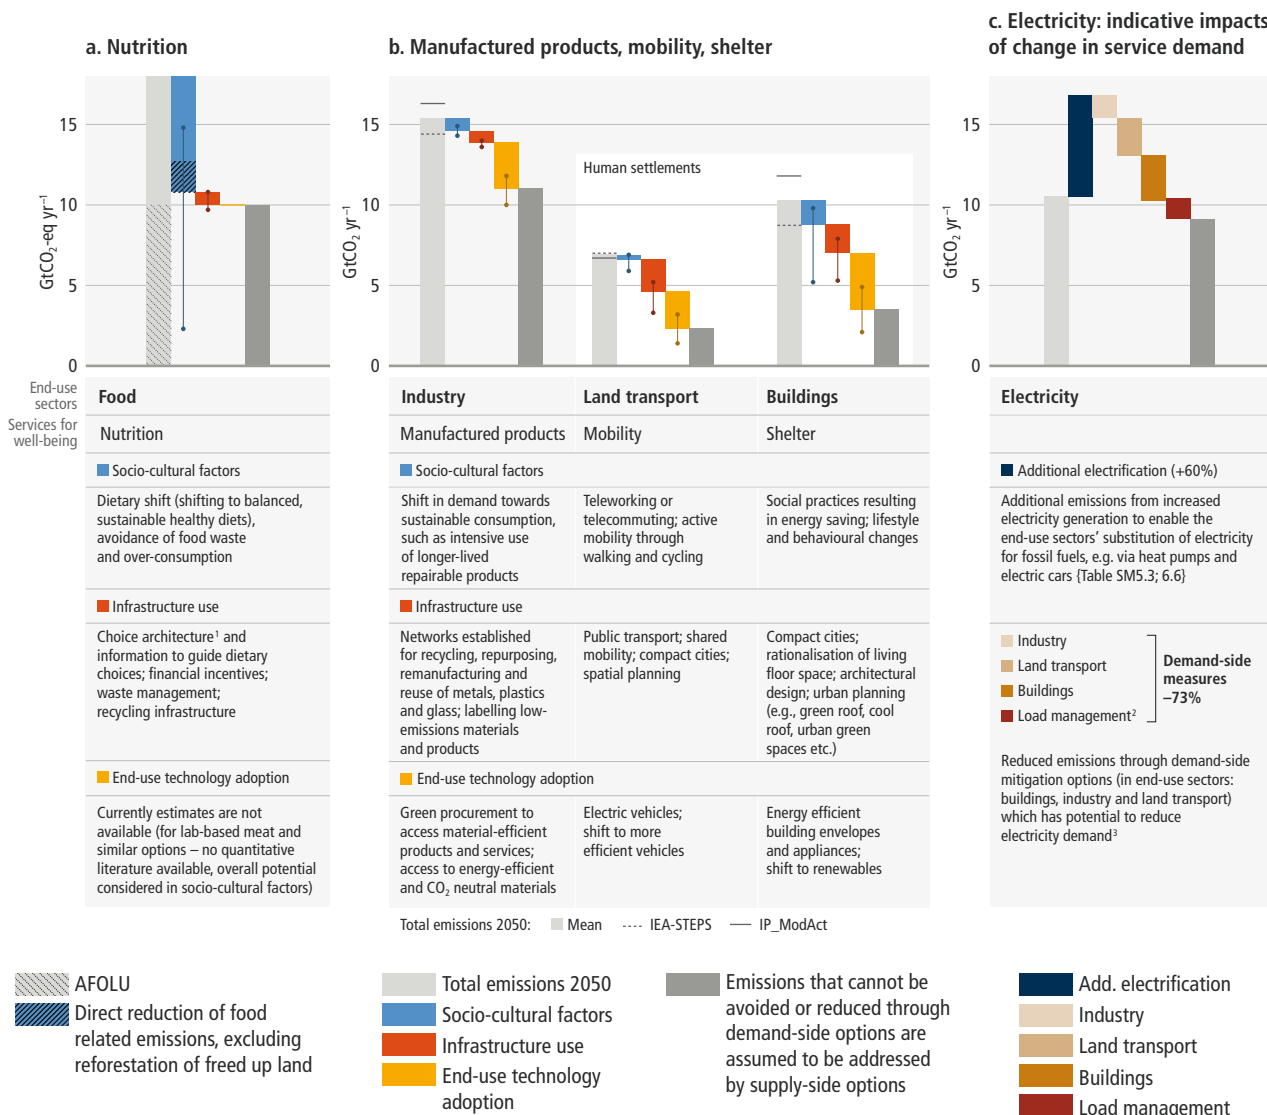

C.10.3 A range of 5–30% of global annual GHG emissions from end-use sectors are avoidable by 2050, compared to 2050 emissions projection of two scenarios consistent with policies announced by national governments until 2020, through changes in the built environment, new and repurposed infrastructures and service provision through compact cities, co-location of jobs and housing, more efficient use of floor space and energy in buildings, and reallocation of street space for active mobility (*high confidence*). (Figure SPM.6) {5.3.1, 5.3.3, 5.4, Figure 5.7, Figure 5.13, Table 5.1, Table 5.5, Supplementary Material Table 5.SM.2, 8.4, 9.5, 10.2, 11.3, 11.4, Table 11.6, Box TS.12}

C.10.4 Choice architecture⁶² can help end-users adopt, as relevant to consumers, culture and country contexts, low-GHG-intensive options such as balanced, sustainable healthy diets⁶¹ acknowledging nutritional needs; food waste reduction; adaptive heating and cooling choices for thermal comfort; building-integrated renewable energy; and electric light-duty vehicles, and shifts to walking, cycling, shared pooled and public transit; and sustainable consumption by intensive use of longer-lived repairable products (*high confidence*). Addressing inequality and many forms of status consumption⁶³ and focusing on wellbeing supports climate change mitigation efforts (*high confidence*). (Figure SPM.6) {2.4.3, 2.6.2, 4.2.5, 5.1, 5.2, 5.3, 5.4, Figure 5.4, Figure 5.10, Table 5.2, Supplementary Material Table 5.SM.2, 7.4.5, 8.2, 8.4, 9.4, 10.2, 12.4, Figure TS.20}

⁶² 'Choice architecture' describes the presentation of choices to consumers, and the impact that presentation has on consumer decision-making.

⁶³ 'Status consumption' refers to the consumption of goods and services which publicly demonstrates social prestige.

Demand-side mitigation can be achieved through changes in socio-cultural factors, infrastructure design and use, and end-use technology adoption by 2050.

¹ The presentation of choices to consumers, and the impact of that presentation on consumer decision-making.

² Load management refers to demand-side flexibility that cuts across all sectors and can be achieved through incentive design like time of use pricing/monitoring by artificial intelligence, diversification of storage facilities, etc.

³ The impact of demand-side mitigation on electricity sector emissions depends on the baseline carbon intensity of electricity supply, which is scenario dependent.

Figure SPM.6 | Indicative potential of demand-side mitigation options by 2050. Figure SPM.6 covers the indicative potential of demand-side options for the year 2050. Figure SPM.7 covers cost and potentials for the year 2030. Demand-side mitigation response options are categorised into three broad domains: 'socio-cultural factors', associated with individual choices, behaviour, lifestyle changes, social norms, and culture; 'infrastructure use', related to the design and use of supporting hard and soft infrastructure that enables changes in individual choices and behaviour; and 'end-use technology adoption', referring to the uptake of technologies by end-users. Demand-side mitigation is a central element of the IMP-LD and IMP-SP scenarios (Figure SPM.5). **Panel a** (Nutrition) demand-side potentials in 2050 assessment is based on bottom-up studies and is estimated following the 2050 baseline for the food sector presented in peer-reviewed literature (more information in Supplementary Material 5.II, and Section 7.4.5). **Panel b** (Manufactured products, mobility, shelter) the assessment of potentials for total emissions in 2050 are estimated based on approximately 500 bottom-up studies representing all global regions (detailed list is in Supplementary Material Table 5.SM.2). Baseline is provided by the sectoral mean GHG emissions in 2050 of the two scenarios consistent with policies announced by national governments until 2020. The heights of the coloured columns represent the potentials represented by the median value. These are based on a range of values available in the case studies from literature shown in Supplementary Material 5.SM.II. The range is shown by the dots connected by dotted lines representing the highest and the lowest potentials reported in the literature. **Panel a** shows the demand-side potential of socio-cultural factors and infrastructure use. The median value of direct emissions (mostly non-CO₂) reduction through socio-cultural factors is 1.9 GtCO₂-eq without considering land-use change through reforestation of freed up land. If changes in land-use pattern enabled by this change in food demand are considered, the indicative potential could reach 7 GtCO₂-eq. Panel b illustrates mitigation potential in industry, land transport and buildings end-use sectors through demand-side options. Key options are presented in the summary table below the figure and the details are in Supplementary Material Table 5.SM.2. **Panel c** visualises how sectoral demand-side mitigation options (presented in panel b) change demand on the electricity distribution system. Electricity accounts for an increasing proportion of final energy demand in 2050 (additional electricity bar) in line with multiple bottom-up studies (detailed list is in Supplementary Material Table 5.SM.3), and Chapter 6 (Section 6.6). These studies are used to compute the impact of end-use electrification which increases overall electricity demand. Some of the projected increase in electricity demand can be avoided through demand-side mitigation options in the domains of socio-cultural factors and infrastructure use in end-use electricity use in buildings, industry, and land transport found in literature based on bottom-up assessments. Dark grey columns show the emissions that cannot be avoided through demand-side mitigation options. (5.3, Figure 5.7, Supplementary Material 5.SM.II)

C.11 The deployment of carbon dioxide removal (CDR) to counterbalance hard-to-abate residual emissions is unavoidable if net zero CO₂ or GHG emissions are to be achieved. The scale and timing of deployment will depend on the trajectories of gross emission reductions in different sectors. Upscaling the deployment of CDR depends on developing effective approaches to address feasibility and sustainability constraints especially at large scales. (*high confidence*) {3.4, 7.4, 12.3, Cross-Chapter Box 8 in Chapter 12}

- C.11.1** CDR refers to anthropogenic activities that remove CO₂ from the atmosphere and store it durably in geological, terrestrial, or ocean reservoirs, or in products. CDR methods vary in terms of their maturity, removal process, time scale of carbon storage, storage medium, mitigation potential, cost, co-benefits, impacts and risks, and governance requirements (*high confidence*). Specifically, maturity ranges from lower maturity (e.g., ocean alkalisation) to higher maturity (e.g., reforestation); removal and storage potential ranges from lower potential (<1 GtCO₂ yr⁻¹, e.g., blue carbon management) to higher potential (>3 GtCO₂ yr⁻¹, e.g., agroforestry); costs range from lower cost (e.g., USD 45–100 per tCO₂ for soil carbon sequestration) to higher cost (e.g., USD 100–300 per tCO₂ for DACCS) (*medium confidence*). Estimated storage time scales vary from decades to centuries for methods that store carbon in vegetation and through soil carbon management, to 10,000 years or more for methods that store carbon in geological formations (*high confidence*). The processes by which CO₂ is removed from the atmosphere are categorised as biological, geochemical or chemical. Afforestation, reforestation, improved forest management, agroforestry and soil carbon sequestration are currently the only widely practiced CDR methods (*high confidence*). {7.4, 7.6, 12.3, Table 12.6, Cross-Chapter Box 8 in Chapter 12, Table TS.7; AR6 WGI 5.6}
- C.11.2** The impacts, risks and co-benefits of CDR deployment for ecosystems, biodiversity and people will be highly variable depending on the method, site-specific context, implementation and scale (*high confidence*). Reforestation, improved forest management, soil carbon sequestration, peatland restoration and blue carbon management are examples of methods that can enhance biodiversity and ecosystem functions, employment and local livelihoods, depending on context (*high confidence*). In contrast, afforestation or production of biomass crops for BECCS or biochar, when poorly implemented, can have adverse socio-economic and environmental impacts, including on biodiversity, food and water security, local livelihoods and on the rights of Indigenous Peoples, especially if implemented at large scales and where land tenure is insecure (*high confidence*). Ocean fertilisation, if implemented, could lead to nutrient redistribution, restructuring of ecosystems, enhanced oxygen consumption and acidification in deeper waters (*medium confidence*). {7.4, 7.6, 12.3, 12.5}
- C.11.3** The removal and storage of CO₂ through vegetation and soil management can be reversed by human or natural disturbances; it is also prone to climate change impacts. In comparison, CO₂ stored in geological and ocean reservoirs (via BECCS, DACCS, ocean alkalisation) and as carbon in biochar is less prone to reversal. (*high confidence*) {6.4, 7.4, 12.3}
- C.11.4** In addition to deep, rapid, and sustained emission reductions CDR can fulfil three different complementary roles globally or at country level: lowering net CO₂ or net GHG emissions in the near term; counterbalancing ‘hard-to-abate’ residual emissions (e.g., emissions from agriculture, aviation, shipping, industrial processes) in order to help reach net zero CO₂ or net zero GHG emissions in the mid-term; and achieving net negative CO₂ or GHG emissions in the long term if deployed at levels exceeding annual residual emissions. (*high confidence*) {3.3, 7.4, 11.3, 12.3, Cross-Chapter Box 8 in Chapter 12}
- C.11.5** Rapid emission reductions in all sectors interact with future scale of deployment of CDR methods, and their associated risks, impacts and co-benefits. Upscaling the deployment of CDR methods depends on developing effective approaches to address sustainability and feasibility constraints, potential impacts, co-benefits and risks. Enablers of CDR include accelerated research, development and demonstration, improved tools for risk assessment and management, targeted incentives and development of agreed methods for measurement, reporting and verification of carbon flows. (*high confidence*) {3.4, 7.6, 12.3}

- C.12 Mitigation options costing USD100 tCO₂-eq⁻¹ or less could reduce global GHG emissions by at least half the 2019 level by 2030 (*high confidence*).** Global GDP continues to grow in modelled pathways⁶⁴ but, without accounting for the economic benefits of mitigation action from avoided damages from climate change nor from reduced adaptation costs, it is a few percent lower in 2050 compared to pathways without mitigation beyond current policies. The global economic benefit of limiting warming to 2°C is reported to exceed the cost of mitigation in most of the assessed literature (*medium confidence*). (Figure SPM.7) {3.6, 3.8, Cross-Working Group Box 1 in Chapter 3, 12.2, Box TS.7}
- C.12.1** Based on a detailed sectoral assessment of mitigation options, it is estimated that mitigation options costing USD100 tCO₂-eq⁻¹ or less could reduce global GHG emissions by at least half of the 2019 level by 2030 (options costing less than USD20 tCO₂-eq⁻¹ are estimated to make up more than half of this potential).⁶⁵ For a smaller part of the potential, deployment leads to net cost savings. Large contributions with costs less than USD20 tCO₂-eq⁻¹ come from solar and wind energy, energy efficiency improvements, reduced conversion of natural ecosystems, and CH₄ emissions reductions (coal mining, oil and gas, waste). The mitigation potentials and mitigation costs of individual technologies in a specific context or region may differ greatly from the provided estimates. The assessment of the underlying literature suggests that the relative contribution of the various options could change beyond 2030. (*medium confidence*) (Figure SPM.7) {12.2}
- C.12.2** The aggregate effects of climate change mitigation on global GDP are small compared to global projected GDP growth in assessed modelled global scenarios that quantify the macroeconomic implications of climate change mitigation, but that do not account for damages from climate change nor adaptation costs (*high confidence*). For example, compared to pathways that assume the continuation of policies implemented by the end of 2020, assessed global GDP reached in 2050 is reduced by 1.3–2.7% in modelled pathways assuming coordinated global action starting between now and 2025 at the latest to limit warming to 2°C (>67%). The corresponding average reduction in annual global GDP growth over 2020–2050 is 0.04–0.09 percentage points. In assessed modelled pathways, regardless of the level of mitigation action, global GDP is projected to at least double (increase by at least 100%) over 2020–2050. For modelled global pathways in other temperature categories, the reductions in global GDP in 2050 compared to pathways that assume the continuation of policies implemented by the end of 2020 are as follows: 2.6–4.2% (C1), 1.6–2.8% (C2), 0.8–2.1% (C4), 0.5–1.2% (C5). The corresponding reductions in average annual global GDP growth over 2020–2050, in percentage points, are as follows: 0.09–0.14 (C1), 0.05–0.09 (C2), 0.03–0.07 (C4), 0.02–0.04 (C5).⁶⁶ There are large variations in the modelled effects of mitigation on GDP across regions, depending notably on economic structure, regional emissions reductions, policy design and level of international cooperation⁶⁷ (*high confidence*). Country-level studies also show large variations in the effect of mitigation on GDP depending notably on the level of mitigation and on the way it is achieved (*high confidence*). Macroeconomic implications of mitigation co-benefits and trade-offs are not quantified comprehensively across the above scenarios and depend strongly on mitigation strategies (*high confidence*). {3.6, 4.2, Box TS.7, Annex III.I.2, Annex III.I.9, Annex III.I.10 and Annex III.II.3}
- C.12.3** Estimates of aggregate economic benefits from avoiding damages from climate change, and from reduced adaptation costs, increase with the stringency of mitigation (*high confidence*). Models that incorporate the economic damages from climate change find that the global cost of limiting warming to 2°C over the 21st century is lower than the global economic benefits of reducing warming, unless: (i) climate damages are towards the low end of the range; or, (ii) future damages are discounted at high rates (*medium confidence*).⁶⁸ Modelled pathways with a peak in global emissions between now and 2025 at the latest, compared to modelled pathways with a later peak in global emissions, entail more rapid near-term transitions and higher up-front investments, but bring long-term gains for the economy, as well as earlier benefits of avoided climate change impacts (*high confidence*). The precise magnitude of these gains and benefits is difficult to quantify. {1.7, 3.6, Cross-Working Group Box 1 in Chapter 3, Box TS.7; AR6 WGII SPM B.4}

⁶⁴ In modelled pathways that limit warming to 2°C (>67%) or lower.

⁶⁵ The methodology underlying the assessment is described in the caption to Figure SPM.7.

⁶⁶ These estimates are based on 311 pathways that report effects of mitigation on GDP and that could be classified in temperature categories, but that do not account for damages from climate change nor adaptation costs and that mostly do not reflect the economic impacts of mitigation co-benefits and trade-offs. The ranges given are interquartile ranges. The macroeconomic implications quantified vary largely depending on technology assumptions, climate/emissions target formulation, model structure and assumptions, and the extent to which pre-existing inefficiencies are considered. Models that produced the pathways classified in temperature categories do not represent the full diversity of existing modelling paradigms, and there are in the literature models that find higher mitigation costs, or conversely lower mitigation costs and even gains. {1.7, 3.2, 3.6, Annex III.I.2, Annex III.I.9, Annex III.I.10 and Annex III.II.3}

⁶⁷ In modelled cost-effective pathways with a globally uniform carbon price, without international financial transfers or complementary policies, carbon intensive and energy exporting countries are projected to bear relatively higher mitigation costs because of a deeper transformation of their economies and changes in international energy markets. {3.6}

⁶⁸ The evidence is too limited to make a similar robust conclusion for limiting warming to 1.5°C.

Many options available now in all sectors are estimated to offer substantial potential to reduce net emissions by 2030. Relative potentials and costs will vary across countries and in the longer term compared to 2030.

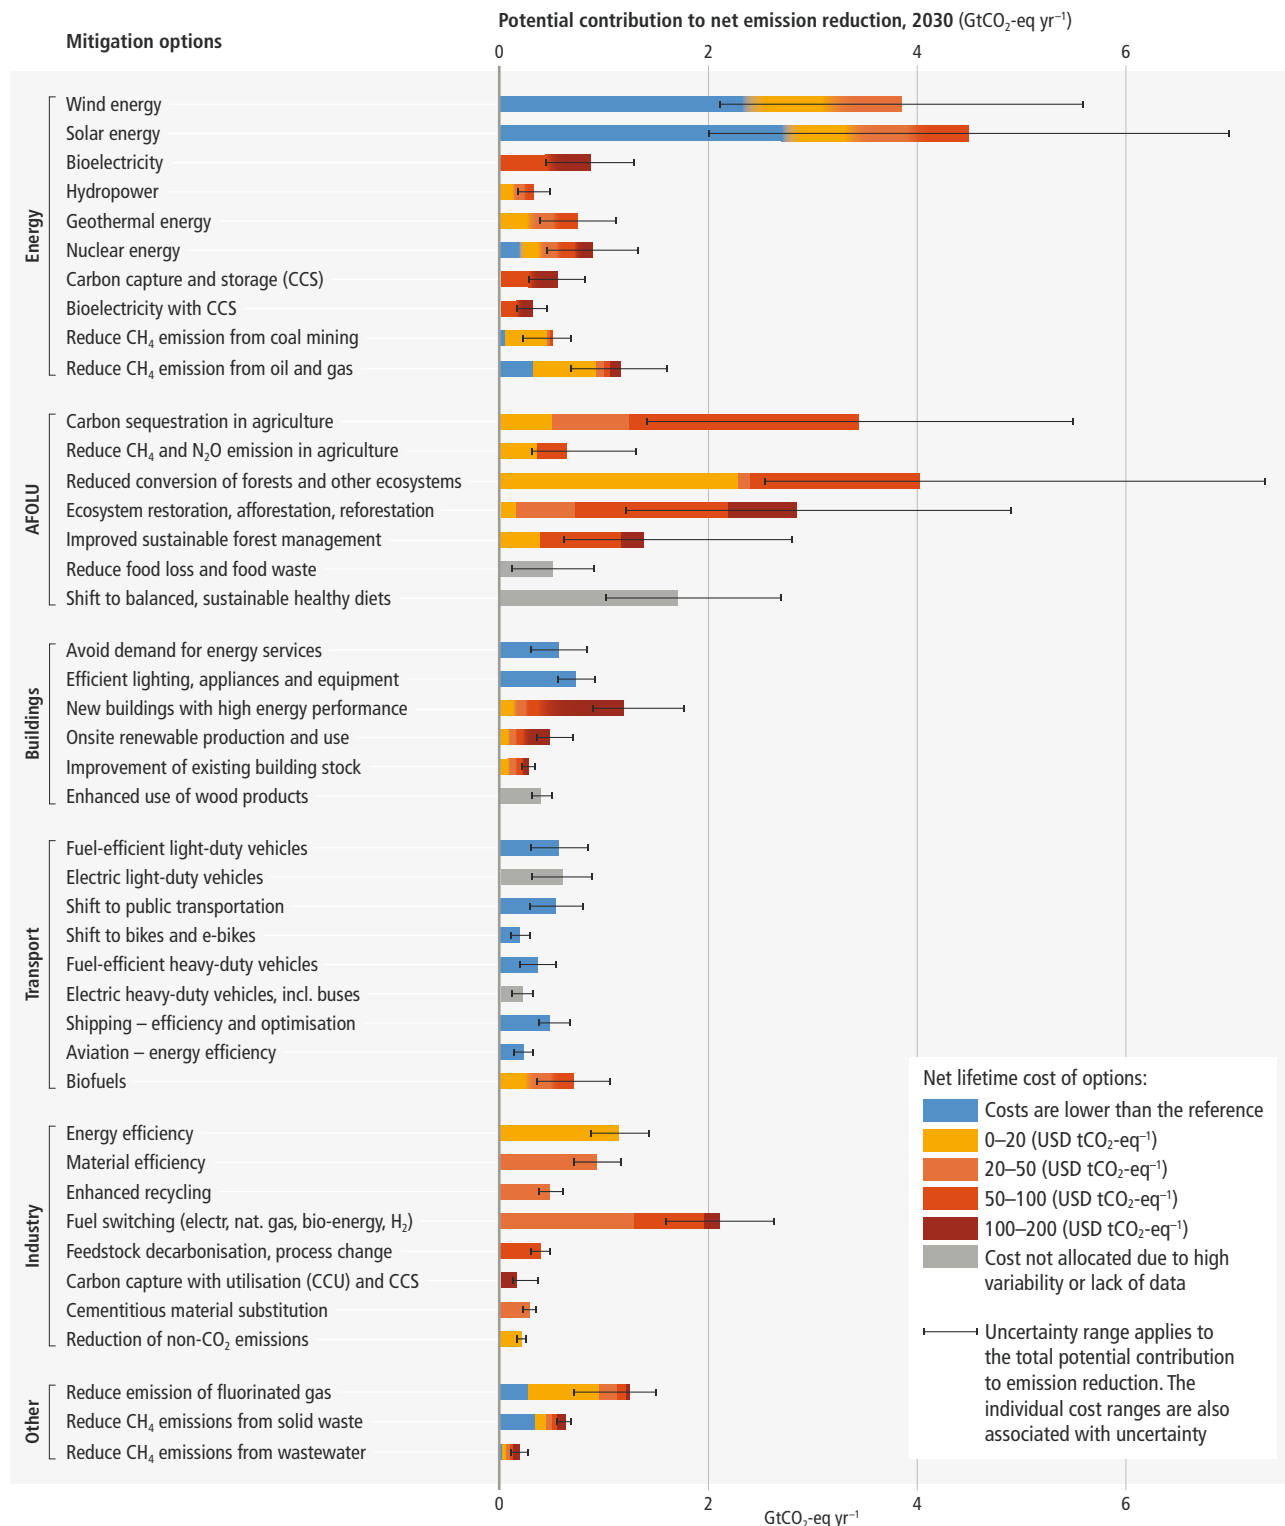

Figure SPM.7 | Overview of mitigation options and their estimated ranges of costs and potentials in 2030.

Figure SPM.7 (continued): Overview of mitigation options and their estimated ranges of costs and potentials in 2030. Costs shown are net lifetime costs of avoided greenhouse gas emissions. Costs are calculated relative to a reference technology. The assessments per sector were carried out using a common methodology, including definition of potentials, target year, reference scenarios, and cost definitions. The mitigation potential (shown in the horizontal axis) is the quantity of net GHG emission reductions that can be achieved by a given mitigation option relative to a specified emission baseline. Net GHG emission reductions are the sum of reduced emissions and/or enhanced sinks. The baseline used consists of current policy (around 2019) reference scenarios from the AR6 scenarios database (25/75 percentile values). The assessment relies on approximately 175 underlying sources, that together give a fair representation of emission reduction potentials across all regions. The mitigation potentials are assessed independently for each option and are not necessarily additive. {12.2.1, 12.2.2} The length of the solid bars represents the mitigation potential of an option. The error bars display the full ranges of the estimates for the total mitigation potentials. Sources of uncertainty for the cost estimates include assumptions on the rate of technological advancement, regional differences, and economies of scale, among others. Those uncertainties are not displayed in the figure. Potentials are broken down into cost categories, indicated by different colours (see legend). Only discounted lifetime monetary costs are considered. Where a gradual colour transition is shown, the breakdown of the potential into cost categories is not well known or depends heavily on factors such as geographical location, resource availability, and regional circumstances, and the colours indicate the range of estimates. Costs were taken directly from the underlying studies (mostly in the period 2015–2020) or recent datasets. No correction for inflation was applied, given the wide cost ranges used. The cost of the reference technologies were also taken from the underlying studies and recent datasets. Cost reductions through technological learning are taken into account.⁶⁹

- When interpreting this figure, the following should be taken into account:
- The mitigation potential is uncertain, as it will depend on the reference technology (and emissions) being displaced, the rate of new technology adoption, and several other factors.
- Cost and mitigation potential estimates were extrapolated from available sectoral studies. Actual costs and potentials would vary by place, context and time.
- Beyond 2030, the relative importance of the assessed mitigation options is expected to change, in particular while pursuing long-term mitigation goals, recognising also that the emphasis for particular options will vary across regions (for specific mitigation options see SPM Sections C4.1, C5.2, C7.3, C8.3 and C9.1).
- Different options have different feasibilities beyond the cost aspects, which are not reflected in the figure (compare with SPM Section E.1).
- The potentials in the cost range USD100–200 tCO₂-eq⁻¹ may be underestimated for some options.
- Costs for accommodating the integration of variable renewable energy sources in electricity systems are expected to be modest until 2030, and are not included because of complexities in attributing such costs to individual technology options.
- Cost range categories are ordered from low to high. This order does not imply any sequence of implementation.
- Externalities are not taken into account. {12.2, Table 12.3, 6.4, Table 7.3, Supplementary Material Table 9.SM.2, Supplementary Material Table 9.SM.3, 10.6, 11.4, Figure 11.13, Supplementary Material 12.SM.1.2.3}

⁶⁹ For nuclear energy, modelled costs for long-term storage of radioactive waste are included.

D. Linkages between Mitigation, Adaptation, and Sustainable Development

- D.1 Accelerated and equitable climate action in mitigating, and adapting to, climate change impacts is critical to sustainable development. Climate change actions can also result in some trade-offs. The trade-offs of individual options could be managed through policy design. The Sustainable Development Goals (SDGs) adopted under the UN 2030 Agenda for Sustainable Development can be used as a basis for evaluating climate action in the context of sustainable development. (*high confidence*) (Figure SPM.8) {1.6, 3.7, 17.3, Figure TS.29}**
- D.1.1** Human-induced climate change is a consequence of more than a century of net GHG emissions from unsustainable energy use, land-use and land use change, lifestyle and patterns of consumption and production. Without urgent, effective and equitable mitigation actions, climate change increasingly threatens the health and livelihoods of people around the globe, ecosystem health and biodiversity. There are both synergies and trade-offs between climate action and the pursuit of other SDGs. Accelerated and equitable climate action in mitigating, and adapting to, climate change impacts is critical to sustainable development. (*high confidence*) {1.6, Cross-Chapter Box 5 in Chapter 4, 7.2, 7.3, 17.3; AR6 WGI SPM.A, Figure SPM.2; AR6 WGII SPM.B2, Figure SPM.3, Figure SPM.4b, Figure SPM.5}
- D.1.2** Synergies and trade-offs depend on the development context including inequalities, with consideration of climate justice. They also depend on means of implementation, intra- and inter-sectoral interactions, cooperation between countries and regions, the sequencing, timing and stringency of mitigation actions, governance, and policy design. Maximising synergies and avoiding trade-offs pose particular challenges for developing countries, vulnerable populations, and Indigenous Peoples with limited institutional, technological and financial capacity, and with constrained social, human, and economic capital. Trade-offs can be evaluated and minimised by giving emphasis to capacity building, finance, governance, technology transfer, investments, and development and social equity considerations with meaningful participation of Indigenous Peoples and vulnerable populations. (*high confidence*) {1.6, 1.7, 3.7, 5.2, 5.6, 7.4, 7.6, 17.4}
- D.1.3** There are potential synergies between sustainable development and energy efficiency, renewable energy, urban planning with more green spaces, reduced air pollution, and demand-side mitigation including shifts to balanced, sustainable healthy diets (*high confidence*). Electrification combined with low-GHG energy, and shifts to public transport can enhance health, employment, and can elicit energy security and deliver equity (*high confidence*). In industry, electrification and circular material flows contribute to reduced environmental pressures and increased economic activity and employment. However, some industrial options could impose high costs (*medium confidence*). (Figure SPM.8) {5.2, 8.2, 11.3, 11.5, 17.3, Figure TS.29}
- D.1.4** Land-based options such as reforestation and forest conservation, avoided deforestation, restoration and conservation of natural ecosystems and biodiversity, improved sustainable forest management, agroforestry, soil carbon management and options that reduce CH₄ and N₂O emissions in agriculture from livestock and soil, can have multiple synergies with the SDGs. These include enhancing sustainable agricultural productivity and resilience, food security, providing additional biomass for human use, and addressing land degradation. Maximising synergies and managing trade-offs depend on specific practices, scale of implementation, governance, capacity building, integration with existing land use, and the involvement of local communities and Indigenous Peoples and through benefit-sharing, supported by frameworks such as Land Degradation Neutrality within the UNCCD. (*high confidence*) {3.7, 7.4, 12.5, 17.3}
- D.1.5** Trade-offs in terms of employment, water use, land-use competition and biodiversity, as well as access to, and the affordability of, energy, food, and water can be avoided by well-implemented land-based mitigation options, especially those that do not threaten existing sustainable land uses and land rights, though more frameworks for integrated policy implementation are required. The sustainability of bioenergy and other bio-based products is influenced by feedstock, land management practice, climatic region, the context of existing land management, and the timing, scale and speed of deployment. (*medium confidence*) {3.5, 3.7, 7.4, 12.4, 12.5, 17.1}
- D.1.6** CDR methods such as soil carbon sequestration and biochar⁷⁰ can improve soil quality and food production capacity. Ecosystem restoration and reforestation sequester carbon in plants and soil, and can enhance biodiversity and provide additional

⁷⁰ Potential risks, knowledge gaps due to the relative immaturity of use of biochar as a soil amendment and unknown impacts of widespread application, and co-benefits of biochar are reviewed in Section 7.4.3.2.

biomass, but can displace food production and livelihoods, which calls for integrated approaches to land-use planning, to meet multiple objectives including food security. However, due to limited application of some of the options today, there are some uncertainties about potential benefits. (*high confidence*) {3.7, 7.4, 7.6, 12.5, 17.3, Table TS.7}

Mitigation options have synergies with many Sustainable Development Goals, but some options can also have trade-offs. The synergies and trade-offs vary dependent on context and scale.

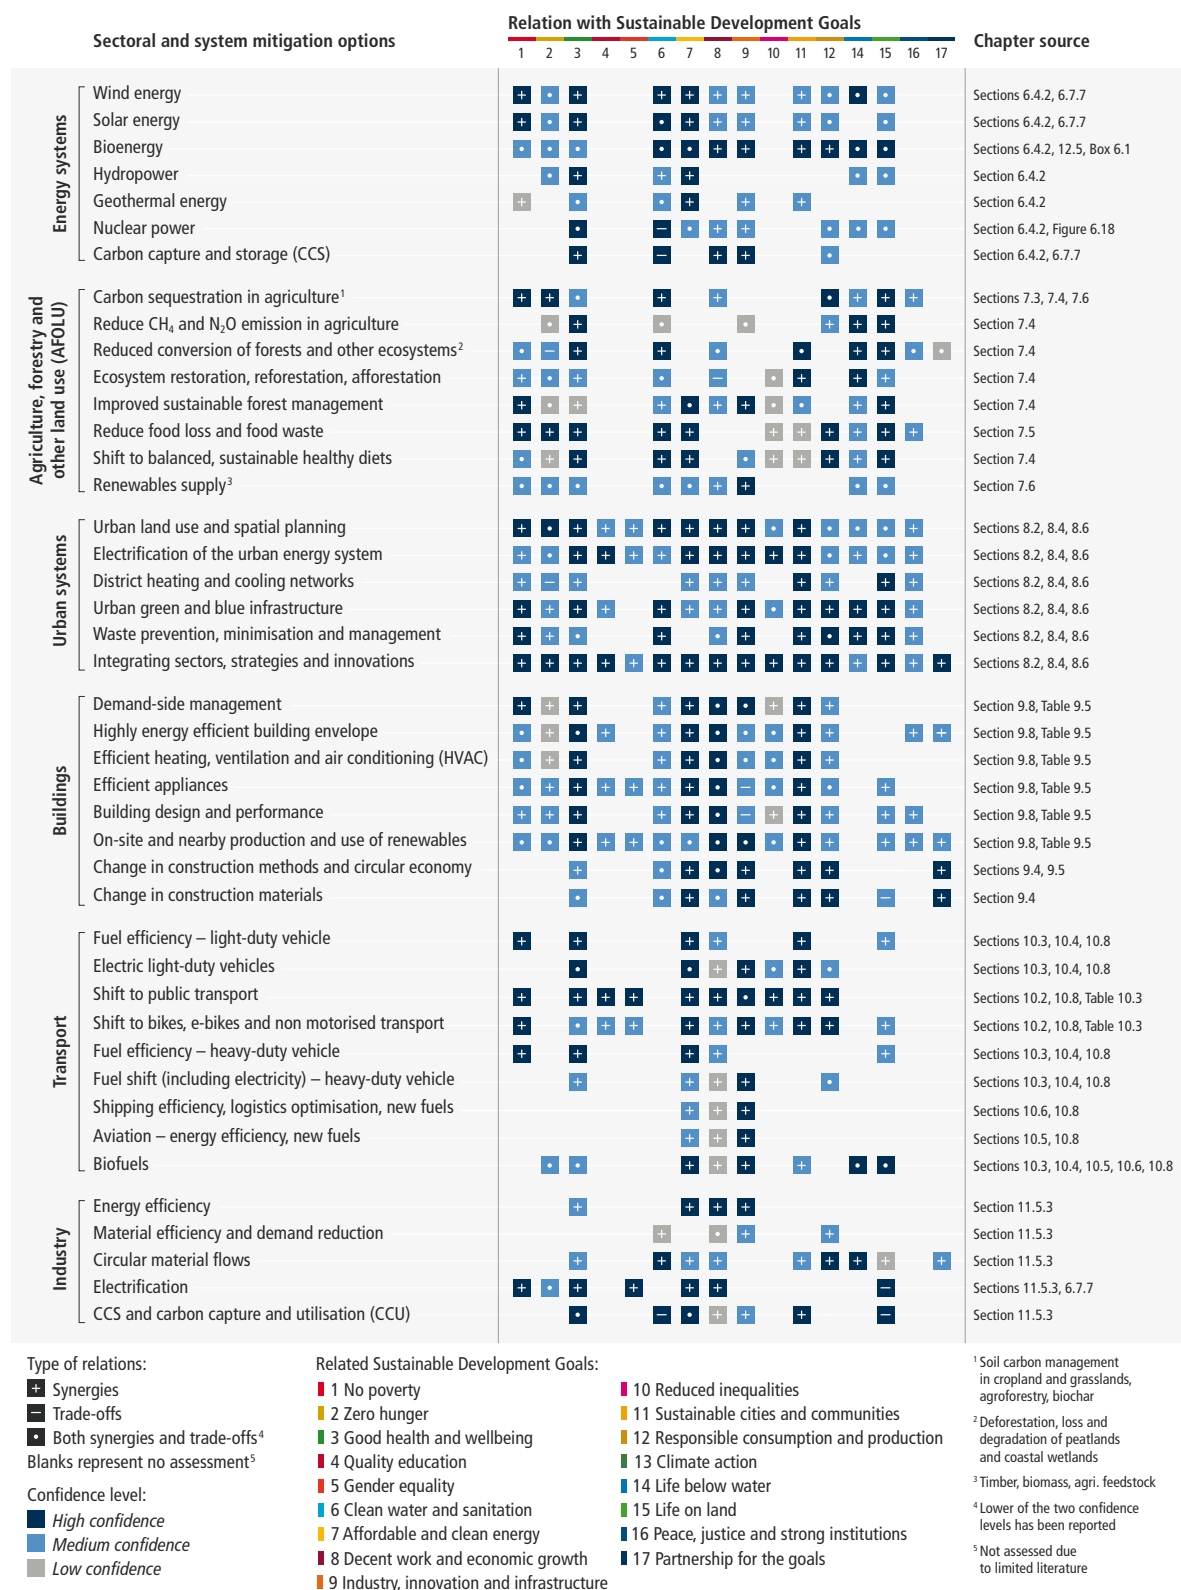

Figure SPM.8 | Synergies and trade-offs between sectoral and system mitigation options and the SDGs.

Figure SPM.8 (continued): Synergies and trade-offs between sectoral and system mitigation options and the SDGs. The sectoral chapters (Chapters 6–11) include qualitative assessments of synergies and trade-offs between sectoral mitigation options and the SDGs. Figure SPM.8 presents a summary of the chapter-level assessment for selected mitigation options (see Supplementary Material Table 17.SM.1 for the underlying assessment). The last column provides a line of sight to the sectoral chapters, which provide details on context specificity and dependence of interactions on the scale of implementation. Blank cells indicate that interactions have not been assessed due to limited literature. They do not indicate the absence of interactions between mitigation options and the SDGs. Confidence levels depend on the quality of evidence and level of agreement in the underlying literature assessed by the sectoral chapters. Where both synergies and trade-offs exist, the lower of the confidence levels for these interactions is used. Some mitigation options may have applications in more than one sector or system. The interactions between mitigation options and the SDGs might differ depending on the sector or system, and also on the context and the scale of implementation. Scale of implementation particularly matters when there is competition for scarce resources. {6.3, 6.4, 6.7, 7.3, 7.4, 7.5, 7.6, 8.2, 8.4, 8.6, Figure 8.4, Supplementary Material Table 8.SM.1, Supplementary Material Table 8.SM.2, 9.4, 9.5, 9.8, Table 9.5, 10.3, 10.4, 10.5, 10.6, 10.8, Table 10.3, 11.5, 12.5, 17.3, Figure 17.1, Supplementary Material Table 17.SM.1, Annex II.IV.12}

D.2 There is a strong link between sustainable development, vulnerability and climate risks. Limited economic, social and institutional resources often result in high vulnerability and low adaptive capacity, especially in developing countries (*medium confidence*). Several response options deliver both mitigation and adaptation outcomes, especially in human settlements, land management, and in relation to ecosystems. However, land and aquatic ecosystems can be adversely affected by some mitigation actions, depending on their implementation (*medium confidence*). Coordinated cross-sectoral policies and planning can maximise synergies and avoid or reduce trade-offs between mitigation and adaptation (*high confidence*). {3.7, 4.4, 13.8, 17.3; AR6 WGII}

D.2.1 Sustainable urban planning and infrastructure design including green roofs and facades, networks of parks and open spaces, management of urban forests and wetlands, urban agriculture, and water-sensitive design can deliver both mitigation and adaptation benefits in settlements (*medium confidence*). These options can also reduce flood risks, pressure on urban sewer systems, urban heat island effects, and can deliver health benefits from reduced air pollution (*high confidence*). There could also be trade-offs. For example, increasing urban density to reduce travel demand, could imply high vulnerability to heat waves and flooding (*high confidence*). (Figure SPM.8) {3.7, 8.2, 8.4, 12.5, 13.8, 17.3}

D.2.2 Land-related mitigation options with potential co-benefits for adaptation include agroforestry, cover crops, intercropping, perennial plants, restoring natural vegetation and rehabilitating degraded land. These can enhance resilience by maintaining land productivity and protecting and diversifying livelihoods. Restoration of mangroves and coastal wetlands sequesters carbon, while also reducing coastal erosion and protecting against storm surges, thus, reducing the risks from sea level rise and extreme weather. (*high confidence*) {4.4, 7.4, 7.6, 12.5, 13.8}

D.2.3 Some mitigation options can increase competition for scarce resources including land, water and biomass. Consequently, these can also reduce adaptive capacity, especially if deployed at larger scale and with high expansion rates thus exacerbating existing risks, in particular where land and water resources are very limited. Examples include the large-scale or poorly planned deployment of bioenergy, biochar, and afforestation of naturally unforested land. (*high confidence*) {12.5, 17.3}

D.2.4 Coordinated policies, equitable partnerships and integration of adaptation and mitigation within and across sectors can maximise synergies and minimise trade-offs and thereby enhance the support for climate action (*medium confidence*). Even if extensive global mitigation efforts are implemented, there will be a large need for financial, technical, and human resources for adaptation. Absence or limited resources in social and institutional systems can lead to poorly coordinated responses, thus reducing the potential for maximising mitigation and adaptation benefits, and increasing risk (*high confidence*). {12.6, 13.8, 17.1, 17.3}

- D.3** Enhanced mitigation and broader action to shift development pathways towards sustainability will have distributional consequences within and between countries. Attention to equity and broad and meaningful participation of all relevant actors in decision-making at all scales can build social trust, and deepen and widen support for transformative changes. (*high confidence*) {3.6, 4.2, 4.5, 5.2, 13.2, 17.3, 17.4}
- D.3.1** Countries at all stages of economic development seek to improve the well-being of people, and their development priorities reflect different starting points and contexts. Different contexts include social, economic, environmental, cultural, or political conditions, resource endowment, capabilities, international environment, and history. The enabling conditions for shifting development pathways towards increased sustainability will therefore also differ, giving rise to different needs. (*high confidence*) (Figure SPM.2) {1.6, 1.7, 2.4, 2.6, Cross-Chapter Box 5 in Chapter 4, 4.3.2, 17.4}
- D.3.2** Ambitious mitigation pathways imply large and sometimes disruptive changes in economic structure, with significant distributional consequences, within and between countries. Equity remains a central element in the UN climate regime, notwithstanding shifts in differentiation between states over time and challenges in assessing fair shares. Distributional consequences within and between countries include shifting of income and employment during the transition from high- to low-emissions activities. While some jobs may be lost, low-emissions development can also open more opportunities to enhance skills and create more jobs that last, with differences across countries and sectors. Integrated policy packages can improve the ability to integrate considerations of equity, gender equality and justice. (*high confidence*) {1.4, 1.6, 3.6, 4.2, 5.2, Box 11.1, 14.3, 15.2, 15.5, 15.6}
- D.3.3** Inequalities in the distribution of emissions and in the impacts of mitigation policies within countries affect social cohesion and the acceptability of mitigation and other environmental policies. Equity and just transitions can enable deeper ambitions for accelerated mitigation. Applying just transition principles and implementing them through collective and participatory decision-making processes is an effective way of integrating equity principles into policies at all scales, in different ways depending on national circumstances (*medium confidence*). This is already taking place in many countries and regions, as national just transition commissions or task forces, and related national policies, have been established in several countries. A multitude of actors, networks, and movements are engaged (*high confidence*). {1.6, 1.7, 2.4, 2.6, 4.5, 13.2, 13.9, 14.3, 14.5}
- D.3.4** Broadening equitable access to domestic and international finance, technologies that facilitate mitigation, and capacity, while explicitly addressing needs can further integrate equity and justice into national and international policies and act as a catalyst for accelerating mitigation and shifting development pathways (*medium confidence*). The consideration of ethics and equity can help address the uneven distribution of adverse impacts associated with 1.5°C and higher levels of global warming, in all societies (*high confidence*). Consideration of climate justice can help to facilitate shifting development pathways towards sustainability, including through equitable sharing of benefits and burdens of mitigation, increasing resilience to the impacts of climate change, especially for vulnerable countries and communities, and equitably supporting those in need (*high confidence*). {1.4, 1.6, 1.7, 3.6, 4.2, 4.5, Box 5.10, 13.4, 13.8, 13.9, 14.3, 14.5, 15.2, 15.5, 15.6, 16.5, 17.3, 17.4; SR1.5 SPM, AR6 WGII Chapter 18}

E. Strengthening the Response

- E.1** There are mitigation options which are feasible⁷¹ to deploy at scale in the near term. Feasibility differs across sectors and regions, and according to capacities and the speed and scale of implementation. Barriers to feasibility would need to be reduced or removed, and enabling conditions⁷² strengthened to deploy mitigation options at scale. These barriers and enablers include geophysical, environmental-ecological, technological, and economic factors, and especially institutional and socio-cultural factors. Strengthened near-term action beyond the NDCs (announced prior to UNFCCC COP26) can reduce and/or avoid long-term feasibility challenges of global modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. (*high confidence*) {3.8, 6.4, 8.5, 9.9, 10.8, 12.3, Figure TS.31, Annex II.IV.11}
- E.1.1** Several mitigation options, notably solar energy, wind energy, electrification of urban systems, urban green infrastructure, energy efficiency, demand-side management, improved forest- and crop/grassland management, and reduced food waste and loss, are technically viable, are becoming increasingly cost effective, and are generally supported by the public. This enables deployment in many regions (*high confidence*). While many mitigation options have environmental co-benefits, including improved air quality and reducing toxic waste, many also have adverse environmental impacts, such as reduced biodiversity, when applied at very large scale, for example very large scale bioenergy or large scale use of battery storage, that would have to be managed (*medium confidence*). Almost all mitigation options face institutional barriers that need to be addressed to enable their application at scale (*medium confidence*). {6.4, Figure 6.19, 7.4, 8.5, Figure 8.19, 9.9, Figure 9.20, 10.8, Figure 10.23, 12.3, Figure 12.4, Figure TS.31}
- E.1.2** The feasibility of mitigation options varies according to context and time. For example, the institutional capacity to support deployment varies across countries; the feasibility of options that involve large-scale land-use changes varies across regions; spatial planning has a higher potential at early stages of urban development; the potential of geothermal is site specific; and capacities, cultural and local conditions can either inhibit or enable demand-side responses. The deployment of solar and wind energy has been assessed to become increasingly feasible over time. The feasibility of some options can increase when combined or integrated, such as using land for both agriculture and centralised solar production. (*high confidence*) {6.4, 6.6, Supplementary Material Table 6.SM, 7.4, 8.5, Supplementary Material Table 8.SM.2, 9.9, Supplementary Material Table 9.SM.1, 10.8, Appendix 10.3, 12.3, Tables 12.SM.2.1 to 12.SM.2.6}
- E.1.3** Feasibility depends on the scale and speed of implementation. Most options face barriers when they are implemented rapidly at a large scale, but the scale at which barriers manifest themselves varies. Strengthened and coordinated near-term actions in cost-effective modelled global pathways that limit warming to 2°C (>67%) or lower, reduce the overall risks to the feasibility of the system transitions, compared to modelled pathways with relatively delayed or uncoordinated action.⁷³ (*high confidence*) {3.8, 6.4, 10.8, 12.3}

⁷¹ In this report, the term 'feasibility' refers to the potential for a mitigation or adaptation option to be implemented. Factors influencing feasibility are context-dependent and may change over time. Feasibility depends on geophysical, environmental-ecological, technological, economic, socio-cultural and institutional factors that enable or constrain the implementation of an option. The feasibility of options may change when different options are combined and increase when enabling conditions are strengthened.

⁷² In this report, the term 'enabling conditions' refers to conditions that enhance the feasibility of adaptation and mitigation options. Enabling conditions include finance, technological innovation, strengthening policy instruments, institutional capacity, multi-level governance, and changes in human behaviour and lifestyles.

⁷³ The future feasibility challenges described in the modelled pathways may differ from the real-world feasibility experiences of the past.

- E.2 In all countries, mitigation efforts embedded within the wider development context can increase the pace, depth and breadth of emissions reductions (*medium confidence*). Policies that shift development pathways towards sustainability can broaden the portfolio of available mitigation responses, and enable the pursuit of synergies with development objectives (*medium confidence*). Actions can be taken now to shift development pathways and accelerate mitigation and transitions across systems (*high confidence*). {4.3, 4.4, Cross-Chapter Box 5 in Chapter 4, 5.2, 5.4, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5}**
- E.2.1** Current development pathways may create behavioural, spatial, economic and social barriers to accelerated mitigation at all scales (*high confidence*). Choices made by policymakers, citizens, the private sector and other stakeholders influence societies' development pathways (*high confidence*). Actions that steer, for example, energy and land systems transitions, economy-wide structural change, and behaviour change, can shift development pathways towards sustainability⁷⁴ (*medium confidence*). {4.3, Cross-Chapter Box 5 in Chapter 4, 5.4, 13.9}
- E.2.2** Combining mitigation with policies to shift development pathways, such as broader sectoral policies, policies that induce lifestyle or behaviour changes, financial regulation, or macroeconomic policies can overcome barriers and open up a broader range of mitigation options (*high confidence*). It can also facilitate the combination of mitigation and other development goals (*high confidence*). For example, measures promoting walkable urban areas combined with electrification and renewable energy can create health co-benefits from cleaner air and benefits from enhanced mobility (*high confidence*). Coordinated housing policies that broaden relocation options can make mitigation measures in transport more effective (*medium confidence*). {3.2, 4.3, 4.4, Cross-Chapter Box 5 in Chapter 4, 5.3, 8.2, 8.4}
- E.2.3** Institutional and regulatory capacity, innovation, finance, improved governance and collaboration across scales, and multi-objective policies enable enhanced mitigation and shifts in development pathways. Such interventions can be mutually reinforcing and establish positive feedback mechanisms, resulting in accelerated mitigation. (*high confidence*) {4.4, 5.4, Figure 5.14, 5.6, 9.9, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5, Cross-Chapter Box 12 in Chapter 16}
- E.2.4** Enhanced action on all the above enabling conditions can be taken now (*high confidence*). In some situations, such as with innovation in technology at an early stage of development and some changes in behaviour towards low emissions, because the enabling conditions may take time to be established, action in the near term can yield accelerated mitigation in the mid-term (*medium confidence*). In other situations, the enabling conditions can be put in place and yield results in a relatively short time frame, for example the provision of energy related information, advice and feedback to promote energy saving behaviour (*high confidence*). {4.4, 5.4, Figure 5.14, 5.6, 6.7, 9.9, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5, Cross-Chapter Box 12 in Chapter 16}
- E.3 Climate governance, acting through laws, strategies and institutions, based on national circumstances, supports mitigation by providing frameworks through which diverse actors interact, and a basis for policy development and implementation (*medium confidence*). Climate governance is most effective when it integrates across multiple policy domains, helps realise synergies and minimise trade-offs, and connects national and sub-national policymaking levels (*high confidence*). Effective and equitable climate governance builds on engagement with civil society actors, political actors, businesses, youth, labour, media, Indigenous Peoples and local communities (*medium confidence*). {5.4, 5.6, 8.5, 9.9, 13.2, 13.7, 13.9}**
- E.3.1** Climate governance enables mitigation by providing an overall direction, setting targets, mainstreaming climate action across policy domains, enhancing regulatory certainty, creating specialised organisations and creating the context to mobilise finance (*medium confidence*). These functions can be promoted by climate-relevant laws, which are growing in number, or climate strategies, among others, based on national and sub-national context (*medium confidence*). Framework laws set an overarching legal basis, either operating through a target and implementation approach, or a sectoral mainstreaming approach, or both, depending on national circumstance (*medium confidence*). Direct national and sub-national laws that explicitly target mitigation and indirect laws that impact emissions through mitigation-related policy domains have both been shown to be relevant to mitigation outcomes (*medium confidence*). {13.2}

⁷⁴ Sustainability may be interpreted differently in various contexts as societies pursue a variety of sustainable development objectives.

- E.3.2** Effective national climate institutions address coordination across sectors, scales and actors, build consensus for action among diverse interests, and inform strategy setting (*medium confidence*). These functions are often accomplished through independent national expert bodies, and high-level coordinating bodies that transcend departmental mandates. Complementary sub-national institutions tailor mitigation actions to local context and enable experimentation but can be limited by inequities and resource and capacity constraints (*high confidence*). Effective governance requires adequate institutional capacity at all levels (*high confidence*). {4.4, 8.5, 9.9, 11.3, 11.5, 11.6, 13.2, 13.5, 13.7, 13.9}
- E.3.3** The extent to which civil society actors, political actors, businesses, youth, labour, media, Indigenous Peoples, and local communities are engaged influences political support for climate change mitigation and eventual policy outcomes. Structural factors of national circumstances and capabilities (e.g., economic and natural endowments, political systems and cultural factors and gender considerations) affect the breadth and depth of climate governance. Mitigation options that align with prevalent ideas, values and beliefs are more easily adopted and implemented. Climate-related litigation, for example by governments, private sector, civil society and individuals, is growing - with a large number of cases in some developed countries, and with a much smaller number in some developing countries - and in some cases, has influenced the outcome and ambition of climate governance. (*medium confidence*) {5.2, 5.4, 5.5, 5.6, 9.9, 13.3, 13.4}
- E.4** **Many regulatory and economic instruments have already been deployed successfully. Instrument design can help address equity and other objectives. These instruments could support deep emissions reductions and stimulate innovation if scaled up and applied more widely (*high confidence*). Policy packages that enable innovation and build capacity are better able to support a shift towards equitable low-emission futures than are individual policies (*high confidence*). Economy-wide packages, consistent with national circumstances, can meet short-term economic goals while reducing emissions and shifting development pathways towards sustainability (*medium confidence*). {Cross-Chapter Box 5 in Chapter 4, 13.6, 13.7, 13.9, 16.3, 16.4, 16.6}**
- E.4.1** A wide range of regulatory instruments at the sectoral level have proven effective in reducing emissions. These instruments, and broad-based approaches including relevant economic instruments,⁷⁵ are complementary (*high confidence*). Regulatory instruments that are designed to be implemented with flexibility mechanisms can reduce costs (*medium confidence*). Scaling up and enhancing the use of regulatory instruments, consistent with national circumstances, could improve mitigation outcomes in sectoral applications, including but not limited to renewable energy, land use and zoning, building codes, vehicle and energy efficiency, fuel standards, and low-emissions industrial processes and materials (*high confidence*). {6.7, 7.6, 8.4, 9.9, 10.4, 11.5, 11.6, 13.6}
- E.4.2** Economic instruments have been effective in reducing emissions, complemented by regulatory instruments mainly at the national and also sub-national and regional level (*high confidence*). Where implemented, carbon pricing instruments have incentivised low-cost emissions reduction measures, but have been less effective, on their own and at prevailing prices during the assessment period, in promoting the higher-cost measures necessary for further reductions (*medium confidence*). Equity and distributional impacts of such carbon pricing instruments can be addressed by using revenue from carbon taxes or emissions trading to support low-income households, among other approaches (*high confidence*). Practical experience has informed instrument design and helped to improve predictability, environmental effectiveness, economic efficiency, distributional goals and social acceptance (*high confidence*). Removing fossil fuel subsidies would reduce emissions, improve public revenue and macroeconomic performance, and yield other environmental and sustainable development benefits; subsidy removal may have adverse distributional impacts especially on the most economically vulnerable groups which, in some cases can be mitigated by measures such as redistributing revenue saved, all of which depend on national circumstances (*high confidence*); fossil fuel subsidy removal is projected by various studies to reduce global CO₂ emissions by 1–4%, and GHG emissions by up to 10% by 2030, varying across regions (*medium confidence*). {6.3, 13.6}
- E.4.3** Low-emission technological innovation is strengthened through the combination of dedicated technology-push policies and investments (e.g., for scientific training, R&D, demonstration), with tailored demand-pull policies (e.g., standards, feed-in tariffs, taxes), which create incentives and market opportunities. Developing countries' abilities to deploy low-emission technologies, seize socio-economic benefits and manage trade-offs would be enhanced with increased financial resources and capacity for innovation which are currently concentrated in developed countries, alongside technology transfer. (*high confidence*) {16.2, 16.3, 16.4, 16.5}

⁷⁵ Economic instruments are structured to provide a financial incentive to reduce emissions and include, among others, market- and price-based instruments.

- E.4.4** Effective policy packages would be comprehensive in coverage, harnessed to a clear vision for change, balanced across objectives, aligned with specific technology and system needs, consistent in terms of design and tailored to national circumstances. They are better able to realise synergies and avoid trade-offs across climate and development objectives. Examples include: emissions reductions from buildings through a mix of efficiency targets, building codes, appliance performance standards, information provision, carbon pricing, finance and technical assistance; and industrial GHG emissions reductions through innovation support, market creation and capacity building. (*high confidence*) {4.4, 6.7, 9.9, 11.6, 13.7, 13.9, 16.3, 16.4}
- E.4.5** Economy-wide packages that support mitigation and avoid negative environmental outcomes include: long-term public spending commitments; pricing reform; and investment in education and training, natural capital, R&D and infrastructure (*high confidence*). They can meet short-term economic goals while reducing emissions and shifting development pathways towards sustainability (*medium confidence*). Infrastructure investments can be designed to promote low-emissions futures that meet development needs (*medium confidence*). {Cross-Chapter Box 5 in Chapter 4, 5.4, 5.6, 8.5, 13.6, 13.9, 16.3, 16.5, 16.6}
- E.4.6** National policies to support technology development and diffusion, and participation in international markets for emission reduction, can bring positive spillover effects for other countries (*medium confidence*), although reduced demand for fossil fuels could result in costs to exporting countries (*high confidence*). There is no consistent evidence that current emission trading systems have led to significant emissions leakage, which can be attributed to design features aimed at minimising competitiveness effects, among other reasons (*medium confidence*). {13.6, 13.7, 13.8, 16.2, 16.3, 16.4}
- E.5** **Tracked financial flows fall short of the levels needed to achieve mitigation goals across all sectors and regions. The challenge of closing gaps is largest in developing countries as a whole. Scaling up mitigation financial flows can be supported by clear policy choices and signals from governments and the international community (*high confidence*). Accelerated international financial cooperation is a critical enabler of low-GHG and just transitions, and can address inequities in access to finance and the costs of, and vulnerability to, the impacts of climate change (*high confidence*). {15.2, 15.3, 15.4, 15.5, 15.6}**
- E.5.1** Average annual modelled investment requirements for 2020 to 2030 in scenarios that limit warming to 2°C or 1.5°C are a factor of three to six greater than current levels, and total mitigation investments (public, private, domestic and international) would need to increase across all sectors and regions (*medium confidence*). Mitigation investment gaps are wide for all sectors, and widest for the AFOLU sector in relative terms and for developing countries⁷⁶ (*high confidence*). Financing and investment requirements for adaptation, reduction of losses and damages, general infrastructure, regulatory environment and capacity building, and climate-responsive social protection further exacerbate the magnitude of the challenges for developing countries to attract financing (*high confidence*). {3.2, 14.4, 15.1, 15.2, 15.3, 15.4, 15.5}
- E.5.2** There is sufficient global capital and liquidity to close global investment gaps, given the size of the global financial system, but there are barriers to redirect capital to climate action both within and outside the global financial sector, and in the macroeconomic headwinds facing developing regions. Barriers to the deployment of commercial finance from within the financial sector as well as macroeconomic considerations include: inadequate assessment of climate-related risks and investment opportunities; regional mismatch between available capital and investment needs; home bias factors; country indebtedness levels; economic vulnerability; and limited institutional capacities (*high confidence*). Challenges from outside the financial sector include: limited local capital markets; unattractive risk-return profiles, in particular due to missing or weak regulatory environments consistent with ambition levels; limited institutional capacity to ensure safeguards; standardisation, aggregation, scalability and replicability of investment opportunities and financing models; and, a pipeline ready for commercial investments. (*high confidence*) {15.2, 15.3, 15.5, 15.6}
- E.5.3** Accelerated financial support for developing countries from developed countries and other sources is a critical enabler to enhance mitigation action and address inequities in access to finance, including its costs, terms and conditions, and economic vulnerability to climate change for developing countries (*high confidence*). Scaled-up public grants for mitigation and adaptation funding for vulnerable regions, especially in Sub-Saharan Africa, would be cost-effective and have high social returns in terms of access to basic energy (*high confidence*). Options for scaling up mitigation in developing regions include: increased levels of public finance and publicly mobilised private finance flows from developed to developing countries in the context of the USD100 billion-a-year goal; increase the use of public guarantees to reduce risks and leverage private flows

⁷⁶ In modelled pathways, regional investments are projected to occur when and where they are most cost-effective to limit global warming. The model quantifications help to identify high-priority areas for cost-effective investments, but do not provide any indication on who would finance the regional investments.

at lower cost; local capital markets development; and building greater trust in international cooperation processes (*high confidence*). A coordinated effort to make the post-pandemic recovery sustainable and increased flows of financing over the next decade can accelerate climate action, including in developing regions and countries facing high debt costs, debt distress and macroeconomic uncertainty (*high confidence*). {15.2, 15.3, 15.4, 15.5, 15.6, Box 15.6}

- E.5.4** Clear signalling by governments and the international community, including a stronger alignment of public sector finance and policy, and higher levels of public sector climate finance, reduces uncertainty and transition risks for the private sector. Depending on national contexts, investors and financial intermediaries, central banks, and financial regulators can support climate action and can shift the systemic underpricing of climate-related risk by increasing awareness, transparency and consideration of climate-related risk, and investment opportunities. Financial flows can also be aligned with funding needs through: greater support for technology development; a continued role for multilateral and national climate funds and development banks; lowering financing costs for underserved groups through entities such as green banks existing in some countries, funds and risk-sharing mechanisms; economic instruments which consider economic and social equity and distributional impacts; gender-responsive and women-empowerment programmes as well as enhanced access to finance for local communities and Indigenous Peoples and small land owners; and greater public-private cooperation. (*high confidence*) {15.2, 15.5, 15.6}

E.6 International cooperation is a critical enabler for achieving ambitious climate change mitigation goals. The UNFCCC, Kyoto Protocol, and Paris Agreement are supporting rising levels of national ambition and encouraging development and implementation of climate policies, although gaps remain. Partnerships, agreements, institutions and initiatives operating at the sub-global and sectoral levels and engaging multiple actors are emerging, with mixed levels of effectiveness. (*high confidence*) {8.5, 14.2, 14.3, 14.5, 14.6, 15.6, 16.5}

- E.6.1** Internationally agreed processes and goals, such as those in the UNFCCC, Kyoto Protocol, and Paris Agreement – including transparency requirements for national reporting on emissions, actions and support, and tracking progress towards the achievement of Nationally Determined Contributions – are enhancing international cooperation, national ambition and policy development. International financial, technology and capacity building support to developing countries will enable greater implementation and encourage ambitious Nationally Determined Contributions over time. (*medium confidence*) {14.3}
- E.6.2** International cooperation on technology development and transfer accompanied by capacity building, knowledge sharing, and technical and financial support can accelerate the global diffusion of mitigation technologies, practices and policies at national and sub-national levels, and align these with other development objectives (*high confidence*). Challenges in and opportunities to enhance innovation cooperation exist, including in the implementation of elements of the UNFCCC and the Paris Agreement as per the literature assessed, such as in relation to technology development and transfer, and finance (*high confidence*). International cooperation on innovation works best when tailored to specific institutional and capability contexts, when it benefits local value chains, when partners collaborate equitably and on voluntary and mutually agreed terms, when all relevant voices are heard, and when capacity building is an integral part of the effort (*medium confidence*). Support to strengthen technological innovation systems and innovation capabilities, including through financial support in developing countries would enhance engagement in and improve international cooperation on innovation (*high confidence*). {4.4, 14.2, 14.4, 16.3, 16.5, 16.6}
- E.6.3** Transnational partnerships can stimulate policy development, low-emissions technology diffusion and emission reductions by linking sub-national and other actors, including cities, regions, non-governmental organisations and private sector entities, and by enhancing interactions between state and non-state actors. While this potential of transnational partnerships is evident, uncertainties remain over their costs, feasibility, and effectiveness. Transnational networks of city governments are leading to enhanced ambition and policy development and a growing exchange of experience and best practices (*medium confidence*). {8.5, 11.6, 14.5, 16.5, Cross-Chapter Box 12 in Chapter 16}
- E.6.4** International environmental and sectoral agreements, institutions, and initiatives are helping, and in some cases may help, to stimulate low-GHG emissions investment and reduce emissions. Agreements addressing ozone depletion and transboundary air pollution are contributing to mitigation, and in other areas, such as atmospheric emissions of mercury, may contribute to mitigation (*high confidence*). Trade rules have the potential to stimulate international adoption of mitigation technologies and policies, but may also limit countries' ability to adopt trade-related climate policies (*medium confidence*). Current sectoral levels of ambition vary, with emission reduction aspirations in international aviation and shipping lower than in many other sectors (*medium confidence*). {14.5, 14.6}

TS.1 Introduction

The Working Group III (WGIII) contribution to the IPCC's Sixth Assessment Report (AR6) assesses the current state of knowledge on the scientific, technological, environmental, economic and social aspects of climate change mitigation. It builds on previous IPCC reports, including the WGIII contribution to the IPCC's Fifth Assessment Report (AR5) and the three Special Reports of the Sixth Assessment cycle on: Global Warming of 1.5°C (SR1.5); Climate Change and Land (SRCCL); and the Ocean and Cryosphere in a Changing Climate (SROCC).¹

The report assesses new literature, methodological and recent developments, and changes in approaches towards climate change mitigation since the IPCC AR5 report was published in 2014.

The global science and policy landscape on climate change mitigation has evolved since AR5. The development of the literature reflects, among other factors, the UN Framework Convention on Climate Change (UNFCCC), the outcomes of its Kyoto Protocol and the goals of the Paris Agreement {13, 14, 15}, and the UN 2030 Agenda for Sustainable Development {1, 4, 17}. Literature further highlights the growing role of non-state and sub-national actors in the global effort to address climate change, including cities, businesses, citizens, transnational initiatives and public-private entities {5, 8, 13}. It draws attention to the decreasing cost of some low-emission technologies {2, 6, 12} and the evolving role of international cooperation {14}, finance {15} and innovation {16}. Emerging literature examines the global spread of climate policies, strengthened mitigation actions in developing countries, sustained reductions in greenhouse gas (GHG) emissions in some developed countries and the continuing challenges for mitigation. {2, 13}

There are ever closer linkages between climate change mitigation, development pathways and the pursuit of Sustainable Development Goals (SDGs). Development pathways largely drive GHG emissions and hence shape the mitigation challenge and the portfolio of available responses {4}. The co-benefits and risks of mitigation responses also differ according to stages of development and national capabilities {1, 2, 3, 4, 13}. Climate change mitigation framed in the context of sustainable development, equity, and poverty eradication, and rooted in the development aspirations of the society within which they take place, will be more acceptable, durable and effective. {1, 4, 17}

This report includes new assessment approaches that go beyond those evaluated in the previous IPCC WGIII reports. In addition to sectoral and systems chapters {6, 7, 8, 9, 10, 11}, this report includes, for the first time, chapters dedicated to cross-sectoral perspectives {12}, demand, services and social aspects of mitigation (Box TS.11) {5}, and innovation, technology development and transfer {16}. The assessment of future pathways combines a forward-looking assessment of near- to medium-term perspectives up to 2050, including ways of shifting development pathways towards sustainability {4}, with an assessment of long-term outcome-oriented

pathways up to 2100 {3}. Collaboration between the IPCC Working Groups is reflected in Cross-Working Group boxes which address topics such as the economic benefits from avoided impacts along mitigation pathways {Cross-Working Group Box 1 in Chapter 3}, climate change and urban areas {Cross-Working Group Box 2 in Chapter 8}, mitigation and adaptation through the bioeconomy {Cross-Working Group Box 3 in Chapter 12} and Solar Radiation Modification (SRM) {Cross-Working Group Box 4 in Chapter 14}. This assessment also gives greater attention than AR5 to social, economic and environmental dimensions of mitigation actions, and institutional, legal and financial aspects. {5, 13, 14, 15}

The report draws from literature on broad and diverse analytic frameworks across multiple disciplines. These include, *inter alia*: economic and environmental efficiency {1}; ethics and equity {4, 5, 17}; innovation and the dynamics of socio-technical transitions {16}; and socio-political-institutional frameworks {1, 5, 13, 14, 17}. These help to identify synergies and trade-offs with Sustainable Development Goals (SDGs), challenges and windows of opportunity for action including co-benefits, and equitable transitions at local, national and global scales. {1, 5, 13, 14, 16}

This Technical Summary (TS) of the WGIII contribution to the IPCC's Sixth Assessment Report (AR6) broadly follows the report chapter order and is structured as follows.

- TS Section 2 (TS.2) sets out how the global context for mitigation has changed and summarises signs of progress and continuing challenges.
- TS Section 3 (TS.3) evaluates emission trends and drivers including recent sectoral, financial, technological and policy developments.
- TS Section 4 (TS.4) identifies mitigation and development pathways in the near and mid-term to 2050, and in the longer term to 2100. This section includes an assessment of how mitigation pathways deploying different portfolios of mitigation responses are consistent with limiting global warming to different levels.
- TS Section 5 (TS.5) summarises recent advances in knowledge across sectors and systems including energy, urban and other settlements, transport, buildings, industry, and agriculture, forestry and other land-use (AFOLU).
- TS Section 6 (TS.6) examines how enabling conditions including behaviour and lifestyle, policy, governance and institutional capacity, international cooperation, finance, and innovation and technology can accelerate mitigation in the context of sustainable development.
- TS Section 7 (TS.7) evaluates how mitigation can be achieved in the context of sustainable development, while maximising co-benefits and minimising risks.

¹ The three Special Reports are: Global Warming of 1.5°C: an IPCC Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty (2018); Climate Change and Land: an IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems (2019); IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (2019).

Technical Summary

Throughout this Technical Summary the validity of findings, confidence in findings, and cross-references to Technical Summary sections, figures and tables are shown in () brackets.² References to the underlying report are shown in { } brackets.

TS

² Each finding is grounded in an evaluation of the underlying evidence, typeset in italics. The validity of a finding is evaluated in terms of the evidence quality – ‘*limited*’, ‘*medium*’, ‘*robust*’ – and the degree of agreement between sources – ‘*low*’, ‘*medium*’, ‘*high*’. A level of confidence is expressed using five qualifiers: *very low*, *low*, *medium*, *high* and *very high*. Generally, the level of confidence is highest where there is robust evidence from multiple sources and high agreement. For findings with, for example, ‘*robust evidence, medium agreement*’, a confidence statement may not always be appropriate. The assessed likelihood of an outcome or a result is described as: *virtually certain* (99–100% probability); *very likely* (90–100%); *likely* (66–100%); *about as likely as not* (33–66%); *unlikely* (0–33%); *very unlikely* (0–10%); *exceptionally unlikely* (0–1%). Additional terms may also be used when appropriate, consistent with the IPCC uncertainty guidance: <https://www.ipcc.ch/site/assets/uploads/2018/05/uncertainty-guidance-note.pdf>.

TS.2 The Changed Global Context, Signs of Progress and Continuing Challenges

Since the IPCC's Fifth Assessment Report (AR5), important changes that have emerged include the specific objectives established in the Paris Agreement of 2015 (for temperature, adaptation and finance), rising climate impacts, and higher levels of societal awareness and support for climate action (*high confidence*). Meeting the long-term temperature goal in the Paris Agreement, however, implies a rapid inflection in GHG emission trends and accelerating decline towards 'net zero'. This is implausible without urgent and ambitious action at all scales. {1.2, 1.3, 1.5, 1.6, Chapters 3 and 4}

Effective and equitable climate policies are largely compatible with the broader goal of sustainable development and efforts to eradicate poverty as enshrined in the UN 2030 Agenda for Sustainable Development and its 17 Sustainable Development Goals (SDGs), notwithstanding trade-offs in some cases (*high confidence*). Taking urgent action to combat climate change and its impacts is one of the 17 SDGs (SDG 13). However, climate change mitigation also has synergies and/or trade-offs with many other SDGs. There has been a strong relationship between development and GHG emissions, as historically both per-capita and absolute emissions have risen with industrialisation. However, recent evidence shows countries can grow their economies while reducing emissions. Countries have different priorities in achieving the SDGs and reducing emissions as informed by their respective national conditions and capabilities. Given the differences in GHG emissions contributions, degree of vulnerability and impacts, as well as capacities within and between nations, equity and justice are important considerations for effective climate policy and for securing national and international support for deep decarbonisation. Achieving sustainable development and eradicating poverty would involve effective and equitable climate policies at all levels from local to global scale. Failure to address questions of equity and justice over time can undermine social cohesion and stability. International cooperation can enhance efforts to achieve ambitious global climate mitigation in the context of sustainable development. Pathways that illustrate movement towards fulfilling the SDGs are shown in Figure TS.1. {1.4, 1.6, Chapters 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 13 and 17}

The transition to a low-carbon economy depends on a wide range of closely intertwined drivers and constraints, including policies and technologies where notable advances over the past decade have opened up new and large-scale opportunities for deep decarbonisation, and for alternative development pathways which could deliver multiple social and developmental goals (*high confidence*). Drivers for, and constraints on, low-carbon societal transitions comprise economic and technological factors (the means by which services such as food, heating and shelter are provided and for whom, the emissions intensity of traded products, finance and investment), socio-political issues (political economy, equity and fairness, social innovation and behaviour change), and institutional factors (legal framework and institutions, and the quality of international cooperation). In addition to being deeply intertwined, all the factors matter to varying degrees,

depending on the prevailing social, economic, cultural and political context. They often both drive and inhibit transitions at the same time, within and across different scales. The development and deployment of innovative technologies and systems at scale are important for achieving deep decarbonisation, and in recent years, the cost of several low-carbon technologies has declined sharply as deployment has risen rapidly. (Figure TS.7) {1.3, 1.4, Chapters 2, 4, 5, 13, 14}

Accelerating mitigation to prevent dangerous anthropogenic interference with the climate system will require the integration of broadened assessment frameworks and tools that combine multiple perspectives, applied in a context of multi-level governance (*high confidence*). Analysing a challenge on the scale of fully decarbonising our economies entails integration of multiple analytic frameworks. Approaches to risk assessment and resilience, established across IPCC Working Groups, are complemented by frameworks for probing the challenges in implementing mitigation. *Aggregate frameworks* include cost-effectiveness analysis towards given objectives, and cost-benefit analysis, both of which have been developing to take fuller account of advances in understanding risks and innovation, the dynamics of sectors and systems and of climate impacts, and welfare economic theory including growing consensus on long-term discounting. *Ethical frameworks* consider the fairness of processes and outcomes which can help ameliorate distributional impacts across income groups, countries and generations. *Transition and transformation frameworks* explain and evaluate the dynamics of transitions to low-carbon systems arising from interactions amongst levels. *Psychological, behavioural and political frameworks* outline the constraints (and opportunities) arising from human psychology and the power of incumbent interests. A comprehensive understanding of climate mitigation must combine these multiple frameworks. Together with established risk frameworks, these collectively help to explain potential synergies and trade-offs in mitigation, implying a need for a wide portfolio of policies attuned to different actors and levels of decision-making, and underpin 'just transition' strategies in diverse contexts. {1.2.2, 1.7, 1.8, Figure 1.7}

The speed, direction, and depth of any transition will be determined by choices in the environmental, technological, economic, socio-cultural and institutional realms (*high confidence*). Transitions in specific systems can be gradual or can be rapid and disruptive. The pace of a transition can be impeded by 'lock-in' generated by existing physical capital, institutions, and social norms. The interaction between politics, economics and power relationships is central to explaining why broad commitments do not always translate to urgent action. At the same time, attention to, and support for, climate policies and low-carbon societal transitions has generally increased, as the impacts have become more salient. Both public and private financing and financial structures strongly affect the scale and balance of high- and low-carbon investments. Societal and behavioural norms, regulations and institutions are essential conditions to accelerate low-carbon transitions in multiple sectors, whilst addressing distributional concerns endemic to any major transition. The COVID-19 pandemic has also had far-reaching impacts on the global economic and social system, and recovery will present both challenges and opportunities for climate mitigation. (Box TS.1) {1.3, Box 1.1, 1.4, 1.8, Chapters 2, 3, 4, 5, 15, 17}

Figure TS.1 | Sustainable development pathways towards fulfilling the Sustainable Development Goals. The graph shows global average per-capita GHG emissions (vertical axis) and relative 'Historic Index of Human Development' (HIHD) levels (horizontal) have increased globally since the industrial revolution (grey line). The bubbles on the graph show regional per-capita GHG emissions and human development levels in the year 2015, illustrating large disparities. Pathways towards fulfilling the Paris Agreement (and SDG 13) involve global average per-capita GHG emissions below about 5 tCO₂-eq by 2030. Likewise, to fulfil SDGs 3, 4 and 8, HIHD levels (see footnote 7 in Chapter 1) need to be at least 0.5 or greater. This suggests a 'sustainable development zone' for year 2030 (in pale brown); the in-figure text also suggests a 'sustainable development corridor', where countries limit per-capita GHG emissions while improving levels of human development over time. The emphasis of pathways into the sustainable development zone differ (dashed brown arrows), but in each case transformations are needed in how human development is attained while limiting GHG emissions.

Achieving the global transition to a low-carbon, climate-resilient and sustainable world requires purposeful and increasingly coordinated planning and decisions at many scales of governance including local, sub-national, national and global levels (*high confidence*). Accelerating mitigation globally would imply strengthening policies adopted to date, expanding the effort across options, sectors, and countries, and broadening responses to include more diverse actors and societal processes at multiple – including international – levels. The effective governance of climate change entails strong action across multiple jurisdictions and decision-making levels, including regular evaluation and learning. Choices that cause climate change as well as the processes for making

and implementing relevant decisions involve a range of non-nation state actors such as cities, businesses, and civil society organisations. At global, national and sub-national levels, climate change actions are interwoven with, and embedded in, the context of much broader social, economic and political goals. Therefore, the governance required to address climate change has to navigate power, political, economic, and social dynamics at all levels of decision-making. Effective climate-governing institutions, and openness to experimentation on a variety of institutional arrangements, policies and programmes can play a vital role in engaging stakeholders and building momentum for effective climate action. {1.4, 1.9, Chapters 8, 13, 15, 17}

Table TS.1 | Signs of progress and continuing challenges.

Signs of progress	Continuing challenges
Emissions trends	
The rate of global GHG emissions growth has slowed in recent years , from 2.1% yr ⁻¹ between 2000 and 2009, to 1.3% yr ⁻¹ in between 2010 and 2019. (TS.3) {2.2}	GHG emissions have continued to grow at high absolute rates. Emissions increased by 8.9 GtCO ₂ -eq from 2000 to 2009 and by 6.5 GtCO ₂ -eq from 2010 to 2019, reaching 59 GtCO ₂ -eq in 2019. (TS.3) {2.2}
A growing number of countries have reduced both territorial carbon dioxide (CO₂) and GHG emissions and consumption-based CO₂ emissions in absolute terms for at least 10 years. These include mainly European countries, some of which have reduced production-based GHG emissions by a third or more since peaking. Some countries have achieved several years of rapid sustained CO ₂ reduction rates of 4% yr ⁻¹ . (TS.3) {2.2}	The combined emissions reductions achieved by some countries have been outweighed by rapid emissions growth elsewhere , particularly among developing countries that have grown from a much lower base of per-capita emissions. Uncertainties in emissions levels and changes over time prevents a precise assessment of reductions in some cases. The per-capita emissions of developed countries remain high, particularly in Australia, Canada, and the United States of America. {2.2}
Lockdown policies in response to COVID-19 led to an estimated global drop of 5.8% in CO₂ emissions in 2020 relative to 2019. Energy demand reduction occurred across sectors, except in residential buildings due to teleworking and homeschooling. The transport sector was particularly impacted and international aviation emissions declined by 45%. (Box TS.1) {2.2}	Atmospheric CO₂ concentrations continued to rise in 2020 and emissions have already rebounded as lockdown policies are eased. Economic recovery packages currently include support for fossil fuel industries. (Boxes TS.1 and TS.8)
Sectors	
Multiple low-carbon electricity generation and storage technologies have made rapid progress: costs have reduced, deployment has scaled up, and performance has improved. These include solar photovoltaics (PV), onshore and offshore wind, and batteries. In many contexts solar PV and onshore wind power are now competitive with fossil-based generation. (TS.3) {2.5, 6.3}	Although deployment is increasing rapidly, low-carbon electricity generation deployment levels and rates are currently insufficient to meet stringent climate goals. The combined market share of solar PV and wind generation technologies are still below 10%. Global low-carbon electricity generation will have to reach 100% by 2050, which is challenged by the continuous global increase in electricity demand. The contribution of biomass has absolute limits. (TS.5) {2.5}
The rate of emissions growth from coal slowed since 2010 as coal power plants were retired in the US and Europe, fewer new plants were added in China, and a large number of planned global plants were scrapped or converted to co-firing with biomass. (TS.3) {2.7, 6.3}	Global coal emissions may not have peaked yet , and a few countries and international development banks continue to fund and develop new coal capacity, especially abroad. The lifetime emissions of current fossil-based energy infrastructures may already exceed the remaining carbon budget for keeping warming below 1.5°C. (TS.3) {2.2, 2.7, 6.7}
Deforestation has declined since 2010 and net forest cover increased. Government initiatives and international moratoria were successful in reducing deforestation in the Amazon between 2004 and 2015, while regrowth and regeneration occurred in Europe, Eurasia and North America. (TS.5.6.1) {7.3.1}	The long-term maintenance of low deforestation rates is challenging. Deforestation in the Amazon has risen again over the past four years. Other parts of the world also face steady, or rapidly increasing, deforestation. {7.3.1}
Electrification of public transport services is demonstrated as a feasible, scalable and affordable mitigation option to decarbonise mass transportation. Electric vehicles (e-vehicles) are the fastest growing segment of the automobile industry, having achieved double-digit market share by 2020 in many countries. When charged with low-carbon electricity, these vehicles can significantly reduce emissions. {10.4}	Transport emissions have remained roughly constant, growing at an average of 2% yr⁻¹ between 2010 and 2019 due to the persistence of high travel demand, heavier vehicles, low efficiencies, and car-centric development. The full decarbonisation of e-vehicles requires that they are charged with zero-carbon electricity, and that car production, shipping, aviation and supply chains are decarbonised. (TS.3) {2.4}
There has been a significant global transition from coal and biomass use in buildings towards modern energy carriers and efficient conversion technologies. This led to efficiency improvements and some emissions reductions in developed countries, as well as significant gains in health and well-being outcomes in developing regions. Nearly zero energy buildings (nZEB) or low-energy buildings are achievable in all regions and climate zones for both new and existing buildings. {9.3, 9.8}	There is a significant lock-in risk in all regions given the long lifespans of buildings and the low ambition of building policies. This is the case for both existing buildings in developed countries, and also for new buildings in developing countries that are also challenged by the lack of technical capacity and effective governance. Emissions reductions in developed countries have been outweighed by the increase in population growth, floor area per capita and the demand for electricity and heat. {9.3, 9.9}
The decarbonisation of most industrial processes has been demonstrated using technologies that include electricity and hydrogen for energy and feedstocks, carbon capture and utilisation technologies, and innovation in circular material flows. (TS.5.5) {11.2}	Industry emissions continue to increase, driven by a strong global demand for basic materials. Without reductions in material demand growth and a very rapid scale-up of low-carbon innovations, the long lifetimes of industrial capital stock risks locking-in emissions for decades to come. (TS.5.5) {11.2}

Table TS.1 (continued):

Signs of progress	Continuing challenges
Policies and investment	
The Paris Agreement established a new global policy architecture to meet stringent climate goals, while avoiding many areas of deadlock that had arisen in trying to extend the Kyoto Protocol. (TS.6.3)	Current national pledges under the Paris Agreement ³ are insufficient to limit warming to 1.5°C (>50%) with no or limited overshoot, and would require an abrupt acceleration of mitigation efforts after 2030 to limit warming to 2°C (>67%). (TS.6.3)
Most wealthy countries, and a growing list of developing countries, have signalled an intention to achieve net zero GHG (or net zero CO ₂) emissions by mid-century. National economy-wide GHG emissions targets covered 90% of global emissions in 2020 compared to 49% in 2010. Direct and indirect climate legislation has also steadily increased and this is supported by a growing list of financial investors. (TS.6.2)	Many net-zero targets are ambiguously defined, and the policies needed to achieve them are not yet in place. Opposition from status quo interests, as well as insufficient low-carbon financial flows, act as barriers to establishing and implementing stringent climate policies covering all sectors. (Box TS.6) {13.4}
The global coverage of mandatory policies – pricing and regulation – has increased, and sectoral coverage of mitigation policies has expanded. Emission trading and carbon taxes now cover over 20% of global CO ₂ emissions. Allowance prices as of 1 April 2021 ranged from just over USD1 to USD50, covering between 9% and 80% of a jurisdiction's emissions {13.6.3}. Many countries have introduced sectoral regulations that block new investment in fossil fuel technologies. (TS.6)	There is incomplete global policy coverage of non-CO ₂ gases, CO ₂ from industrial processes, and emissions outside the energy sector. Few of the world's carbon prices are at a level consistent with various estimates of the carbon price needed to limit warming to 2°C or 1.5°C. {13.6}
There has been a marked increase in civic and private engagement with climate governance. This includes business measures to limit emissions, invest in reforestation and develop carbon-neutral value chains such as using wood for construction. There is an upsurge in climate activism, and growing engagement of groups such as labour unions {1.3.3, 5.2.3}. The media coverage of climate change has also grown steadily across platforms and has generally become more accurate over time. (TS.6.2)	There is no conclusive evidence that an increase in engagement results in overall pro-mitigation outcomes. A broad group of actors influence how climate governance develops over time, including a range of civic organisations, encompassing both pro-and anti-climate action groups. Accurate transference of the climate science has been undermined significantly by climate change counter-movements, in both legacy and new/social media environments through misinformation. (TS.6.2)

GHG emissions continued to rise to 2019, although the growth of global GHG emissions has slowed over the past decade (*high confidence*). Delivering the updated Nationally Determined Contributions (NDCs) to 2030 would turn this into decline, but the implied global emissions by 2030, still exceed pathways consistent with 1.5°C by a large margin and are near the upper end of the range of modelled pathways that limit warming to 2°C (>67%) or below. In all chapters of this report there is evidence of progress towards deeper mitigation, but there remain many obstacles to be overcome. Table TS.1 summarises some of the key signs of progress in emission trends, sectors, policies and investment, as well as the challenges that persist.

3 Current NDCs refer to Nationally Determined Contributions submitted to the UNFCCC, as well as publicly announced but not yet submitted mitigation pledges with sufficient detail on targets, reflected in studies published up to 11 October 2021. Revised NDCs submitted or announced after 11 October 2021 are not included. Intended Nationally Determined Contributions (INDCs) were converted to NDCs as countries ratified the Paris Agreement. Original INDCs and NDCs refer to those submitted to the UNFCCC in 2015 and 2016.

TS.3 Emission Trends and Drivers

Global net anthropogenic GHG emissions during the decade 2010–2019 were higher than any previous time in human history (*high confidence*). Since 2010, GHG emissions have continued to grow reaching 59 ± 6.6 GtCO₂-eq in 2019,⁴ but the average annual growth in the last decade (1.3%, 2010–2019) was lower than in the previous decade (2.1%, 2000–2009) (*high confidence*). Average annual GHG emissions were 56 GtCO₂-eq yr⁻¹ for 2010–2019 (the highest decadal average on record) growing by about 9.1 GtCO₂-eq yr⁻¹ from the previous decade (2000–2009) (*high confidence*). (Figure TS.2) {2.2.2, Table 2.1, Figure 2.5}

Emissions growth has varied, but has persisted, across all groups of greenhouse gases (*high confidence*). The average annual emission levels of the last decade (2010–2019) were higher than in any previous decade for each group of greenhouse gases (*high confidence*). In 2019, CO₂ emissions were 45 ± 5.5 GtCO₂,⁵ methane (CH₄) 11 ± 3.2 GtCO₂-eq, nitrous oxide (N₂O) 2.7 ± 1.6 GtCO₂-eq and fluorinated gases (F-gases⁶) 1.4 ± 0.41 GtCO₂-eq. Compared to 1990, the magnitude and speed of these increases differed across gases: CO₂ from fossil fuel and industry (FFI) grew by 15 GtCO₂-eq yr⁻¹ (67%), CH₄ by 2.4 GtCO₂-eq yr⁻¹ (29%), F-gases by 0.97 GtCO₂-eq yr⁻¹ (250%), N₂O by 0.65 GtCO₂-eq yr⁻¹ (33%). CO₂ emissions from net land use, land-use change and forestry (LULUCF) have shown

TS

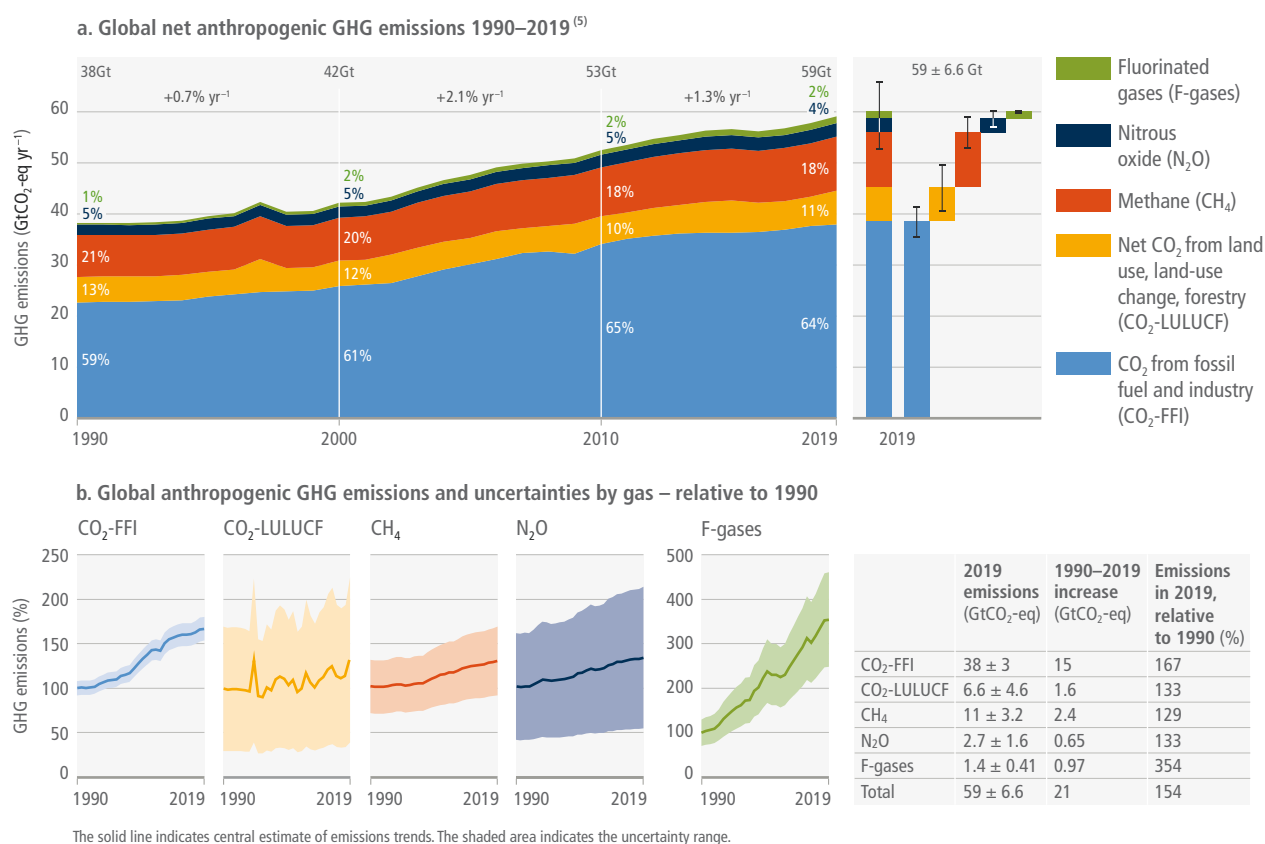

Figure TS.2 | Global net anthropogenic GHG emissions (GtCO₂-eq yr⁻¹) 1990–2019. Global net anthropogenic GHG emissions include CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI); net CO₂ from land use, land-use change and forestry (CO₂-LULUCF⁵); methane (CH₄); nitrous oxide (N₂O); and fluorinated gases (HFCs, PFCs, SF₆, NF₃).⁶ **Panel a** shows aggregate annual global net anthropogenic GHG emissions by groups of gases from 1990 to 2019 reported in GtCO₂-eq converted based on global warming potentials with a 100-year time horizon (GWP100-AR6) from the IPCC Sixth Assessment Report Working Group I (Chapter 7). The fraction of global emissions for each gas is shown for 1990, 2000, 2010 and 2019; as well as the aggregate average annual growth rate between these decades. At the right side of Panel a, GHG emissions in 2019 are broken down into individual components with the associated uncertainties (90% confidence interval) indicated by the error bars: CO₂-FFI $\pm 8\%$; CO₂-LULUCF $\pm 70\%$; CH₄ $\pm 30\%$; N₂O $\pm 60\%$; F-gases $\pm 30\%$; GHG $\pm 11\%$. Uncertainties in GHG emissions are assessed in Supplementary Material 2.2. The single-year peak of emissions in 1997 was due to higher CO₂-LULUCF emissions from a forest and peat fire event in South East Asia. **Panel b** shows global anthropogenic CO₂-FFI, net CO₂-LULUCF, CH₄, N₂O and F-gas emissions individually for the period 1990–2019, normalised relative to 100 in 1990. Note the different scale for the included F-gas emissions compared to other gases, highlighting its rapid growth from a low base. Shaded areas indicate the uncertainty range. Uncertainty ranges as shown here are specific for individual groups of greenhouse gases and cannot be compared. The table shows the central estimate for: absolute emissions in 2019; the absolute change in emissions between 1990 and 2019; and emissions in 2019 expressed as a percentage of 1990 emissions. {2.2, Figure 2.5, Supplementary Material 2.2, Figure TS.2}

4 Emissions of GHGs are weighed by global warming potentials (GWPs) with a 100-year time horizon (GWP100) from the Sixth Assessment Report. GWP100 is commonly used in wide parts of the literature on climate change mitigation and is required for reporting emissions under the United Nations Framework Convention on Climate Change (UNFCCC). All metrics have limitations and uncertainties. [Cross-Chapter Box 2, Annex II.II.8]

5 In 2019, CO₂ from fossil fuel and industry (FFI) was 38 ± 3.0 Gt; CO₂ from net land use, land-use change and forestry (LULUCF) was 6.6 ± 4.6 Gt.

6 Fluorinated gases, also known as 'F-gases', include: hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆) and nitrogen trifluoride (NF₃).

little long-term change, with large uncertainties preventing the detection of statistically significant trends. F-gases excluded from GHG emissions inventories such as *chlorofluorocarbons* and *hydrochlorofluorocarbons* are about the same size as those included (*high confidence*). (Figure TS.2) {2.2.1, 2.2.2, Table 2.1, Figures 2.2, 2.3 and 2.5}

Globally, gross domestic product (GDP) per capita and population growth remained the strongest drivers of CO₂ emissions from fossil fuel combustion in the last decade (*high confidence*). Trends since 1990 continued in the years 2010 to 2019 with GDP per capita and population growth increasing emissions by 2.3% yr⁻¹ and 1.2% yr⁻¹, respectively. This growth outpaced the reduction in the use of energy per unit of GDP (–2% yr⁻¹, globally) as well as improvements in the carbon intensity of energy (–0.3% yr⁻¹). {2.4.1, Figure 2.19}

Box TS.1 | The COVID-19 Pandemic: Impact on Emissions and Opportunities for Mitigation

The COVID-19 pandemic triggered the deepest global economic contraction as well as CO₂ emission reductions since the Second World War {2.2.2}. While emissions and most economies rebounded in 2020, some impacts of the pandemic could last well beyond this. Owing to the very recent nature of this event, it remains unclear what the exact short- and long-term impacts on global emissions drivers, trends, macroeconomics and finance will be.

Starting in the spring of 2020 a major break in global emissions trends was observed due to lockdown policies implemented in response to the pandemic. Overall, global CO₂-FFI emissions are estimated to have declined by 5.8% (5.1–6.3%) in 2020, or about 2.2 (1.9–2.4%) GtCO₂ in total. This exceeds any previous global emissions decline since 1970 both in relative and absolute terms (Box TS.1, Figure 1). During periods of economic lockdown, daily emissions, estimated based on activity and power-generation data, declined substantially compared to 2019, particularly in April 2020 – as shown in Box TS.1, Figure 1 – but rebounded by the end of 2020. Impacts were differentiated by sector, with road transport and aviation particularly affected. Different databases estimate the total power-sector CO₂ reduction from 2019 to 2020 at 3% (IEA⁷) and 4.5% (EDGAR⁸). Approaches that predict near real-time estimates of the power-sector reduction are more uncertain and estimates range more widely between 1.8%, 4.1% and 6.8%, the latter taking into account the over-proportional reduction of coal generation due to low gas prices and merit order effects.

The lockdowns implemented in many countries accelerated some specific trends, such as the uptake in urban cycling. The acceptability of collective social change over a longer term towards less resource-intensive lifestyles, however, depends on the social mandate for change. This mandate can be built through public participation, discussion and debate, to produce recommendations that inform policymaking. {Box 5.2}

Most countries were forced to undertake unprecedented levels of short-term public expenditures in 2021. This is expected to slow economic growth and may squeeze financial resources for mitigation and relevant investments in the near future. Pandemic responses have increased sovereign debt across countries in all income bands and the sharp increase in most developing economies and regions has caused debt distress, widening the gap in developing countries' access to capital. {15.6.3}

The wider overall reduction in energy investment has prompted a relative shift towards low-carbon investment particularly for major future investment decisions by the private sector {15.2.1, 15.3.1, 15.6.1}. Some countries and regions have prioritised green stimulus expenditures, for example, as part of a 'Green New Deal' {Box 13.1}. This is motivated by assessments that investing in new growth industries can boost the macroeconomic effectiveness ('multipliers') of public spending, crowd-in and revive private investment, whilst also delivering on mitigation commitments. {15.2.3}

The impacts of COVID-19 may have temporarily set back development and the delivery of many SDGs. It also distracts political and financial capacity away from efforts to accelerate climate change mitigation and shift development pathways to increased sustainability. Yet, studies of previous post-shock periods suggest that waves of innovation that are ready to emerge can be accelerated by crises, which may prompt new behaviours, weaken incumbent systems, and initiate rapid reform. {1.6.5}

Institutional change can be slow but major economic dislocation can create significant opportunities for new ways of financing and enabling 'leapfrogging' investment {10.8}. Given the unambiguous risks of climate change, and consequent stranded asset risks from new fossil fuel investments {Box 6.11}, the most robust recoveries may well be those which align with lower carbon and resilient development pathways.

8 EDGAR: Emissions Database for Global Atmospheric Research

Box TS.1 (continued)

Box TS.1, Figure 1 | Global carbon emissions in 2020 and the impact of COVID-19. Panel (a) depicts carbon emissions from fossil fuel and industry over the past five decades. The single-year declines in emissions following major economic and geopolitical events are shown, as well as the decline recorded in five different datasets for emissions in 2020 compared to 2019. Panel (b) depicts the perturbation of daily carbon emissions in 2020 compared to 2019, showing the impact of COVID-19 lockdown policies. {Figure 2.6}

Cumulative net CO₂ emissions over the last decade (2010–2019) are about the same size as the remaining carbon budget to limit warming to 1.5°C (>67%) (medium confidence). 62% of total cumulative CO₂ emissions from 1850 to 2019 occurred since 1970 (1500 ± 140 GtCO₂), about 43% since 1990 (1000 ± 90 GtCO₂), and about 17% since 2010 (410 ± 30 GtCO₂). For comparison, the remaining carbon budget for keeping warming to 1.5°C with a 67% (50%) probability is about 400 (500) \pm 220 GtCO₂ (Figure TS.3). {2.2.2, Figure 2.7, AR6 WGI Chapter 5.5, AR6 WGI Chapter 5, Table 5.8}

A growing number of countries have achieved GHG emission reductions over periods longer than 10 years – a few at rates that are broadly consistent with the global rates described in climate change mitigation scenarios that limit warming to 2°C (>67%) (high confidence). At least 18 countries have reduced CO₂ and GHG emissions for longer than 10 years. Reduction rates in a few countries have reached 4% in some years, in line with global rates observed in pathways that limit warming to 2°C (>67%). However, the total reduction in annual GHG emissions of these countries is small (about 3.2 GtCO₂-eq yr⁻¹) compared to global emissions growth

observed over the last decades. Complementary evidence suggests that countries have decoupled territorial CO₂ emissions from GDP, but fewer have decoupled consumption-based emissions from GDP. Decoupling has mostly occurred in countries with high per-capita GDP and high per-capita CO₂ emissions. (Figure TS.4, Box TS.2) {2.2.3, 2.3.3, Figure 2.11, Tables 2.3 and 2.4}

(a) Long term trend of anthropogenic CO₂ emissions sources

(b) Historic emissions vs. future carbon budgets

Figure TS.3 | Historic anthropogenic CO₂ emission and cumulative CO₂ emissions (1850–2019) as well as remaining carbon budgets for limiting warming to 1.5°C (>67%) and 2°C (>67%). Panel (a) shows historic annual anthropogenic CO₂ emissions (GtCO₂ yr⁻¹) by fuel type and process. Panel (b) shows historic cumulative anthropogenic CO₂ emissions for the periods 1850–1989, 1990–2009, and 2010–2019 as well as remaining future carbon budgets as of 1 January 2020 to limit warming to 1.5°C and 2°C at the 67th percentile of the transient climate response to cumulative CO₂ emissions. The whiskers indicate a budget uncertainty of ±220 GtCO₂-eq for each budget and the aggregate uncertainty range at one standard deviation for historical cumulative CO₂ emissions, consistent with WGI. {Figure 2.7}

(a) Global net anthropogenic GHG emissions by region (1990–2019)

(b) Average annual emissions change (2010–2019)

Figure TS.4 | Emissions have grown in most regions, although some countries have achieved sustained emission reductions in line with 2°C scenarios.

Figure TS.4 (continued): Emissions have grown in most regions, although some countries have achieved sustained emission reductions in line with 2°C scenarios. Change in regional GHG emissions and rates of change compatible with warming targets. **Panel (a):** Regional GHG emission trends (in GtCO₂-eq yr⁻¹ (GWP100;AR6) for the time period 1990–2019. **Panel (b):** Historical GHG emissions change by region (2010–2019). Circles depict countries, scaled by total emissions in 2019, short horizontal lines depict the average change by region. Also shown are global rates of reduction over the period 2020–2040 in scenarios assessed in AR6 that limit global warming to 1.5°C and 2°C with different probabilities. The 5–95th percentile range of emissions changes for scenarios below 1.5°C with no or limited overshoot (scenario category C1) and scenarios below 2°C (>67%) with immediate action (scenario category C3a) are shown as a shaded area with a horizontal line at the mean value. Panel b excludes CO₂ LULUCF due to a lack of consistent historical national data, and International Shipping and Aviation, which cannot be allocated to regions. Global rates of reduction in scenarios are shown for illustrative purposes only and do not suggest rates of reduction at the regional or national level. [Figures 2.9 and 2.11]

Box TS.2 | Greenhouse Gas (GHG) Emission Metrics Provide Simplified Information About the Effects of Different Greenhouse Gases

Comprehensive mitigation policy relies on consideration of all anthropogenic forcing agents, which differ widely in their atmospheric lifetimes and impacts on the climate system. GHG emission metrics provide simplified information about the effect that emissions of different gases have on global temperature or other aspects of climate, usually expressed relative to the effect of emitting CO₂.⁹ This information can support choices about priorities, trade-offs and synergies in mitigation policies and emission targets for non-CO₂ gases relative to CO₂ as well as baskets of gases expressed in CO₂-eq.

The choice of metric can affect the timing and emphasis placed on reducing emissions of short-lived climate forcers (SLCFs) relative to CO₂ within multi-gas abatement strategies as well as the costs of such strategies. Different metric choices can also alter the time at which net zero GHG emissions are calculated to be reached for any given emissions scenario. A wide range of GHG emission metrics has been published in the scientific literature, which differ in terms of: (i) the key measure of climate change they consider, (ii) whether they consider climate outcomes for a specified point in time or integrated over a specified time horizon, (iii) the time horizon over which the metric is applied, (iv) whether they apply to a single emission pulse, to emissions sustained over a period of time, or to a combination of both, and (v) whether they consider the climate effect from an emission compared to the absence of that emission, or compared to a reference emissions level or climate state. [Annex II]

Parties to the Paris Agreement decided to report aggregated emissions and removals (expressed as CO₂-eq) based on the Global Warming Potential (GWP) with a time horizon of 100 years (GWP100) using values from IPCC AR5 or from a subsequent IPCC report as agreed upon by the CMA,¹⁰ and to account for future Nationally Determined Contributions (NDCs) in accordance with this approach. Parties may also report supplemental information on aggregate emissions and removals, expressed as CO₂-eq, using other GHG emission metrics assessed by the IPCC.

The WGIII contribution to AR6 uses updated GWP100 values from AR6 WGI to report aggregate emissions and removals unless stated otherwise. These reflect updated scientific understanding of the response of the climate system to emissions of different gases and include a methodological update to incorporate climate-carbon cycle feedbacks associated with the emission of non-CO₂ gases (see Annex II.II.8 for a list of GWP100 metric values). The choice of GWP100 was made *inter alia* for consistency with decisions under the Rulebook for the Paris Agreement and because it is the dominant metric used in the literature assessed by WGIII. Furthermore, for mitigation pathways that limit global warming to 2°C (>67%) or lower, using GWP100 to inform cost-effective abatement choices between gases would achieve such long-term temperature goals at close to least global cost within a few percent (*high confidence*).

However, GWP100 is not well-suited to estimate the cumulative effect on climate from sustained SLCF emissions and the resulting warming at specific points in time. This is because the warming caused by an individual SLCF emission pulse is not permanent, and hence, unlike CO₂, the warming from successive SLCF emission pulses over multiple decades or centuries depends mostly on their ongoing rate of emissions rather than cumulative emissions. Recently developed step/pulse metrics such as the CGTP (combined global temperature change potential) and GWP* (referred to as GWP-star and indicated by an asterisk) recognise that a sustained increase/decrease in the rate of SLCF emissions has indeed a similar effect on global surface temperature as one-off emission/removal of CO₂. These metrics use this relationship to calculate the CO₂ emissions or removals that would result in roughly the same temperature change as a sustained change in the rate of SLCF emissions (CGTP) over a given time period, or as a varying time series of CH₄ emissions (GWP*). From a mitigation perspective, this makes these metrics well-suited in principle to estimate the effect on the remaining carbon budget from more, or less, ambitious SLCF mitigation over multiple decades compared to a given reference scenario (*high confidence*). However, potential application in wider climate policy (e.g., to inform equitable and ambitious emission targets or to support sector-specific mitigation policies) is contested and relevant literature still limited.

⁹ Emission metrics also exist for aerosols, but these are not commonly used in climate policy. This assessment focuses on GHG emission metrics only.

¹⁰ The CMA is the Conference of the Parties serving as the Meeting of the Parties to the Paris Agreement. See 18/CMA.1 (Annex, para. 37) and 4/CMA.1 (Annex II, para. 1) regarding the use of GHG emission metrics in reporting of emissions and removals and accounting for Parties' NDCs.

Box TS.2 (continued)

All metrics have limitations and uncertainties, given that they simplify the complexity of the physical climate system and its response to past and future GHG emissions. For this reason, the WGIII contribution to the AR6 reports emissions and mitigation options for individual gases where possible; CO₂-equivalent emissions are reported in addition to individual gas emissions where this is judged to be policy-relevant. This approach aims to reduce the ambiguity regarding actual climate outcomes over time arising from the use of any specific GHG emission metric. {Cross-Chapter Box 2 in Chapter 2, SM.2.3, Annex II.II.8; AR6 WGI Chapter 7.6}

(c) Regional indicators (2019) and regional production vs consumption accounting (2018)

	Africa	Australia, Japan, New Zealand	Eastern Asia	Eastern Europe, West Central Asia	Europe	Latin America and Caribbean	Middle East	North America	South-East Asia and Pacific	Southern Asia

¹ GDP per capita in 2019 in USD2017 currency purchasing power basis.

² Includes CO₂-FFI, CO₂-LULUCF and Other GHGs, excluding international aviation and shipping.

The regional groupings used in this figure are for statistical purposes only and are described in Annex II, Part I.

Figure TS.5 | Global emissions are distributed unevenly, both in the present day and cumulatively since 1850. Panel (a) shows the distribution of regional GHG emissions in tonnes CO₂-eq per capita by region in 2019. GHG emissions are categorised into: CO₂ fossil fuel and industry (CO₂-FFI); CO₂ land use, land-use change and forestry (CO₂-LULUCF); and other GHG emissions (CH₄, nitrous oxide, F-gas, expressed in CO₂-eq using GWP100). The height of each rectangle shows per-capita emissions, the width shows the population of the region, so that the area of the rectangles refers to the total emissions for each regional. Percentages refer to overall GHG contributions to total global emissions in 2019. Emissions from international aviation and shipping are not included. Panel (b) shows the share of historical net CO₂ emissions per region from 1850 to 2019. This includes CO₂-FFI and CO₂-LULUCF (GtCO₂). Other GHG emissions are not included. Emissions from international aviation and shipping are included. Panel (c) shows population, GDP per person, emission indicators by region in 2019 for percentage GHG contributions, total GHG per person, and total GHG emissions intensity, together with production-based and consumption-based CO₂-FFI data, which is assessed in this report up to 2018. Consumption-based emissions are emissions released to the atmosphere in order to generate the goods and services consumed by a certain entity (e.g., region). Emissions from international aviation and shipping are not included. {1.3, Figure 1.2a, 2.2, Figure 2.10}

Consumption-based CO₂ emissions in Developed Countries and the Asia and Pacific region are higher than in other regions (*high confidence*). In Developed Countries, consumption-based CO₂ emissions peaked at 15 GtCO₂ in 2007, declining to about 13 GtCO₂ in 2018. The Asia and Developing Pacific region, with 52% of the current global population, has become a major contributor to consumption-based CO₂ emission growth since 2000 (5.5% yr⁻¹ for 2000–2018); in 2015 it exceeded the Developed Countries region, with 16% of global population, as the largest emitter of consumption-based CO₂. {2.3.2, Figure 2.14}

Carbon-intensity improvements in the production of traded products has led to a net reduction in CO₂ emissions embodied in international trade (*high confidence*). A decrease in the carbon intensity of traded products has offset increased trade volumes between 2006 and 2016. Emissions embodied in internationally traded products depend on the composition of the global supply chain across sectors and countries and the respective carbon intensity of production processes (emissions per unit of economic output). {2.3, 2.4}

Developed Countries tend to be net CO₂ emission importers, whereas developing countries tend to be net emission exporters (*high confidence*). Net CO₂ emission transfers from developing to Developed Countries via global supply chains have decreased between 2006 and 2016. Between 2004 and 2011, CO₂ emissions embodied in trade between developing countries have more than doubled (from 0.47 to 1.1 Gt) with the centre of trade activities shifting from Europe to Asia. {2.3.4, Figure 2.15}

Territorial emissions from developing country regions continue to grow, mostly driven by increased consumption and investment, albeit starting from a low base of per-capita emissions and with a lower historic contribution to cumulative emissions than developed countries (*high confidence*). Average 2019 per-capita CO₂-FFI emissions in three developing regions, Africa (1.2 tCO₂), Asia and Pacific (4.4 tCO₂), and Latin America and Caribbean (2.7 tCO₂), remained less than half of Developed Countries' 2019 CO₂-FFI emissions (9.5 tCO₂). In these three developing regions together, CO₂-FFI emissions grew by 26% between 2010 and 2019 (compared to 260% between 1990 and 2010). In contrast, in Developed Countries emissions contracted by 9.9% between 2010 and 2019 and by 9.6% between 1990 and 2010. Historically, these three developing regions together contributed 28% to cumulative CO₂-FFI emissions between 1850 and 2019, whereas Developed Countries contributed 57%, and least developed countries contributed 0.4%. (Figure TS.5) {2.2, Figures 2.9 and 2.10}

Globally, households with income in the top 10% contribute about 36–45% of global GHG emissions (*robust evidence, medium agreement*). About two thirds of the top 10% live in Developed Countries and one third in other economies. The lifestyle consumption emissions of the middle income and poorest citizens in emerging economies are between five and 50 times below their counterparts in high-income countries (*medium confidence*). Increasing inequality within a country can exacerbate dilemmas of

redistribution and social cohesion, and affect the willingness of the rich and poor to accept policies to protect the environment, and to accept and afford lifestyle changes that favour mitigation (*medium confidence*). {2.6.1, 2.6.2, Figure 2.29}

Globally, GHG emissions continued to rise across all sectors and subsectors, and most rapidly in transport and industry (*high confidence*). In 2019, 34% (20 GtCO₂-eq) of global GHG emissions came from the energy sector, 24% (14 GtCO₂-eq) from industry, 22% (13 GtCO₂-eq) from agriculture, forestry and other land use (AFOLU), 15% (8.7 GtCO₂-eq) from transport, and 5.6% (3.3 GtCO₂-eq) from buildings. Once indirect emissions from energy use are considered, the relative shares of industry and buildings emissions rise to 34% and 16%, respectively. Average annual GHG emissions growth during 2010–2019 slowed compared to the previous decade in energy supply (from 2.3% to 1.0%) and industry (from 3.4% to 1.4%, direct emissions only), but remained roughly constant at about 2% yr⁻¹ in the transport sector (*high confidence*). Emission growth in AFOLU is more uncertain due to the high share of CO₂-LULUCF emissions (*medium confidence*). (Figure TS.8) {2.2.4, Figure 2.13 and Figures 2.16–2.21}

There is a discrepancy, equating to 5.5 GtCO₂ yr⁻¹, between alternative methods of accounting for anthropogenic land CO₂ fluxes. Accounting for this discrepancy would assist in assessing collective progress in a global stocktake (*high confidence*). The principal accounting approaches are national GHG inventories (NGHGI) and global modelling¹¹ approaches. NGHGI, based on IPCC guidelines, consider a much larger area of forest to be under human management than global models. NGHGI consider the fluxes due to human-induced environmental change on this area to be anthropogenic and are thus reported. Global models, in contrast, consider these fluxes to be natural and are excluded from the total reported anthropogenic land CO₂ flux. The accounting method used will affect the assessment of collective progress in a global stocktake (*medium confidence*) {Cross-Chapter Box 6 in Chapter 7}. In the absence of these adjustments, allowing a like-with-like comparison, collective progress would appear better than it is. {7.2}

This accounting discrepancy also applies to Integrated Assessment Models (IAMs), with the consequence that anthropogenic land CO₂ fluxes reported in IAM pathways cannot be compared directly with those reported in national GHG inventories (*high confidence*). Methodologies enabling a more like-for-like comparison between models' and countries' approaches would support more accurate assessment of the collective progress achieved under the Paris Agreement. {3.4, 7.2.2}

Average annual growth in GHG emissions from energy supply decreased from 2.3% for 2000–2009 to 1.0% for 2010–2019 (*high confidence*). This slowing of growth is attributable to further improvements in energy efficiency and reductions in the carbon intensity of energy supply driven by fuel switching from coal to gas, reduced expansion of coal capacity, particularly in Eastern Asia, and the increased use of renewables (*medium confidence*). (Figure TS.6) {2.2.4, 2.4.2.1, Figure 2.17}

11 Bookkeeping models and dynamic global vegetation models.

Direct emissions by sector (59 GtCO₂-eq)

Direct+indirect emissions by sector (59 GtCO₂-eq)

Figure TS.6 | Total anthropogenic direct and indirect GHG emissions for the year 2019 (in GtCO₂-eq) by sector and subsector. Direct emissions estimates assign emissions to the sector in which they arise (scope 1 reporting). Indirect emissions – as used here – refer to the reallocation of emissions from electricity and heat to the sector of final use (scope 2 reporting). Note that cement refers to process emissions only, as a lack of data prevents the full reallocation of indirect emissions to this sector. More comprehensive conceptualisations of indirect emissions including all products and services (scope 3 reporting) are discussed in Section 2.3. Emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report. Percentages may not add up to 100 across categories due to rounding at the second significant digit. [Figure 2.12, 2.3]

The industry, buildings and transport sectors make up 44% of global GHG emissions, or 66% when the emissions from electricity and heat production are reallocated as *indirect emissions (high confidence)*. This reallocation makes a substantial difference to overall industry and buildings emissions as shown in Figure TS.6. Industry, buildings, and transport emissions are driven, respectively, by the large rise in demand for basic materials and manufactured products, a global trend of increasing floor space per capita, building energy service use, travel distances, and vehicle size and weight. Between 2010 and 2019, aviation grew particularly fast on average at about 3.3% per annum. Globally, energy efficiency has improved in all three demand sectors, but carbon intensities have not. (Figure TS.6) {2.2.4, Figures 2.18, 2.19 and 2.20}

Providing access to modern energy services universally would increase global GHG emissions by a few percent at most (*high confidence*). The additional energy demand needed to support *decent living standards*¹² for all is estimated to be well below current average energy consumption (*medium evidence, high agreement*). More equitable income distribution could also reduce carbon emissions, but the nature of this relationship can vary by level of income and development (*limited evidence, medium agreement*). {2.4.3}

Evidence of rapid energy transitions exists in some case studies (*medium confidence*). Emerging evidence since AR5 on past energy transitions identifies a growing number of cases of accelerated technology diffusion at sub-global scales and describes mechanisms by which future energy transitions may occur more quickly than those in the past. Important drivers include technology transfer and cooperation, international policy and financial support, and harnessing synergies among technologies within a sustainable energy system perspective (*medium confidence*). A fast global low-carbon energy transition enabled by finance to facilitate low-carbon technology adoption in developing and particularly in least developed countries can facilitate achieving climate stabilisation targets (*high confidence*). {2.5.2, Table 2.5}

¹² Decent Living Standards (DLS) – a benchmark of material conditions for human well-being – overlaps with many Sustainable Development Goals (SDGs). Minimum requirements of energy use consistent with enabling well-being for all is between 20 and 50 GJ per capita yr⁻¹ depending on the context. (Figure TS.22) {5.2.2, 5.2.2, Box 5.3}

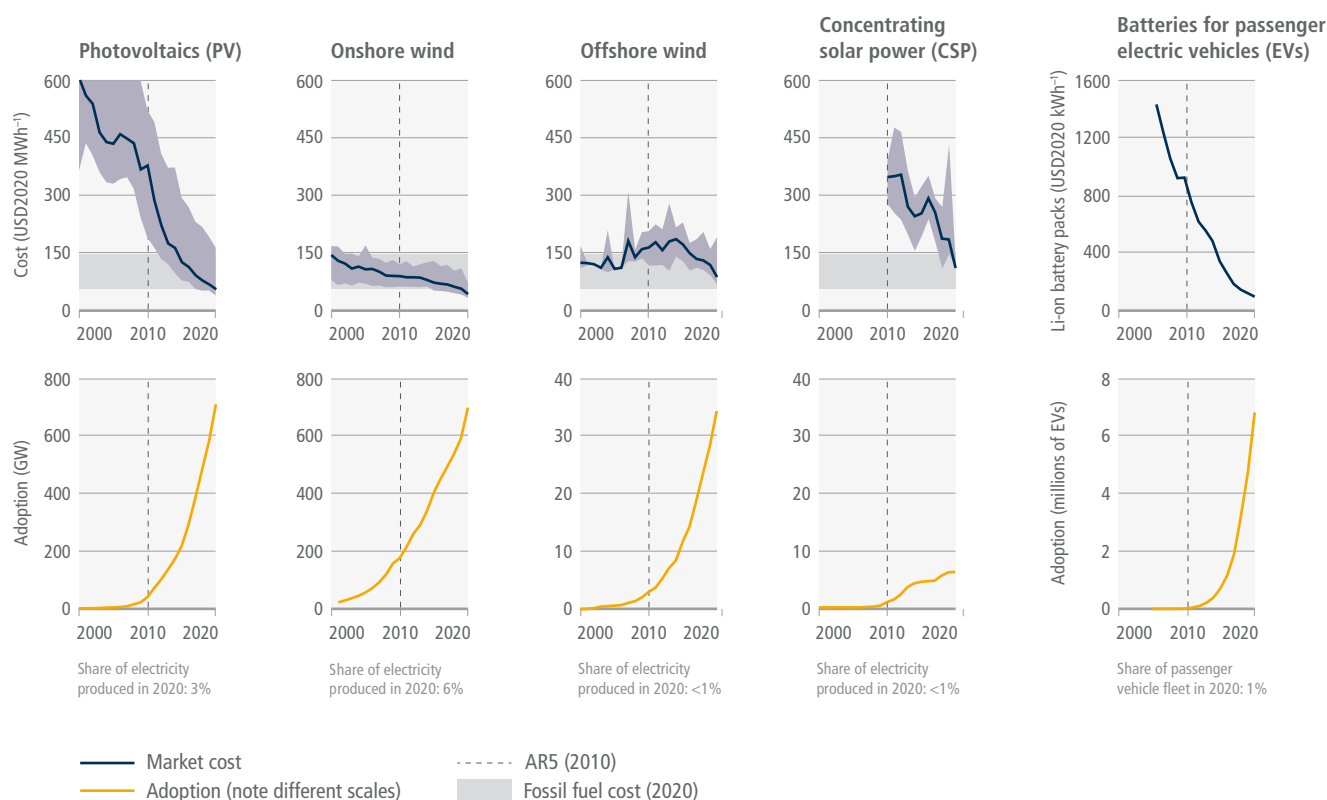

Figure TS.7 | The unit costs of batteries and some forms of renewable energy have fallen significantly, and their adoption continues to increase. The **top panel** shows global costs per unit of energy (USD per MWh) for some rapidly changing mitigation technologies. Solid blue lines indicate average unit cost in each year. Light blue shaded areas show the range between the 5th and 95th percentiles in each year. Grey shading indicates the range of unit costs for new fossil fuel (coal and gas) power in 2020 (corresponding to USD55–148 per MWh). In 2020, the levelised costs of energy (LCOE) of the four renewable energy technologies could compete with fossil fuels in many places. For batteries, costs shown are for 1 kWh of battery storage capacity; for the others, costs are LCOE, which includes installation, capital, operations, and maintenance costs per MWh of electricity produced. The literature uses LCOE because it allows consistent comparisons of cost trends across a diverse set of energy technologies to be made. However, it does not include the costs of grid integration or climate impacts. Further, LCOE does not take into account other environmental and social externalities that may modify the overall (monetary and non-monetary) costs of technologies and alter their deployment. The **bottom panel** shows cumulative global adoption for each technology, in GW of installed capacity for renewable energy and in millions of vehicles for battery-electric vehicles. A vertical dashed line is placed in 2010 to indicate the change since AR5. Shares of electricity produced and share of passenger vehicle fleet are indicated in text for 2020 based on provisional data, i.e., percentage of total electricity production (for PV, onshore wind, offshore wind, CSP) and of total stock of passenger vehicles (for EVs). The electricity production share reflects different capacity factors; for example, for the same amount of installed capacity, wind produces about twice as much electricity as solar PV. {2.5, 6.4} Renewable energy and battery technologies were selected as illustrative examples because they have recently shown rapid changes in costs and adoption, and because consistent data are available. Other mitigation options assessed in the report are not included as they do not meet these criteria.

Multiple low-carbon technologies have shown rapid progress since AR5 – in cost, performance, and adoption – enhancing the feasibility of rapid energy transitions (*high confidence*). The rapid deployment and unit cost decrease of modular technologies like solar, wind, and batteries have occurred much faster than anticipated by experts and modelled in previous mitigation scenarios, as shown in Figure TS.7 (*high confidence*). The political, economic, social, and technical feasibility of solar energy, wind energy and electricity storage technologies has improved dramatically over the past few years. In contrast, the adoption of nuclear energy and CO₂ capture and storage (CCS) in the electricity sector has been slower than the growth rates anticipated in stabilisation scenarios. Emerging evidence since AR5 indicates that small-scale technologies (e.g., solar, batteries) tend to improve faster and be adopted more quickly than large-scale technologies (nuclear, CCS) (*medium confidence*). (Figure TS.7, Box TS.15) {2.5.3, 2.5.4, Figures 2.22 and 2.23}

Robust incentives for investment in innovation, especially incentives reinforced by national policy and international agreements, are central to accelerating low-carbon technological change (*robust evidence, medium agreement*). Policies have driven innovation, including instruments for technology push (e.g., scientific training, research and development (R&D)) and demand pull (e.g., carbon pricing, adoption subsidies), as well as those promoting knowledge flows and especially technology transfer. The magnitude of the scale-up challenge elevates the importance of rapid technology development and adoption. This includes ensuring participation of developing countries in an enhanced global flow of knowledge, skills, experience, equipment, and technology; which in turn requires strong financial, institutional, and capacity-building support. {16.4, 16.5}

Figure TS.8 | Future CO₂ emissions from existing and currently planned fossil fuel infrastructure in the context of the Paris Agreement carbon budgets in GtCO₂ based on historic patterns of infrastructure lifetimes and Future CO₂ emissions estimates of existing infrastructure for the electricity sector as well as all other sectors (industry, transport, buildings, other fossil fuel infrastructures) and of proposed infrastructures for coal power as well as gas and oil power. Grey bars on the right depict the range (5–95th percentile) in overall cumulative net CO₂ emissions until reaching net zero CO₂ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot (1.5°C scenarios), and in pathways that limit warming to 2°C (>67%) (2°C scenarios). (Figure 2.26)

Estimates of future CO₂ emissions from existing fossil fuel infrastructures already exceed remaining cumulative net CO₂ emissions in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (*high confidence*). Assuming variations in historic patterns of use and decommissioning, estimated future CO₂ emissions from existing fossil fuel infrastructure alone are 660 (460–890) GtCO₂ and from existing and currently planned infrastructure 850 (600–1100) GtCO₂. This compares to overall cumulative net CO₂ emissions until reaching net zero CO₂ of 510 (330–710) GtCO₂ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and 890 (640–1160) GtCO₂ in pathways that limit warming to 2°C (>67%) (*high confidence*). While most future CO₂ emissions from existing and currently planned fossil fuel infrastructure are situated in the power sector, most remaining fossil fuel CO₂ emissions in pathways that limit warming to 2°C (>67%) and below are from non-electric energy – most importantly from the industry and transportation sectors (*high confidence*). Decommissioning and reduced utilisation of existing fossil fuel installations in the power sector as well as cancellation of new installations are required to align future CO₂ emissions from the power sector with projections in these pathways (*high confidence*). (Figure TS.8) {2.7.2, 2.7.3, Figure 2.26, Tables 2.6 and 2.7}

TS.4 Mitigation and Development Pathways

While previous WGIII assessments have explored mitigation pathways, since AR5 there has been an increasing emphasis in the literature on development pathways, and in particular at the national scale. Chapter 4 assesses near-term (2019–2030) to mid-term (2030–2050) pathways, complementing Chapter 3 which focuses on long-term pathways (up to 2100). While there is considerable literature on country-level mitigation pathways, including but not limited to NDCs, the country distribution of this literature is very unequal (*high confidence*). {4.2.1, Cross-Chapter Box 4 in Chapter 4}

TS.4.1 Mitigation and Development Pathways in the Near- to Mid-term

An emissions gap persists, exacerbated by an implementation gap, despite mitigation efforts including those in Nationally Determined Contributions (NDCs). In this report the *emissions gap* is understood as the difference between projected global emissions with Nationally Determined Contributions (NDCs) in 2030, and emissions in 2030 if mitigation pathways consistent with the Paris temperature goals were achieved. The term *implementation gap* refers to the gap between NDC mitigation pledges and the expected outcome of existing policies.

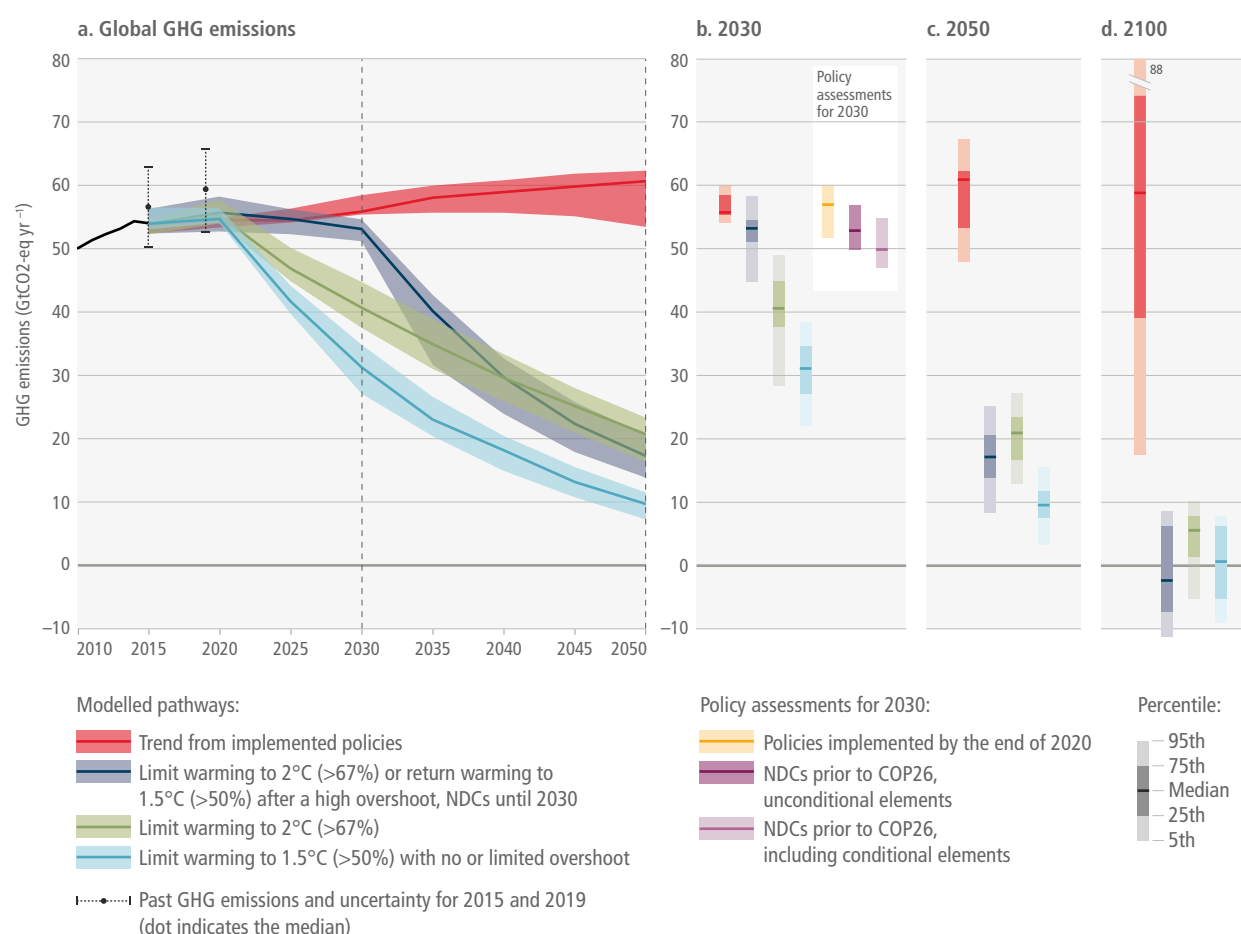

Figure TS.9 | Aggregate greenhouse gas (GHG) emissions of global mitigation pathways (coloured funnels and bars) and projected emission outcomes from current policies and emissions implied by unconditional and conditional elements of NDCs, based on updates available by 11 October 2021 (grey bars). Shaded areas show GHG emission medians and 25–75th percentiles over 2020–2050 for four types of pathways in the AR6 scenario database: (i) pathways with near-term emissions developments in line with current policies and extended with comparable ambition levels beyond 2030; (ii) pathways *likely* to limit warming to 2°C with near-term emissions developments reflecting 2030 emissions implied by current NDCs followed by accelerated emissions reductions; (iii) pathways *likely* to limit warming to 2°C based on immediate actions from 2020 onwards; (iv) pathways that limit warming to 1.5°C with no or limited overshoot. Right-hand panels show two snapshots of the 2030 and 2050 emission ranges of the pathways in detail (median, 25–75th and 5–95th percentiles). The 2030 snapshot includes the projected emissions from the implementation of the NDCs as assessed in Section 4.2 (Table 4.1; median and full range). Historic GHG emissions trends as used in model studies are shown for 2010–2015. GHG emissions are in CO₂-equivalent using GWP100 values from AR6. {3.5, Table 4.1, Cross-Chapter Box 4 in Chapter 4}

Pathways consistent with the implementation and extrapolation of countries' current¹³ policies see GHG emissions reaching 57 (52–60) GtCO₂-eq yr⁻¹ by 2030 and to 46–67 GtCO₂-eq yr⁻¹ by 2050, leading to a median global warming of 2.4°C to 3.5°C by 2100 (*medium confidence*). NDCs with unconditional and conditional elements¹⁴ lead to 53 (50–57) and 50 (47–55) GtCO₂-eq, respectively (*medium confidence*) {Table 4.1}. This leaves median estimated *emissions gaps* of 14–23 GtCO₂-eq to limit warming to 2°C and 25–34 GtCO₂-eq to limit warming to 1.5°C relative to mitigation pathways. (Figure TS.9) {Cross-Chapter Box 4, Figure 1 in Chapter 4}

Projected global emissions from aggregated NDCs place limiting global warming to 1.5°C beyond reach and make it harder after 2030 to limit warming to 2°C (*high confidence*). Pathways following NDCs until 2030 show a smaller reduction in fossil fuel use, slower deployment of low-carbon alternatives, and a smaller reduction in CO₂, CH₄ and overall GHG emissions in 2030 compared to immediate action scenarios. This is followed by a much faster reduction of emissions and fossil fuels after 2030, and a larger increase in the deployment of low-carbon alternatives during the medium term in order to get close to the levels of the immediate action pathways in 2050. Those pathways also deploy a larger amount of carbon dioxide removal (CDR) to compensate for higher emissions before 2030. The faster transition during 2030 to 2050 entails greater investment in fossil fuel infrastructure and lower deployment of low-carbon alternatives in 2030, which adds to the socio-economic challenges in realising the higher transition rates. (TS.4.2) {3.5}

Studies evaluating up to 105 updated NDCs¹⁵ indicate that emissions in NDCs with conditional elements have been reduced by 4.5 (2.7–6.3) GtCO₂-eq. This closes the emission gaps by about one third to 2°C and about 20% to 1.5°C compared to the original NDCs submitted in 2015/16 (*medium confidence*) {4.2.2, Cross-Chapter Box 4 in Chapter 4}. An *implementation gap* also exists between the projected emissions with 'current policies' and the projected emissions resulting from the implementation of the unconditional and conditional elements of NDCs; this is estimated to be around 4 and 7 GtCO₂-eq in 2030, respectively (*medium confidence*) {4.2.2}. Many countries would therefore require additional policies and associated action on climate change to meet their autonomously determined mitigation targets as specified under the first NDCs (*limited evidence*). The disruptions triggered by the COVID-19 pandemic increase uncertainty over the range of projections relative to pre-COVID-19 literature. As indicated by a growing number of studies at the national and global level, how large near- to mid-term emissions implications of the COVID-19 pandemic are, to a large degree depends on how stimulus or recovery packages are designed. {4.2}

There is a need to explore how accelerated mitigation – relative to NDCs and current policies – could close both emission gaps and implementation gaps. There is increasing understanding of the technical content of accelerated mitigation pathways, differentiated by national circumstances, with considerable, though uneven, literature at country-level (*medium evidence, high agreement*). Transformative technological and institutional changes for the near term include demand reductions through efficiency and reduced activity, rapid decarbonisation of the electricity sector and low-carbon electrification of buildings, industry and transport (*robust evidence, medium agreement*). A focus on energy use and supply is essential, but not sufficient on its own – the land sector and food systems deserve attention. The literature does not adequately include demand-side options and systems analysis, and captures the impact from non-CO₂ GHGs (*medium confidence*). {4.2.5}

If obstacles to accelerated mitigation are rooted in underlying structural features of society, then transforming such structures can support emission reductions {4.2.6}. Countries and regions will have different starting points for transition pathways. Some critical differences between countries include climate conditions resulting in different heating and cooling needs, endowments with different energy resources, patterns of spatial development, and political and economic conditions {4.2.5}. The way countries develop determines their capacity to accelerate mitigation and achieve other sustainable development objectives simultaneously (*medium confidence*) {4.3.1, 4.3.2}. Yet meeting ambitious mitigation and development goals cannot be achieved through incremental change (*robust evidence, medium agreement*). Though development pathways result from the actions of a wide range of actors, it is possible to shift development pathways through policies and enhancing enabling conditions (*limited evidence, medium agreement*).

Shifting development pathways towards sustainability offers ways to broaden the range of levers and enablers that a society can use to accelerate mitigation and increases the likelihood of making progress simultaneously on climate action and other development goals (Box TS.3) {Cross-Chapter Box 5 in Chapter 4, Figure 4.7, 4.3}. There are practical options to shift development pathways in ways that advance mitigation and other sustainable development objectives, support political feasibility, increase resources to meet multiple goals, and reduce emissions (*limited evidence, high agreement*). Concrete examples, assessed in Chapter 4 of this report, include high-employment and low-emissions structural change; fiscal reforms for mitigation and social contract, combining housing policies to deliver both housing and transport mitigation; and changed economic, social and spatial patterns of agriculture sector development, providing the basis for sustained reductions in emissions from deforestation. {4.4.1, 4.4, 1.10}

13 Current NDCs refers to the most recent Nationally Determined Contributions submitted to the UNFCCC as well as those publicly announced (with sufficient detail on targets, but not yet submitted) up to 11 October 2021, and reflected in literature published up to 11 October 2021. Original INDCs and NDCs refer to those submitted to the UNFCCC in 2015 and 2016.

14 See {4.2.1} for descriptions of 'unconditional' and 'conditional' elements of NDCs.

15 Submitted by 11 October 2021.

Table TS.2 | Comparison of key characteristics of mitigation pathways with immediate action towards limiting warming to 1.5-2°C vs. pathways following NDCs announced prior to COP26 until 2030. Key characteristics are reported for five groups of mitigation pathways: (i) immediate action to limit warming to 1.5°C (>50%) with no or limited overshoot (C1 in Table TS.3; 97 scenarios), (ii) near term action following the NDCs until 2030 and returning warming to 1.5°C (> 50%) by 2100 after a high overshoot (subset of 42 scenarios following the NDCs until 2030 in C2), (iii) immediate action to limit warming to 2°C (>67%), (C3a in Table TS.3; 204 scenarios), (iv) near term action following the NDCs until 2030 followed by post-2030 action to limit warming to 2°C (>67%) (C3b in Table TS.3; 97 scenarios). Also shown are the characteristics for (v) the combined class of all scenarios that limit warming to 2°C (>67%). The groups (i), (iii), and the combination of (ii) and (iv) are depicted in Figure TS.9. Reported are median and interquartile ranges (in brackets) for selected global indicators. Numbers are rounded to the nearest five, with the exception of cumulative net negative CO₂ emissions rounded to the nearest 10. Changes from 2019 are relative to modelled 2019 values. Emissions reductions are based on harmonised model emissions used for the climate assessment. {Section 3.5} {Table 3.6}

Global indicators	1.5°C (>50%)	1.5°C (>50%) by 2100	2°C (>67%)		
	Immediate action, with no or limited overshoot	NDCs until 2030, with overshoot before 2100	Immediate action	NDCs until 2030	All
Cumulative net negative CO ₂ emissions until 2100 (GtCO ₂)	220 (70,430)	380 (300,470)	30 (0,130)	60 (20,210)	40 (10,180)

Box TS.3 | Shifting Development Pathways to Increase Sustainability and Broaden Mitigation Options

In this report, *development pathways* refer to the patterns of development resulting from multiple decisions and choices made by many actors in the national and global contexts. Each society whether in developing or developed regions follows its own pattern of growth (Figure TS.13). Development pathways can also be described at smaller scales (e.g., for regions or cities) and for sectoral systems.

Development pathways are major drivers of GHG emissions {1, 2}. There is compelling evidence to show that continuing along existing development pathways will not achieve rapid and deep emission reductions. In the absence of shifts in development pathways, conventional mitigation policy instruments may not be able to limit global emissions to a degree sufficient to meet ambitious mitigation goals or they may only be able to do so at very high economic and social costs.

Policies to shift development pathways, on the other hand, make mitigation policies more effective. Shifting development pathways broadens the scope for synergies between sustainable development objectives and mitigation. Development pathways also determine the enablers and levers available for adaptation {AR6 WGII TS.E.1.2} and for achieving other SDGs.

There are many instances in which reducing GHG emissions and moving towards the achievement of other development objectives can go hand in hand {Chapter 3, Figure 3.33, Chapters 6–12, and 17}. Integrated policies can support the creation of synergies between *action to combat climate change and its impacts* (SDG 13 – climate action) and other SDGs. For example, when measures promoting walkable urban areas are combined with electrification and clean renewable energy, there are several co-benefits to be attained. These include reduced pressures on agricultural land from reduced urban growth, health co-benefits from cleaner air, and benefits from enhanced mobility {8.2, 8.4, 4.4.1}. Energy efficiency in buildings and energy poverty alleviation through improved access to clean fuels also deliver significant health benefits. {9.8.1 and 9.8.2}

However, decisions about mitigation actions, and their timing and scale, may entail trade-offs with the achievement of other national development objectives in the near, mid- and long term {Chapter 12}. In the near term, for example, regulations may ban vehicles from city centres to reduce congestion and local air pollution but reduce mobility and choice. Increasing green spaces within cities without caps on housing prices may involve trade-offs with affordable housing and push low-income residents outside the city {8.2.2}. In the mid- and long term, large-scale deployment of biomass energy raises concerns about food security and biodiversity conservation {3.7.1, 3.7.5, 7.4.4, 9.8.1, 12.5.2, 12.5.3}. Prioritising is one way to manage these trade-offs, addressing some national development objectives earlier than others. Another way is to adopt policy packages aimed at shifting development pathways towards increased sustainability (SDPS) as they expand the range of tools available to simultaneously achieve multiple development objectives and accelerate mitigation. (Box TS.3, Figure 1)

What does *shifting development pathways towards increased sustainability* entail?

Shifting development pathways towards increased sustainability implies making transformative changes that disrupt existing developmental trends. Such choices would not be marginal, but include technological, systemic and socio-behavioural changes {4.4}. Decision points also arise with new infrastructure, sustainable supply chains, institutional capacities for evidence-based and integrated decision-making, financial alignment towards low-carbon socially responsible investments, just transitions and shifts in behaviour and norms to support shifts away from fossil fuel consumption. Adopting multi-level governance modes, tackling corruption where it inhibits shifts to sustainability, and improving social and political trust are also key for aligning and supporting long-term environmentally just policies and processes. {4.4, Cross-Chapter Box 5 in Chapter 4}

How can development pathways be ‘shifted’?

Shifting development paths is complex. Changes that involve ‘dissimilar, unfamiliar and more complex science-based components’ take more time, acceptance and legitimation and involve complex social learning, even when they promise large gains. Despite the complexities of the interactions that result in patterns of development, history also shows that societies can influence the direction of development pathways based on choices made by decision-makers, citizens, the private sector, and social stakeholders. Shifts in development pathways result from both sustained political interventions and bottom-up changes in public opinion. Collective action by individuals as part of social movements or lifestyle changes underpins system change. {5.2.3, 5.4.1, 5.4.5}

Sectoral transitions that aim to shift development pathways often have multiple objectives and deploy a diverse mix of policies and institutional measures. Context-specific governance conditions can significantly enable or disable sectoral transitions. {Cross-Chapter Box 12 in Chapter 16}

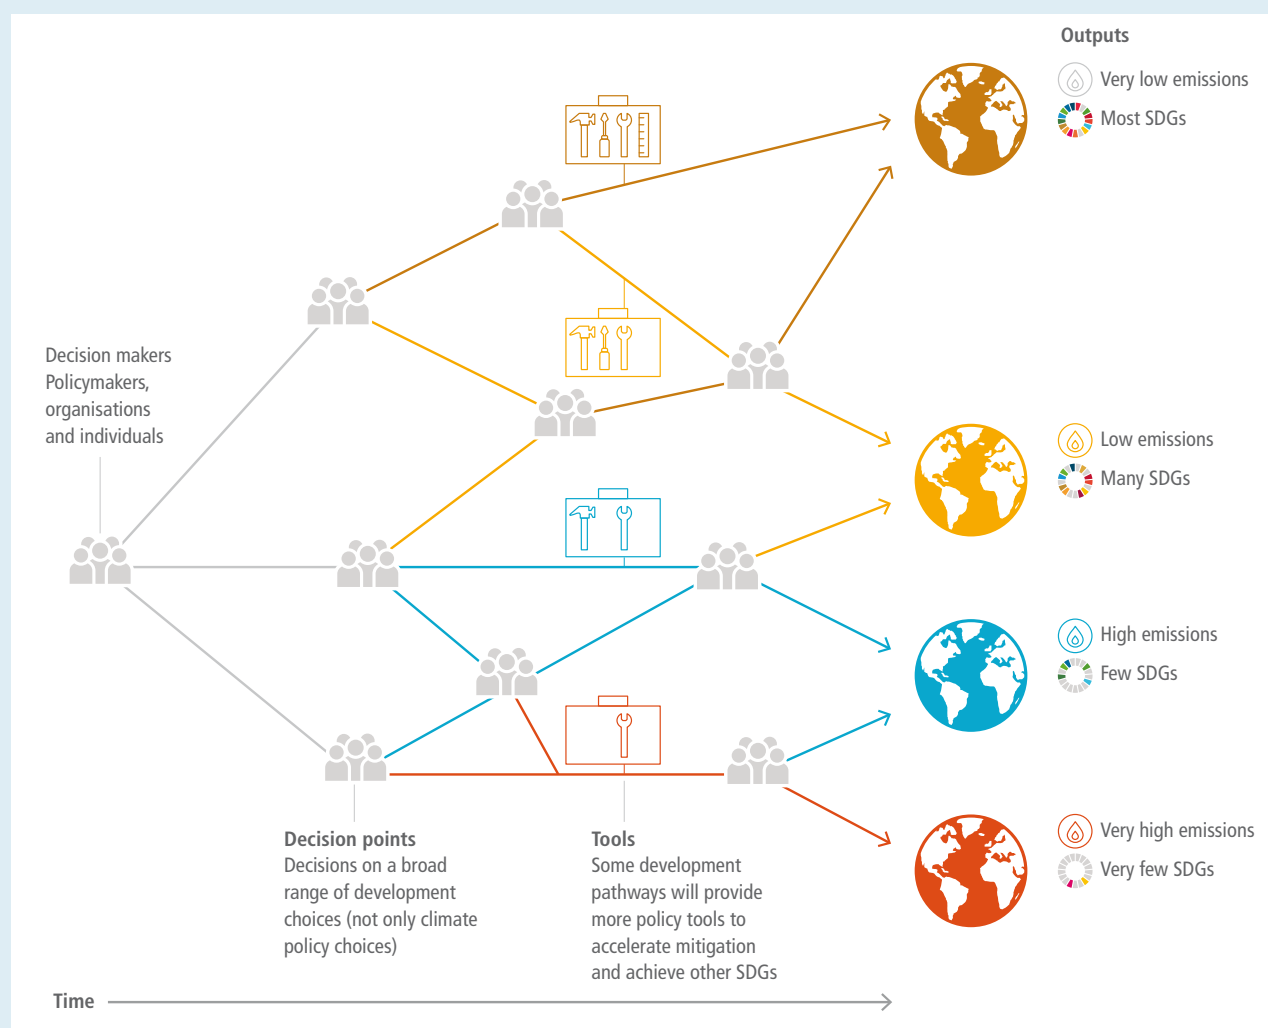

Box TS.3 (continued)

The necessary transformational changes are anticipated to be more acceptable if rooted in the development aspirations of the economy and society within which they take place and may enable a new social contract to address a complex set of interlinkages across sectors, classes, and the whole economy. Taking advantage of windows of opportunity and disruptions to mindsets and socio-technical systems could advance deeper transformations.

How can shifts in development pathways be implemented by actors in different contexts?

Shifting development pathways to increased sustainability is a shared aspiration. Yet since countries differ in starting points (e.g., social, economic, cultural, political) and historical backgrounds, they have different urgent needs in terms of facilitating the economic, social, and environmental dimensions of sustainable development and, therefore, give different priorities {4.3.2, 17.1}. The appropriate set of policies to shift development pathways thus depends on national circumstances and capacities.

Shifting development pathways towards sustainability needs to be supported by multilateral partnerships to strengthen suitable capacity, technological innovation (TS.6.5), and financial flows (TS.6.4). The international community can play a particularly key role by helping ensure the necessary broad participation in climate-mitigation efforts, including by countries at different development levels, through sustained support for policies and partnerships that support shifting development pathways towards sustainability while promoting equity and being mindful of different transition capacities. {4.3, 16.5, 16.6}

Box TS.3, Figure 1 | Shifting development pathways to increased sustainability: choices by a wide range of actors at key decision points on development pathways can reduce barriers and provide more tools to accelerate mitigation and achieve other Sustainable Development Goals. {4.7}

Policies can shift development pathways. There are examples of policies implemented in the pursuit of overall societal development objectives, such as job creation, macroeconomic stability, economic growth, and public health and welfare.

In some countries, such policies are framed as part of a *Just Transition* (Box TS.3), however, they can have major influence on mitigative capacity, and hence can be seen as tools to broaden mitigation options (*medium confidence*) {4.3.3}. Coordinated policy mixes would need to orchestrate multiple actors – individuals, groups and collectives, corporate actors, institutions and infrastructure actors – to deepen decarbonisation and shift pathways towards sustainability. Shifts in one country may spill over to other countries. Shifting development pathways can jointly support mitigation and adaptation {4.4.2}. Some studies explore the risks of high complexity and potential delay attached to shifting development pathways. (Box TS.4, Figure TS.11) {4.4.3}

An increasing number of mitigation strategies up to 2050 (mid-term) have been developed by various actors. A growing number of such strategies aim at net zero GHG or CO₂ emissions, but it is not yet possible to draw global implications due to the limited size of sample (*medium evidence, low agreement*) {4.2.4}. Non-state actors are also engaging in a wide range of mitigation initiatives. When adding up emission reduction potentials, sub-national and non-state international cooperative initiatives could reduce emissions by up to about 20 GtCO₂-eq in 2030 (*limited evidence, medium agreement*) {4.2.3}. Yet perceived or real conflicts between mitigation and other SDGs can impede such action. If undertaken without precaution, accelerated mitigation is found to have significant implications for development objectives and macroeconomic costs at country level. The literature shows that the employment effect of mitigation policies tends to be limited on aggregate but can be significant at sectoral level (*limited evidence, medium agreement*). Detailed design of mitigation policies is critical for distributional impacts and avoiding lock-in (*high confidence*), though further research is needed in that direction. {4.2.6}

The literature identifies a broad set of enabling conditions that can both foster shifting development pathways and accelerated mitigation (*medium evidence, high agreement*).

Policy integration is a necessary component of shifting development pathways, addressing multiple objectives. To this aim, mobilising a range of policies is preferable to single policy instruments (*high confidence*). {4.4.1}. Governance for climate mitigation and shifting development pathways is enhanced when tailored to national and local contexts. Improved institutions and effective governance enable ambitious action on climate and can help bridge implementation gaps (*medium evidence, high agreement*). Given that strengthening institutions may be a long-term endeavour, it needs attention in the near term {4.4.1}. Accelerated mitigation and shifting development pathways necessitates both redirecting existing financial flows from high- to low-emissions technologies and systems, and providing additional resources to overcome current financial barriers (*high confidence*) {4.4.1}. Opportunities exist in the near term to close the finance gap {15.2.2}. At the national level, public finance for actions promoting sustainable development helps broaden the scope of mitigation (*medium confidence*). Changes in behaviour and lifestyles

are important to move beyond mitigation as incremental change, and when supporting shifts to more sustainable development pathways will broaden the scope of mitigation (*medium confidence*). {4.4.1, Figure 4.8}

Some enabling conditions can be put in place relatively quickly while some others may take time to establish underscoring the importance of early action (*high confidence*). Depending on context, some enabling conditions such as promoting innovation may take time to establish. Other enabling conditions, such as improved access to financing, can be put in place in a relatively short time frame, and can yield rapid results {4.4, Figure 5.14, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5, Cross-Chapter Box 12 in Chapter 16}. Focusing on development pathways and considering how to shift them may also yield rapid results by providing tools to accelerate mitigation and achieve other sustainable development goals {4.4.1}. Charting just transitions to net zero may provide a vision, which policy measures can help achieve (Boxes TS.4 and TS.8).

Equity can be an important enabler, increasing the level of ambition for accelerated mitigation (*high confidence*) {4.5}.

Equity deals with the distribution of costs and benefits and how these are shared, as per social contracts, national policy and international agreements. Transition pathways have distributional consequences such as large changes in employment and economic structure (*high confidence*). The *Just Transition* concept has become an international focal point tying together social movements, trade unions, and other key stakeholders to ensure equity is better accounted for in low-carbon transitions (Box TS.4). The effectiveness of cooperative action and the perception of fairness of such arrangements are closely related in that pathways that prioritise equity and allow broad stakeholder participation can enable broader consensus for the transformational change implicit in the need for deeper mitigation (*robust evidence, medium agreement*). (Box TS.4) {4.5, Figure 4.9}

Box TS.4 | Just Transition

The Just Transition framework refers to a set of principles, processes and practices aimed at ensuring that no people, workers, places, sectors, countries or regions are left behind in the move from a high-carbon to a low-carbon economy. It includes respect and dignity for vulnerable groups; creation of decent jobs; social protection; employment rights; fairness in energy access and use and social dialogue and democratic consultation with relevant stakeholders.

The concept has evolved, becoming prominent in the United States of America in 1980, related to environmental regulations that resulted in job losses from highly polluting industries. Traced from a purely labour movement, trade union space, the Just Transition framework emphasises that decent work and environmental protection are not incompatible. During COP 24, with the Just Transition Silesia Declaration, the concept gained in recognition and was signed by 56 heads of state.

Implicit in a Just Transition is the notion of well-being, equity and justice – the realisation that transitions are inherently disruptive and deliberate effort may be required to ensure communities dependent on fossil-fuel based economies and industries do not suffer disproportionately {Chapter 4}. ‘Just Transitions’ are integral to the European Union as mentioned in the EU Green Deal, the Scottish Government’s development plans and other national low-carbon transition strategies. The US Green New Deal Resolution puts structural inequality, poverty mitigation, and ‘Just Transitions’ at its centre. There is a growing awareness of the need for shifting finance towards Just Transition in the context of COVID-19, in particular, public finance and governance have a major role in allowing a Just Transition more broadly {Chapter 15}.

In the immediate aftermath of the COVID-19 pandemic, low oil prices created additional financial problems for fossil fuel producer countries faced with loss of revenue and reduced fiscal latitude and space. Public spending and social safety nets associated with the proceeds from producer economies can be affected as assets become stranded and spending on strategic sustainable development goals such as free education and health-care services are neglected. Fiscal challenges are intricately linked to ‘Just Transitions’ and the management associated with sustainable energy transition. There is no certainty on how energy systems will recover post-COVID-19. However, ‘Just Transitions’ will have equity implications if stimulus packages are implemented without due regard for the differentiated scales and speeds and national and regional contexts, especially in the context of developing countries.

A Just Transition entails targeted and proactive measures from governments, agencies, and other non-state authorities to ensure that any negative social, environmental, or economic impacts of economy-wide transitions are minimised, whilst benefits are maximised for those disproportionately affected. These proactive measures include eradication of poverty, regulating prosperity and creating jobs in ‘green’ sectors. In addition, governments, polluting industries, corporations, and those more able to pay higher associated taxes, can pay for transition costs by providing a welfare safety net and adequate compensation to people, communities, and regions that have been impacted by pollution, or are marginalised, or are negatively impacted by a transition from a high- to low-carbon economy and society. There is, nonetheless, increased recognition that resources that can enable the transition, international development institutions, as well as other transitional drivers such as tools, strategies and finance, are scarce. A sample of global efforts is summarised in Box TS.4, Figure 1.

TS.4.2 Long-term Mitigation Pathways

The characteristics of a wide range of long-term mitigation pathways, their common elements and differences are assessed in Chapter 3. Differences between pathways typically represent choices that can steer the system in alternative directions through the selection of different combinations of response options (*high confidence*). More than 2000 quantitative emissions pathways were submitted to the AR6 scenarios database, of which more than 1200 pathways included sufficient information for the associated warming to be assessed (consistent with AR6 WGI methods). (Box TS.5) {3.2, 3.3}

Many pathways in the literature show how to limit global warming to 2°C (>67%) with no overshoot or to limit warming to 1.5°C (>50%) with limited overshoot compared to 1850–1900. The likelihood of limiting warming to 1.5°C with no or limited overshoot has dropped in AR6 WGIII compared to AR6 SR1.5 because global GHG emissions have risen since 2017, leading to higher near-term emissions (2030) and higher cumulative CO₂ emissions until the time of net zero (*medium confidence*). Only a small number of published pathways limit

global warming to 1.5°C without overshoot over the course of the 21st century. {3.3, Annex III.II.3}

Mitigation pathways limiting warming to 1.5°C with no or limited overshoot reach 50% CO₂ reductions in the 2030s, relative to 2019, then reduce emissions further to reach net zero CO₂ emissions in the 2050s. Pathways limiting warming to 2°C (>67%) reach 50% reductions in the 2040s and net zero CO₂ by the 2070s (*medium confidence*). (Figure TS.10, Box TS.6) {3.3}

Cost-effective mitigation pathways assuming immediate action to limit warming to 2°C (>67%) are associated with net global GHG emissions of 30–49 GtCO₂-eq yr⁻¹ by 2030 and 14–27 GtCO₂-eq yr⁻¹ by 2050 (*medium confidence*). This corresponds to reductions, relative to 2019 levels, of 13–45% by 2030 and 52–76% by 2050. Pathways that limit global warming to below 1.5°C with no or limited overshoot require a further acceleration in the pace of transformation, with net GHG emissions typically around 21–36 GtCO₂-eq yr⁻¹ by 2030 and 1–15 GtCO₂-eq yr⁻¹ by 2050; this corresponds to reductions of 34–60% by 2030 and 73–98% by 2050 relative to 2019 levels. {3.3}

TS

Box TS.5 | Illustrative Mitigation Pathways (IMPs), and Shared Socio-economic Pathways (SSPs)

The Illustrative Mitigation Pathways (IMPs)

The over 2500 model-based pathways submitted to the AR6 scenarios database pathways explore different possible evolutions of future energy and land use (with and without climate policy) and the consequences for greenhouse gas emissions.

From the full range of pathways, five archetype scenarios – referred to in this report as *Illustrative Mitigation Pathways* (IMPs) – were selected to illustrate key mitigation-strategy themes that flow through several chapters in this report. A further two *pathways illustrative of high emissions* assuming continuation of current policies or moderately increased action were selected to show the consequences of current policies and pledges. Together these pathways provide illustrations of potential future developments that can be shaped by human choices, including: Where are current policies and pledges leading us? What is needed to reach specific temperature goals? What are the consequences of using different strategies to meet these goals? What are the consequences of delay? How can we shift development from current practices to give higher priority to sustainability and the SDGs?

Each of the IMPs comprises: a *storyline* and a *quantitative illustration*. The *storyline* describes the key characteristics of the pathway qualitatively; the *quantitative illustration* is selected from the literature on long-term scenarios to effectively represent the IMP numerically. The five Illustrative Mitigation Pathways (IMPs) each emphasise a different scenario element as its defining feature, and are named accordingly: heavy reliance on renewables (IMP-Ren), strong emphasis on low demand for energy (IMP-LD), extensive use of carbon dioxide removal (CDR) in the energy and the industry sectors to achieve net negative emissions (IMP-Neg), mitigation in the context of broader sustainable development and shifting development pathways (IMP-SP), and the implications of a less rapid and gradual strengthening of near-term mitigation actions (IMP-GS). In some cases, sectoral chapters may use different quantifications that follow the same storyline narrative but contain data that better exemplify the chapter's assessment. Some IMP variants are also used to explore the sensitivity around alternative temperature goals. {3.2, 3.3}

The two additional *pathways illustrative of higher emissions* are current policies (CurPol) and moderate action (ModAct).

This framework is summarised in Box TS.5, Table.1 below, which also shows where the IMPs are situated with respect to the classification of emissions scenarios into warming levels (C1–C8) introduced in Chapter 3, and the CMIP6 (Coupled Model Intercomparison Project 6) scenarios used in the AR6 WGI report.

Box TS.5 (continued)

Box TS.5, Table.1 | *Illustrative Mitigation Pathways (IMPs) and pathways illustrative of higher emissions in relation to scenarios' categories, and CMIP6 scenarios.*

Classification of emissions scenarios into warming levels: C1–C8	Pathways illustrative of higher emissions	Illustrative mitigation pathways (IMPs)	CMIP6 scenarios
C8 exceeding warming of 4°C ($\geq 50\%$)			SSP5-8.5
C7 limit warming to 4°C ($>50\%$)	CurPol		SSP3-7.0
C6 limit warming to 3°C ($>50\%$)	ModAct		SSP2-4.5
C5 limit warming to 2.5°C ($>50\%$)			SSP4-3.7
C4 limit warming to 2°C ($>50\%$)			
C3 limit warming to 2°C ($>67\%$)		IMP-GS (Sensitivities: Neg; Ren)	SSP2-2.6
C2 return warming to 1.5°C ($>50\%$) after a high overshoot		IMP-Neg	
C1 limit warming to 1.5°C ($>50\%$) with no or limited overshoot		IMP-LD IMP-Ren IMP-SP	SSP1-1.9

The Shared Socio-economic Pathways (SSPs)

First published in 2017, the Shared Socio-economic Pathways (SSPs) are alternative projections of socio-economic developments that may influence future GHG emissions.

The initial set of SSP narratives described worlds with different challenges to mitigation and adaptation: SSP1 (*sustainability*), SSP2 (*middle of the road*), SSP3 (*regional rivalry*), SSP4 (*inequality*) and SSP5 (*rapid growth*). The SSPs were subsequently quantified in terms of energy, land-use change, and emission pathways for both (i) no-climate-policy reference scenarios and (ii) mitigation scenarios that follow similar radiative forcing pathways as the representative concentration pathways (RCPs) assessed in AR5 WGI. {3.2.3}

Most of the scenarios in the AR6 database are SSP-based. The majority of the assessed scenarios are consistent with SSP2. Using the SSPs permits a more systematic assessment of future GHG emissions and their uncertainties than was possible in AR5. The main emissions drivers across the SSPs include growth in population reaching 8.5–9.7 billion by 2050, and an increase in global GDP of 2.7–4.1% per year between 2015 and 2050. Final energy demand in the absence of any new climate policies is projected to grow to around 480 to 750 EJ yr⁻¹ in 2050 (compared to around 390 EJ yr⁻¹ in 2015) (*medium confidence*). The highest emissions scenarios in the literature result in global warming of $>5^{\circ}\text{C}$ by 2100, based on assumptions of rapid economic growth and pervasive climate policy failures (*high confidence*). {3.3}

Table TS.3 | GHG, CO₂ emissions and warming characteristics of different mitigation pathways submitted to the AR6 scenarios database, and as categorised in the climate assessment. (Table 3.2)

p50 [p5–p95] ^a			GHG emissions (GtCO ₂ -eq yr ⁻¹) ^g			GHG emissions reductions from 2019 (%) ^h			Emissions milestones ^{i,j}				Cumulative CO ₂ emissions (GtCO ₂) ^m		Cumulative net-negative CO ₂ emissions (GtCO ₂)	Global mean temperature changes 50% probability (°C) ⁿ		Likelihood of peak global warming staying below (%) ^o

Table TS.3 (continued):

^a Values in the table refer to the 50th and [5th–95th] percentile values across the pathways falling within a given category as defined in Box SPM.1. For emissions-related columns these values relate to the distribution of all the pathways in that category. Harmonised emissions values are given for consistency with projected global warming outcomes using climate emulators. Based on the assessment of climate emulators in AR6 WGI (WG1 Chapter 7, Box 7.1), two climate emulators are used for the probabilistic assessment of the resulting warming of the pathways. For the 'Temperature change' and 'Likelihood' columns, the single upper-row values represent the 50th percentile across the pathways in that category and the median [50th percentile] across the warming estimates of the probabilistic MAGICC climate model emulator. For the bracketed ranges, the median warming for every pathway in that category is calculated for each of the two climate model emulators (MAGICC and FaIR). Subsequently, the 5th and 95th percentile values across all pathways for each emulator are calculated. The coolest and warmest outcomes (i.e., the lowest p5 of two emulators, and the highest p95, respectively) are shown in square brackets. These ranges therefore cover both the uncertainty of the emissions pathways as well as the climate emulators' uncertainty.

^b For a description of pathways categories see Box SPM.1 and Table 3.1.

^c All global warming levels are relative to 1850–1900. (See footnote n below and Box SPM.1 for more details.)

^d C3 pathways are sub-categorised according to the timing of policy action to match the emissions pathways in Figure SPM.4. Two pathways derived from a cost-benefit analysis have been added to C3a, whilst 10 pathways with specifically designed near-term action until 2030, whose emissions fall below those implied by NDCs announced prior to COP26, are not included in either of the two subsets.

^e Alignment with the categories of the illustrative SSP scenarios considered in AR6 WGI, and the Illustrative (Mitigation) Pathways (IPs/IMPs) of WGIII. The IMPs have common features such as deep and rapid emissions reductions, but also different combinations of sectoral mitigation strategies. See Box SPM.1 for an introduction of the IPs and IMPs, and Chapter 3 for full descriptions. {3.2, 3.3, Annex III.II.4}

^f The Illustrative Mitigation Pathway 'Neg' has extensive use of carbon dioxide removal (CDR) in the AFOLU, energy and the industry sectors to achieve net negative emissions. Warming peaks around 2060 and declines to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as C3, it strongly exhibits the characteristics of C2 high-overshoot pathways, hence it has been placed in the C2 category. See Box SPM.1 for an introduction of the IPs and IMPs.

^g The 2019 range of harmonised GHG emissions across the pathways [53–58 GtCO₂-eq] is within the uncertainty ranges of 2019 emissions assessed in Chapter 2 [53–66 GtCO₂-eq]. (Figure SPM.1, Figure SPM.2, Box SPM.1)

^h Rates of global emission reduction in mitigation pathways are reported on a pathway-by-pathway basis relative to harmonised modelled global emissions in 2019 rather than the global emissions reported in SPM Section B and Chapter 2; this ensures internal consistency in assumptions about emission sources and activities, as well as consistency with temperature projections based on the physical climate science assessment by WGI. {Annex III.II.2.5}. Negative values (e.g., in C7, C8) represent an increase in emissions.

ⁱ Emissions milestones are provided for five-year intervals in order to be consistent with the underlying five-year time-step data of the modelled pathways. Peak emissions (CO₂ and GHGs) are assessed for five-year reporting intervals starting in 2020. The interval 2020–2025 signifies that projected emissions peak as soon as possible between 2020 and at latest before 2025. The upper five-year interval refers to the median interval within which the emissions peak or reach net zero. Ranges in square brackets underneath refer to the range across the pathways, comprising the lower bound of the 5th percentile five-year interval and the upper bound of the 95th percentile five-year interval. Numbers in round brackets signify the fraction of pathways that reach specific milestones.

^j Percentiles reported across all pathways in that category include those that do not reach net zero before 2100 (fraction of pathways reaching net zero is given in round brackets). If the fraction of pathways that reach net zero before 2100 is lower than the fraction of pathways covered by a percentile (e.g., 0.95 for the 95th percentile), the percentile is not defined and denoted with '...'. The fraction of pathways reaching net zero includes all with reported non-harmonised, and/or harmonised emissions profiles that reach net zero. Pathways were counted when at least one of the two profiles fell below 100 MtCO₂ yr⁻¹ until 2100.

^k The timing of net zero is further discussed in SPM C2.4 and Cross-Chapter Box 3 in Chapter 3 on net zero CO₂ and net zero GHG emissions.

^l For cases where models do not report all GHGs, missing GHG species are infilled and aggregated into a Kyoto basket of GHG emissions in CO₂-eq defined by the 100-year global warming potential. For each pathway, reporting of CO₂, CH₄, and N₂O emissions was the minimum required for the assessment of the climate response and the assignment to a climate category. Emissions pathways without climate assessment are not included in the ranges presented here. {See Annex III.II.5}

^m Cumulative emissions are calculated from the start of 2020 to the time of net zero and 2100, respectively. They are based on harmonised net CO₂ emissions, ensuring consistency with the WGI assessment of the remaining carbon budget. {Box 3.4}

ⁿ Global mean temperature change for category (at peak, if peak temperature occurs before 2100, and in 2100) relative to 1850–1900, based on the median global warming for each pathway assessed using the probabilistic climate model emulators calibrated to the AR6 WGI assessment. (See also Box SPM.1) {Annex III.II.2.5; WGI Cross-Chapter Box 7.1}

^o Probability of staying below the temperature thresholds for the pathways in each category, taking into consideration the range of uncertainty from the climate model emulators consistent with the AR6 WGI assessment. The probabilities refer to the probability at peak temperature. Note that in the case of temperature overshoot (e.g., category C2 and some pathways in C1), the probabilities of staying below at the end of the century are higher than the probabilities at peak temperature.

Pathways following current NDCs until 2030 reach annual emissions of 47–57 GtCO₂-eq yr⁻¹ by 2030, thereby making it impossible to limit warming to 1.5°C (>50%) with no or limited overshoot and strongly increasing the challenge of limiting warming to 2°C (>67%) (*high confidence*). A high overshoot of 1.5°C increases the risks from climate impacts and increases dependence on large-scale carbon dioxide removal (CDR) from the atmosphere. A future consistent with current NDCs implies higher fossil fuel deployment and lower reliance on low-carbon alternatives until 2030, compared to mitigation pathways describing immediate action that limits warming to 1.5°C (>50%) with no or limited overshoot, or limits warming to 2°C (>67%) and below. After following the NDCs to 2030, to limit warming to 2°C (>67%) the pace of global GHG emission reductions would need to abruptly increase from 2030 onward to an average of 1.3–2.1 GtCO₂-eq per year between 2030 and 2050. This is similar to the global CO₂ emission reductions in 2020 that occurred due to the COVID-19 pandemic lockdowns, and around 70% faster than in pathways where immediate action is taken to limit warming to 2°C (>67%). Accelerating emission reductions after following an NDC pathway to 2030 would also be particularly challenging because of the continued buildup of fossil fuel infrastructure that would take place between now and 2030. (TS4.1, Table TS.3) {3.5, 4.2}

Pathways accelerating action compared to current NDCs – that reduce annual GHG emissions to 47 (38–51) GtCO₂-eq by 2030 (which is 3–9 GtCO₂-eq below projected emissions from fully implementing current NDCs) – make it less challenging to limit warming to 2°C (>67%) after 2030 (*medium confidence*). The accelerated action pathways are characterised by a global, but regionally differentiated, roll-out of regulatory and pricing policies. Compared to current NDCs, they describe less fossil fuel use and more low-carbon fuel use until 2030; they narrow, but do not close the gap to pathways that assume immediate global action using all available least-cost abatement options. All delayed or accelerated action pathways limiting warming to below 2°C (>67%) converge to a global mitigation regime at some point after 2030 by putting a significant value on reducing carbon and other GHG emissions in all sectors and regions. {3.5}

In mitigation pathways, peak warming is determined by the cumulative net CO₂ emissions until the time of net zero CO₂ together with the warming contribution of other GHGs and climate forcers at that time (*high confidence*). Cumulative net CO₂ emissions from 2020 to the time of net zero CO₂ are 510 (330–710) GtCO₂ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot and 890 (640–1160) GtCO₂ in pathways limiting warming to 2°C (>67%). These estimates are consistent with the AR6 WGI assessment of remaining carbon budgets adjusting for methodological differences and non-CO₂ warming. {3.3, Box 3.4}

Rapid reductions in non-CO₂ GHGs, particularly CH₄, would lower the level of peak warming (*high confidence*). Non-CO₂ emissions – at the time of reaching net zero CO₂ – range between 4–11 GtCO₂-eq yr⁻¹ in pathways limiting warming to 2°C (>67%) or below. CH₄ is reduced by around 20% (1–46%) in 2030 and almost

50% (26–64%) in 2050, relative to 2019. CH₄ emission reductions in pathways limiting warming to 1.5°C with no or limited overshoot are substantially higher by 2030, 33% (19–57%), but only moderately so by 2050, 50% (33–69%). CH₄ emissions reductions are thus attainable at comparatively low costs, but, at the same time, reductions are limited in scope in most 1.5°C–2°C pathways. Deeper CH₄ emissions reductions by 2050 could further constrain the peak warming. N₂O emissions are also reduced, but similar to CH₄, N₂O emission reductions saturate for more stringent climate goals. The emissions of cooling aerosols in mitigation pathways decrease as fossil fuels use is reduced. The overall impact on non-CO₂-related warming combines all these factors. {3.3}

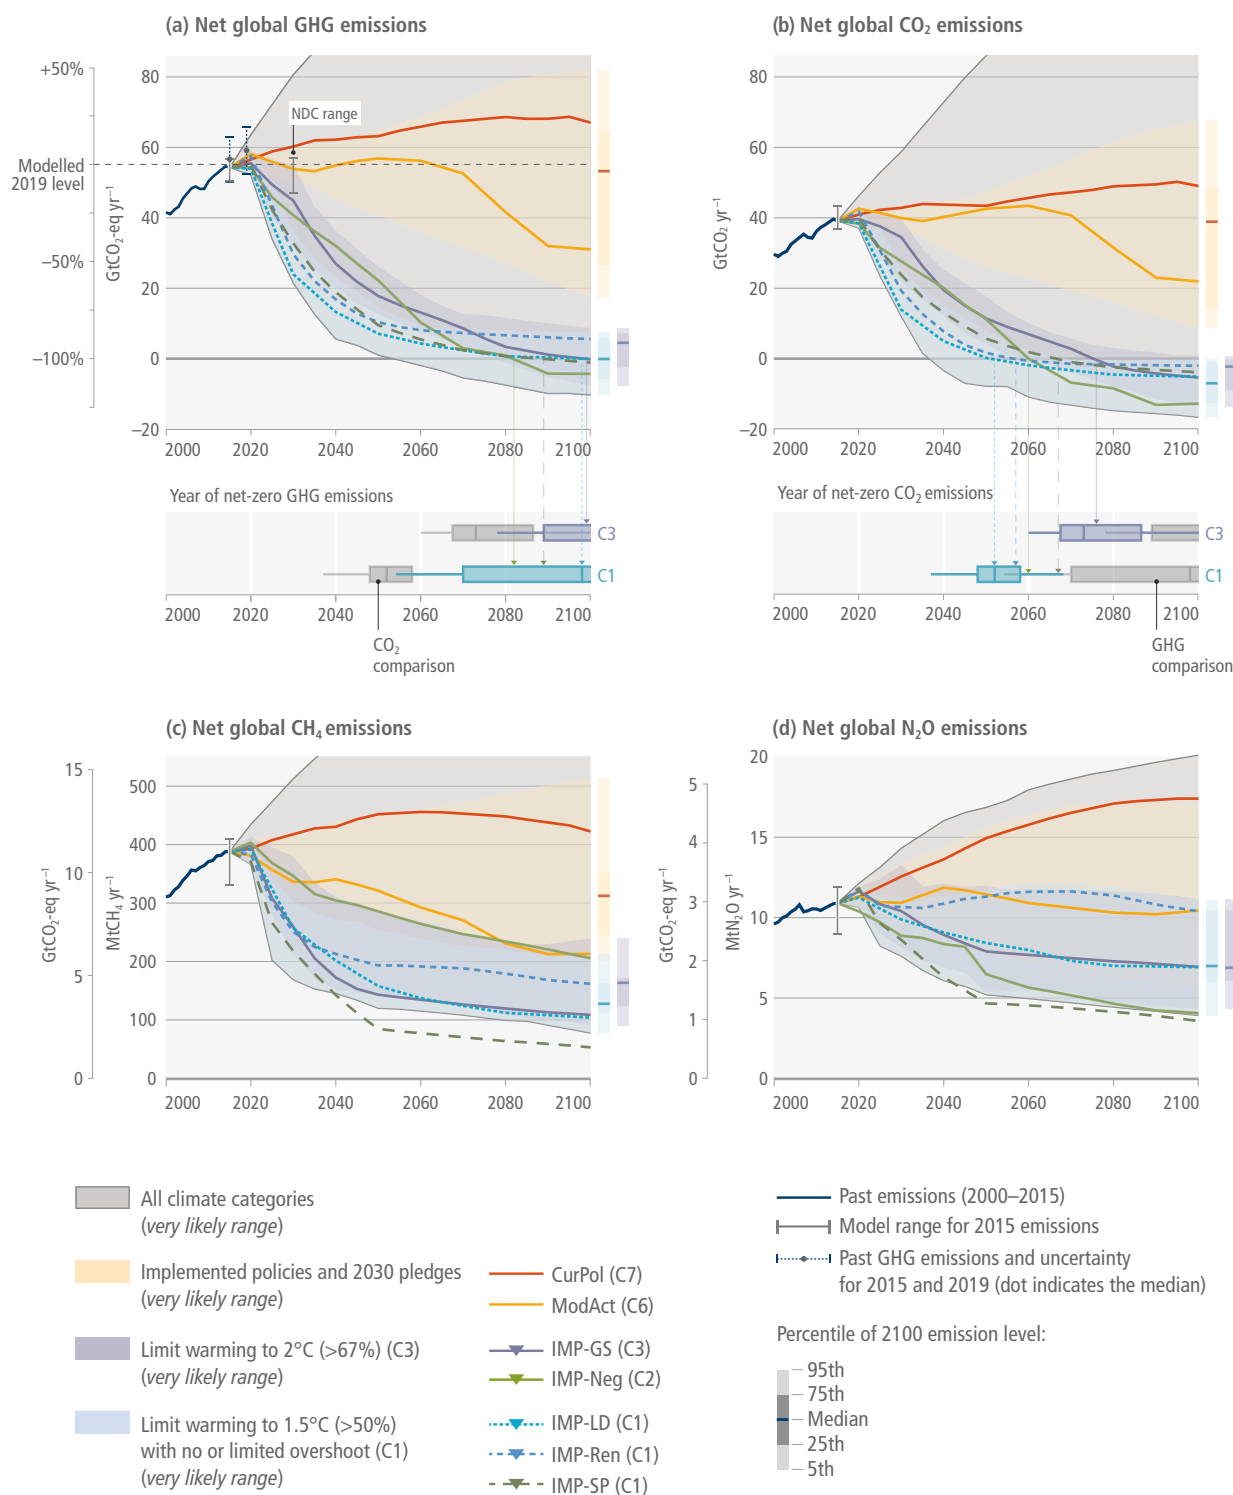

Net zero GHG emissions imply net negative CO₂ emissions at a level that compensates for residual non-CO₂ emissions. Only 30% of the pathways limiting warming to 2°C (>67%) or below reach net zero GHG emissions in the 21st century (*high confidence*). In those pathways reaching net zero GHGs, net zero GHGs is achieved around 10–20 years later than net zero CO₂ is achieved (*medium confidence*). The reported quantity of residual non-CO₂ emissions depends on accounting choices, and in particular the choice of GHG metric (Box TS.2). Reaching and sustaining global net zero GHG emissions – when emissions are measured and reported in terms of GWP100 – results in a gradual decline in temperature (*high confidence*). (Box TS.6) {3.3}

Pathways that limit warming to 2°C (>67%) or lower exhibit substantial reductions in emissions from all sectors (*high confidence*). Pathways that limit warming to 1.5°C (>50%) with no or limited overshoot entail CO₂ emissions reductions between 2019 and 2050 of around 77% (31–96%) for energy demand, around 115% (90–167%) for energy supply, and around 148% (94–387%) for AFOLU.¹⁶ In pathways that limit warming to 2°C (>67%), projected CO₂ emissions are reduced between 2019 and 2050 by around 49% for energy demand, 97% for energy supply, and 136% for AFOLU (*medium confidence*). {3.4}

If warming is to be limited, delaying or failing to achieve emissions reductions in one sector or region necessitates compensating reductions in other sectors or regions (*high confidence*). Mitigation pathways show differences in the timing of decarbonisation and when net zero CO₂ emissions are achieved across sectors and regions. At the time of *global net zero CO₂ emissions*, emissions in some sectors and regions are positive while others are negative; whether specific sectors and regions are positive or negative depends on the availability and cost of mitigation options in those regions, and the policies implemented. In cost-effective mitigation pathways, the energy supply sector typically reaches net zero CO₂ before the economy as a whole, while the demand sectors reach net zero CO₂ later, if ever (*high confidence*). (Figure TS.10) {3.4}

Pathways limiting warming to 2°C (>67%) or 1.5°C involve substantial reductions in fossil fuel consumption and a near elimination of coal use without CCS (*high confidence*). These pathways show an increase in low-carbon energy, with 88% (69–97%) of primary energy coming from low-carbon sources by 2100. {3.4}

16 Reductions greater than 100% in energy supply and AFOLU indicate that these sectors would become carbon sinks.

Net zero CO₂ and net zero GHG emissions are possible through different modelled mitigation pathways.

Figure TS.10 (continued): Mitigation pathways that limit warming to 1.5°C, or 2°C, involve deep, rapid and sustained emissions reductions. Net zero CO₂ and net zero GHG emissions are possible through different mitigation portfolios. Panels (a) and (b) show the development of global GHG and CO₂ emissions in modelled global pathways (upper sub-panels) and the associated timing of when GHG and CO₂ emissions reach net zero (lower sub-panels). Panels (c) and (d) show the development of global CH₄ and N₂O emissions, respectively. Coloured ranges denote the 5th to 95th percentile across pathways. The red ranges depict emissions pathways assuming policies that were implemented by the end of 2020 and pathways assuming implementation of NDCs (announced prior to COP26). Ranges of modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot are shown in light blue (category C1) and pathways that limit warming to 2°C (>67%) are shown in light purple (category C3). The grey range comprises all assessed pathways (C1–C8) from the 5th percentile of the lowest warming category (C1) to the 95th percentile of the highest warming category (C8). The modelled pathway ranges are compared to the emissions from two pathways illustrative of high emissions (CurPol and ModAct) and five IMPs: IMP-LD, IMP-Ren, IMP-SP, IMP-Neg and IMP-GS. Emissions are harmonised to the same 2015 base year. The vertical error bars in 2015 show the 5–95th percentile uncertainty range of the non-harmonised emissions across the pathways, and the uncertainty range, and median value, in emission estimates for 2015 and 2019. The vertical error bars in 2030 (panel a) depict the assessed range of the NDCs, as announced prior to COP26.¹⁷ Panel (e) shows the sectoral contributions of CO₂ and non-CO₂ emissions sources and sinks at the time when net zero CO₂ emissions are reached in the IMPs. Positive and negative emissions for different IMPs are compared to the GHG emissions from the year 2019. Energy supply (neg.) includes BECCS and DACCS. DACCS features in only two of the five IMPs (IMP-REN and IMP-GS) and contributes <1% and 64%, respectively, to the net negative emissions in Energy Supply (neg.). Panel (f) shows the contribution of different sectors and sources to the emissions reductions from a 2019 baseline for reaching net zero GHG emissions. Bars denote the median emissions reductions for all pathways that reach net zero GHG emissions. The whiskers indicate the p5–p95 range. The contributions of the service sectors (transport, buildings, industry) are split into direct (demand-side) as well as indirect (supply-side) CO₂ emissions reductions. Direct emissions represent demand-side emissions due to the fuel use in the respective demand sector. Indirect emissions represent upstream emissions due to industrial processes and energy conversion, transmission and distribution. In addition, the contributions from the LULUCF sector and reductions from non-CO₂ emissions sources (green and grey bars) are displayed. {3.3, 3.4}

Stringent emissions reductions at the level required for 2°C or 1.5°C are achieved through the increased electrification of buildings, transport, and industry, consequently all pathways entail increased electricity generation (high confidence). Nearly all electricity in pathways limiting warming to 2°C (>67%) or 1.5°C (>50%) is also from low- or no-carbon technologies, with different shares across pathways of: nuclear, biomass, non-biomass renewables, and fossil fuels in combination with CCS. {3.4}

Measures required to limit warming to 2°C (>67%) or below can result in large-scale transformation of the land surface (high confidence). These pathways are projected to reach net zero CO₂ emissions in the AFOLU sector between the 2020s and 2070.

¹⁷ NDCs announced prior to COP26 refer to the most recent Nationally Determined Contributions submitted to the UNFCCC up to the literature cut-off date of this report, 11 October 2021, and revised NDCs announced by China, Japan and the Republic of Korea prior to October 2021 but only submitted thereafter. 25 NDC updates were submitted between 12 October 2021 and the start of COP26.

Pathways limiting warming to 1.5°C with no or limited overshoot show an increase in forest cover of about 322 (–67 to 890) million ha in 2050 (*high confidence*). In these pathways the cropland area to supply biomass for bioenergy (including bioenergy with carbon capture and storage (BECCS)) is around 199 (56–482) million ha in 2050. The use of bioenergy can lead to either increased or reduced emissions, depending on the scale of deployment, conversion technology, fuel displaced, and how, and where, the biomass is produced (*high confidence*). {3.4}

Pathways limiting warming to 2°C (>67%) or 1.5°C (>50%) require some amount of CDR to compensate for residual GHG emissions, even alongside substantial direct emissions reductions are achieved in all sectors and regions (*high confidence*). CDR deployment in pathways serves multiple purposes: accelerating the pace of emissions reductions, offsetting residual emissions, and creating the option for net negative CO₂ emissions in case temperature reductions need to be achieved in the long term (*high confidence*). CDR options in pathways are mostly limited to BECCS, afforestation and direct air CO₂ capture and storage (DACCS). CDR through some measures in AFOLU can be maintained for decades but not over the very long term because these sinks will ultimately saturate (*high confidence*). {3.4}

Mitigation pathways show reductions in energy demand, relative to reference scenarios that assume continuation of current policies, through a diverse set of demand-side interventions (*high confidence*). Bottom-up and non-IAM studies show significant potential for demand-side mitigation. A stronger emphasis on demand-side mitigation implies less dependence on CDR and, consequently, reduced pressure on land and biodiversity. {3.4, 3.7}

Limiting warming requires shifting energy investments away from fossil fuels and towards low-carbon technologies (*high confidence*). The bulk of investments are needed in medium- and low-income regions. Investment needs in the electricity sector are on average 2.3 trillion USD2015 yr^{–1} over 2023–2052 for pathways limiting temperature to 1.5°C (>50%) with no or limited overshoot, and 1.7 trillion USD2015 yr^{–1} for pathways limiting warming to 2°C (>67%). {3.6.1}

Pathways that avoid overshoot of 2°C (>67%) warming require more rapid near-term transformations and are associated with higher upfront transition costs, but at the same time bring long-term gains for the economy as well as earlier benefits in avoided climate change impacts (*high confidence*). This conclusion is independent of the discount rate applied, though the modelled cost-optimal balance of mitigation action over time does depend on the discount rate. Lower discount rates favour earlier mitigation, reducing reliance on CDR and temperature overshoot. {3.6.1, 3.8}

Mitigation pathways that limit warming to 2°C (>67%) entail losses in global GDP with respect to reference scenarios of between 1.3% and 2.7% in 2050. In pathways limiting warming to 1.5°C (>50%) with no or limited overshoot, losses are between 2.6% and 4.2%. These estimates do not account for the economic benefits of avoided climate change impacts (*medium confidence*). In mitigation pathways limiting warming to 2°C (>67%), marginal abatement costs of carbon are about 90 (60–120) USD2015 tCO₂ in 2030 and about 210 (140–340) USD2015/tCO₂ in 2050. This compares with about 220 (170–290) USD2015 tCO₂ in 2030 and about 630 (430–990) USD2015 tCO₂ in 2050¹⁸ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. Reference scenarios, in the AR6 scenarios database, describe possible emission trajectories in the absence of new stringent climate policies. Reference scenarios have a broad range depending on socio-economic assumptions and model characteristics. {3.2.1, 3.6.1}

The global benefits of pathways limiting warming to 2°C (>67%) outweigh global mitigation costs over the 21st century, if aggregated economic impacts of climate change are at the moderate to high end of the assessed range, and a weight consistent with economic theory is given to economic impacts over the long term. This holds true even without accounting for benefits in other sustainable development dimensions or non-market damages from climate change (*medium confidence*). The aggregate global economic repercussions of mitigation pathways include: the macroeconomic impacts of investments in low-carbon solutions and structural changes away from emitting activities; co-benefits and adverse side effects of mitigation; avoided climate change impacts; and reduced adaptation costs. Existing quantifications of the global aggregate economic impacts show a strong dependence on socio-economic development conditions, as these shape exposure and vulnerability and adaptation opportunities and responses. Avoided impacts for poorer households and poorer countries represent a smaller share in aggregate economic quantifications expressed in GDP or monetary terms, whereas their well-being and welfare effects are comparatively larger. When aggregate economic benefits from avoided climate change impacts are accounted for, mitigation is a welfare-enhancing strategy (*high confidence*). {3.6.2}

The economic benefits on human health from air quality improvement arising from mitigation action can be of the same order of magnitude as mitigation costs, and potentially even larger (*medium confidence*). {3.6.3}

Differences in aggregate employment between mitigation pathways and reference scenarios are relatively small, although there may be substantial reallocations across sectors, with job creation in some sectors and job losses in others (*medium confidence*). The net employment effect (and whether employment increases or decreases) depends on the scenario assumptions, modelling framework, and modelled policy design. Mitigation has implications for employment through multiple channels, each of which impacts geographies, sectors and skill categories differently. {3.6.4}

18 Numbers in parentheses represent the interquartile range of the scenario samples.

The economic repercussions of mitigation vary widely across regions and households, depending on policy design and the level of international cooperation (*high confidence*). Delayed global cooperation increases policy costs across regions, especially in those that are relatively carbon intensive at present (*high confidence*). Pathways with uniform carbon values show higher mitigation costs in more carbon-intensive regions, in fossil fuel-exporting regions, and in poorer regions (*high confidence*). Aggregate quantifications

expressed in GDP or monetary terms undervalue the economic effects on households in poorer countries; the actual effects on welfare and well-being are comparatively larger (*high confidence*). Mitigation at the speed and scale required to limit warming to 2°C (>67%) or below implies deep economic and structural changes, thereby raising multiple types of distributional concerns across regions, income classes, and sectors (*high confidence*). (Box TS.7) {3.6.1, 3.6.4}

Box TS.6 | Understanding Net Zero CO₂ and Net Zero GHG Emissions

Reaching net zero CO₂ emissions¹⁹ globally along with reductions in other GHG emissions is necessary to halt global warming at any level. At the point of net zero, the amount of CO₂ human activity is putting into the atmosphere equals the amount of CO₂ human activity is removing from the atmosphere. Reaching and sustaining net zero CO₂ emissions globally would stabilise CO₂-induced warming. Moving to net negative CO₂ emissions globally would reduce peak cumulative net CO₂ emissions – which occurs at the time of reaching net zero CO₂ emissions – and lead to a peak and decline in CO₂-induced warming. {Cross-Chapter Box 3 in Chapter 3}

Reaching net zero CO₂ emissions sooner can reduce cumulative CO₂ emissions and result in less human-induced global warming. Overall human-induced warming depends not only on CO₂ emissions but also on the contribution from other anthropogenic climate forcers, including aerosols and other GHGs (e.g., CH₄ and F-gases). To halt total human-induced warming, emissions of other GHGs, in particular CH₄, need to be strongly reduced.

In the AR6 scenario database, global emissions pathways limiting warming to 1.5°C (>50%) with no or limited overshoot reach net zero CO₂ emissions between 2050–2055 (2035–2070) (median and 5–95th percentile ranges; 100% of pathways); pathways limiting warming to 2°C (>67%) reach net zero CO₂ emissions between 2070–2075 (2055–...) (median and 5–95th percentile ranges; 90% of pathways). This is later than assessed in the AR6 SR1.5 primarily due to more pathways in the literature that approach net zero CO₂ emissions more gradually after a rapid decline of emissions until 2040. (Box TS.6, Figure 1)

It does not mean that the world has more time for emissions reductions while still limiting warming to 1.5°C than reported in the SR1.5. It only means that the exact timing of reaching net zero CO₂ after a steep decline of CO₂ emissions until 2040 can show some variation. The SR1.5 median value of 2050 is still close to the middle of the current range. If emissions are reduced less rapidly in the period up to 2030, an earlier net zero year is needed.

Reaching net zero GHG emissions requires net negative CO₂ emissions to balance residual CH₄, N₂O and F-gas emissions. If achieved globally, net zero GHG emissions would reduce global warming from an earlier peak. Around half global emission pathways limiting warming to 1.5°C (>50%), and a third of pathways limiting warming to 2°C (>67%), reach net zero GHG emissions (based on GWP100) in the second half of the century, around 10 to 40 years later than net zero CO₂ emissions. They show warming being halted at some peak value followed by a gradual decline towards the end of the century. The remainder of the pathways do not reach net zero GHG emissions during the 21st century and show little decline of warming after it stabilised.

Global net zero CO₂ or GHG emissions can be achieved even while some sectors and regions continue to be net emitters, provided that others achieve net GHG removal. Sectors and regions have different potentials and costs to achieve net zero or even net GHG removal. The adoption and implementation of net zero emission targets by countries and regions depends on multiple factors, including equity and capacity criteria and international and cross-sectoral mechanisms to balance emissions and removals. The formulation of net zero pathways by countries will benefit from clarity on scope, plans of action, and fairness. Achieving net zero emission targets relies on policies, institutions and milestones against which to track progress.

19 In this assessment the terms *net zero CO₂ emissions* and *carbon neutrality* have different meanings and are only equivalent at the global scale. At the scale of regions, or sectors, each term applies different system boundaries. This is also the case for the related terms *net zero GHG* and *GHG neutrality*. {Cross-Chapter Box 3 in Chapter 3}

Box TS.6 (continued)

Box TS.6, Figure 1 | CO₂ Emissions (panel (a)) and temperature change (panel (b)) of three alternative pathways limiting warming to 2°C (>67%) and reaching net zero CO₂ emissions at different points in time. Limiting warming to a specific level can be consistent with a range of dates when net zero CO₂ emissions need to be achieved. This difference in the date of net zero CO₂ emissions reflects the different emissions profiles that are possible while staying within a specific carbon budget and the associated warming limit. Shifting the year of net zero to a later point in time (>2050), however, requires more rapid and deeper near-term emissions reductions (in 2030 and 2040) if warming is to be limited to the same level. Funnels show pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (light blue) and limiting warming to 2°C (>67%) (beige).

Box TS.7 | The Long-term Economic Benefits of Mitigation from Avoided Climate Change Impacts

Integrated studies use either a cost-effectiveness analysis (CEA) approach (minimising the total mitigation costs of achieving a given policy goal) or a cost-benefit analysis (CBA) approach (balancing the cost and benefits of climate action). In the majority of studies that have produced the body of work on the cost of mitigation assessed in this report, a CEA approach is adopted, and the feedbacks of climate change impacts on the economic development pathways are not accounted for. This omission of climate impacts leads to overly optimistic economic projections in the reference scenarios, in particular in reference scenarios with no or limited mitigation action where the extent of global warming is the greatest. Mitigation cost estimates computed against no or limited policy reference scenarios therefore omit economic benefits brought by avoided climate change impact along mitigation pathways. {1.7, 3.6.1}

The difference in aggregate economic impacts from climate change between two given temperature levels represents the aggregate economic benefits arising from avoided climate change impacts due to mitigation action. Estimates of these benefits vary widely, depending on the methodology used and impacts included, as well as on assumed socio-economic development conditions, which shape exposure and vulnerability. The aggregate economic benefits of avoiding climate impacts increase with the stringency of the mitigation. Global economic impact studies with regional estimates find large differences across regions, with developing and transitional economies typically more vulnerable. Furthermore, avoided impacts for poorer households and poorer countries represent a smaller share in aggregate quantifications expressed in GDP terms or monetary terms, compared to their influence on well-being and welfare (*high confidence*). {3.6.2, Cross-Working Group Box 1 in Chapter 3}

Box TS.7 (continued)

CBA analysis and CBA integrated assessment models (IAMs) remain limited in their ability to represent all damages from climate change, including non-monetary damages, and capture the uncertain and heterogeneous nature of damages and the risk of catastrophic damages, such that other lines of evidence should be considered in decision-making. However, emerging evidence suggests that, even without accounting for co-benefits of mitigation on other sustainable development dimensions, the global benefits of pathways limiting warming to 2°C (>67%) outweigh global mitigation costs over the 21st century (*medium confidence*). Depending on the study, the reason for this result lies in assumptions of economic damages from climate change in the higher end of available estimates, in the consideration of risks of tipping points or damages to natural capital and non-market goods, or in the combination of updated representations of carbon cycle and climate modules, updated damage estimates and updated representations of economic and mitigation dynamics. In the studies that perform a sensitivity analysis, this result is found to be robust to a wide range of assumptions on social preferences (in particular on inequality aversion and pure rate of time preference), and holds except if assumptions of economic damages from climate change are in the lower end of available estimates and the pure rate of time preference is in the higher range of values usually considered (typically above 1.5%). However, although such pathways bring overall net benefits over time (in terms of aggregate discounted present value), they involve distributional consequences between and within generations. {3.6.2}

TS.5 Mitigation Responses in Sectors and Systems

Chapters 5 to 12 assess recent advances in knowledge in individual sectors and systems. These chapters – *Energy* (Chapter 6), *Urban and Other Settlements* (Chapter 8), *Transport* (Chapter 10), *Buildings* (Chapter 9), *Industry* (Chapter 11), and *Agriculture, Forestry and Other Land Use (AFOLU)* (Chapter 7) – correspond broadly to the IPCC National Greenhouse Gas Inventory reporting categories and build on similar chapters in previous WGIII reports. Chapters 5 and 12 tie together the cross-sectoral aspects of this group of chapters including the assessment of costs and potentials, demand-side aspects of mitigation, and carbon dioxide removal (CDR).

TS.5.1 Energy

A broad-based approach to deploying energy-sector mitigation options can reduce emissions over the next ten years and set the stage for still deeper reductions beyond 2030 (*high confidence*). There are substantial, cost-effective opportunities to reduce emissions rapidly, including in electricity generation, but near-term reductions will not be sufficient to limit warming to 2°C (>67%) or limit warming to 1.5°C (>50%) with no or limited overshoot. {6.4, 6.6, 6.7}

Warming cannot be limited to 2°C or 1.5°C without rapid and deep reductions in energy system CO₂ and GHG emissions (*high confidence*). In scenarios limiting warming to 1.5°C (>50%) with no or limited overshoot (*likely* below 2°C), net energy system CO₂ emissions fall by 87–97% (interquartile range 60–79%) in 2050. In 2030, in scenarios limiting warming to 1.5°C with no or limited overshoot, net CO₂ and GHG emissions fall by 35–51% and 38–52% respectively. In scenarios limiting warming to 1.5°C with no or limited overshoot (*likely* below 2°C), net electricity sector CO₂ emissions reach zero globally between 2045 and 2055 (2050 and 2080) (*high confidence*). {6.7}

Limiting warming to 2°C or 1.5°C will require substantial energy system changes over the next 30 years. This includes reduced fossil fuel consumption, increased production from low- and zero-carbon energy sources, and increased use of electricity and alternative energy carriers (*high confidence*). Coal consumption without CCS falls by 67–82% (interquartile range) in 2030 in scenarios limiting warming to 1.5°C with no or limited overshoot. Oil and gas consumption fall more slowly. Low-carbon sources produce 93–97% of global electricity by 2050 in scenarios that limit warming to 2°C (>67%) or below. In scenarios limiting warming to 1.5°C with no or limited overshoot (*likely* below 2°C), electricity supplies 48–58% (36–47%) of final energy in 2050, up from 20% in 2019. {6.7}

Net zero energy systems will share common characteristics, but the approach in every country will depend on national circumstances (*high confidence*). Common characteristics of net-zero energy systems will include: (i) electricity systems that produce no net CO₂ or remove CO₂ from the atmosphere; (ii) widespread electrification of end uses, including light-duty transport, space heating, and cooking; (iii) substantially lower use of fossil fuels

than today; (iv) use of alternative energy carriers such as hydrogen, bioenergy, and ammonia to substitute for fossil fuels in sectors less amenable to electrification; (v) more efficient use of energy than today; (vi) greater energy system integration across regions and across components of the energy system; and (vii) use of CO₂ removal including DACCS and BECCS to offset residual emissions. {6.6}

Energy demands and energy sector emissions have continued to rise (*high confidence*). From 2015 to 2019, global final energy consumption grew by 6.6%, CO₂ emissions from the global energy system grew by 4.6%, and total GHG emissions from energy supply rose by 2.7%. Fugitive CH₄ emissions from oil, gas, and coal, accounted for 18% of GHG emissions in 2019. Coal electricity capacity grew by 7.6% between 2015 and 2019, as new builds in some countries offset declines in others. Total consumption of oil and oil products increased by 5%, and natural gas consumption grew by 15%. Declining energy intensity in almost all regions has been balanced by increased energy consumption. {6.3}

The unit costs for several key energy system mitigation options have dropped rapidly over the last five years, notably solar PV, wind power, and batteries (*high confidence*). From 2015 to 2020, the costs of electricity from PV and wind dropped 56% and 45%, respectively, and battery prices dropped by 64%. Electricity from PV and wind is now cheaper than electricity from fossil sources in many regions, electric vehicles are increasingly competitive with internal combustion engines, and large-scale battery storage on electricity grids is increasingly viable. (Figure TS.7) {6.3, 6.4}

Global wind and solar PV capacity and generation have increased rapidly driven by policy, societal pressure to limit fossil generation, low interest rates, and cost reductions (*high confidence*). Solar PV grew by 170% (to 680 TWh); wind grew by 70% (to 1420 TWh) from 2015 to 2019. Solar PV and wind together accounted for 21% of total low-carbon electricity generation and 8% of total electricity generation in 2019. Nuclear generation grew 9% between 2015 and 2019 and accounted for 10% of total generation in 2019 (2790 TWh); hydro-electric power grew by 10% and accounted for 16% (4290 TWh) of total generation. In total, low- and zero-carbon electricity generation technologies produced 37% of global electricity in 2019. {6.3, 6.4}

If investments in coal and other fossil infrastructure continue, energy systems will be locked-in to higher emissions, making it harder to limit warming to 2°C or 1.5°C (*high confidence*). Many aspects of the energy system – physical infrastructure; institutions, laws, and regulations; and behaviour – are resistant to change or take many years to change. New investments in coal-fired electricity without CCS are inconsistent with limiting warming to well below 2°C. {6.3, 6.7}

Limiting warming to 2°C or 1.5°C will strand fossil-related assets, including fossil infrastructure and unburned fossil fuel resources (*high confidence*). The economic impacts of stranded assets could amount to trillions of dollars. Coal assets are most vulnerable over the coming decade; oil and gas assets are more vulnerable toward mid-century. CCS can allow fossil fuels to be used longer, reducing potential stranded assets. (Box TS.8) {6.7}

Box TS.8 | Stranded Assets

Limiting warming to 2°C or 1.5°C is expected to result in the ‘stranding’ of carbon-intensive assets. Stranded assets can be broadly defined as assets which ‘suffer from unanticipated or premature write-offs, downward revaluations or conversion to liabilities’. Climate policies, other policies and regulations, innovation in competing technologies, and shifts in fuel prices could all lead to stranded assets. The loss of wealth from stranded assets would create risks for financial market stability and reduce fiscal revenue for hydrocarbon-dependent economies, which in turn could affect macroeconomic stability and the prospects for a Just Transition. (Box TS.4) {6.7, 15.6, Chapter 17}

Two types of assets are at risk of being stranded: (i) in-ground fossil resources and (ii) human-made capital assets (e.g., power plants and cars). About 30% of oil, 50% of gas, and 80% of coal reserves will remain unburnable if warming is limited to 2°C. {6.7, Box 6.11}

Practically all long-lived technologies and investments that cannot be adapted to low-carbon and zero-emission modes could face stranding under climate policy – depending on their current age and expected lifetimes. Scenario evidence suggests that without carbon capture, the worldwide fleet of coal- and gas power plants would need to retire about 23 and 17 years earlier than expected lifetimes, respectively, in order to limit global warming to 1.5°C and 2°C {2.7}. Blast furnaces and cement factories without CCS {11.4}, new fleets of airplanes and internal combustion engine vehicles {10.4, 10.5}, and new urban infrastructures adapted to sprawl and motorisation may also be stranded. {Chapter 8; Box 10.1}

Many countries, businesses, and individuals stand to lose wealth from stranded assets. Countries, businesses, and individuals may therefore desire to keep assets in operation even if financial, social, or environmental concerns call for retirement. This creates political economic risks, including actions by asset owners to hinder climate policy reform {6.7; Box 6.11}. It will be easier to retire these assets if the risks are communicated, if sustainability reporting is mandated and enforced, and if corporations are protected with arrangements that shield them from short-term shareholder value maximisation.

Without early retirements, or reductions in utilisation, the current fossil infrastructure will emit more GHGs than is compatible with limiting warming to 1.5°C {2.7}. Including the pipeline of planned investments would push these future emissions into the uncertainty range of 2°C carbon budgets {2.7}. Continuing to build new coal-fired power plants and other fossil infrastructure will increase future transition costs and may jeopardise efforts to limit warming to 2°C (>67%) or 1.5°C with no or limited overshoot. One study has estimated that USD11.8 trillion in current assets will need to be stranded by 2050 for a 2°C world; further delaying action for another 10 years would result in an additional USD7.7 trillion in stranded assets by 2050. {15.5.2}

Experience from past stranding indicates that compensation for the devaluation costs of private-sector stakeholders by the public sector is common. Limiting new investments in fossil technologies hence also reduces public finance risks in the long term. {15.6.3}

A low-carbon energy transition will shift investment patterns and create new economic opportunities (*high confidence*). Total energy investment needs will rise, relative to today, over the next decades, if warming is limited to 2°C or lower (>67%), or if warming is limited to 1.5°C (>50%) with no or limited overshoot. These increases will be far less pronounced, however, than the reallocations of investment flows that are anticipated across subsectors, namely from fossil fuels (extraction, conversion, and electricity generation) without CCS and toward renewables, nuclear power, CCS, electricity networks and storage, and end-use energy efficiency. A significant and growing share of investments between now and 2050 will be made in emerging economies, particularly in Asia. {6.7}

Climate change will affect many future local and national low-carbon energy systems. The impacts, however, are uncertain, particularly at the regional scale (*high confidence*). Climate change will alter hydropower production, bioenergy and agricultural yields, thermal power plant efficiencies, and demands for heating and cooling, and it will directly impact power system infrastructure. Climate change will not affect wind and solar resources to the extent that it would compromise their ability to reduce emissions. {6.5}

Electricity systems powered predominantly by renewables will be increasingly viable over the coming decades, but it will be challenging to supply the entire energy system with renewable energy (*high confidence*). Large shares of variable solar PV and wind power can be incorporated in electricity grids through batteries, hydrogen, and other forms of storage; transmission; flexible non-renewable generation; advanced controls; and greater demand-side responses. Because some applications (e.g., aviation) are not currently amenable to electrification, it is anticipated that 100% renewable energy systems will need to include alternative fuels such as hydrogen or biofuels. Economic, regulatory, social, and operational challenges increase with higher shares of renewable electricity and energy. The ability to overcome these challenges in practice is not fully understood. (Box TS.9) {6.6}

Box TS.9 | The Transformation in Energy Carriers: Electrification and Hydrogen

To use energy, it must be ‘carried’ from where it was produced – at a power plant, for example, or a refinery, or a coal mine – to where it is used. As countries reduce CO₂ emissions, they will need to switch from gasoline and other petroleum-based fuels, natural gas, coal, and electricity produced from these fossil fuels to energy carriers with little or no carbon footprint. An important question is which new energy carriers will emerge to support low-carbon transitions.

Low-carbon energy systems are expected to rely heavily on end-use electrification, where electricity produced with low GHG emissions is used for building and industrial heating, transport and other applications that rely heavily on fossil fuels at present. But not all end-uses are expected to be commercially electrifiable in the short to medium term {11.3.5}, and many will require low GHG liquid and gaseous fuels, that is, hydrogen, ammonia, and biogenic and synthetic low GHG hydrocarbons made from low GHG hydrogen, oxygen and carbon sources (the latter from CCU,²⁰ biomass, or direct air capture {11.3.6}). The future role of hydrogen and hydrogen derivatives will depend on how quickly and how far production technology improves, that is, from electrolysis (‘green’), biogasification, and fossil fuel reforming with CCS (‘blue’) sources. As a general rule, and across all sectors, it is more efficient to use electricity directly and avoid the progressively larger conversion losses from producing hydrogen, ammonia, or constructed low GHG hydrocarbons. What hydrogen does do, however, is add time and space option value to electricity produced using variable clean sources, for use as hydrogen, as stored future electricity via a fuel cell or turbine, or as an industrial feedstock. Furthermore, electrification and hydrogen involve a symbiotic range of general-purpose technologies, such as electric motors, power electronics, heat pumps, batteries, electrolysis, fuel cells, and so on, that have different applications across sectors but cumulative economies of innovation and production scale benefits. Finally, neither electrification nor hydrogen produce local air pollutants at point of end-use.

For almost 140 years we have primarily produced electricity by burning coal, oil, and gas to drive steam turbines connected to electricity generators. When switching to low-carbon energy sources – renewable sources, nuclear power, and fossil or bioenergy with CCS – electricity is expected to become a more pervasive energy carrier. Electricity is a versatile energy carrier, with much higher end-use efficiencies than fuels, and it can be used directly to avoid conversion losses.

An increasing reliance on electricity from variable renewable sources, notably wind and solar power, disrupts old concepts and makes many existing guidelines obsolete for power system planning, for example, that specific generation types are needed for baseload, intermediate load, and peak load to follow and meet demand. In future power systems with high shares of variable electricity from renewable sources, system planning and markets will focus more on demand flexibility, grid infrastructure and interconnections, storage on various timelines (on the minute, hourly, overnight and seasonal scale), and increased coupling between the energy sector and the building, transport and industrial sectors. This shifts the focus to energy systems that can handle variable supply rather than always follow demand. Hydrogen may prove valuable to improve the resilience of electricity systems with high penetration of variable renewable electricity. Flexible hydrogen electrolysis, hydrogen power plants and long-duration hydrogen storage may all improve resilience. Electricity-to-hydrogen-to-electricity round-trip efficiencies are projected to reach up to 50% by 2030. {6.4.3}

Electrification is expected to be the dominant strategy in buildings as electricity is increasingly used for heating and for cooking. Electricity will help to integrate renewable energy into buildings and will also lead to more flexible demand for heating, cooling, and electricity. District heating and cooling offers potential for demand flexibility through energy storage and supply flexibility through cogeneration. Heat pumps are increasingly used in buildings and industry for heating and cooling {9.3.3, Box 9.3}. The ease of switching to electricity means that hydrogen is not expected to be a dominant pathway for buildings {Box 9.6}. Using electricity directly for heating, cooling and other building energy demand is more efficient than using hydrogen as a fuel, for example, in boilers or fuel cells. In addition, electricity distribution is already well developed in many regions compared to essentially non-existent hydrogen infrastructure, except for a few chemicals industry pipelines. At the same time, hydrogen could potentially be used for on-site storage should technology advance sufficiently.

20 Carbon dioxide capture and utilisation (CCU) refers to a process in which CO₂ is captured and the carbon is then used in a product. The climate effect of CCU depends on the product lifetime, the product it displaces, and the CO₂ source (fossil, biomass or atmosphere). CCU is sometimes referred to as carbon dioxide capture and use, or carbon capture and utilisation.

Box TS.9 (continued)

Electrification is already occurring in several modes of personal and light-freight transport, and vehicle-to-grid solutions for flexibility have been extensively explored in the literature and small-scale pilots. The role of hydrogen in transport depends on how far technology develops. Batteries are currently a more attractive option than hydrogen and fuel cells for light-duty vehicles. Hydrogen and hydrogen-derived synthetic fuels, such as ammonia and methanol, may have a more important role in heavy vehicles, shipping, and aviation {10.3}. Current transport of fossil fuels may be replaced by future transport of hydrogen and hydrogen carriers such as ammonia and methanol, or energy-intensive basic materials processed with hydrogen (e.g., reduced iron) in regions with bountiful renewable resources. {Box 11.1}

Both light and heavy industry are potentially large and flexible users of electricity for both final energy use (e.g., directly and using heat pumps in light industry) and for feedstocks (e.g., hydrogen for steel-making and chemicals). For example, industrial process heat demand, ranging from below 100°C to above 1000°C, can be met through a wide range of electrically powered technologies instead of using fuels. Future demand for hydrogen (e.g., for nitrogen fertiliser or as a reduction agent in steel production) also offers electricity-demand flexibility for electrolysis through hydrogen storage and flexible production cycles {11.3.5}. The main use of hydrogen and hydrogen carriers in industry is expected to be as feedstock (e.g., for ammonia and organic chemicals) rather than for energy as industrial electrification increases.

TS

Multiple energy supply options are available to reduce emissions over the next decade (*high confidence*). Nuclear power and hydropower are already established technologies. Solar PV and wind are now cheaper than fossil-generated electricity in many locations. Bioenergy accounts for about a tenth of global primary energy. Carbon capture is widely used in the oil and gas industry, with early applications in electricity production and biofuels. It will not be possible to widely deploy all of these and other options without efforts to address the geophysical, environmental-ecological, economic, technological, socio-cultural, and institutional factors

that can facilitate or hinder their implementation (*high confidence*). (Figures TS.11 and TS.31) {6.4}

Enhanced integration across energy system sectors and across scales will lower costs and facilitate low-carbon energy system transitions (*high confidence*). Greater integration between the electricity sector and end-use sectors can facilitate integration of variable renewable energy options. Energy systems can be integrated across district, regional, national, and international scales (*high confidence*). {6.4, 6.6}

Figure TS.11 | Global energy flows within the 2019 global energy system (top panel) and within two illustrative future, net-zero CO₂ emissions global energy system (bottom panels).

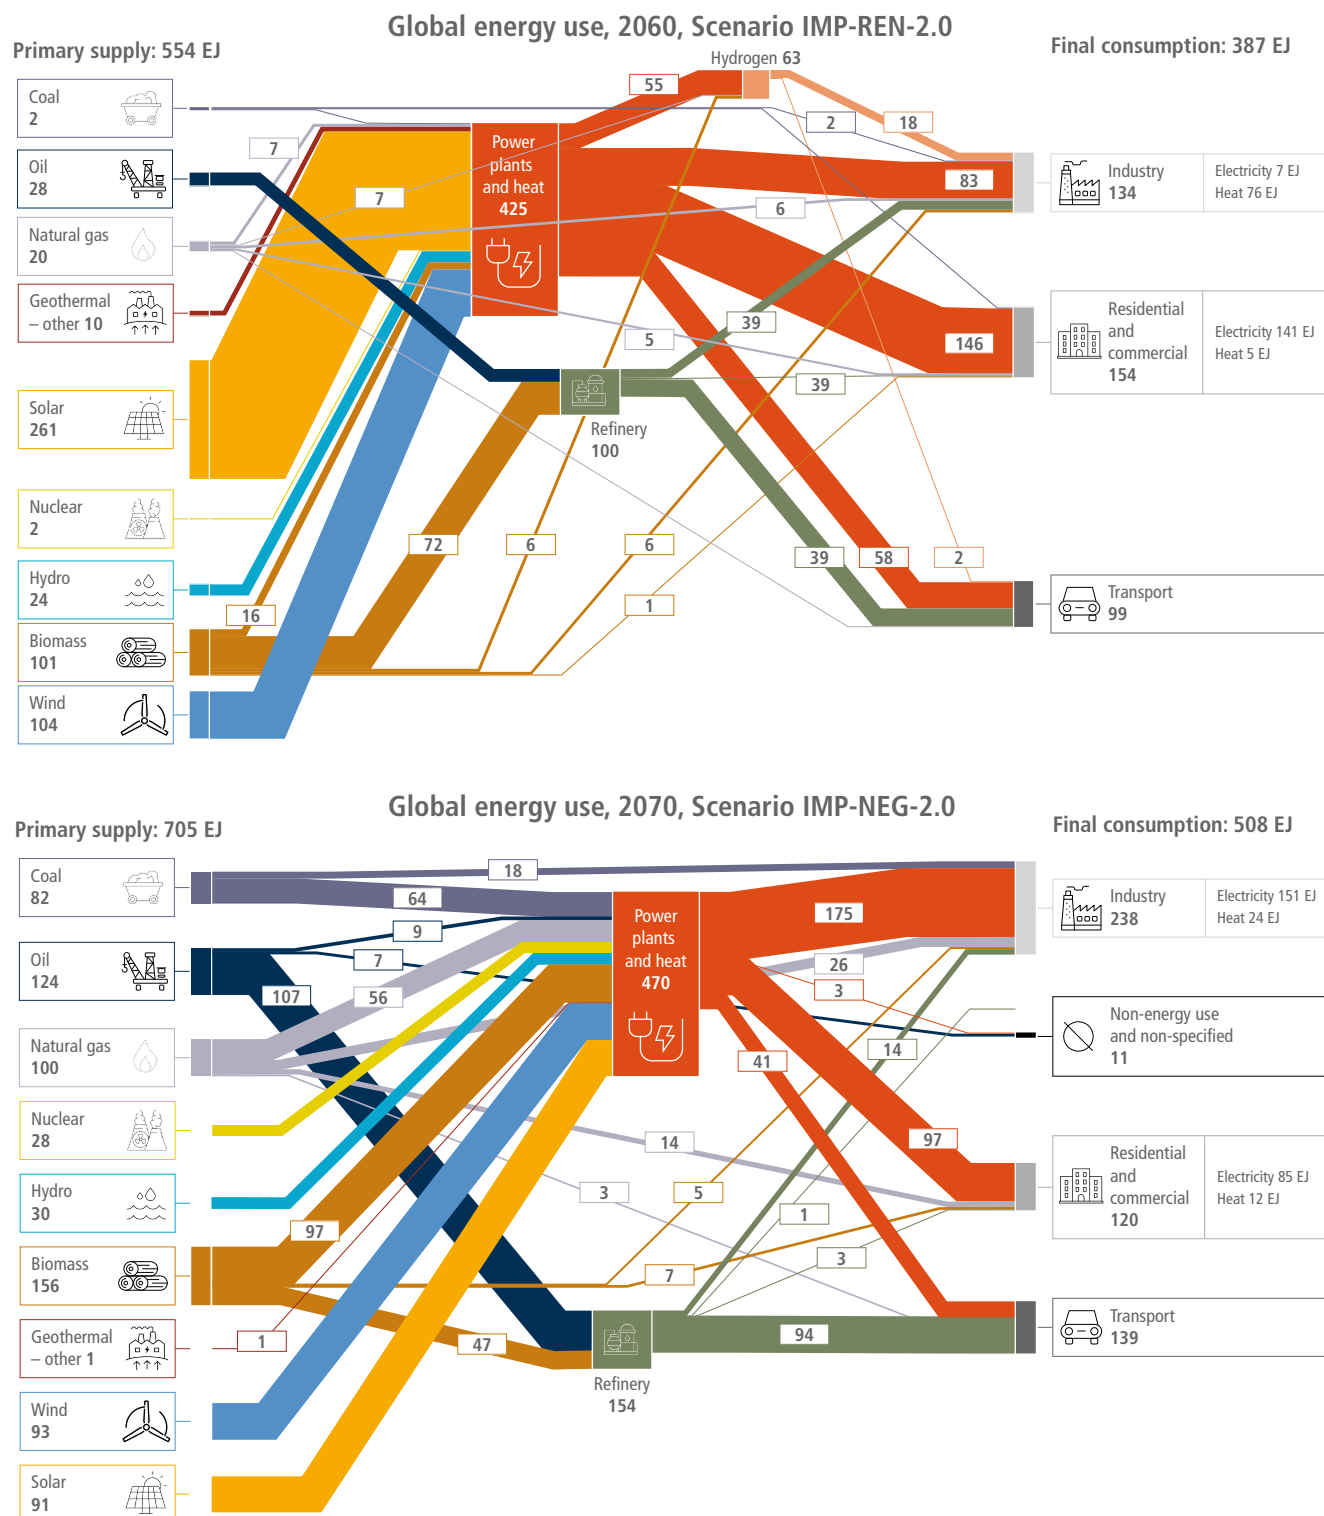

Figure TS.11 continued: Global energy flows within the 2019 global energy system (top panel) and within two illustrative future, net-zero CO₂ emissions global energy system (bottom panels). Source: IEA, AR6 Scenarios Database. Flows below 1 EJ are not represented. The illustrative net-zero scenarios correspond to the years in which net energy system CO₂ emissions reach zero – 2045 in IMP-Ren and 2060 in IMP-Neg-2.0. Source: data from IMP-Ren: Luderer et al.(2022); IMP-Neg-2.0: Riahi, K. et al. 2021.

The viable speed and scope of a low-carbon energy system transition will depend on how well it can support SDGs and other societal objectives (*high confidence*). Energy systems are linked to a range of societal objectives, including energy access, air and water pollution, health, energy security, water security, food security, economic prosperity, international competitiveness, and employment. These linkages and their importance vary among regions. Energy-sector mitigation and efforts to achieve SDGs generally support one another, though there are important region-specific exceptions (*high confidence*). (Figure TS.29) {6.1, 6.7}

The economic outcomes of low-carbon transitions in some sectors and regions may be on par with, or superior to those of an emissions-intensive future (*high confidence*). Cost reductions in key technologies, particularly in electricity and light-duty transport, have increased the economic attractiveness of near-term low-carbon transitions. Long-term mitigation costs are not well understood and depend on policy design and implementation, and the future costs and availability of technologies. Advances in low-carbon energy resources and carriers such as next-generation biofuels, hydrogen produced from electrolysis, synthetic fuels, and carbon-neutral ammonia would substantially improve the economics of net zero energy systems (*medium confidence*). {6.4, 6.7}

TS.5.2 Urban Systems and Other Settlements

Although urbanisation is a global trend often associated with increased incomes and higher consumption, the growing concentration of people and activities is an opportunity to increase resource efficiency and decarbonise at scale (*very high confidence*). The same urbanisation level can have large variations in per-capita urban carbon emissions. For most regions, per-capita urban emissions are lower than per-capita national emissions (excluding aviation, shipping and biogenic sources) (*very high confidence*). {8.1.4, 8.3.3, 8.4, Box 8.1}

Most future urban population growth will occur in developing countries, where per-capita emissions are currently low, but are expected to increase with the construction and use of new infrastructure, and the built environment, and changes in incomes and lifestyles (*very high confidence*). The drivers of urban GHG emissions are complex and include an interplay of population size, income, state of urbanisation, and how cities are laid out (i.e., urban form). How new cities and towns are designed, constructed, managed, and powered will lock-in behaviour, lifestyles, and future urban GHG emissions. Urban strategies can improve well-being while minimising impact on GHG emissions. However, urbanisation can result in increased global GHG emissions through emissions outside the city's boundaries (*very high confidence*). {8.1.4, 8.3, Box 8.1, 8.4, 8.6}

The urban share of combined global CO₂ and CH₄ emissions is substantial and continues to increase (*high confidence*). In 2015, urban emissions were estimated to be 25GtCO₂-eq (about 62% of the global share) and in 2020 were 29 GtCO₂-eq (67–72% of the global share).²¹ Around 100 of the highest-emitting urban areas account for approximately 18% of the global carbon footprint (*high confidence*). {8.1, 8.3}

The urban share of regional GHG emissions increased between 2000 and 2015, with much inter-regional variation in the magnitude of the increase (*high confidence*). Globally, the urban share of national emissions increased six percentage points, from 56% in 2000 to 62% in 2015. For 2000 to 2015, the urban emissions share increased from 28% to 38% in Africa, from 46% to 54% in Asia and Pacific, from 62% to 72% in Developed Countries, from 57% to 62% in Eastern Europe and West Central Asia, from 55% to 66% in Latin America and Caribbean, and from 68% to 69% in the Middle East (*high confidence*). {8.1.6, 8.3.3}

Per-capita urban GHG emissions increased between 2000 and 2015, with cities in developed countries accounting for nearly seven times more per capita than the lowest emitting region (*medium confidence*). From 2000 to 2015, global urban GHG emissions per capita increased from 5.5 to 6.2 tCO₂-eq per person (an increase of 11.8%). Emissions in Africa increased from 1.3 to 1.5 tCO₂-eq per person (22.6%); in Asia and Pacific from 3.0 to 5.1 tCO₂-eq per person (71.7%); in Eastern Europe and West Central Asia from 6.9 to 9.8 tCO₂-eq per person (40.9%); in Latin America and the Caribbean from 2.7 to 3.7 tCO₂-eq per person (40.4%); and in the Middle East from 7.4 to 9.6 tCO₂-eq per person (30.1%). Albeit starting from the highest level, developed countries showed a modest decline of 11.4 to 10.7 tCO₂-eq per person (–6.5%). (Figure TS.12) {8.3.3}

21 These estimates are based on consumption-based accounting, including both direct emissions from within urban areas, and indirect emissions from outside urban areas related to the production of electricity, goods, and services consumed in cities. Estimates include all CO₂ and CH₄ emission categories except for aviation and marine bunker fuels, land-use change, forestry, and agriculture. {8.1, Annex I: Glossary}

Figure TS.12 | Changes in six metrics associated with urban and national-scale combined CO₂ and CH₄ emissions represented in the AR6 WGIII six-region aggregation, with (a) 2000 and (b) 2015. The trends in Luqman et al. (2021) were combined with the work of Moran et al. (2018) to estimate the regional urban CO₂-eq share of global urban emissions, the urban share of national CO₂-eq emissions, and the urban per capita CO₂-eq emissions by region. This estimate is derived from consumption-based accounting that includes both direct emissions from within urban areas and indirect emissions from outside urban areas related to the production of electricity, goods, and services consumed in cities. It incorporates all CO₂ and CH₄ emissions except aviation, shipping and biogenic sources (i.e., land-use change, forestry, and agriculture). The dashed grey line represents the global average urban per capita CO₂-eq emissions. The regional urban population share, regional CO₂-eq share in total emissions, and national per capita CO₂-eq emissions by region are given for comparison. Source: adapted from Gurney et al. (2022).

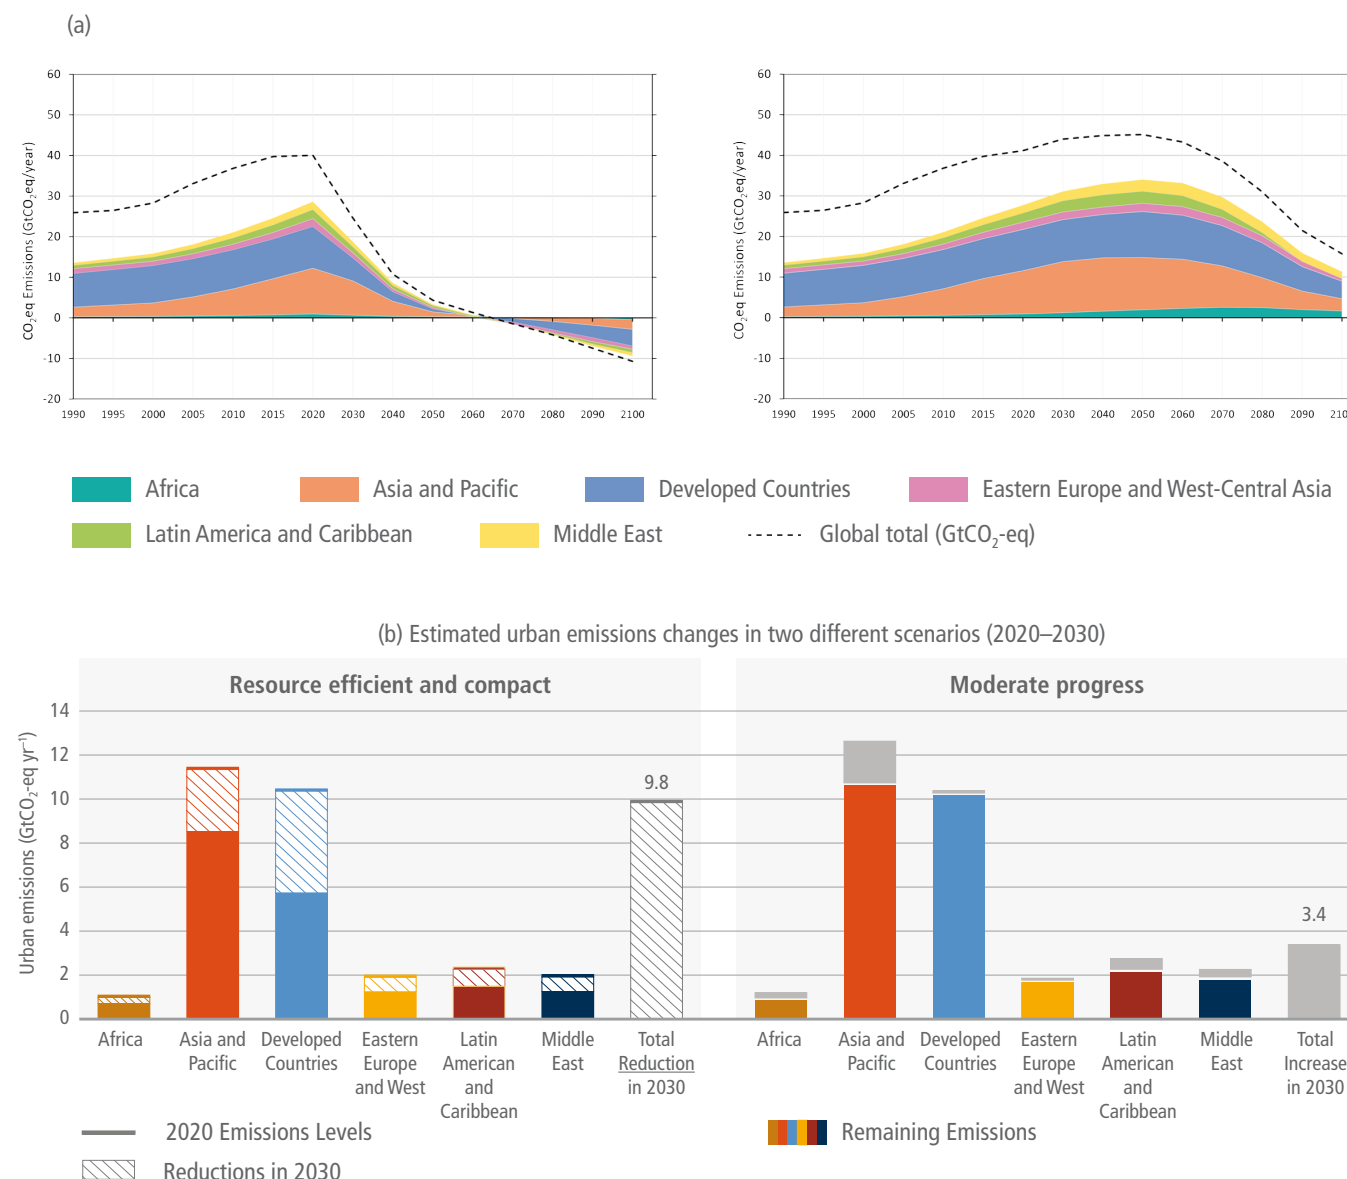

Figure TS.13 | Panel (a): carbon dioxide-equivalent emissions from global urban areas from 1990 to 2100. Urban areas are aggregated to six regional domains; Panel (b): comparison of urban emissions under different urbanisation scenarios (GtCO₂-eq yr⁻¹) for different regions.²¹ [Figures 8.13 and 8.14]

The global share of future urban GHG emissions is expected to increase through 2050 with moderate to low mitigation efforts due to growth trends in population, urban land expansion, and infrastructure and service demands, but the extent of the increase depends on the scenario and the scale and timing of urban mitigation action (*medium confidence*). In modelled scenarios, global consumption-based urban CO₂ and CH₄ emissions are projected to rise from 29 GtCO₂-eq in 2020 to 34 GtCO₂-eq in 2050 with moderate mitigation efforts (intermediate GHG emissions, SSP2-4.5), and up to 40 GtCO₂-eq in 2050 with low mitigation efforts (high GHG emissions, SSP 3-7.0). With aggressive and immediate mitigation efforts to limit global warming to 1.5°C (>50%) with no or limited overshoot by the end of the century (very low emissions,

SSP1-1.9), including high levels of electrification, energy and material efficiency, renewable energy preferences, and socio-behavioural responses, urban GHG emissions could approach net-zero and reach a maximum of 3 GtCO₂-eq in 2050. Under a scenario with aggressive but not immediate urban mitigation policies to limit global warming to 2°C (>67%) (low emissions, SSP1-2.6), urban emissions could reach 17 GtCO₂-eq in 2050.²³ (Figure TS.13) {8.3.4}

Urban land areas could triple between 2015 and 2050, with significant implications for future carbon lock-in (*medium confidence*). There is a large range in the forecasts of urban land expansion across scenarios and models, which highlights an opportunity to shape future urban development towards low- or net zero GHG

22 These scenarios have been assessed by WGI to correspond to intermediate, high, and very low GHG emissions.

23 These scenarios have been assessed by WGI to correspond to intermediate, high, and very low GHG emissions.

emissions. By 2050, urban areas could increase up to 211% over the 2015 global urban extent, with the median projected increase ranging from 43% to 106%. While the largest absolute amount of new urban land is forecasted to occur in Asia and Pacific, and in Developed Countries, the highest rate of urban land growth is projected to occur in Africa, Eastern Europe and West Central Asia, and in the Middle East. Given past trends, the expansion of urban areas is expected to take place on agricultural lands and forests, with implications for the loss of carbon stocks. The infrastructure that will be constructed concomitant with urban land expansion will lock-in patterns of energy consumption that will persist for decades. {8.3.1, 8.3.4, 8.4.1, 8.6}

The construction of new, and upgrading of existing, urban infrastructure through 2030 will add to emissions (*medium evidence, high agreement*). The construction of new and upgrading of existing urban infrastructure using conventional practices and technologies can result in a significant increase in CO₂ emissions, ranging from 8.5 GtCO₂ to 14 GtCO₂ annually up to 2030 and more than double annual resource requirements for raw materials to about 90 billion tonnes per year by 2050, up from 40 billion tonnes in 2010. {8.4.1, 8.6}

Given the dual challenges of rising urban GHG emissions and future projections of more frequent extreme climate events, there is an urgent need to integrate urban mitigation and adaptation strategies for cities to address climate change (*very high confidence*). Mitigation strategies can enhance resilience against climate change impacts while contributing to social equity, public health, and human well-being. Urban mitigation actions that facilitate economic decoupling can have positive impacts on employment and local economic competitiveness. {8.2, Cross-Working Group Box 2 in Chapter 8, 8.4}

Cities can achieve net-zero GHG emissions only through deep decarbonisation and systemic transformation (*very high confidence*). Three broad mitigation strategies have been found to be effective in reducing emissions when implemented concurrently: (i) reducing or changing urban energy and material use towards more sustainable production and consumption across all sectors, including through compact and efficient urban forms and supporting infrastructure; (ii) electrification and switching to low-carbon energy sources; and (iii) enhancing carbon uptake and storage in the urban environment (*high confidence*). Given the regional and global reach of urban supply chains, cities can achieve net-zero emissions only if emissions are reduced both within and outside of their administrative boundaries through supply chains. {8.1.6, 8.3.4, 8.4, 8.6}

Packages of mitigation policies that implement multiple urban-scale interventions can have cascading effects across sectors, reduce GHG emissions outside a city's administrative boundaries, and reduce emissions more than the net sum of individual interventions, particularly if multiple scales of governance are included (*high confidence*). Cities have the ability to implement policy packages across sectors using an urban systems approach, especially those that affect key infrastructure

based on spatial planning, electrification of the urban energy system, and urban green and blue infrastructure. The institutional capacity of cities to develop, coordinate, and integrate sectoral mitigation strategies within their jurisdiction varies by context, particularly those related to governance, the regulatory system, and budgetary control. {8.4, 8.5, 8.6}

Integrated spatial planning to achieve compact and resource-efficient urban growth through co-location of higher residential and job densities, mixed land use, and transit-oriented development could reduce urban energy use between 23% and 26% by 2050 compared to the business-as-usual scenario (*high confidence*). Compact cities with shortened distances between housing and jobs, and interventions that support a modal shift away from private motor vehicles towards walking, cycling, and low-emissions shared, or public, transportation, passive energy comfort in buildings, and urban green infrastructure can deliver significant public health benefits and lower GHG emissions. {8.2, 8.3.4, 8.4, 8.6}

Urban green and blue infrastructure can mitigate climate change through carbon sinks, avoided emissions, and reduced energy use while offering multiple co-benefits (*high confidence*). Urban green and blue infrastructure, including urban forests and street trees, permeable surfaces, and green roofs²⁴ offer potentials to mitigate climate change directly through storing carbon, and indirectly by inducing a cooling effect that both reduces energy demand and reduces energy use for water treatment. Globally, urban trees store approximately 7.4 billion tonnes of carbon, and sequester approximately 217 million tonnes of carbon annually, although carbon storage is highly dependent on biome. Among the multiple co-benefits of green and blue infrastructure are reducing the urban heat island (UHI) effect and heat stress, reducing stormwater runoff, improving air quality, and improving the mental and physical health of urban dwellers. Many of these options also provide benefits to climate adaptation. (*high agreement, robust evidence*) {8.2, 8.4.4}

The potential and sequencing of mitigation strategies to reduce GHG emissions will vary depending on a city's land use, spatial form, development level, and state of urbanisation (i.e., whether it is an established city with existing infrastructure, a rapidly growing city with new infrastructure, or an emerging city with infrastructure buildup) (*high confidence*). New and emerging cities will have significant infrastructure development needs to achieve high quality of life, which can be met through energy-efficient infrastructures and services, and people-centred urban design (*high confidence*). The long lifespan of urban infrastructures locks in behaviour and committed emissions. Urban infrastructures and urban form can enable sociocultural and lifestyle changes that can significantly reduce carbon footprints. Rapidly growing cities can avoid higher future emissions through urban planning to co-locate jobs and housing to achieve compact urban form, and by leapfrogging to low-carbon technologies. Established cities will achieve the largest GHG emissions savings by replacing, repurposing, or retrofitting the building stock, targeted infilling and densifying, as well as through modal shift and the electrification of the urban energy system. New and emerging cities

24 These examples are considered to be a subset of 'nature-based solutions' or 'ecosystem-based approaches'.

have unparalleled potential to become low or net zero GHG emissions while achieving high quality of life by creating compact, co-located, and walkable urban areas with mixed land use and transit-oriented design, that also preserve existing green and blue assets. {8.2, 8.4, 8.6}

With over 880 million people living in informal settlements, there are opportunities to harness and enable informal practices and institutions in cities related to housing, waste, energy, water, and sanitation to reduce resource use and mitigate climate change (*low evidence, medium agreement*). The upgrading of informal settlements and inadequate housing to improve resilience and well-being offers a chance to create a low-carbon transition. However, there is limited quantifiable data on these practices and their cumulative impacts on GHG emissions. {8.1.4, 8.2.2, Cross-Working Group Box 2 in Chapter 8, 8.3.2, 8.4, 8.6, 8.7}

Achieving transformational changes in cities for climate change mitigation and adaptation will require engaging multiple scales of governance, including governments and non-state actors, and in connection with substantial financing beyond sectoral approaches (*very high confidence*). Large and complex infrastructure projects for urban mitigation are often beyond the capacity of local municipality budgets, jurisdictions, and institutions. Partnerships between cities and international institutions, national and regional governments, transnational networks, and local stakeholders play a pivotal role in mobilising global climate finance resources for a range of infrastructure projects with low-carbon emissions and related spatial planning programs across key sectors. {8.4, 8.5}

TS.5.3 Transport

Meeting climate mitigation goals would require transformative changes in the transport sector. In 2019, direct GHG emissions from the transport sector were 8.7 GtCO₂-eq (up from 5.0 GtCO₂-eq in 1990) and accounted for 23% of global energy-related CO₂ emissions. Road vehicles accounted for 70% of direct transport emissions, while 1%, 11%, and 12% of direct emissions came from rail, shipping, and aviation, respectively. Emissions from shipping and aviation continue to grow rapidly. Transport-related emissions in developing regions of the world have increased more rapidly than in Europe or North America, a trend that is expected to continue in coming decades (*high confidence*). {10.1, 10.5, 10.6}

Since AR5 there has been a growing awareness of the need for demand management solutions combined with new technologies, such as the rapidly growing use of electromobility for land transport and the emerging options in advanced biofuels and hydrogen-based fuels for shipping and aviation and in other specific land-based contexts (*high confidence*). There is a growing need for systemic infrastructure changes that enable behavioural modifications and reductions in demand for transport services that can in turn reduce energy demand. The response to the COVID-19 pandemic has also shown that behavioural interventions can

reduce transport-related GHG emissions. For example, COVID-19-based lockdowns have confirmed the transformative value of telecommuting replacing significant numbers of work and personal journeys as well as promoting local active transport. There are growing opportunities to implement strategies that drive behavioural change and support the adoption of new transport technology options. {Chapter 5, 10.2, 10.3, 10.4, 10.8}

Changes in urban form, behaviour programs, the circular economy, the shared economy, and digitalisation trends can support systemic changes that lead to reductions in demand for transport services or expand the use of more efficient transport modes (*high confidence*). Cities can reduce their transport-related fuel consumption by around 25% through combinations of more compact land use and the provision of less car-dependent transport infrastructure. Appropriate infrastructure, including protected pedestrian and bike pathways, can also support much greater localised active travel.²⁵ Transport demand management incentives are expected to be necessary to support these systemic changes. There is mixed evidence of the effect of circular economy initiatives, shared economy initiatives, and digitalisation on demand for transport services (Box TS.14). For example, while dematerialisation can reduce the amount of material that needs to be transported to manufacturing facilities, an increase in online shopping with priority delivery can increase demand for freight transport. Similarly, while teleworking could reduce travel demand, increased ride-sharing could increase vehicle kilometres travelled (VKT). {Chapters 1 and 5, 10.2, 10.8}

Battery electric vehicles (BEVs) have lower lifecycle greenhouse gas (GHG) emissions than internal combustion engine vehicles (ICEVs) when BEVs are charged with low-carbon electricity (*high confidence*). Electromobility is being rapidly implemented in micro-mobility (e-autorickshaws, e-scooters, e-bikes), in transit systems, especially buses, and to a lesser degree, in personal vehicles. BEVs could also have the added benefit of supporting grid operations. The commercial availability of mature lithium-ion batteries (LIBs) has underpinned this growth in electromobility. As global battery production increases, unit costs are declining. Further efforts to reduce the GHG footprint of battery production, however, are essential for maximising the mitigation potential of BEVs. The continued growth of electromobility for land transport would entail investments in electric charging and related grid infrastructure. Electromobility powered by low-carbon electricity has the potential to rapidly reduce transport GHG and can be applied with multiple co-benefits, especially in developing countries. {10.3, 10.4, 10.8}

Land-based, long-range, heavy-duty trucks can be decarbonised through battery-electric haulage (including the use of electric road systems), complemented by hydrogen- and biofuel-based fuels in some contexts. These same technologies and expanded use of available electric rail systems can support rail decarbonisation (*medium confidence*). Initial deployments of battery-electric, hydrogen- and bio-based haulage are underway, and commercial operations of some of these technologies are considered

25 'Active travel' is travel that requires physical effort, for example journeys made by walking or cycling.

feasible by 2030 (*medium confidence*). These technologies nevertheless face challenges regarding driving range, capital and operating costs, and infrastructure availability. In particular, fuel-cell durability, high energy consumption, and costs continue to challenge the commercialisation of hydrogen-based fuel-cell vehicles. Increased capacity for low-carbon hydrogen production would also be essential for hydrogen-based fuels to serve as an emissions reduction strategy (*high confidence*). (Box TS.15) {10.3, 10.4, 10.8}

Decarbonisation options for shipping and aviation still require R&D, though advanced biofuels, ammonia, and synthetic fuels are emerging as viable options (*medium confidence*). Increased efficiency has been insufficient to limit the emissions from shipping and aviation, and natural gas-based fuels are expected to be inadequate to meet stringent decarbonisation goals for these segments (*high confidence*). High-energy density, low-carbon fuels are required, but they have not yet reached commercial scale. Advanced biofuels could provide low-carbon jet fuel (*medium confidence*). The production of synthetic fuels using low-carbon hydrogen with CO₂ captured through DACCS/BECCS could provide jet and marine fuels but these options still require demonstration at scale (*low confidence*). Ammonia produced with low-carbon hydrogen could also serve as a marine fuel (*medium confidence*). Deployment of these fuels requires reductions in production costs. (Figure TS.14) {10.2, 10.3, 10.4, 10.5, 10.6, 10.8}

Scenarios from bottom-up and top-down models indicate that, without intervention, CO₂ emissions from transport could grow in the range of 16% and 50% by 2050 (*medium confidence*). The scenarios literature projects continued growth in demand for freight and passenger services, particularly in developing countries in Africa and Asia (*high confidence*). This growth is projected to take place across all transport modes. Increases in demand notwithstanding, scenarios that limit warming to 1.5°C degree with no or limited overshoot suggest that a 59% reduction (42–68% interquartile range) in transport-related CO₂ emissions by 2050, compared to modelled 2020 levels is required. While many global scenarios place greater reliance on emissions reduction in sectors other than transport, a quarter of the 1.5°C scenarios describe transport-related CO₂ emissions reductions in excess of 68% (relative to modelled 2020 levels) (*medium confidence*). Illustrative Mitigation Pathways IMP-Ren and IMP-LD (TS 4.2) describe emission reductions of 80% and 90% in the transport sector, respectively, by 2050. Transport-related emission reductions, however, may not happen uniformly across regions. For example, transport emissions from the Developed Countries, and Eastern Europe and West Central Asia countries decrease from 2020 levels by 2050 across all scenarios limiting global warming to 1.5°C by 2100, but could increase in Africa, Asia and Pacific (APC), Latin America and Caribbean, and the Middle East in some of these scenarios. {10.7}

The scenarios literature indicates that fuel and technology shifts are crucial in reducing carbon emissions to meet temperature goals (*high confidence*). In general terms, electrification tends to play the key role in land-based transport, but biofuels and hydrogen (and derivatives) could play a role in decarbonisation of freight in some contexts. Biofuels and hydrogen (and derivatives) are expected

to be more prominent in shipping and aviation. The shifts towards these alternative fuels must occur alongside shifts towards clean technologies in other sectors. {10.7}

There is a growing awareness of the need to plan for the significant expansion of low-carbon energy infrastructure, including low-carbon power generation and hydrogen production, to support emissions reductions in the transport sector (*high confidence*). Integrated energy planning and operations that take into account energy demand and system constraints across all sectors (transport, buildings, and industry) offer the opportunity to leverage sectoral synergies and avoid inefficient allocation of energy resources. Integrated planning of transport and power infrastructure would be particularly useful in developing countries where ‘greenfield’ development doesn’t suffer from constraints imposed by legacy systems. {10.3, 10.4, 10.8}

The deployment of low-carbon aviation and shipping fuels that support decarbonisation of the transport sector could require changes to national and international governance structures (*medium confidence*). The UNFCCC does not specifically cover emissions from international shipping and aviation. Reporting emissions from international transport is at the discretion of each country. While the International Civil Aviation Organization (ICAO) and International Maritime Organization (IMO) have established emissions reductions targets, only strategies to improve fuel efficiency and demand reductions have been pursued, and there has been minimal commitment to new technologies. {10.5, 10.6, 10.7}

There are growing concerns about resource availability, labour rights, non-climate environmental impacts, and costs of critical minerals needed for lithium-ion batteries (*medium confidence*). Emerging national strategies on critical minerals and the requirements from major vehicle manufacturers are leading to new, more geographically diverse mines. The standardisation of battery modules and packaging within and across vehicle platforms, as well as increased focus on design for recyclability are important. Given the high degree of potential recyclability of lithium-ion batteries, a nearly closed-loop system in the future could mitigate concerns about critical mineral issues (*medium confidence*). {10.3, 10.8}

Legislated climate strategies are emerging at all levels of government, and together with pledges for personal choices, could spur the deployment of demand- and supply-side transport mitigation strategies (*medium confidence*). At the local level, legislation can support local transport plans that include commitments or pledges from local institutions to encourage behaviour change by adopting an organisational culture that motivates sustainable behaviour with inputs from the creative arts. Such institution-led mechanisms could include bike-to-work campaigns, free transport passes, parking charges, or eliminating car benefits. Community-based solutions such as *solar sharing*, *community charging*, and *mobility as a service* can generate new opportunities to facilitate low-carbon transport futures. At the regional and national levels, legislation can include vehicle and fuel efficiency standards, R&D support, and large-scale investments in low-carbon transport infrastructure. (Figure TS.14) {10.8, Chapter 15}

Figure TS.14 | Mitigation options and enabling conditions for transport. 'Niche' scale includes strategies that still require innovation. {Figure 10.22} ASI: Avoid-Shift-Improve; TRL: technology readiness level.

TS.5.4 Buildings

Global GHG emissions from buildings were 12 GtCO₂-eq in 2019, equivalent to 21% of global GHG emissions. Of this, 57% (6.8 GtCO₂-eq) were indirect emissions from off-site generation of electricity and heat, 24% (2.9 GtCO₂-eq) were direct emissions produced on-site and 18% (2.2 GtCO₂-eq) were embodied emissions from the production of cement and steel used in buildings (*high confidence*). Most building-sector emissions are CO₂. Final energy demand from buildings reached 128 EJ globally in 2019 (around 31% of global final energy demand), and electricity demand from buildings was slightly above 43 EJ globally (around 18% of global electricity demand). Residential buildings consumed 70% (90 EJ) of the global final energy demand from buildings. Over the period 1990–2019, global CO₂ emissions from buildings increased by 50%, global final energy demand from buildings grew by 38%, and global final electricity demand increased by 161%. {9.3}

In most regions, historical improvements in efficiency have been approximately matched by growth in floor area per capita (*high confidence*). At the global level, building-specific drivers of GHG emissions include: (i) population growth, especially in developing countries; (ii) increasing floor area per capita, driven by the increasing size of dwellings while the size of households kept decreasing, especially in developed countries; (iii) the inefficiency of newly constructed buildings, especially in developing countries, and the low renovation rates and low ambition level in developed countries when existing buildings are renovated; (iv) the increase in use, number and size of appliances and equipment, especially information and communication technologies (ICT) and cooling, driven by income; and, (v) the continued reliance on carbon-intensive electricity and heat. These factors taken together are projected to continue driving increased GHG emissions in the building sector in the future. {9.3, 9.6, 9.9}

Building-sector GHG emissions were assessed using the Sufficiency, Efficiency, Renewable (SER) framework. Sufficiency measures tackle the causes of GHG emissions by limiting the demand for energy and materials over the lifecycle of buildings and appliances (*high confidence*). In Chapter 9 of this report, *sufficiency* differs from *efficiency*: *sufficiency* is about long-term actions driven by non-technological solutions, which consume less energy in absolute terms; *efficiency*, in contrast is about continuous short-term marginal technological improvements. Sufficiency policies are a set of measures and daily practices that avoid demand for energy, materials, land and water while delivering human well-being-for-all within planetary boundaries. Use of the SER framework aims to reduce the cost of constructing and using buildings without reducing occupants' well-being and comfort. {9.1, 9.4, 9.5, 9.9}

Sufficiency interventions do not consume energy during the use phase of buildings and do not require maintenance nor replacement over the lifetime of buildings. Density, compactness, bioclimatic design to optimise the use of nature-based solutions, multi-functionality of space through shared space and to allow for adjusting the size of buildings to the evolving needs of households, circular use of materials and repurposing unused existing buildings to avoid using virgin materials, optimisation of the use of buildings through lifestyle changes, use of the thermal mass of buildings to reduce thermal needs, and moving from ownership to usership of appliances, are among the sufficiency interventions implemented in leading municipalities (*high confidence*). At a global level, up to 17% of the mitigation potential in the buildings sector could be captured by 2050 through sufficiency interventions (*medium confidence*). (Figure TS.15) {9.2, 9.3, 9.4, 9.5, 9.9}

The potential associated with sufficiency measures, as well as the replacement of appliances, equipment and lights by efficient ones, is below zero cost (*high confidence*). The construction of high-performance buildings is expected to become a business-as-usual technology by 2050 with costs below USD20 tCO₂⁻¹ in developed countries and below USD100 tCO₂⁻¹ in developing countries (*medium confidence*). For existing buildings, there have been many examples of deep retrofits where additional costs per CO₂ abated are not significantly higher than those of shallow retrofits. However, for the whole building stock they tend to be in cost intervals of USD–200 tCO₂⁻¹ and >USD200 tCO₂⁻¹ (*medium confidence*). Literature emphasises the critical role of the 2020–2030 decade in accelerating the learning of know-how and skills to reduce the costs and remove feasibility constraints for achieving high-efficiency buildings at scale and set the sector on the pathway to realise its full potential (*high confidence*). {9.3, 9.6, 9.9}.

The development, since AR5, of integrated approaches to the construction and retrofit of buildings has led to increasing the number of zero-energy or zero-carbon buildings in almost all climate zones. The complementarity and interdependency of measures leads to cost reductions, while optimising the mitigation potential achieved and avoiding the lock-in-effect (*medium confidence*). {9.6, 9.9}

TS

Figure TS.15 | Decompositions of changes in historical residential energy emissions 1990–2019, changes in emissions projected by baseline scenarios for 2020–2050, and differences between scenarios in 2050 using scenarios from three models: IEA, IMAGE, and RECC.

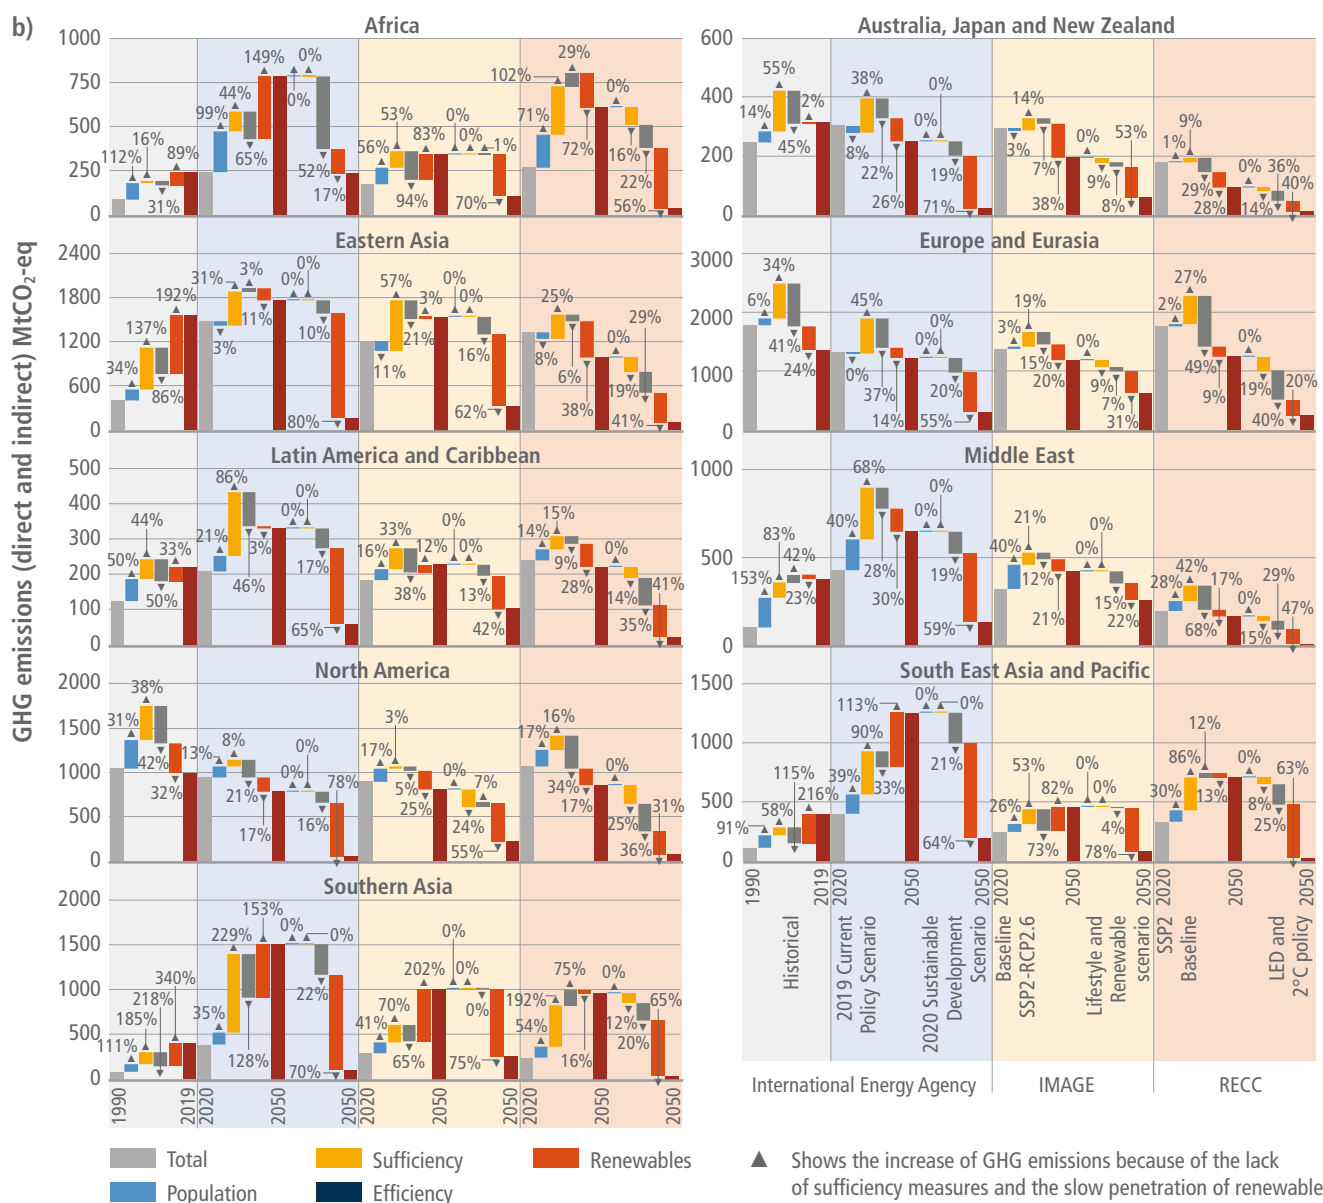

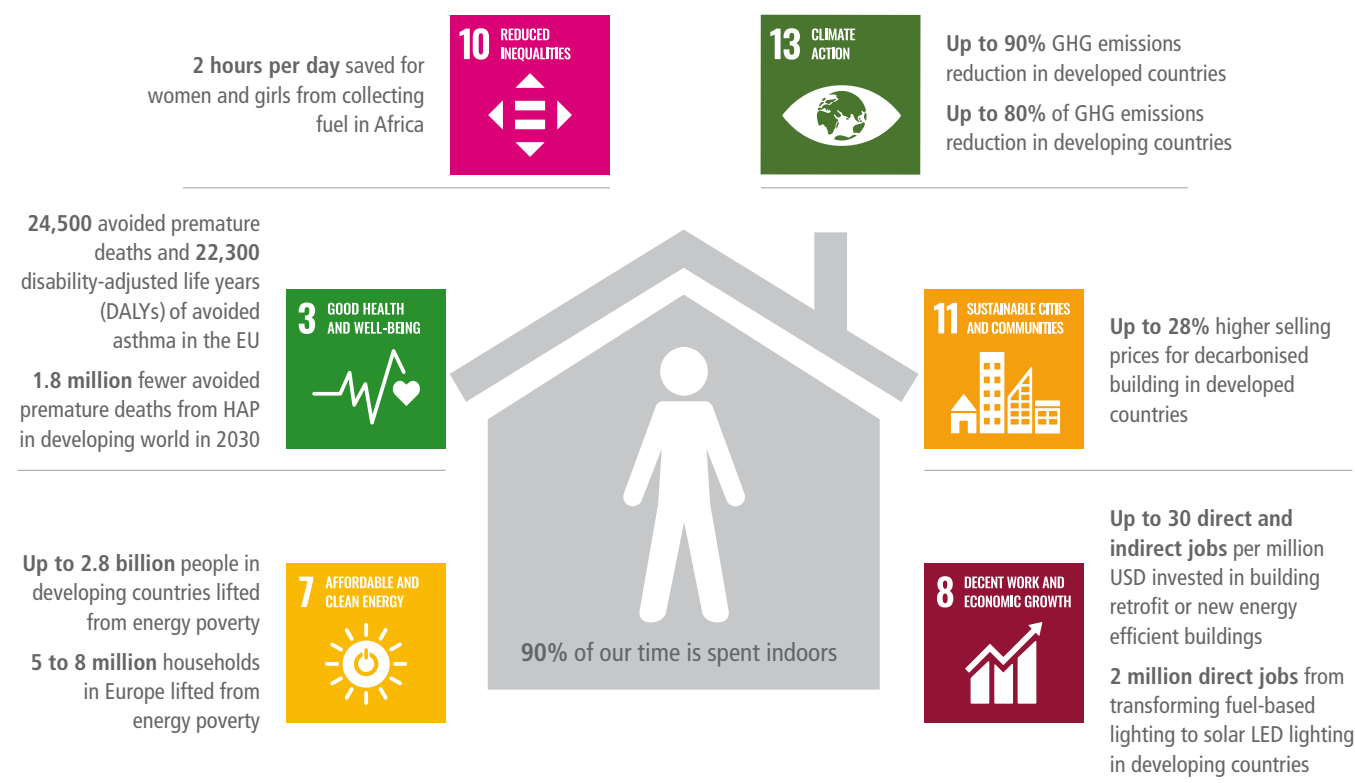

Figure TS.15 (continued): Decompositions of changes in historical residential energy emissions 1990–2019, changes in emissions projected by baseline scenarios for 2020–2050, and differences between scenarios in 2050 using scenarios from three models: IEA, IMAGE, and RECC. RECC-LED data for (a) global, and (b) for nine world regions, include only space heating and cooling and water heating in residential buildings. Emissions are decomposed using the equation, which shows changes in driver variables of population, sufficiency (floor area per capita), efficiency (final energy per floor area), and renewables (GHG emissions per final energy). ‘Renewables’ is a summary term describing changes in GHG intensity of energy supply. Emission projections to 2050, and differences between scenarios in 2050, demonstrate mitigation potentials from the dimensions of the SER framework realised in each model scenario. In most regions, historical improvements in efficiency have been approximately matched by growth in floor area per capita. Implementing sufficiency measures that limit growth in floor area per capita, particularly in developed regions, reduces the dependence of climate mitigation on technological solutions. (Figure 9.5, Box 9.2)

The decarbonisation of buildings is constrained by multiple barriers and obstacles as well as limited finance flows (*high confidence*). The lack of institutional capacity, especially in developing countries, and appropriate governance structures slow down the decarbonisation of the global building stock (*medium confidence*). The building sector is highly heterogeneous with many different building types, sizes, and operational uses. The sub-segment representing rented property faces principal/agent problems where the tenant benefits from the decarbonisation's investment made by the landlord. The organisational context and the governance structure could trigger or hinder the decarbonisation of buildings. Global investment in the decarbonisation of buildings was estimated at USD164 billion in 2020. However, this is not enough by far to close the investment gap (*high confidence*). {9.9}

Policy packages could grasp the full mitigation potential of the global building stock. Building energy codes represent the main regulatory instrument to reduce emissions from both new and existing buildings (*high confidence*). The most advanced building energy codes include requirements on each of the three pillars of the SER framework in the *use* and *construction* phase of buildings. Building energy codes have proven to be effective if compulsory and combined with other regulatory instruments such as minimum energy performance standard for appliances and equipment, if the performance level is set at the level of the best

available technologies in the market (*high confidence*). Market-based instruments such as carbon taxes with recycling of the revenues and personal or building carbon allowances could also contribute to fostering the decarbonisation of the building sector (*medium confidence*). {9.9}

Adapting buildings to future climate while ensuring well-being for all requires action. Expected heatwaves will inevitably increase cooling needs to limit the health impacts of climate change (*medium confidence*). Global warming will impact cooling and heating needs but also the performance, durability and safety of buildings, especially historical and coastal ones, through changes in temperature, humidity, atmospheric concentrations of CO₂ and chloride, and sea level rise. Adaptation measures to cope with climate change may increase the demand for energy and materials leading to an increase in GHG emissions if not mitigated. Sufficiency measures which anticipate climate change, and include natural ventilation, white walls, and nature-based solutions (e.g., green roofs) will decrease the demand for cooling. Shared cooled spaces with highly efficient cooling solutions are among the mitigation strategies which can limit the effect of the expected heatwaves on people's health. {9.7, 9.8}

Key point: Achieving SDG targets requires implementation of ambitious climate mitigation policies which include sufficiency measures to align building design, size and use with SDGs, efficiency measures to ensure high penetration of best available technologies and supplying the remaining energy needs with renewable energy sources.

Figure TS.16 | Contribution of building-sector mitigation policies to meeting Sustainable Development Goals. {Figure 9.18}

Well-designed and effectively implemented mitigation actions in the buildings sector have significant potential to help achieve the SDGs (*high confidence*). As shown in Figure TS.16, the impacts of mitigation actions in the building sector go far beyond the goal of climate action (SDG 13) and contribute to meeting 15 other SDGs. Mitigation actions in the building sector bring health gains through improved indoor air quality and thermal comfort, and have positive significant macro- and micro-economic effects, such as increased productivity of labour, job creation, reduced poverty, especially energy poverty, and improved energy security (*high confidence*). (Figure TS.29) {9.8}

The COVID-19 pandemic emphasised the importance of buildings for human well-being and highlighted the inequalities in access for all to suitable, healthy buildings, which provide natural daylight and clean air to their occupants (*medium confidence*). Recent WHO health recommendations have also emphasise indoor air quality, preventive maintenance of centralised mechanical heating, ventilation, and cooling systems. There are opportunities for repurposing existing non-residential buildings, no longer in use due to the expected spread of teleworking triggered by the health crisis and enabled by digitalisation. (Box TS.14) {9.1}

TS.5.5 Industry

The industry chapter focuses on new developments since AR5 and emphasises the role of the energy-intensive and emissions-intensive basic materials industries in strategies for reaching net zero emissions. The Paris Agreement, the SDGs and the COVID-19 pandemic provide a new context for the evolution of industry and mitigation of industry greenhouse gas (GHG) emissions (*high confidence*). {11.1.1}

Net zero CO₂ industrial-sector emissions are possible but challenging (*high confidence*). Energy efficiency will continue to be important. Reduced materials demand, material efficiency, and circular economy solutions can reduce the need for primary production. Primary production options include switching to new processes that use low-to-zero GHG energy carriers and feedstocks (e.g., electricity, hydrogen, biofuels, and carbon dioxide capture and utilisation (CCU) to provide carbon feedstocks). Carbon capture and storage (CCS) will be required to mitigate remaining CO₂ emissions {11.3}. These options require substantial scaling up of electricity, hydrogen, recycling, CO₂, and other infrastructure, as well as phase-out or conversion of existing industrial plants. While improvements in the GHG intensities of major basic materials have nearly stagnated over the last 30 years, analysis of historical technology shifts and newly available technologies indicate these intensities can be significantly reduced by mid-century. {11.2, 11.3, 11.4}

Industry-sector emissions have been growing faster since 2000 than emissions in any other sector, driven by increased basic materials extraction and production (*high confidence*). GHG emissions attributed to the industrial sector originate from fuel combustion, process emissions, product use and waste, which jointly accounted for 14.1 GtCO₂-eq or 24% of all direct anthropogenic emissions in 2019, second behind the energy supply sector. Industry is

a leading GHG emitter – 20 GtCO₂-eq or 34% of global emissions in 2019 – if indirect emissions from power and heat generation are included. The share of emissions originating from direct fuel combustion is decreasing and was 7 GtCO₂-eq, 50% of direct industrial emissions in 2019. {11.2.2}

Global material intensity – the in-use stock of manufactured capital in tonnes per unit of GDP – is increasing (*high confidence*). In-use stock of manufactured capital per capita has been growing faster than GDP per capita since 2000. Total global in-use stock of manufactured capital grew by 3.4% yr⁻¹ in 2000–2019. At the same time, per-capita material stocks in several developed countries have stopped growing, showing a decoupling from GDP per capita. {11.2.1, 11.3.1}

The demand for plastic has been growing most strongly since 1970 (*high confidence*). The current >99% reliance on fossil feedstock, very low recycling, and high emissions from petrochemical processes is a challenge for reaching net zero emissions. At the same time, plastics are important for reducing emissions elsewhere, for example, light-weighting vehicles. There are as yet no shared visions for fossil-free plastics, but several possibilities. {11.4.1.3}

Scenario analyses show that significant reductions in global GHG emissions and even close to net zero emissions from GHG intensive industry (e.g., steel, plastics, ammonia, and cement) can be achieved by 2050 by deploying multiple available and emerging options (*medium confidence*). Significant reductions in industry emissions require a reorientation from the historic focus on important but incremental improvements (e.g., energy efficiency) to transformational changes in energy and feedstock sourcing, materials efficiency, and more circular material flows. {11.3, 11.4}

Key mitigation options such as materials efficiency, circular material flows and emerging primary processes, are not well represented in climate change scenario modelling and integrated assessment models (IAMs), albeit with some progress in recent years (*high confidence*). The character of these interventions (e.g., appearing in many forms across complex value chains, making cost estimates difficult) combined with the limited data on new fossil-free primary processes help explain why they are less represented in models than, for example, CCS. As a result, overall mitigation costs and the need for CCS may be overestimated. {11.4.2.1}

Electrification is emerging as a key mitigation option for industry (*high confidence*). Using electricity directly, or indirectly via hydrogen from electrolysis for high temperature and chemical feedstock requirements, offers many options to reduce emissions. It also can provide substantial grid-balancing services, for example, through electrolysis and storage of hydrogen for chemical process use or demand response. (Box TS.9) {11.3.5}

Carbon is a key building block in organic chemicals, fuels and materials and will remain important (*high confidence*). In order to reach net zero CO₂ emissions for the carbon needed in society (e.g., plastics, wood, aviation fuels, solvents, etc.), it is important to

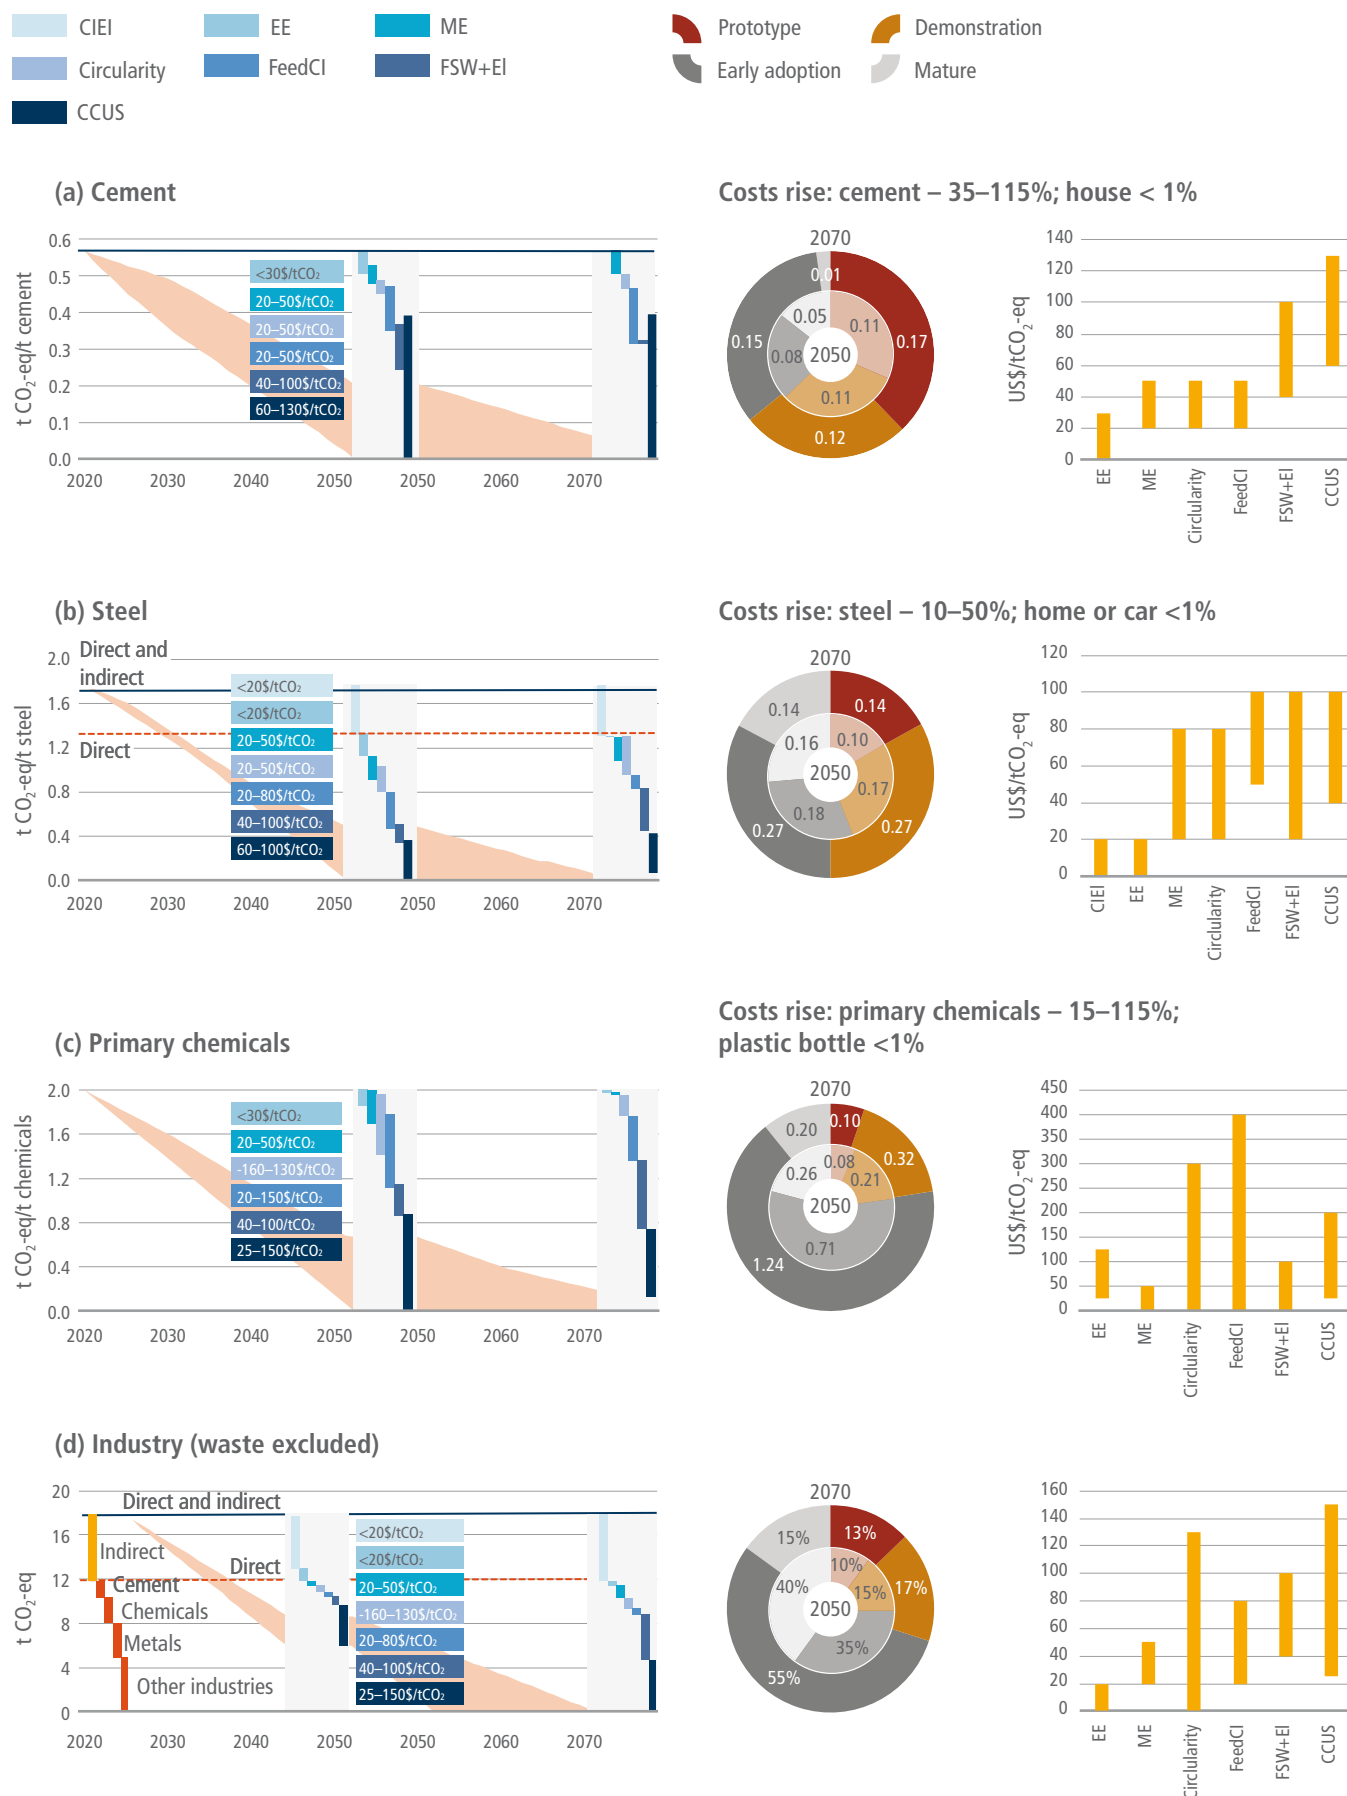

Figure TS.17 (continued): Potentials and costs for zero-carbon mitigation options for industry and basic materials. CIEI – carbon intensity of electricity for indirect emissions; EE – energy efficiency; ME – material efficiency; Circularity – material flows (clinker substituted by coal fly ash, blast furnace slag or other by-products and waste, steel scrap, plastic recycling, etc.); FeedCI – feedstock carbon intensity (hydrogen, biomass, novel cement, natural clinker substitutes); FSW+EI – fuel switch and processes electrification with low-carbon electricity. Ranges for mitigation options are shown based on bottom-up studies for grouped technologies packages, not for single technologies. In circles, contribution to mitigation from technologies based on their readiness are shown for 2050 (2040) and 2070. Direct emissions include fuel combustion and process emissions. Indirect emissions include emissions attributed to consumed electricity and purchased heat. For basic chemicals, only methanol, ammonia and high-value chemicals are considered. Total for industry does not include emissions from waste. Negative mitigation costs for some options such as Circularity are not reflected. {Figure 11.13}

close the use loops for carbon and carbon dioxide through increased circularity with mechanical and chemical recycling, more efficient use of biomass feedstock with addition of low-GHG hydrogen to increase product yields (e.g., for biomethane and methanol), and potentially direct air capture of CO₂ as a new carbon source. {11.3, 11.4.1}

Production costs for very low to zero emissions basic materials may be high but the cost for final consumers and the general economy will be low (medium confidence). Costs and emissions reductions potential in industry, and especially heavy industry, are highly contingent on innovation, commercialisation, and market-uptake policies. Technologies exist to take all industry sectors to very low or zero emissions, but require five to fifteen years of intensive innovation, commercialisation, and policy to ensure uptake. Mitigation costs are in the rough range of USD50–150 tCO₂-eq⁻¹, with wide variation within and outside this band. This affects competitiveness and requires supporting policy. Although production cost increases can be significant, they translate to very small increases in the costs for final products, typically less than a few percent depending on product, assumptions, and system boundaries. (Figure TS.17) {11.4.1.5}

Several technological options exist for very low to zero emissions steel, but their uptake will require integrated material efficiency, recycling, and production decarbonisation policies (high confidence). Material efficiency can potentially reduce steel demand by up to 40% based on design for less steel use, long life, reuse, constructability, and low-contamination recycling. Secondary production through high-quality recycling must be maximised. Production decarbonisation will also be required, starting with the retrofitting of existing facilities for partial fuel switching (e.g., to biomass or hydrogen), CCU and CCS, followed by very low and zero emissions production based on high-capture CCS or direct hydrogen, or electrolytic iron-ore reduction followed by an electric arc furnace. {11.3.2, 11.4.1.1}

Several current and emerging options can significantly reduce cement and concrete emissions. Producer, user, and regulator education, as well as innovation and commercialisation policy are needed (medium confidence). Cement and concrete are currently overused because they are inexpensive, durable, and ubiquitous, and consumption decisions typically do not give weight to their production emissions. Basic material efficiency efforts to use only well-made concrete thoughtfully and only where needed (e.g., using right-sized, prefabricated components) could reduce emissions by 24–50% through lower demand for clinker. Cementitious material substitution with various materials (e.g., ground limestone and calcined clays) can reduce process calcination emissions by up to 50% and occasionally much more. Until a very low GHG emissions alternative binder to Portland cement is commercialised – which is

not anticipated in the near to mid-term – CCS will be essential for eliminating the limestone calcination process emissions for making clinker, which currently represent 60% of GHG emissions in best-available technology plants. {11.3.2, 11.3.6, 11.4.1.2}

While several technological options exist for decarbonising the main industrial feedstock chemicals and their derivatives, the costs vary widely (high confidence). Fossil fuel-based feedstocks are inexpensive and still without carbon pricing, and their biomass- and electricity-based replacements are expected to be more expensive. The chemical industry consumes large amounts of hydrogen, ammonia, methanol, carbon monoxide, ethylene, propylene, benzene, toluene, and mixed xylenes and aromatics from fossil feedstock, and from these basic chemicals produces tens of thousands of derivative end-use chemicals. Hydrogen, biogenic or air-capture carbon, and collected plastic waste for the primary feedstocks can greatly reduce total emissions. Biogenic carbon feedstock is expected to be limited due to competing land uses. {11.4.1}

Light industry and manufacturing can be largely decarbonised through switching to low-GHG fuels (e.g., biofuels and hydrogen) and electricity (e.g., for electrothermal heating and heat pumps) (high confidence). Most of these technologies are already mature, for example for low-temperature heat, but a major challenge is the current low cost of fossil CH₄ and coal relative to low- and zero-GHG electricity, hydrogen, and biofuels. {11.4.1}

The pulp and paper industry has significant biogenic carbon emissions but relatively small fossil carbon emissions. Pulp mills have access to biomass residues and by-products and in paper mills the use of process heat at low to medium temperatures allows for electrification (high confidence). Competition for feedstock will increase if wood substitutes for building materials and petrochemicals feedstock. The pulp and paper industry can also be a source of biogenic carbon dioxide, carbon for organic chemicals feedstock, and for CDR using CCS. {11.4.1}

The geographical distribution of renewable resources has implications for industry (medium confidence). The potential for zero-emission electricity and low-cost hydrogen from electrolysis powered by solar and wind, or hydrogen from other very low emission sources, may reshape where currently energy- and emissions-intensive basic materials production is located, how value chains are organised, trade patterns, and what gets transported in international shipping. Regions with bountiful solar and wind resources, or low fugitive CH₄ co-located with CCS geology, may become exporters of hydrogen or hydrogen carriers such as methanol and ammonia, or home to the production of iron and steel, organic platform chemicals, and other energy-intensive basic materials. {11.2, 11.4, Box 11.1}

The level of policy maturity and experience varies widely across the mitigation options (*high confidence*). Energy efficiency is a well-established policy field with decades of experience from voluntary and negotiated agreements, regulations, energy auditing and demand-side management (DSM) programmes. In contrast, materials demand management and efficiency are not well understood and addressed from a policy perspective. Barriers to recycling that policy could address are often specific to the different material loops (e.g., copper contamination for steel and lack of technologies or poor economics for plastics) or waste-management systems. For electrification and fuel switching the focus has so far been mainly on innovation and developing technical supply-side solutions rather than creating market demand. {11.5.2, 11.6}

Industry has so far largely been sheltered from the impacts of climate policy and carbon pricing due to concerns about carbon leakage²⁶ and reducing competitiveness (*high confidence*). New approaches to industrial development policy are emerging for a transition to net zero GHG emissions. The transition requires a clear direction towards net zero, technology development, market demand for low-carbon materials and products, governance capacity and learning, socially inclusive phase-out plans, as well as international coordination of climate and trade policies (see also TS.6.5). It requires comprehensive and sequential industrial policy strategies leading to immediate action as well as preparedness for future decarbonisation, governance at different levels (from international to local) and integration with other policy domains. {11.6}

TS.5.6 Agriculture, Forestry, Other Land Uses, and Food Systems

TS.5.6.1 Agriculture, Forestry, and Other Land Use (AFOLU)

The agriculture, forestry and other land use (AFOLU)²⁷ sector encompasses managed ecosystems and offers significant mitigation opportunities while providing food, wood and other renewable resources as well as biodiversity conservation, provided the sector adapts to climate change. Land-based mitigation measures can reduce GHG emissions within the AFOLU sector, deliver CDR and provide biomass thereby enabling emission reductions in other sectors.²⁸ The rapid deployment of AFOLU measures features in all pathways that limit global warming to 1.5°C. Where carefully and appropriately implemented, AFOLU mitigation measures are positioned to deliver substantial co-benefits and help address many of the wider challenges associated with land management. If AFOLU measures are deployed badly, when taken together with the increasing need to produce sufficient food, feed, fuel and wood, they may exacerbate trade-offs with the conservation of habitats, adaptation, biodiversity and other services.

At the same time the capacity of the land to support these functions may be threatened by climate change (*high confidence*). {AR6 WGI Figure SPM.7; AR6 WGII, 7.1, 7.6}

The AFOLU sector, on average, accounted for 13–21% of global total anthropogenic GHG emissions in the period 2010–2019. At the same time managed and natural terrestrial ecosystems were a carbon sink, absorbing around one third of anthropogenic CO₂ emissions (*medium confidence*). Estimated anthropogenic net CO₂ emissions from AFOLU (based on bookkeeping models) result in a net source of $+5.9 \pm 4.1$ GtCO₂ yr⁻¹ between 2010 and 2019 with an unclear trend. Based on FAOSTAT or national GHG inventories, the net CO₂ emissions from AFOLU were 0.0 to $+0.8$ GtCO₂ yr⁻¹ over the same period. There is a discrepancy in the reported CO₂ AFOLU emissions magnitude because alternative methodological approaches that incorporate different assumptions are used {7.2.2}. If the responses of all managed and natural land to both anthropogenic environmental change and natural climate variability, estimated to be a gross sink of -12.5 ± 3.2 GtCO₂ yr⁻¹ for the period 2010–2019, are added to land-use emissions, then land overall constituted a net sink of -6.6 ± 5.2 GtCO₂ yr⁻¹ in terms of CO₂ emissions (*medium confidence*). (Table TS.4) {7.2, Table 7.1}

Land-use change drives net AFOLU CO₂ emission fluxes. The rate of deforestation, which accounts for 45% of total AFOLU emissions, has generally declined, while global tree cover and global forest-growing stock levels are likely increasing (*medium confidence*). There are substantial regional differences, with losses of carbon generally observed in tropical regions and gains in temperate and boreal regions. Agricultural CH₄ and N₂O emissions are estimated to average 157 ± 47.1 MtCH₄ yr⁻¹ and 6.6 ± 4.0 MtN₂O yr⁻¹ or 4.2 ± 1.3 and 1.8 ± 1.1 GtCO₂-eq yr⁻¹ (using IPCC AR6 GWP100 values for CH₄ and N₂O) respectively between 2010 and 2019 {7.2.1, 7.2.3}. AFOLU CH₄ emissions continue to increase, the main source of which is enteric fermentation from ruminant animals. Similarly, AFOLU N₂O emissions are increasing, dominated by agriculture, notably from manure application, nitrogen deposition, and nitrogen fertiliser use (*high confidence*). In addition to being a net carbon sink and source of GHG emissions, land plays an important role in climate through albedo effects, evapotranspiration, and aerosol loading through emissions of volatile organic compounds (VOCs). The combined role of CH₄, N₂O and aerosols in total climate forcing, however, is unclear and varies strongly with bioclimatic region and management practice. {2.4.2.5, 7.2, 7.3}

²⁶ See section TS.5.9.

²⁷ AFOLU is a sector in the 2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories. AFOLU anthropogenic greenhouse gas emissions and removals by sinks reported by governments under the UNFCCC are defined as all those occurring on 'managed land'. Managed land is land where human interventions and practices have been applied to perform production, ecological or social functions.

²⁸ For example: in the 2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories, CO₂ emissions from biomass used for energy are reported in the AFOLU sector, calculated as an implicit component of carbon stock changes. In the energy sector, CO₂ emissions from biomass combustion for energy are recorded as an information item that is not included in the sectoral total emissions for the that sector.

Table TS.4 | Net anthropogenic emissions (annual averages for 2010–2019^a) from agriculture, forestry and other land use (AFOLU). For context, the net flux due to the natural response of land to climate and environmental change is also shown for CO₂ in column E. Positive values represent emissions, negative values represent removals. Due to different approaches to estimate anthropogenic fluxes, AFOLU CO₂ estimates in the table below are not directly comparable to LULUCF in national greenhouse gas inventories (NGHGs).

Anthropogenic						Natural response	Natural and anthropogenic
Gas	Units	AFOLU net anthropogenic emissions	Non-AFOLU anthropogenic GHG emissions	Total net anthropogenic emissions (AFOLU and non-AFOLU) by gas	AFOLU as a % of total net anthropogenic emissions by gas	Natural land sinks including natural response of land to anthropogenic environmental change and climate variability	Net-land atmosphere CO ₂ flux (i.e., anthropogenic AFOLU and natural fluxes across entire land surface)
		A	B	C = A + B	D = (A/C) * 100	E	F = A + E
CO ₂	GtCO ₂ -eq yr ⁻¹	5.9 ± 4.1 (bookkeeping models, managed soils and pasture). 0 to 0.8 (NGHGI/FAOSTAT data)	36.2 ± 2.9	42.0 ± 29.0	14%	-12.5 ± 3.2	-6.6 ± 4.6
CH ₄	MtCH ₄ yr ⁻¹	157.0 ± 47.1	207.5 ± 62.2	364.4 ± 109.3			
	GtCO ₂ -eq yr ⁻¹	4.2 ± 1.3	5.9 ± 1.8	10.2 ± 3.0	41 %		
N ₂ O	MtN ₂ O yr ⁻¹	6.6 ± 4.0	2.8 ± 1.7	9.4 ± 5.6			
	GtCO ₂ -eq yr ⁻¹	1.8 ± 1.1	0.8 ± 0.5	2.6 ± 1.5	69%		
Total	GtCO ₂ -eq yr ⁻¹	11.9 ± 4.4 (CO ₂ component considers bookkeeping models only)	44 ± 3.4	55.9 ± 6.1	21 %		

^a Estimates are given for 2019 as this is the latest date when data are available for all gases, consistent with Chapter 2 of this report. Positive fluxes are emission from land to the atmosphere. Negative fluxes are removals. For all Table footnotes see Table 7.1. {Table 7.1}

The AFOLU sector offers significant near-term mitigation potential at relatively low cost and can provide 20–30% of the 2050 emissions reduction described in scenarios that limit warming to 2°C (>67%) or lower (*high evidence, medium agreement*). The AFOLU sector can provide 20–30% (interquartile range) of the global mitigation needed for a 1.5°C or 2°C pathway towards 2050, though there are highly variable mitigation strategies for how AFOLU potential can be deployed for achieving climate targets {Illustrative Mitigation Pathways in 7.5}. The estimated economic (<USD100 tCO₂-eq⁻¹) AFOLU sector mitigation potential is 8 to 14 GtCO₂-eq yr⁻¹ between 2020–2050, with the bottom end of this range representing the mean from IAMs and the upper end representing the mean estimate from global sectoral studies. The economic potential is about half of the technical potential from AFOLU, and about 30–50% could be achieved under USD20 tCO₂-eq⁻¹ {7.4}. The implementation of robust measurement, reporting and verification processes is paramount to improving the transparency of changes in land carbon stocks and this can help prevent misleading assumptions or claims on mitigation. {7.1, 7.4, 7.5}

Between 2020 and 2050, mitigation measures in forests and other natural ecosystems provide the largest share of the AFOLU mitigation potential (up to USD100 tCO₂-eq⁻¹), followed by agriculture and demand-side measures (*high confidence*). In the global sectoral studies, the protection, improved management, and restoration of forests, peatlands, coastal wetlands,

savannas and grasslands have the potential to reduce emissions and/or sequester 7.3 mean (3.9–13.1) GtCO₂-eq yr⁻¹. Agriculture provides the second largest share of the mitigation potential, with 4.1 (1.7–6.7) GtCO₂-eq yr⁻¹ (up to USD100 tCO₂-eq⁻¹) from cropland and grassland soil carbon management, agroforestry, use of biochar, improved rice cultivation, and livestock and nutrient management. Demand-side measures including shifting to sustainable healthy diets, reducing food waste, building with wood, biochemicals, and bio-textiles, have a mitigation potential of 2.2 (1.1–3.6) GtCO₂-eq yr⁻¹. Most mitigation options are available and ready to deploy. Emissions reductions can be achieved relatively quickly, whereas CDR needs upfront investment. Sustainable intensification in agriculture, shifting diets, and reducing food waste could enhance efficiencies and reduce agricultural land needs, and are therefore critical for enabling supply-side measures such as reforestation, restoration, as well as decreasing CH₄ and N₂O emissions from agricultural production. In addition, emerging technologies (e.g., vaccines or CH₄ inhibitors) have the potential to substantially increase the CH₄ mitigation potential beyond current estimates. AFOLU mitigation is not only relevant in countries with large land areas. Many smaller countries and regions, particularly with wetlands, have disproportionately high levels of AFOLU mitigation potential density. {7.4, 7.5}

The economic and political feasibility of implementing AFOLU mitigation measures is hampered by persistent barriers. Assisting countries to overcome barriers will help to achieve

significant short-term mitigation (*medium confidence*). Finance forms a critical barrier to achieving these gains as currently mitigation efforts rely principally on government sources and funding mechanisms which do not provide sufficient resources to enable the economic potential to be realised. Differences in cultural values, governance, accountability and institutional capacity are also important barriers. Climate change itself could reduce the mitigation potential from the AFOLU sector, although an increase in the capacity of natural sinks could occur despite changes in climate (*medium confidence*) {AR6 WGI Figure SPM.7 and Sections 7.4 and 7.6}. The continued loss of biodiversity makes ecosystems less resilient to climate change extremes and this may further jeopardise the achievement of the AFOLU mitigation potentials indicated in this chapter (*high confidence*). (Box TS.15) {7.6}

The provision of biomass for bioenergy (with/without BECCS) and other bio-based products represents an important share of the total mitigation potential associated with the AFOLU sector, though these mitigation effects accrue to other sectors (*high confidence*). Recent estimates of the technical bioenergy potential, when constrained by food security and environmental considerations, are within the ranges 5–50 and 50–250 EJ yr⁻¹ by 2050 for residues and dedicated biomass production systems, respectively.²⁹ (TS.5.7) {7.4, 12.3}

Bioenergy is the most land-intensive energy option, but total land occupation of other renewable energy options can also become significant in high deployment scenarios. While not as closely connected to the AFOLU sector as bioenergy, other renewable energy options can influence AFOLU activities in both synergistic and detrimental ways (*high confidence*). The character of land occupation, and associated impacts, vary considerably among mitigation options and also for the same option depending on geographic location, scale, system design and deployment strategy. Land occupation can be large uniform areas, for example, reservoir hydropower dams and tree plantations, and more distributed occupation that is integrated with other land uses, for example, wind turbines and agroforestry in agriculture landscapes. Deployment can be partly decoupled from additional land use, for example, use of organic waste and residues and integration of solar PV into buildings and other infrastructure (*high confidence*). Wind and solar power can coexist with agriculture in beneficial ways (*medium confidence*). Indirect land occupation includes new agriculture areas following displacement of food production with bioenergy plantations and expansion of mining activities providing minerals required for manufacture of EV batteries, PV, and wind power. {7.4, 12.5}

The deployment of land-based mitigation measures can provide co-benefits, but there are also risks and trade-offs from inappropriate land management (*high confidence*). Such risks can best be managed if AFOLU mitigation is pursued in response to the needs and perspectives of multiple stakeholders to achieve outcomes that maximise synergies

while limiting trade-offs (*medium confidence*). The results of implementing AFOLU measures are often variable and highly context-specific. Depending on local conditions (e.g., ecosystem, climate, food system, land ownership) and management strategies (e.g., scale, method), mitigation measures can positively or negatively affect biodiversity, ecosystem functioning, air quality, water availability and quality, soil productivity, rights infringements, food security, and human well-being. The agriculture and forestry sectors can devise management approaches that enable biomass production and use for energy in conjunction with the production of food and timber, thereby reducing the conversion pressure on natural ecosystems (*medium confidence*). Mitigation measures addressing GHGs may also affect other climate forcers such as albedo and evapotranspiration. Integrated responses that contribute to mitigation, adaptation, and other land challenges will have greater likelihood of being successful (*high confidence*); measures which provide additional benefits to biodiversity and human well-being are sometimes described as 'Nature-based Solutions'. {7.1, 7.4, 7.6, 12.4, 12.5}

AFOLU mitigation measures have been well understood for decades but deployment remains slow, and emissions trends indicate unsatisfactory progress despite beneficial contributions to global emissions reduction from forest-related options (*high confidence*). Globally, the AFOLU sector has so far contributed modestly to net mitigation, as past policies have delivered about 0.65 GtCO₂ yr⁻¹ of mitigation during 2010–2019 or 1.4% of global gross emissions. The majority (>80%) of emission reduction resulted from forestry measures. Although the mitigation potential of AFOLU measures is large from a biophysical and ecological perspective, its feasibility is hampered by lack of institutional support, uncertainty over long-term additionality and trade-offs, weak governance, fragmented land ownership, and uncertain permanence effects. Despite these impediments to change, AFOLU mitigation options are demonstrably effective and with appropriate support can enable rapid emission reductions in most countries. {7.4, 7.6}

Concerted, rapid and sustained effort by all stakeholders, from policymakers and investors to land owners and managers is a pre-requisite for achieving high levels of mitigation in the AFOLU sector (*high confidence*). To date USD0.7 billion yr⁻¹ is estimated to have been spent on AFOLU mitigation. This is well short of the more than USD400 billion yr⁻¹ that is estimated to be necessary to deliver the up to 30% of global mitigation effort envisaged in deep mitigation scenarios (*medium confidence*). This estimate of the global funding requirement is smaller than current subsidies provided to agriculture and forestry. A gradual redirection of existing agriculture and forestry subsidies would greatly advance mitigation. Effective policy interventions and national (investment) plans as part of NDCs, specific to local circumstances and needs, are urgently needed to accelerate the deployment of AFOLU mitigation options. These interventions are effective when they include funding schemes and long-term consistent support for implementation with governments taking the initiative together with private funders and non-state actors. {7.6}

29 These potentials do not include avoided emissions resulting from bioenergy use associated with BECCS, which depends on energy substitution patterns, conversion efficiencies, and supply chain emissions for both the BECCS and substituted energy systems. Estimates of substitution effects of bioenergy indicate that this additional mitigation would be of the same magnitude as provided through CDR using BECCS. Bio-based products with long service life, for example, construction timber, can also provide mitigation through substitution of steel, concrete, and other products, and through carbon storage in the bio-based product pool. See section TS.5.7 for the CDR potential of BECCS. {7.4, 12.3}

Realising the mitigation potential of the AFOLU sector depends strongly on policies that directly address emissions and drive the deployment of land-based mitigation options, consistent with carbon prices in deep mitigation scenarios (*high confidence*). Examples of successful policies and measures include establishing and respecting tenure rights and community forestry, improved agricultural management and sustainable intensification, biodiversity conservation, payments for ecosystem services, improved forest management and wood-chain usage, bioenergy, voluntary supply chain management efforts, consumer behaviour campaigns, private funding and joint regulatory efforts to avoid, for example, leakage. The efficacy of different policies, however, will depend on numerous region-specific factors. In addition to funding, these factors include governance, institutions, long-term consistent execution of measures, and the specific policy setting. While the governance of land-based mitigation can draw on lessons from previous experience with regulating biofuels and forest carbon, integrating these insights requires governance that goes beyond project-level approaches emphasising integrated land-use planning and management within the frame of the Sustainable Development Goals. {7.4, Box 7.2, 7.6}

Addressing the many knowledge gaps in the development and testing of AFOLU mitigation options can rapidly advance the likelihood of achieving sustained mitigation (*high confidence*).

Research priorities include improved quantification of anthropogenic and natural GHG fluxes and emissions modelling, better understanding of the impacts of climate change on the mitigation potential, permanence and additionality of estimated mitigation actions, and improved (real-time and cheap) measurement, reporting and verification. There is a need to include a greater suite of mitigation measures in IAMs, informed by more realistic assessments that take into account local circumstances and socio-economic factors and cross-sector synergies and trade-offs. Finally, there is a critical need for more targeted research to develop appropriate country-level, locally specific, policy and land-management response options. These options could support more specific NDCs with AFOLU measures that enable mitigation while also contributing to biodiversity conservation, ecosystem functioning, livelihoods for millions of farmers and foresters, and many other SDGs. {7.7, Figure 17.1}

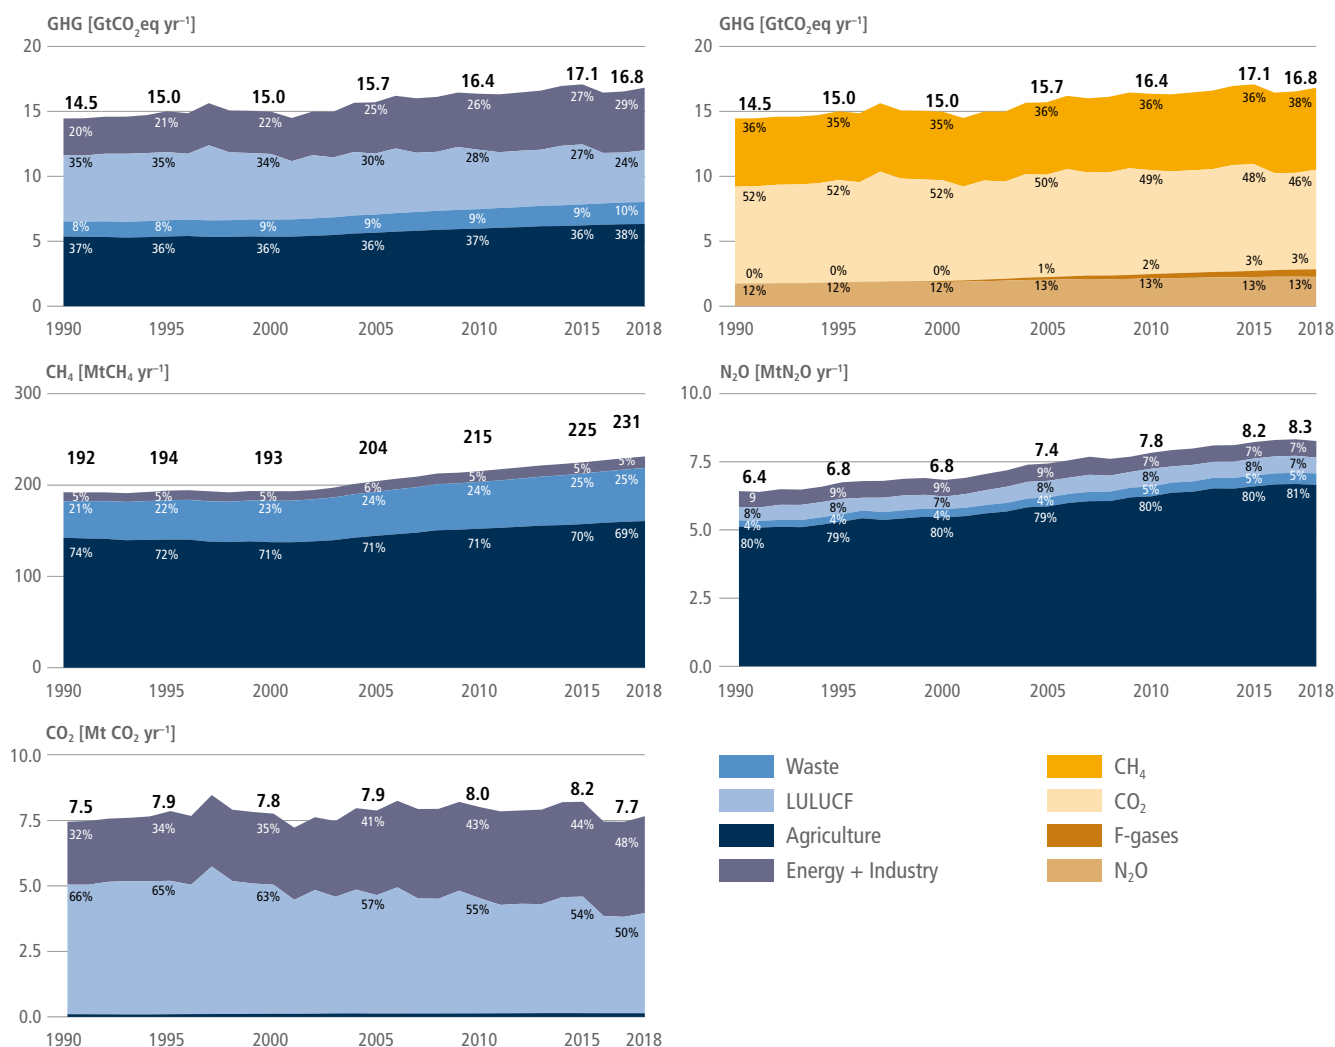

Figure TS.18 | Food-system GHG emissions from the agriculture, and land use, land-use change and forestry (LULUCF), waste, and energy and industry sectors. {Figure 12.5}

TS.5.6.2 Food Systems

Realising the full mitigation potential from the food system requires change at all stages from producer to consumer and waste management, which can be facilitated through integrated policy packages (*high confidence*). Food systems are associated with 23–42% of global GHG emissions, while there is still widespread food insecurity and malnutrition. Absolute GHG emissions from food systems increased from 14 to 17 GtCO₂-eq yr⁻¹ in the period 1990–2018. Both supply- and demand-side measures are important to reduce the GHG intensity of food systems. Integrated food policy packages based on a combination of market-based, administrative, informative, and behavioural policies can reduce cost compared to uncoordinated interventions, address multiple sustainability goals, and increase acceptance across stakeholders and civil society (*limited evidence, medium agreement*). Food systems governance may be pioneered through local food policy

initiatives complemented by national and international initiatives, but governance on the national level tends to be fragmented, and thus has limited capacity to address structural issues like inequities in access. (Figure TS.18, Table TS.5, Table TS.6) {7.2, 7.4, 12.4}

Diets high in plant protein and low in meat and dairy are associated with lower GHG emissions (*high confidence*). Ruminant meat shows the highest GHG intensity. Beef from dairy systems has lower emissions intensity than beef from beef herds (8–23 and 17–94 kgCO₂-eq (100 g protein)⁻¹, respectively) when some emissions are allocated to dairy products. The wide variation in emissions reflects differences in production systems, which range from intensive feedlots with stock raised largely on grains through to rangeland and transhumance production systems. Where appropriate, a shift to diets with a higher share of plant protein, moderate intake of animal-source foods and reduced intake of saturated fats could lead to substantial decreases in GHG emissions. Benefits would also include reduced land

Figure TS.19 | Regional differences in health outcome, territorial per-capita GHG emissions from national food systems, and share of food system GHG emission from energy use. GHG emissions are calculated according to the IPCC Tier 1 approach and are assigned to the country where they occur, not necessarily where the food is consumed. Health outcome is expressed as relative contribution of each of the following risk factors to their combined risk for deaths: Child and maternal malnutrition (red), Dietary risks (yellow) or High body-mass index (blue). {Figure 12.7}

Table TS.5 | Food system mitigation opportunities.

Food system mitigation options (I: incremental; T: transformative)		Direct and indirect effect on GHG mitigation (+/0/–) ^a	Co-benefits/adverse effects ^b
Food from agriculture, aquaculture and fisheries	(I) Dietary shift, in particular increased share of plant-based protein sources	D+ ↓ GHG footprint	A+ Animal welfare L+ Land sparing H+ Good nutritional properties, potentially ↓ risk from zoonotic diseases, pesticides and antibiotics
	(I/T) Digital agriculture	D+ ↑ logistics	L+ Land sparing R+ ↑ resource-use efficiencies
	(T) Gene technology	D+ ↑ productivity or efficiency	H+ ↑ nutritional quality E0 ↓ use of agrochemicals; ↑ probability of off-target impacts
	(I) Sustainable intensification Land-use optimisation	D+ ↓ GHG footprint E0 Mixed effects	L+ Land sparing R– Might ↑ pollution/biodiversity loss
	(I) Agroecology	D+ ↓ GHG/area, positive micro-climatic effects E+ ↓ energy, possibly ↓ transport FL+ Circular approaches	E+ Focus on co-benefits/ecosystem services R+ Circular, ↑ nutrient and water use efficiencies
Controlled environment agriculture	(T) Soil-less agriculture	D+ ↑ productivity, weather independent FL+ Harvest on demand E– Currently ↑ energy demand, but ↓ transport, building spaces can be used for renewable energy	R+ Controlled loops ↑ nutrient- and water-use efficiency L+ Land sparing H+ Crop breeding can be optimised for taste and/or nutritional quality
Emerging food production technologies	(T) Insects	D0 Good feed conversion efficiency FW+ Can be fed on food waste	H0 Good nutritional qualities but attention to allergies and food safety issues required
	(I/T) Algae and bivalves	D+ ↓ GHG footprints	A+ Animal welfare L+ Land sparing H+ Good nutritional qualities; risk of heavy-metal and pathogen contamination R+ Biofiltration of nutrient-polluted waters
	(I/T) Plant-based alternatives to animal-based food products	D+ No emissions from animals, ↓ inputs for feed	A+ Animal welfare L+ Land sparing H+ Potentially ↓ risk from zoonotic diseases, pesticides and antibiotics; but ↑ processing demand
	(T) Cellular agriculture (including cultured meat, microbial protein)	D+ No emissions from animals, high protein conversion efficiency E– ↑ energy need FLW+ ↓ food loss and waste	A+ Animal welfare R+ ↓ emissions of reactive nitrogen or other pollutants H0 Potentially ↓ risk from zoonotic diseases, pesticides and antibiotics; ↑ research on safety aspects needed
Food processing and packaging	(I) Valorisation of by-products, FLW logistics and management	M+ Substitution of bio-based materials FL+ ↓ of food losses	
	(I) Food conservation	FW+ ↓ of food waste E0 ↑ energy demand but also energy savings possible (e.g., refrigeration, transport)	
	(I) Smart packaging and other technologies	FW+ ↓ of food waste M0 ↑ material demand and ↑ material efficiency E0 ↑ energy demand; energy savings possible	H+ Possibly ↑ freshness/reduced food safety risks
	(I) Energy efficiency	E+ ↓ energy	
Storage and distribution	(I) Improved logistics	D+ ↓ transport emissions FL+ ↓ losses in transport FW– Easier access to food could ↑ food waste	
	(I) Specific measures to reduce food waste in retail and food catering	FW+ ↓ of food waste E+ ↓ downstream energy demand M+ ↓ downstream material demand	
	(I) Alternative fuels/transport modes	D+ ↓ emissions from transport	
	(I) Energy efficiency	E+ ↓ energy in refrigeration, lightening, climatisation	
	(I) Replacing refrigerants	D+ ↓ emissions from the cold chain	

^a Direct and indirect GHG effects: D – direct emissions except emissions from energy use, E – energy demand, M – material demand, FL – food losses, FW – food waste; direction of effect on GHG mitigation: (+) increased mitigation, (0) neutral, (–) decreased mitigation.

^b Co-benefits/adverse effects: H – health aspects, A – animal welfare, R – resource use, L – land demand, E – ecosystem services; (+) co-benefits, (–) adverse effects. {Table 12.8}

occupation and nutrient losses to the surrounding environment, while at the same time providing health benefits and reducing mortality from diet-related non-communicable diseases. (Figure TS.19) {7.4.5, 12.4}

Emerging food technologies such as cellular fermentation, cultured meat, plant-based alternatives to animal-based food products, and controlled environment agriculture, can bring substantial reduction in direct GHG emissions from food production (*limited evidence, high agreement*). These technologies have lower land, water, and nutrient footprints, and address concerns over animal welfare. Realising the full mitigation potential depends on access to low-carbon energy as some emerging technologies are relatively more energy intensive. This also holds for

deployment of cold-chain and packaging technologies, which can help reduce food loss and waste, but increase energy and materials use in the food system. (Table TS.5) {11.4.1.3, 12.4}

TS.5.7 Carbon Dioxide Removal (CDR)

CDR is a key element in scenarios that limit warming to 2°C (>67%) or 1.5°C (>50%) by 2100 (*high confidence*). Implementation strategies need to reflect that CDR methods differ in terms of removal process, timescale of carbon storage, technological maturity, mitigation potential, cost, co-benefits, adverse side effects, and governance requirements. (Box TS.10)

Table TS.6 | Assessment of food system policies targeting (post-farm gate) food-chain actors and consumers.

	Level G: global/multinational; N: national; L: local	Transformative potential	Environmental effectiveness	Feasibility	Distributional effects	Cost	Co-benefits ^a and adverse side effect	Implications for coordination, coherence and consistency in policy package ^b
Integrated food policy packages	NL				can be controlled	cost efficient	+ balanced, addresses multiple sustainability goals	Reduces cost of uncoordinated interventions; increases acceptance across stakeholders and civil society (<i>robust evidence, high agreement</i>)
Taxes on food products	GN				regressive	low ^{#1}	– unintended substitution effects	High enforcing effect on other food policies; higher acceptance if compensation or hypothecated taxes (<i>medium evidence, high agreement</i>)
GHG taxes on food	GN				regressive	low ^{#2}	– unintended substitution effects + high spillover effect	Supportive, enabling effect on other food policies, agricultural/fishery policies; requires changes in power distribution and trade agreements (<i>medium evidence, medium agreement</i>)
Trade policies	G				impacts global distribution	complex effects	+ counters leakage effects +/- effects on market structure and jobs	Requires changes in existing trade agreements (<i>medium evidence, high agreement</i>)
Investment into research and innovation	GN				none	medium	+ high spillover effect + converging with digital society	Can fill targeted gaps for coordinated policy packages (e.g., monitoring methods) (<i>robust evidence, high agreement</i>)
Food and marketing regulations	N					low		Can be supportive; might be supportive to realise innovation; voluntary standards might be less effective (<i>medium evidence, medium agreement</i>)
Organisational-level procurement policies	NL					low	+ can address multiple sustainability goals	Enabling effect on other food policies; reaches large share of population (<i>medium evidence, high agreement</i>)
Sustainable food-based dietary guidelines	GNL				none	low	+ can address multiple sustainability goals	Little attention so far on environmental aspects; can serve as benchmark for other policies (labels, food formulation standards, etc.) (<i>medium evidence, medium agreement</i>)
Food labels/information	GNL				education level relevant	low	+ empowers citizens + increases awareness + multiple objectives	Effective mainly as part of a policy package; incorporation of other objectives (e.g., animal welfare, fair trade); higher effect if mandatory (<i>medium evidence, medium agreement</i>)
Nudges	NL				none	low	+ possibly counteracting information deficits in population subgroups	High enabling effect on other food policies (<i>medium evidence, high agreement</i>)

Effect of measures: ■ negative ■ none/unclear ■ slightly positive ■ positive

Notes: ^{#1} Minimum level to be effective 20% price increase; ^{#2} Minimum level to be effective USD50–80 tCO₂-eq. ^a In addition, all interventions are assumed to address health and climate change mitigation. ^b Requires coordination between policy areas, participation of stakeholders, transparent methods and indicators to manage trade-offs and prioritisation between possibly conflicting objectives; and suitable indicators for monitoring and evaluation against objectives.

All the illustrative mitigation pathways (IMPs) assessed in this report use land-based biological CDR (primarily afforestation/reforestation (A/R)) and/or bioenergy with carbon capture and storage (BECCS). Some also include direct air CO₂ capture and storage (DACCS) (*high confidence*). Across the scenarios limiting warming to 2°C (>67%) or below, cumulative volumes³⁰ of BECCS reach 328 (168–763) GtCO₂, CO₂ removal from AFOLU (mainly A/R) reaches 252 (20–418) GtCO₂, and DACCS reaches 29 (0–339) GtCO₂, for the 2020–2100 period. Annual volumes in 2050 are 2.75 (0.52–9.45) GtCO₂ yr⁻¹ for BECCS, 2.98 (0.23–6.38) GtCO₂ yr⁻¹ for the CO₂ removal from AFOLU (mainly A/R), and 0.02 (0–1.74) GtCO₂ yr⁻¹ for DACCS. (Box TS.10) {12.3, Cross-Chapter Box 8 in Chapter 12}

Despite limited current deployment, estimated mitigation potentials for DACCS, enhanced weathering (EW) and ocean-based CDR methods (including ocean alkalinity enhancement and ocean fertilisation) are moderate to large

(*medium confidence*). The potential for DACCS (5–40 GtCO₂ yr⁻¹) is limited mainly by requirements for low-carbon energy and by cost (100–300 (full range: 84–386) USD tCO₂⁻¹). DACCS is currently at a medium technology readiness level. EW has the potential to remove 2–4 (full range: <1 to around 100) GtCO₂ yr⁻¹, at costs ranging from 50 to 200 (full range: 24–578) USD tCO₂⁻¹. Ocean-based methods have a combined potential to remove 1–100 GtCO₂ yr⁻¹ at costs of USD40–500 tCO₂⁻¹, but their feasibility is uncertain due to possible side effects on the marine environment. EW and ocean-based methods are currently at a low technology readiness level. {12.3}

CDR governance and policymaking can draw on widespread experience with emissions reduction measures (*high confidence*). Additionally, to accelerate research, development, and demonstration, and to incentivise CDR deployment, a political commitment to formal integration into existing climate policy frameworks is required, including reliable measurement, reporting and verification (MRV) of carbon flows. {12.3.3, 12.4, 12.5}

Box TS.10 | Carbon Dioxide Removal (CDR)

Carbon Dioxide Removal (CDR) is necessary to achieve net zero CO₂ and GHG emissions both globally and nationally, counterbalancing ‘hard-to-abate’ residual emissions. CDR is also an essential element of scenarios that limit warming to 1.5°C or below 2°C (>67%) by 2100, regardless of whether global emissions reach near zero, net zero or net negative levels. While national mitigation portfolios aiming at net zero emissions or lower will need to include some level of CDR, the choice of methods and the scale and timing of their deployment will depend on the achievement of gross emission reductions, and managing multiple sustainability and feasibility constraints, including political preferences and social acceptability.

CDR refers to anthropogenic activities removing CO₂ from the atmosphere and durably storing it in *geological, terrestrial, or ocean* reservoirs, or in products. It includes existing and potential anthropogenic enhancement of biological, geochemical or chemical CO₂ sinks, but excludes natural CO₂ uptake not directly caused by human activities (Annex I). Carbon Capture and Storage (CCS) and Carbon Capture and Utilisation (CCU) applied to fossil CO₂ do not count as removal technologies. CCS and CCU can only be part of CDR methods if the CO₂ is biogenic or directly captured from ambient air, and stored durably in geological reservoirs or products. {12.3}

There is a great variety of CDR methods and respective implementation options {Cross-Chapter Box 8, Figure 1 in Chapter 12}. Some of these methods (like afforestation and soil carbon sequestration) have been practiced for decades to millennia, although not necessarily with the intention to remove carbon from the atmosphere. Conversely, for methods such as DACCS and BECCS, experience is growing but still limited in scale. A categorisation of CDR methods can be based on several criteria, depending on the highlighted characteristics. In this report, the categorisation is focused on the role of CDR methods in the carbon cycle, that is on the removal process (*land-based biological; ocean-based biological; geochemical; chemical*) and on the time scale of storage (*decades to centuries; centuries to millennia; 10,000 years or longer*), the latter being closely linked to different carbon storage media. Within one category (e.g., ocean-based biological CDR) options often differ with respect to other dynamic or context-specific dimensions such as mitigation potential, cost, potential for co-benefits and adverse side effects, and technology readiness level. (Table TS.7, TS.5.6, TS. 5.7) {12.3}

It is useful to distinguish between CO₂ removal from the atmosphere as the outcome of deliberate activities implementing CDR options, and the net emissions outcome achieved with the help of CDR deployment (i.e., gross emissions minus gross removals). As part of ambitious mitigation strategies at global or national levels, gross CDR can fulfil three different roles in complementing emissions abatement: (i) lowering net CO₂ or GHG emissions in the near term; (ii) counterbalancing ‘hard-to-abate’ residual emissions such as CO₂ from industrial activities and long-distance transport, or CH₄ and nitrous oxide from agriculture, in order to help reach net zero CO₂ or GHG emissions in the mid-term; (iii) achieving net negative CO₂ or GHG emissions in the long term if deployed at levels exceeding annual residual emissions {2.7, 3.3, 3.4, 3.5}. These roles of CDR are not mutually exclusive: for example, achieving net zero CO₂ or GHG emissions globally might involve individual developed countries attaining net negative CO₂ emissions at the time of global net zero, thereby allowing developing countries a smoother transition. {Cross-Chapter Box 8, Figure 2 in Chapter 12}

30 As a median value [5–95th percentile range].

Table TS.7 | Summary of status, costs, potentials, risk and impacts, co-benefits, trade-offs and spillover effects and the role in mitigation pathways for CDR methods {12.3.2, 7.4}. (TRL = technology readiness level.)

CDR method	Status (TRL)	Cost ¹ (USD tCO ₂ ⁻¹)	Mitigation potential ¹ (GtCO ₂ yr ⁻¹)	Risk and impacts	Co-benefits	Trade-offs and spillover effects	Role in mitigation pathways	Section
Afforestation/ reforestation	8–9	0–240	0.5–10	Reversal of carbon removal through wildfire, disease, pests may occur. Reduced catchment water yield and lower groundwater level if species and biome are inappropriate.	Enhanced employment and local livelihoods, improved biodiversity, improved renewable wood products provision, soil carbon and nutrient cycling. Possibly less pressure on primary forest.	Inappropriate deployment at large scale can lead to competition for land with biodiversity conservation and food production.	Substantial contribution in IAMs and also in bottom-up sectoral studies.	{7.4}
Soil carbon sequestration in croplands and grasslands	8–9	–45–100	0.6–9.3	Risk of increased nitrous oxide emissions due to higher levels of organic nitrogen in the soil; risk of reversal of carbon sequestration.	Improved soil quality, resilience and agricultural productivity.	Attempts to increase carbon sequestration potential at the expense of production. Net addition per hectare is very small; hard to monitor.	In development – not yet in global mitigation pathways simulated by IAMs in bottom-up studies: with medium contribution.	{7.4}
Peatland and coastal wetland restoration	8–9	Insufficient data	0.5–2.1	Reversal of carbon removal in drought or future disturbance. Risk of increased CH ₄ emissions.	Enhanced employment and local livelihoods, increased productivity of fisheries, improved biodiversity, soil carbon and nutrient cycling.	Competition for land for food production on some peatlands used for food production.	Not in IAMs but some bottom-up studies with medium contribution.	{7.4}
Agroforestry	8–9	Insufficient data	0.3–9.4	Risk that some land area lost from food production; requires very high skills.	Enhanced employment and local livelihoods, variety of products improved soil quality, more resilient systems.	Some trade-off with agricultural crop production, but enhanced biodiversity, and resilience of system.	No data from IAMs, but in bottom-up sectoral studies with medium contribution.	{7.4}
Improved forest management	8–9	Insufficient data	0.1–2.1	If improved management is understood as merely intensification involving increased fertiliser use and introduced species, then it could reduce biodiversity and increase eutrophication.	In case of sustainable forest management, it leads to enhanced employment and local livelihoods, enhanced biodiversity, improved productivity.	If it involves increased fertiliser use and introduced species it could reduce biodiversity and increase eutrophication and upstream GHG emissions.	No data from IAMs, but in bottom-up sectoral studies with medium contribution.	{7.4}
Biochar	6–7	10–345	0.3–6.6	Particulate and GHG emissions from production; biodiversity and carbon stock loss from unsustainable biomass harvest.	Increased crop yields and reduced non-CO ₂ emissions from soil; and resilience to drought.	Environmental impacts associated particulate matter; competition for biomass resource.	In development – not yet in global mitigation pathways simulated by IAMs.	{7.4}
Direct air carbon capture and storage (DACCS)	6	100–300 (84–386)	5–40	Increased energy and water use.	Water produced (solid sorbent DAC designs only).	Potentially increased emissions from water supply and energy generation.	In a few IAMs; DACCS complements other CDR methods.	{12.3}
Bioenergy with carbon capture and storage (BECCS)	5–6	15–400	0.5–11	Inappropriate deployment at very large scale leads to additional land and water use to grow biomass feedstock. Biodiversity and carbon stock loss if from unsustainable biomass harvest.	Reduction of air pollutants, fuel security, optimal use of residues, additional income, health benefits, and if implemented well, it can enhance biodiversity.	Competition for land with biodiversity conservation and food production.	Substantial contribution in IAMs and bottom-up sectoral studies. Note – mitigation through avoided GHG emissions resulting from bioenergy use is of the same magnitude as the mitigation from CDR (TS.5.6).	{7.4}
Enhanced weathering (EW)	3–4	50–200 (24–578)	2–4 (<1–95)	Mining impacts; air quality impacts of rock dust when spreading on soil.	Enhanced plant growth, reduced erosion, enhanced soil carbon, reduced soil acidity, enhanced soil water retention.	Potentially increased emissions from water supply and energy generation.	In a few IAMs; EW complements other CDR methods.	{12.3}

Table TS.7 (continued):

CDR method	Status (TRL)	Cost ¹ (USD tCO ₂ ⁻¹)	Mitigation potential ¹ (GtCO ₂ yr ⁻¹)	Risk and impacts	Co-benefits	Trade-offs and spillover effects	Role in mitigation pathways	Section
'Blue carbon management' in coastal wetlands	2–3	Insufficient data	<1	If degraded or lost, coastal blue carbon ecosystems are expected to release most of their carbon back to the atmosphere; potential for sediment contaminants, toxicity, bioaccumulation and biomagnification in organisms; issues related to altering degradability of coastal plants; use of sub-tidal areas for tidal wetland carbon removal; effect of shoreline modifications on sediment redeposition and natural marsh accretion; abusive use of coastal blue carbon as means to reclaim land for purposes that degrade capacity for carbon removal.	Provide many non-climatic benefits and can contribute to ecosystem-based adaptation, coastal protection, increased biodiversity, reduced upper ocean acidification; could potentially benefit human nutrition or produce fertiliser for terrestrial agriculture, anti-methanogenic feed additive, or as an industrial or materials feedstock.	If degraded or lost, coastal blue carbon ecosystems are likely to release most of their carbon back to the atmosphere. The full delivery of the benefits at their maximum global capacity will require years to decades to be achieved.	Not incorporated in IAMs, but in some bottom-up studies: small contribution.	{7.4, 12.3.1}
Ocean fertilisation	1–2	50–500	1–3	Nutrient redistribution, restructuring of the ecosystem, enhanced oxygen consumption and acidification in deeper waters, potential for decadal-to-millennial-scale return to the atmosphere of nearly all the extra carbon removed, risks of unintended side effects.	Increased productivity and fisheries, reduced upper-ocean acidification.	Sub-surface ocean acidification, deoxygenation; altered meridional supply of macro-nutrients as they are utilised in the iron-fertilised region and become unavailable for transport to, and utilisation in other regions, fundamental alteration of food webs, biodiversity.	No data.	{12.3.1}
Ocean alkalinity enhancement (OAE)	1–2	40–260	1–100	Increased seawater pH and saturation states and may impact marine biota. Possible release of nutritive or toxic elements and compounds. Mining impacts.	Limiting ocean acidification.	Potentially increased emissions of CO ₂ and dust from mining, transport and deployment operations.	No data.	{12.3.1}

¹ Range based on authors' estimates (as assessed from literature) are shown, with full literature ranges shown in () brackets.

TS.5.8 Demand-side Aspects of Mitigation

The assessment of the social science literature and regional case studies reveals how social norms, culture, and individual choices interact with infrastructure and other structural changes over time. This provides new insight into climate change mitigation strategies, and how economic and social activity might be organised across sectors to support emission reductions. To enhance well-being, people demand services and not primary energy and physical resources per se. Focusing on demand for services and the different social and political roles people play broadens the participation in climate action. (Box TS.11)

Demand-side mitigation and new ways of providing services can help *Avoid* and *Shift* final service demands and *Improve* service delivery. Rapid and deep changes in demand make it easier for every sector to reduce GHG emissions in the near and mid-term (*high confidence*). {5.2, 5.3}

The indicative potential of demand-side strategies to reduce emissions of direct and indirect CO₂ and non-CO₂ GHG emissions in three end-use sectors (buildings, land transport, and food) is 40–70% globally by 2050 (*high confidence*). Technical mitigation potentials compared to the 2050 emissions projection of two scenarios

consistent with policies announced by national governments until 2020 amount to 6.8 GtCO₂ for building use and construction, 4.6 GtCO₂ for land transport and 8.0 GtCO₂-eq for food demand, and amount to 4.4 GtCO₂ for industry. Mitigation strategies can be classified as *Avoid-Shift-Improve* (ASI) options, that reflect opportunities for socio-cultural, infrastructural, and technological change. The greatest *Avoid* potential comes from reducing long-haul aviation and providing short-distance low-carbon urban infrastructures. The greatest *Shift* potential would come from switching to plant-based diets. The greatest *Improve* potential comes from within the building sector, and in particular increased use of energy-efficient end-use technologies and passive housing. (Figures TS.20 and TS.21) {5.3.1, 5.3.2, Figures 5.7 and 5.8, Table 5.1 and Table SM.5.2}

Socio-cultural and lifestyle changes can accelerate climate change mitigation (*medium confidence*). Among 60 identified actions that could change individual consumption, individual mobility choices have the largest potential to reduce carbon footprints. Prioritising car-free mobility by walking and cycling and adoption of electric mobility could save 2 tCO₂-eq cap⁻¹ yr⁻¹. Other options with high mitigation potential include reducing air travel, cooling setpoint adjustments, reduced appliance use, shifts to public transit, and shifting consumption towards plant-based diets. {5.3.1, 5.3.1.2, Figure 5.8}

TS

Box TS.11 | A New Chapter in AR6 WGIII Focusing on the Social Science of Demand, and Social Aspects of Mitigation

The WGIII contribution to the Sixth Assessment Report of the IPCC (AR6) features a distinct chapter on demand, services and social aspects of mitigation {5}. The scope, theories, and evidence for such an assessment are addressed in Sections 5.1 and 5.4 within Chapter 5 and a Social Science Primer as an Appendix to Chapter 5.

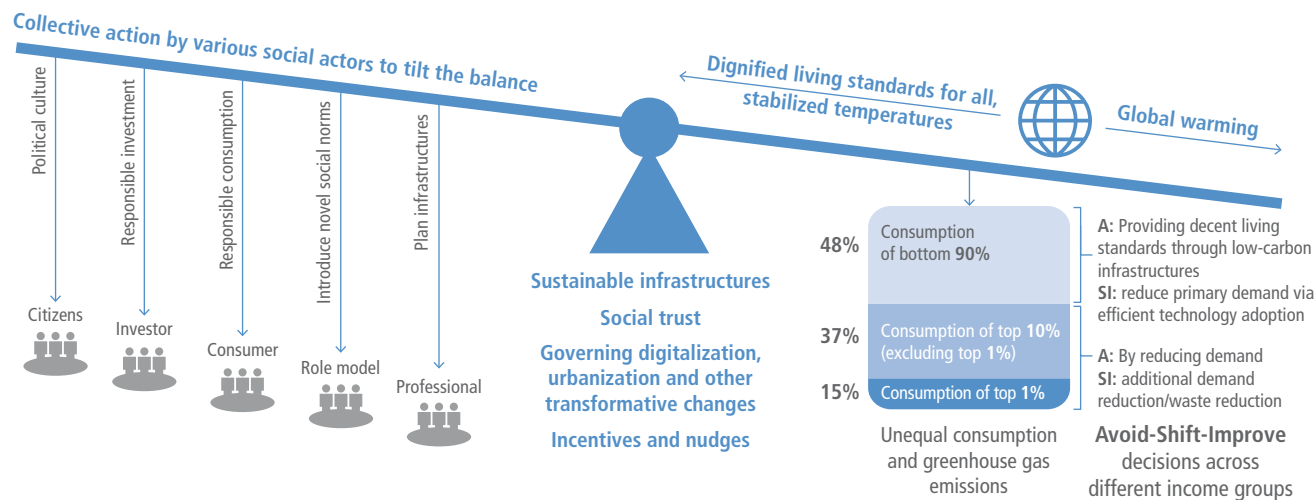

The literature on social science – from sociology, psychology, gender studies and political science for example – and climate change mitigation is growing rapidly. A bibliometric search of the literature identified 99,065 peer-reviewed academic papers, based on 34 search queries with content relevant to Chapter 5. This literature is expanding by 15% per year, with twice as many publications in the AR6 period (2014–2020) as in all previous years.

The models of stakeholders' decisions assessed by IPCC have continuously evolved. From AR1 to AR4, rational choice was the implicit assumption: agents with perfect information and unlimited processing capacity maximising self-focused expected utility and differing only in wealth, risk attitude, and time discount rate. The AR5 introduced a broader range of goals (material, social, and psychological) and decision processes (calculation-based, affect-based, and rule-based processes). However, its perspective was still individual- and agency-focused, neglecting structural, cultural, and institutional constraints and the influence of physical and social context.

A social science perspective is important in two ways. By adding new actors and perspectives, it (i) provides more options for climate mitigation; and (ii) helps to identify and address important social and cultural barriers and opportunities to socio-economic, technological, and institutional change. Demand-side mitigation involves five sets of social actors: individuals (e.g., consumption choices, habits), groups and collectives (e.g., social movements, values), corporate actors (e.g., investments, advertising), institutions (e.g., political agency, regulations), and infrastructure actors (e.g., very long-term investments and financing). Actors either contribute to the status-quo of global high-carbon consumption, and a GDP growth-oriented economy, or help generate the desired change to a low-carbon energy-services, well-being, and equity-oriented economy. Each set of actors has novel implications for the design and implementation of both demand- and supply-side mitigation policies. They show important synergies, making energy demand mitigation a dynamic problem where the packaging and/or sequencing of different policies play a role in their effectiveness {5.5, 5.6}. Incremental interventions change social practices, simultaneously affecting emissions and well-being. The transformative change requires coordinated action across all five sets of actors (Table 5.4), using social science insights about intersection of behaviour, culture, institutional and infrastructural changes for policy design and implementation. *Avoid*, *Shift*, and *Improve* choices by individuals, households and communities support mitigation {5.3.1.1, Table 5.1}. They are instigated by role models, changing social norms driven by policies and social movements. They also require appropriate infrastructures designed by urban planners and building and transport professionals, corresponding investments, and a political culture supportive of demand-side mitigation action.

Demand side mitigation is about more than behavioural change. Reconfiguring the way services are provided while simultaneously changing social norms and preferences will help reduce emissions and access. Transformation happens through societal, technological and institutional changes.

(a) Tilting the balance towards less resource intensive service provisioning

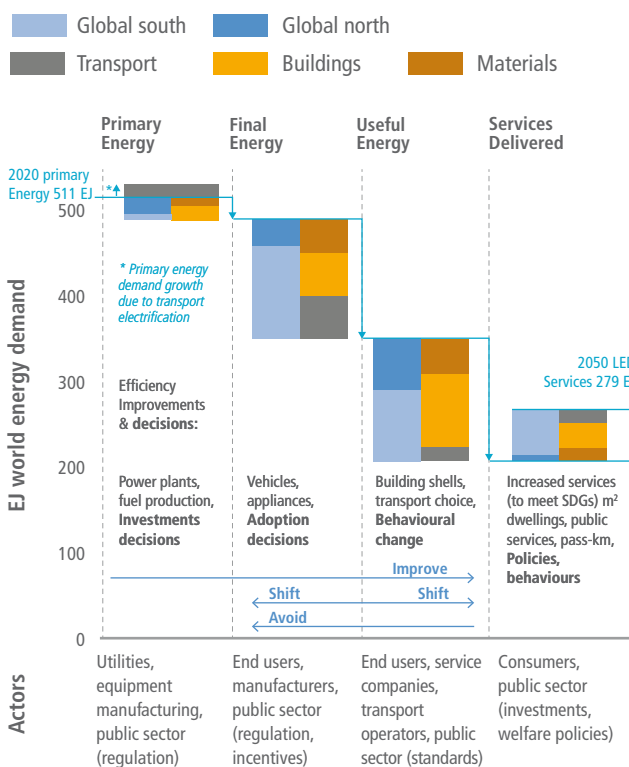

(b) Using wide range of demand-side options

Low-carbon lifestyle transition can be classified into Avoid, Shift, and Improve options. Individual potential to reduce emissions is highest in mobility systems.

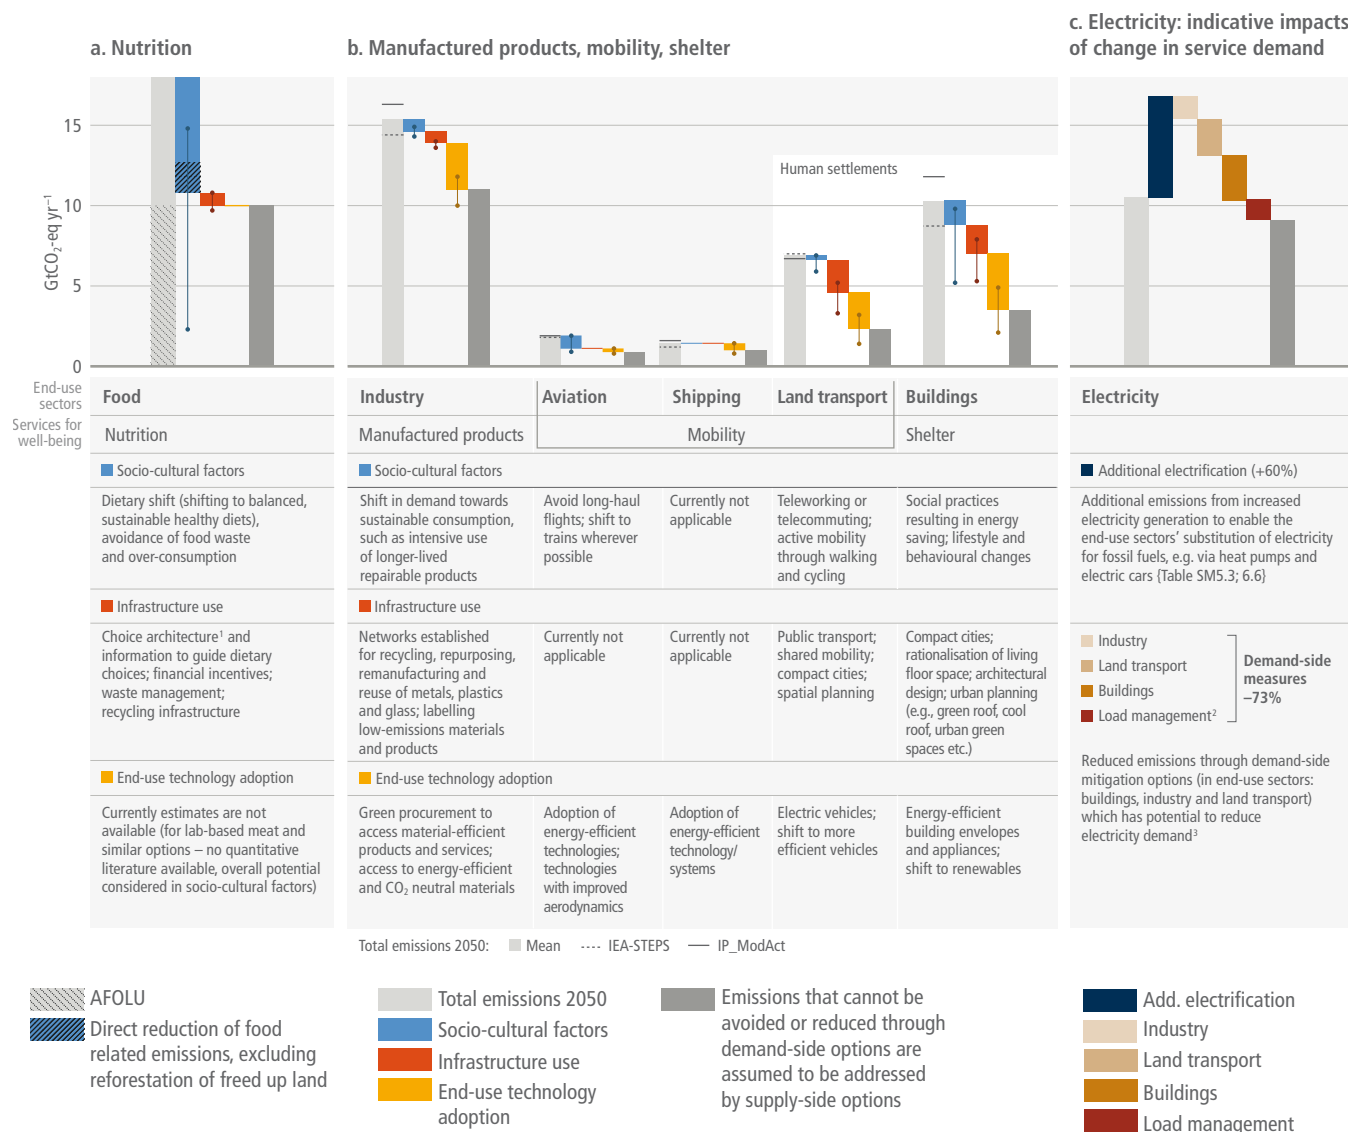

(c) Achieving a Low Demand scenario by 2050

Improved service provisioning systems enable increases in service levels and at the same time a reduction in upstream energy demand by 45%.

Figure TS.20 | Demand-side strategies for mitigation. Demand-side mitigation is about more than behavioural change and transformation happens through societal, technological and institutional changes. (Figure 5.10, Figure 5.14)

Demand-side mitigation can be achieved through changes in socio-cultural factors, infrastructure design and use, and end-use technology adoption by 2050.

¹ The presentation of choices to consumers, and the impact of that presentation on consumer decision-making.

² Load management refers to demand-side flexibility that cuts across all sectors and can be achieved through incentive design like time of use pricing/monitoring by artificial intelligence, diversification of storage facilities, etc.

³ The impact of demand-side mitigation on electricity sector emissions depends on the baseline carbon intensity of electricity supply, which is scenario dependent.

Figure TS.21 | Demand-side mitigation can be achieved through changes in socio-cultural factors, infrastructure design and use, and technology adoption.

Mitigation response options related to demand for services have been categorised into three domains: 'socio-cultural factors', related to social norms, culture, and individual choices and behaviour; 'infrastructure use', related to the provision and use of supporting infrastructure that enables individual choices and behaviour; and 'technology adoption', which refers to the uptake of technologies by end users. Potentials in 2050 are estimated using the International Energy Agency's 2020 World Energy Outlook STEPS (Stated Policy Scenarios) as a baseline. This scenario is based on a sector-by-sector assessment of specific policies in place, as well as those that have been announced by countries by mid-2020. This scenario was selected due to the detailed representation of options across sectors and sub-sectors. The heights of the coloured columns represent the potentials on which there is a high level of agreement in the literature, based on a range of case studies. The range shown by the dots connected by dotted lines represents the highest and lowest potentials reported in the literature which have low to medium levels of agreement. The demand-side potential of socio-cultural factors in the food system has two parts. The economic potential of direct emissions (mostly non-CO₂) demand reduction through socio-cultural factors alone is 1.9 GtCO₂-eq without considering land-use change by diversion of agricultural land from food production to carbon sequestration. If further changes in land use enabled by this change in demand are considered, the indicative potential could reach 7 GtCO₂-eq. The electricity panel presents separately the mitigation potential from changes in electricity demand and changes associated with enhanced electrification in end-use sectors. Electrification increases electricity demand, while it is avoided through demand-side mitigation strategies. Load management refers to demand-side flexibility that can be achieved through incentive design such as time-of-use pricing/monitoring by artificial intelligence, diversification of storage facilities, and so on. NZE (IEA Net-Zero Emissions by 2050 scenario) is used to compute the impact of end-use sector electrification, while the impact of demand-side response options is based on bottom-up assessments. Dark grey columns show the emissions that cannot be avoided through demand-side mitigation options. The table indicates which demand-side mitigation options are included. Options are categorised according to: socio-cultural factors, infrastructure use, and technology adoption. Figure SPM.7 covers potential of demand-side options for the year 2050. Figure SPM.8 covers both supply- and demand-side options and their potentials for the year 2030. [5.3, Figure 5.7, 5.SM.II]

Leveraging improvements in end-use service delivery through behavioural and technological innovations, and innovations in market organisation, leads to large reductions in upstream resource use (*high confidence*). Analysis of indicative potentials range from a factor 10- to 20-fold improvement in the case of available energy (exergy) analysis, with the highest improvement potentials at the end-user and service-provisioning levels. Realisable service level efficiency improvements could reduce upstream energy demand by 45% in 2050. (Figure TS.20) {5.3.2, Figure 5.10}

Decent living standards (DLS) and well-being for all (SDG 3) are achievable if high-efficiency low-demand mitigation pathways are followed (*medium confidence*). Minimum requirements of energy use consistent with enabling *well-being for all* is between 20 and 50 GJ cap⁻¹ yr⁻¹ depending on the context. (Figure TS.22) {5.2.2.1, 5.2.2.2, Box 5.3}

Alternative service provision systems, for example, those enabled through digitalisation, sharing economy initiatives and circular economy initiatives, have to date made a limited contribution to climate change mitigation (*medium confidence*). While digitalisation through specific new products and applications holds potential for improvement in service-level efficiencies, without public policies and regulations, it also has the potential to increase consumption and energy use. Reducing the energy use of data centres, networks, and connected devices is possible in managing low-carbon digitalisation. Claims on the benefits of the circular economy for sustainability and climate change mitigation have limited evidence. (Box TS.12, Box TS.14) {5.3.4, Figures 5.12 and 5.13}

Box TS.12 | Circular Economy (CE)

In AR6, the circular economy (CE) concept {Annex I} is highlighted as an increasingly important mitigation approach that can help deliver human well-being by minimising waste of energy and resources. While definitions of CE vary, its essence is to shift away from linear ‘make and dispose’ economic models to those that emphasise product longevity, reuse, refurbishment, recycling, and material efficiency, thereby enabling more circular material systems that reduce embodied energy and emissions. {5.3.4, 8.4, 8.5, 9.5, 11.3.3}

Whereas IPCC AR4 {WGIII, Chapter 10} included a separate chapter on waste-sector emissions and waste-management practices, and AR5 {WGIII, Chapter 10} reviewed the importance of ‘reduce, reuse, recycle’ and related policies, AR6 focuses on how CE can reduce waste in materials production and consumption by optimising materials’ end-use service utility. Specific examples of CE implementations, policies, and mitigation potentials are included in Chapters 5, 8, 9, 11 and 12. {5.3, 8.4, 9.5, 11.3, 12.6}

CE is shown to empower new social actors in mitigation actions, given that it relies on the synergistic actions of producers, sellers, and consumers {11.3.3}. As an energy and resource demand-reduction strategy, it is consistent with high levels of human well-being {5.3.4.3} and ensures better environmental quality (Figure TS.22) {5.2.1}. It also creates jobs through increased sharing, reuse, refurbishment, and recycling activities. Therefore, CE contributes to several SDGs, including clean water and sanitation (SDG 6), affordable energy and clean energy (SDG 7), decent work and economic growth (SDG 8), responsible production and consumption (SDG 12) and climate action (SDG 13). {11.5.3.2}

Emissions savings derive from reduced primary material production and transport. For example, in buildings, lifetime extension, material efficiency, and reusable components reduce embodied emissions by avoiding demand for structural materials {9.3, 9.5}. At regional scales, urban/industrial symbiosis reduce primary material demand through by-product exchange networks {11.3.3}. CE strategies also exhibit enabling effects, such as material-efficient and circular vehicle designs that also improve fuel economy {10.2.2.2}. There is growing interest in ‘circular bioeconomy’ concepts applied to bio-based materials {Box 12.2} and even a ‘circular carbon economy’, wherein carbon captured via CCU {11.3.6} or CDR {3.4.6} is converted into reusable materials, which is especially relevant for the transitions of economies dependent on fossil fuel revenue. {12.6}

While there are many recycling policies, CE-oriented policies for more efficient material use with higher value retention are comparatively far fewer; these policy gaps have been attributed to institutional failures, lack of coordination, and lack of strong advocates {5.3, 9.5.3.6, Boxes 11.5 and 12.2}. Reviews of mitigation potentials reveal unevenness in the savings of CE applications and potential risks of rebound effects {5.3}. Therefore, CE policies that identify system determinants maximise potential emissions reductions, which vary by material, location, and application.

There are knowledge gaps for assessing CE opportunities within mitigation models due to CE’s many cross-sectoral linkages and data gaps related to its nascent state {3.4.4}. Opportunity exists to bridge knowledge from the industrial ecology field, which has historically studied CE, to the mitigation modelling community for improved analysis of interventions and policies for AR7. For instance, a global CE knowledge-sharing platform is helpful for CE performance measurement, reporting and accounting. {5.3, 9.5, 11.7}

Providing better services with less energy and resource input has high technical potential and is consistent with providing well-being for all (*medium confidence*). The assessment of 19 demand-side mitigation options and 18 different constituents of well-being showed that positive impacts on well-being outweigh negative ones by a factor of 11. {5.2, 5.2.3, Figure 5.6}

Demand-side mitigation options bring multiple interacting benefits (*high confidence*). Energy services to meet human needs for nutrition, shelter, health, and so on, are met in many different ways with different emissions implications that depend on local contexts, cultures, geography, available technologies, and social preferences. In the near term, many less-developed countries, and poor people everywhere, require better access to safe and low-emissions energy sources to ensure decent living standards and increase energy savings from service improvements by about 20–25%. (Figure TS.22) {5.2, 5.4.5, Figures 5.3, 5.4, 5.5 and 5.6, Boxes 5.2 and 5.3}

Granular technologies and decentralised energy end-use, characterised by modularity, small unit sizes and small unit costs, diffuse faster into markets and are associated with faster technological learning benefits, greater efficiency, more opportunities to escape technological lock-in, and greater employment (*high confidence*). Examples include solar PV systems, batteries, and thermal heat pumps. {5.3, 5.5, 5.5.3}

Wealthy individuals contribute disproportionately to higher emissions and have a high potential for emissions reductions while maintaining decent living standards and well-being (*high confidence*). Individuals with high socio-economic status are capable of reducing their GHG emissions by becoming role models of low-carbon lifestyles, investing in low-carbon businesses, and advocating for stringent climate policies. {5.4.1, 5.4.3, 5.4.4, Figure 5.14}

Demand-side solutions require both motivation and capacity for change (*high confidence*). Motivation by individuals or households worldwide to change energy consumption behaviour is generally low. Individual behavioural change is insufficient for climate change mitigation unless embedded in structural and cultural change. Different factors influence individual motivation and capacity for change in different demographics and geographies. These factors go beyond traditional socio-demographic and economic predictors and include psychological variables such as awareness, perceived risk, subjective and social norms, values, and perceived behavioural control. Behavioural nudges promote easy behaviour change, for example, ‘*Improve*’ actions such as making investments in energy efficiency, but fail to motivate harder lifestyle changes (*high confidence*). {5.4}

Behavioural interventions, including the way choices are presented to end users (an intervention practice known as choice architecture), work synergistically with price signals, making the combination more effective (*medium confidence*). Behavioural interventions through nudges, and alternative ways of redesigning and motivating decisions, alone provide small to medium contributions to reduce energy consumption and GHG

emissions. Green defaults, such as automatic enrolment in ‘green energy’ provision, are highly effective. Judicious labelling, framing, and communication of social norms can also increase the effect of mandates, subsidies, or taxes. {5.4, 5.4.1, Table 5.3, 5.3}

Cultural change, in combination with new or adapted infrastructure, is necessary to enable and realise many *Avoid* and *Shift* options (*medium confidence*). By drawing support from diverse actors, narratives of change can enable coalitions to form, providing the basis for social movements to campaign in favour of (or against) societal transformations. People act and contribute to climate change mitigation in their diverse capacities as consumers, citizens, professionals, role models, investors, and policymakers. {5.4, 5.5, 5.6}

Collective action as part of social or lifestyle movements underpins system change (*high confidence*). Collective action and social organising are crucial to shift the possibility space of public policy on climate change mitigation. For example, climate strikes have given voice to youth in more than 180 countries. In other instances, mitigation policies allow the active participation of all stakeholders, resulting in building social trust, new coalitions, legitimising change, and thus initiate a positive cycle in climate governance capacity and policies. {5.4.2, Figure 5.14}

Transition pathways and changes in social norms often start with pilot experiments led by dedicated individuals and niche groups (*high confidence*). Collectively, such initiatives can find entry points to prompt policy, infrastructure, and policy reconfigurations, supporting the further uptake of technological and lifestyle innovations. Individuals’ agency is central as social change agents and narrators of meaning. These bottom-up socio-cultural forces catalyse a supportive policy environment, which enables changes. {5.5.2}

The current effects of climate change, as well as some mitigation strategies, are threatening the viability of existing business practices, while some corporate efforts also delay mitigation action (*medium confidence*). Policy packages that include job creation programmes can help to preserve social trust, livelihoods, respect, and dignity of all workers and employees involved. Business models that protect rent-extracting behaviour may sometimes delay political action. Corporate advertisement and brand-building strategies may also attempt to deflect corporate responsibility to individuals or aim to appropriate climate-care sentiments in their own brand-building. {5.4.3, 5.6.4}

Middle actors – professionals, experts, and regulators – play a crucial, albeit underestimated and underutilised, role in establishing low-carbon standards and practices (*medium confidence*). Building managers, landlords, energy-efficiency advisers, technology installers, and car dealers influence patterns of mobility and energy consumption by acting as middle actors or intermediaries in the provision of building or mobility services and need greater capacity and motivation to play this role. (Figure TS.20a) {5.4.3}

Figure TS.23 | Overview of emission mitigation options and their cost and potential for the year 2030. The mitigation potential of each option is the quantity of net greenhouse gas emission reductions that can be achieved by a given mitigation option relative to specified emission baselines that reflects what would be considered current policies in the period 2015–2019. Mitigation options may overlap or interact and cannot simply be summed together. The potential for each option is broken down into cost categories (see legend). Only monetary costs and revenues are considered. If costs are less than zero, lifetime monetary revenues are higher than lifetime monetary costs. For wind energy, for example, negative cost indicates that the cost is lower than that of fossil-based electricity production. The error bars refer to the total potential for each option. The breakdown into cost categories is subject to uncertainty. Where a smooth colour transition is shown, the breakdown of the potential into cost categories is not well researched, and the colours indicate only into which cost category the potential can predominantly be found in the literature. [Figure SPM.8, 6.4, Table 7.3, Supplementary Material Table 9.SM.2, Supplementary Material Table 9.SM.3, 10.6, 11.4, Figure 11.13, 12.2, Supplementary Material 12.SM.1.2.3]

Social influencers and thought leaders can increase the adoption of low-carbon technologies, behaviours, and lifestyles (*high confidence*). Preferences are malleable and can align with a cultural shift. The modelling of such shifts by salient and respected community members can help bring about changes in different service provisioning systems. Between 10% and 30% of committed individuals are required to set new social norms. {5.2.1, 5.4}

TS.5.9 Mitigation Potential Across Sectors and Systems

The total emission mitigation potential achievable by the year 2030, calculated based on sectoral assessments, is sufficient to reduce global greenhouse gas (GHG) emissions to half of the current (2019) level or less (*high confidence*). This potential – 31–44 GtCO₂-eq – requires the implementation of a wide range of mitigation options. Options with mitigation costs lower than USD20 tCO₂⁻¹ make up more than half of this potential and are available for all sectors. The market benefits of some options exceed their costs. (Figure TS.23) {12.2, Table 12.3}

Cross-sectoral considerations in mitigation finance are critical for the effectiveness of mitigation action as well as for balancing the often conflicting social, developmental, and environmental policy goals at the sectoral level (*medium confidence*). True resource mobilisation plans that properly address mitigation costs and benefits at sectoral level cannot be developed in isolation of their cross-sectoral implications. There is an urgent need for multilateral financing institutions to align their frameworks and delivery mechanisms, including the use of blended financing to facilitate cross-sectoral solutions as opposed to causing competition for resources among sectors. {12.6.4}

Carbon leakage is a cross-sectoral and cross-country consequence of differentiated climate policy (*robust evidence, medium agreement*). Carbon leakage occurs when mitigation measures implemented in one country/sector leads to increased emissions in other countries/sectors. Global commodity value chains and associated international transport are important mechanisms through which carbon leakage occurs. Reducing emissions from the value chain and transportation can offer opportunities to mitigate three elements of cross-sectoral spillovers and related leakage: (i) domestic cross-sectoral spillovers within the same country; (ii) international spillovers within a single sector resulting from substitution of domestic production of carbon-intensive goods with their imports from abroad; and (iii) international cross-sectoral spillovers among sectors in different countries. {12.6.3}

TS.6 Implementation and Enabling Conditions

Chapters 13 to 16 address the enabling conditions that can accelerate or impede rapid progress on mitigation. Chapters 13 and 14 focus on policy, governance and institutional capacity, and international cooperation, respectively taking a national and international perspective; Chapter 15 focuses on investment and finance; and Chapter 16 focuses on innovation and technology. The assessment of social aspects of mitigation draws on material assessed in Chapter 5.

TS.6.1 Policy and Institutions

Long-term deep emission reductions, including the reduction of emissions to net zero, is best achieved through institutions and governance that nurture new mitigation policies, while at the same time reconsidering existing policies that support the continued emission of GHGs (*high confidence*). To do so effectively, the scope of climate governance needs to include both direct efforts to target GHG emissions and indirect opportunities to tackle GHG emissions that result from efforts directed towards other policy objectives. {13.2, 13.5, 13.6, 13.7, 13.9}

Institutions and governance underpin mitigation by providing the legal basis for action. This includes setting up implementing organisations and the frameworks through which diverse actors interact (*medium evidence, high agreement*). Institutions can create mitigation and sectoral policy instruments; policy packages for low-carbon system transition; and economy-wide measures for systemic restructuring. {13.2, 13.7, 13.9}

Policies have had a discernible impact on mitigation for specific countries, sectors, and technologies (*high confidence*), avoiding emissions of several GtCO₂-eq yr⁻¹ (*medium confidence*). Both market-based and regulatory policies have distinct but complementary roles. The share of global GHG emissions subject to mitigation policy has increased rapidly in recent years, but big gaps remain in policy coverage, and the stringency of many policies falls short of what is needed to achieve the desired mitigation outcomes. (Box TS.13) {13.6, Cross-Chapter Box 10 in Chapter 14}

Climate laws enable mitigation action by signalling the direction of travel, setting targets, mainstreaming mitigation into sector policies, enhancing regulatory certainty, creating law-backed agencies, creating focal points for social mobilisation, and attracting international finance (*medium evidence, high agreement*). By 2020, 'direct' climate laws primarily focused on GHG reductions were present in 56 countries covering 53% of global emissions (Figure TS.24). More than 690 laws, including 'indirect' laws, however, may also have an effect on mitigation. Among direct laws, 'framework' laws set an overarching legal basis for mitigation either by pursuing a target and implementation approach, or by seeking to mainstream climate objectives through sectoral plans and integrative institutions. (Figure TS.24) {13.2}

Institutions can enable improved governance by coordinating across sectors, scales and actors, building consensus for action, and setting strategies (*medium evidence, high agreement*). Institutions are more stable and effective when they are congruent with national contexts, leading to mitigation-focused institutions in some countries and the pursuit of multiple objectives in others. Sub-national institutions play a complementary role to national institutions by developing locally relevant visions and plans, addressing policy gaps or limits in national institutions, building local administrative structures and convening actors for place-based decarbonisation. {13.2}

Mitigation strategies, instruments and policies that fit with dominant ideas, values and belief systems within a country or within a sector are more easily adopted and implemented (*medium confidence*). Ideas, values and beliefs may change over time. Policies that bring perceived direct benefits, such as subsidies, usually receive greater support. The awareness of co-benefits for the public increases support of climate policies (*high confidence*). {13.2, 13.3, 13.4}

Climate governance is constrained and enabled by domestic structural factors, but it is still possible for actors to make substantial changes (*medium evidence, high agreement*). Key structural factors are domestic material endowments (such as fossil fuels and land-based resources); domestic political systems; and prevalent ideas, values and belief systems. Developing Countries face additional material constraints in climate governance due to development challenges and scarce economic or natural resources. A broad group of actors influence how climate governance develop over time, including a range of civic organisations, encompassing both pro- and anti-climate action groups. {13.3, 13.4}

Sub-national actors are important for mitigation because municipalities and regional governments have jurisdiction over climate-relevant sectors such as land use, waste and urban policy. They are able to experiment with climate solutions and can forge partnerships with the private sector and internationally to leverage enhanced climate action (*high confidence*). More than 10,500 cities and nearly 250 regions representing more than 2 billion people have pledged largely voluntary action to reduce emissions. Indirect gains include innovation, establishing norms and developing capacity. However, sub-national actors often lack national support, funding, and capacity to mobilise finance and human resources, and create new institutional competences. {13.5}

Climate litigation is growing and can affect the outcome and ambition of climate governance (*medium evidence, high agreement*). Since 2015, at least 37 systemic cases have been initiated against states that challenge the overall effort of a state to mitigate or adapt to climate change. If successful, such cases can lead to an increase in a country's overall ambition to tackle climate change. Climate litigation has also successfully challenged governments' authorisations of high-emitting projects, setting precedents in favour of climate action. Climate litigation against private sector and financial institutions is also on the rise. {13.4}

Figure TS.24 | Prevalence of legislation and emissions targets across regions. Panel (a): shares of global GHG emissions under national climate change legislations – in 2010, 2015 and 2020. Climate legislation is defined as an act passed by a parliament that includes the reduction of GHGs in its title or objectives. Panel (b): shares of global GHG emissions under national climate emission targets – in 2010, 2015 and 2020. Emissions reductions targets were taken into account as a legislative target when they were defined in a law or as part of a country's submission under the Kyoto Protocol, or as an executive target when they were included in a national policy or official submissions under the UNFCCC. Targets were included if they were economy-wide or included at least the energy sector. The proportion of national emissions covered are scaled to reflect coverage and whether targets are in GHG or CO₂ terms. Emissions data used are for 2019. 2020 data was excluded as emissions shares across regions deviated from past patterns due to COVID-19. AR6 regions: DEV = Developed countries; APC = Asia and Pacific; EEA = Eastern Europe and West Central Asia; AFR = Africa; LAM = Latin America and the Caribbean; ME = Middle East. {Figure 13.1 and 13.2}

The media shapes the public discourse about climate mitigation. This can usefully build public support to accelerate mitigation action but may also be used to impede decarbonisation (*medium evidence, high agreement*). Global media coverage (across a study of 59 countries) has been growing, from about 47,000 articles in 2016–17 to about 87,000 in 2020–21. Generally, the media representation of climate science has increased and become more accurate over time. On occasion, the propagation of scientifically misleading information by organised counter-movements has fuelled polarisation, with negative implications for climate policy. {13.4}

Explicit attention to equity and justice is salient to both social acceptance and fair and effective policymaking for mitigation (*high confidence*). Distributional implications of alternative climate policy choices can be usefully evaluated at city, local and national scales as an input to policymaking. It is anticipated that institutions and governance frameworks that enable consideration of justice and Just Transitions can build broader support for climate policymaking. {13.2, 13.6, 13.8, 13.9}

Carbon pricing is effective in promoting implementation of low-cost emissions reductions (*high confidence*). While the coverage of emissions trading and carbon taxes has risen to over 20 percent of global CO₂ emissions, both coverage and price are lower than is needed for deep reductions. Market mechanisms ideally are designed to be effective as well as efficient, balance distributional goals and find social acceptance. Practical experience has driven progress in market mechanism design, especially of emissions trading schemes. Carbon pricing is limited in its effect on adoption of higher-cost mitigation options, and where decisions are often not sensitive to price incentives, such as in energy efficiency, urban planning, and infrastructure (*robust evidence, medium agreement*). Subsidies have been used to improve energy efficiency, encourage the uptake of renewable energy and other sector-specific emissions-saving options. {13.6}

Carbon pricing is most effective if revenues are redistributed or used impartially (*high confidence*). A carbon levy earmarked for green infrastructures or saliently returned to taxpayers corresponding to widely accepted notions of fairness increases the political acceptability of carbon pricing. {5.6, Box 5.11}

Removing fossil fuel subsidies would reduce emissions, improve public revenue and macroeconomic performance, and yield other environmental and sustainable development benefits. Subsidy removal may have adverse distributional impacts especially on the most economically vulnerable groups which, in some cases can be mitigated by measures such as redistributing revenue saved, all of which depend on national circumstances (*high confidence*); fossil fuel subsidy removal is projected by various studies (using alternative methodologies) to reduce global CO₂ emissions by 1–4%, and GHG emissions by up to 10% by 2030, varying across regions (*medium confidence*). {6.3, 13.6} {13.6}

Regulatory instruments play an important role in achieving specific mitigation outcomes in sectoral applications (*high confidence*). Regulation is effective in particular applications and often enjoys greater political support, but tends to be more economically costly than pricing instruments (*robust evidence, medium agreement*). Flexible forms of regulation (e.g., performance standards) have achieved aggregate goals for renewable energy generation, vehicle efficiency and fuel standards, and energy efficiency in buildings and industry. Infrastructure investment decisions are significant for mitigation because they lock-in high- or low-emissions trajectories over long periods. Information and voluntary programs can contribute to overall mitigation outcomes (*medium evidence, high agreement*). Designing for overlap and interactions among mitigation policies enhances their effectiveness. {13.6}

National mitigation policies interact internationally with effects that both support and hinder mitigation action (*medium evidence, high agreement*). Reductions in demand for fossil fuels tend to negatively affect fossil fuel-exporting countries. Creation of markets for emission reduction credits tends to benefit countries able to supply credits. Policies to support technology development and diffusion tend to have positive spillover effects. There is no consistent evidence of significant emissions leakage or competitiveness effects between countries, including for emissions-intensive trade-exposed industries covered by emission-trading systems (*medium confidence*). {13.6}

Policy packages are better able to support socio-technical transitions and shifts in development pathways toward low-carbon futures than are individual policies (*high confidence*). For best effect, they need to be harnessed to a clear vision for change and designed with attention to local governance context. Comprehensiveness in coverage, coherence to ensure complementarity, and consistency of policies with the overarching vision and its objectives are important design criteria. Integration across objectives occurs when a policy package is informed by a clear problem framing and identification of the full range of relevant policy subsystems. The climate policy landscape is outlined in Table TS.8, which maps framings of desired national policy outcomes to policymaking approaches. {13.7, Figure 13.6}

Table TS.8 | Mapping the landscape of climate policy. {Figure 13.6}

Approach to policymaking	Framing of outcome	
	Enhancing mitigation	Addressing multiple objectives of mitigation and development
Shifting incentives	<p>'Direct mitigation focus' {2.8, 13.6}</p> <p>Objective: reduce GHG emissions now.</p> <p>Literature: how to design and implement policy instruments, with attention to distributional and other concerns.</p> <p>Examples: carbon tax, cap and trade, border carbon adjustment (BCA), disclosure policies.</p>	<p>'Co-benefits' {5.6.2, 12.4.4, 17.3}</p> <p>Objective: synergies between mitigation and development.</p> <p>Literature: scope for and policies to realise synergies and avoid trade-offs across climate and development objectives.</p> <p>Examples: appliance standards, fuel taxes, community forest management, sustainable dietary guidelines, green building codes, packages for air pollution, packages for public transport.</p>
Enabling transition	<p>'Socio-technical transitions' {1.7.3, 5.5, 6.7, 10.8, Cross-Chapter Box 12 in Chapter 16}</p> <p>Objective: accelerate low-carbon shifts in socio-technical systems.</p> <p>Literature: understand socio-technical transition processes, integrated policies for different stages of a technology 'S curve' and explore structural, social and political elements of transitions.</p> <p>Examples: packages for renewable-energy transition and coal phase-out; diffusion of electric vehicles, process and fuel switching in key industries.</p>	<p>'System transitions to shift development pathways' {7.4.5, 11.6.6, 13.9, 17.3.3, Cross-Chapter Box 5 in Chapter 4, Cross-Chapter Box 12 in Chapter 16}</p> <p>Objective: accelerate system transitions and shift development pathways to expand mitigation options and meet other development goals.</p> <p>Literature: examines how structural development patterns and broad cross-sector and economy-wide measures drive ability to mitigate while achieving development goals through integrated policies and aligning enabling conditions.</p> <p>Examples: packages for sustainable urbanisation, land-energy-water nexus approaches, green industrial policy, regional Just Transition plans.</p>

The co-benefits and trade-offs of integrating adaptation and mitigation are most usefully identified and assessed prior to policymaking rather than being accidentally discovered (*high confidence*). This requires strengthening relevant national institutions to reduce silos and overlaps, increasing knowledge exchange at the country and regional levels, and supporting engagement with bilateral and multilateral funding partners. Local governments are well placed to develop policies that generate social and environmental co-benefits but to do so require legal backing and adequate capacity and resources. {13.8}

Climate change mitigation is accelerated when attention is given to integrated policy and economy-wide approaches, and when enabling conditions (*governance, institutions, behaviour and lifestyle, innovation, policy, and finance*), are present (*robust evidence, medium agreement*). Accelerating climate mitigation includes simultaneously weakening high-carbon systems and encouraging low-carbon systems; ensuring interaction between adjacent systems (e.g., energy and agriculture); overcoming resistance to policies (e.g., from incumbents in high-carbon-emitting industries), including by providing transitional support to the vulnerable and negatively affected by distributional impacts; inducing changes in consumer practices and routines; providing transition support; and addressing coordination challenges in policy and governance. Table TS.9 elucidates the complexity of policymaking in driving sectoral transitions by summarising case studies of sectoral transitions from Chapters 5 to 12. These real-world sectoral transitions reinforce critical lessons on policy integration. (Table TS.9) {13.7, 13.9}

Economy-wide packages, including economic-stimulus packages, can contribute to shifting sustainable development pathways and achieving net zero outcomes whilst meeting short-term economic goals (*medium evidence, high agreement*). The 2008–9 global recession showed that policies for sustained economic recovery go beyond short-term fiscal stimulus to include long-term commitments of public spending on the low-carbon economy, pricing reform, addressing affordability, and minimising distributional impacts. COVID-19 spurred stimulus packages and multi-objective recovery policies may also have potential to meet short-term economic goals while enabling longer-term sustainability goals. (Table TS.8) {13.9}

Table TS.9 | Case studies of integrated policymaking for sectoral transitions. Real-world sectoral transitions reinforce critical lessons on policy integration: a high-level strategic goal (column A), the need for a clear sectoral outcome framing (column B), a carefully coordinated mix of policy instruments and governance actions (column C), and the importance of context-specific governance factors (column D). Illustrative examples, drawn from sectors, help elucidate the complexity of policymaking in driving sectoral transitions. [Cross-Chapter Box 9 in Chapter 13, Table 1]

			Enablers	Barriers
African electromobility – trackless trams with solar in Bulawayo and e-motorbikes in Kampala {Box 10.4}	<ul style="list-style-type: none"> – Leapfrog into a decarbonised transport future – Achieve multiple social benefits beyond mobility provision 	<ul style="list-style-type: none"> – Develop urban centres with solar at station precincts – Public-private partnerships for financing – Sanction demonstration projects for new electric transit and new electric motorbikes (for freight) 	<ul style="list-style-type: none"> – ‘Achieving SDGs’ was an enabling policy framing – Multi-objective policy process for mobility, mitigation and manufacturing – Potential for funding through climate finance – Co-benefits such as local employment generation 	<ul style="list-style-type: none"> – Economic decline in the first decade of the 21st century – Limited fiscal capacity for public funding of infrastructure – Inadequate charging infrastructure for e-motorbikes
Initiative for a climate-friendly industry in North Rhine Westphalia (NRW), Germany {Box 11.3}	<ul style="list-style-type: none"> – Collaboratively develop innovative strategies towards a net zero GHG industrial sector, while securing competitiveness 	<ul style="list-style-type: none"> – Build platform to bring together industry, scientists and government in self-organised innovation teams – Intensive cross-branch cooperation to articulate policy/infrastructure needs 	<ul style="list-style-type: none"> – NRW is Germany’s industrial heartland, with an export-oriented industrial base – Established government-industry ties – Active discourse between industry and public 	<ul style="list-style-type: none"> – Compliance rules preventing in-depth co-operation
Food2030 strategy, Finland {Box 12.2}	<ul style="list-style-type: none"> – Local, organic and climate-friendly food production – Responsible and healthy food consumption – A competitive food supply chain 	<ul style="list-style-type: none"> – Target funding and knowledge support for innovations – Apply administrative means (legislation, guidance) to increase organic food production and procurement – Use education and information instruments to shift behaviour (media campaigns, websites) 	<ul style="list-style-type: none"> – Year-long deliberative stakeholder engagement process across sectors – Institutional structures for agenda-setting, guiding policy implementation and reflexive discussions 	<ul style="list-style-type: none"> – Weak role of integrated impact assessments (IAMS) to inform agenda-setting – Monitoring and evaluation close to ministry in charge – Lack of standardised indicators of food system sustainability

Box TS.13 | Policy Attribution: Methodologies For – and Estimations of – the Macro-level Impact of Mitigation Policies on Indices of GHG Mitigation

Policy attribution examines the extent to which *GHG emission reductions*, the *proximate drivers of emissions*, and the deployment of *technologies that reduce emissions* may be reasonably attributed to policies implemented prior to the observed changes. Such policies include regulatory instruments such as energy-efficiency programmes or technical standards and codes, carbon pricing, financial support for low-carbon energy technologies and efficiency, voluntary agreements, and regulation of land-use practices.

The vast majority of literature reviewed for this report examines the effect of particular instruments in particular contexts {13.6, 14.3, 16.4}, and only a small number directly or plausibly infer global impacts of policies. Policies also differ in design, scope, and stringency, may change over time as they require amendments or new laws, and often partially overlap with other instruments. These factors complicate analysis, because they give rise to the potential for double counting emissions reductions that have been observed. These lines of evidence on the impact of policies include:

- **GHG Emissions.** Evidence from econometric assessments of the impact of policies in countries which took on Kyoto Protocol targets; decomposition analyses that identify policy-related, absolute reductions from historical levels in particular countries. {13.6.2, 14.3.3, Cross-Chapter Box 10 in Chapter 14}
- **Proximate emission drivers.** Trends in the factors that drive emissions including reduced rates of deforestation {7.6.2}, industrial energy efficiency {Box 16.3}, buildings energy efficiency {Figure 2.22}, and the policy-driven displacement of fossil fuel combustion by renewable energy. (Box TS.13, Table 1; Box TS.13, Figure 1) {Chapters 2 and 6, Cross-Chapter Box 10 in Chapter 14}
- **Technologies.** The literature indicates unambiguously that the rapid expansion of low-carbon energy technologies is substantially attributable to policy. {6.7.5, 16.5}

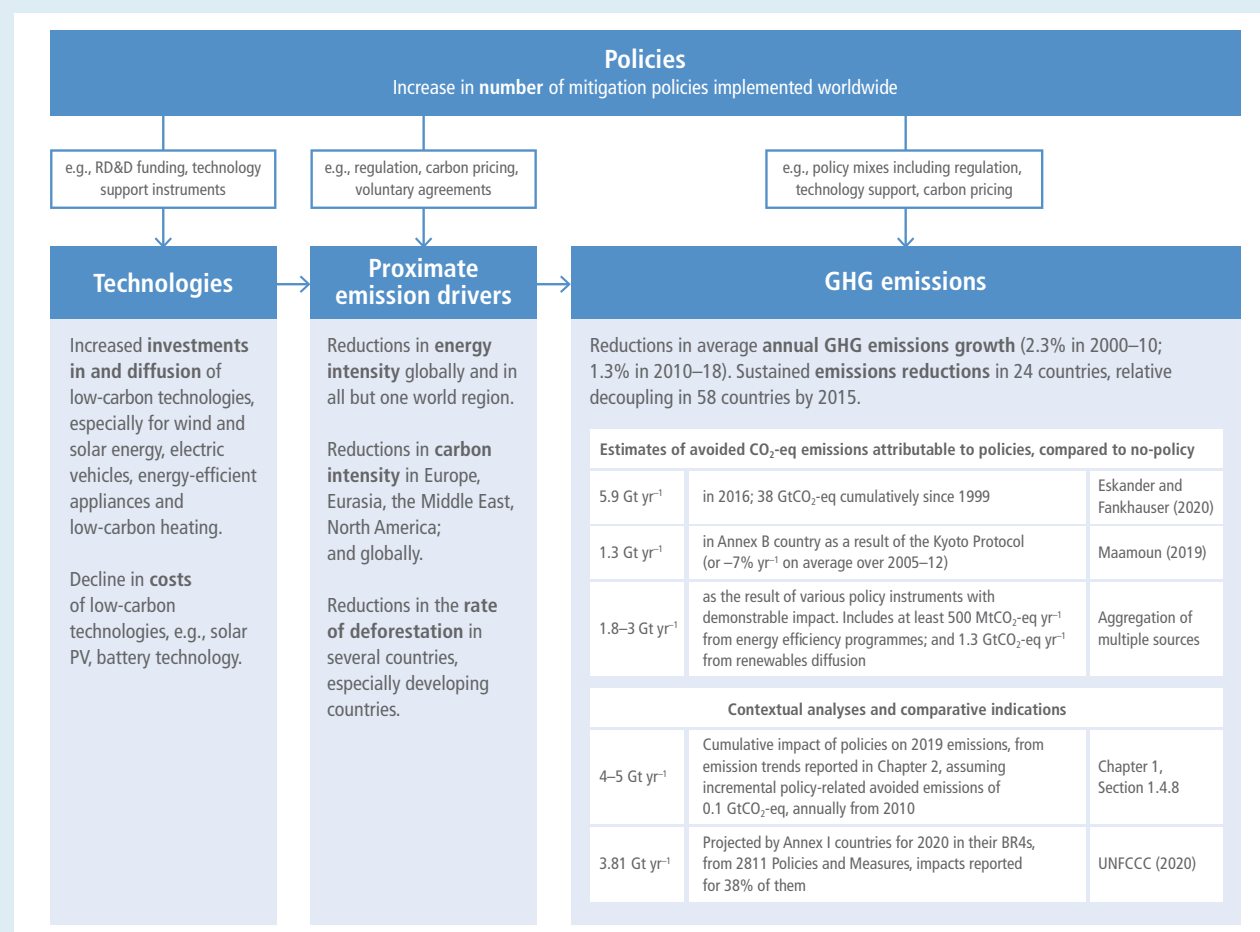

As illustrated in Box TS.13, Figure 1, these multiple lines of evidence point to policies having had a discernible impact on mitigation for specific countries, sectors, and technologies (*high confidence*), avoiding emissions of several GtCO₂-eq yr⁻¹ globally (*medium confidence*).

Box TS.13 (continued)

Box TS.13, Table 1 | The effects of policy on GHG emissions, drivers of emissions, and technology deployment.

Sector	Effects on emissions	Effects on immediate drivers	Effects on low-carbon technology
Energy supply {Chapter 6}	Carbon pricing, emissions standards, and technology support have led to declining emissions associated with the supply of energy.	Carbon pricing and technology support have led to improvements in the efficiency of energy conversion.	A variety of market-based instruments, especially technology-support policies have led to high diffusion rates and cost reductions for renewable energy technologies.
AFOLU {Chapter 7}	Regulation of land-use rights and practices have led to falling aggregate AFOLU-sector emissions.	Regulation of land-use rights and practices, payments for ecosystem service, and offsets, have led to decreasing rates of deforestation (<i>medium confidence</i>).	
Buildings {Chapter 9}	Regulatory standards have led to reduced emissions from new buildings.	Regulatory standards, financial support for building renovation and market-based instruments have led to improvements in building and building-system efficiencies.	Technology support and regulatory standards have led to adoption of low-carbon heating systems and high-efficiency appliances.
Transport {Chapter 10}	Vehicle standards, land-use planning, and carbon pricing have led to avoided emissions in ground transportation.	Vehicle standard, carbon pricing, and support for electrification have led to automobile efficiency improvements.	Technology support and emissions standards have increased diffusion rates and cost reductions for electric vehicles.
Industry {Chapter 11}		Carbon pricing has led to efficiency improvements in industrial facilities.	

Note: statements describe the effects of policies across those countries where policies are in place. Unless otherwise noted, all findings are of *high confidence*.

Box TS.13, Figure 1 | Policy impacts on key outcome indices: GHG emissions, proximate emission drivers, and technologies, including several lines of evidence on GHG abatement attributable to policies. {Cross-Chapter Box 10, Figure 1 in Chapter 14}

TS.6.2 International Cooperation

International cooperation is having positive and measurable results (*high confidence*). The Kyoto Protocol led to measurable and substantial avoided emissions, including in 20 countries with Kyoto first-commitment period targets that have experienced a decade of declining absolute emissions. It also built national capacity for GHG accounting, catalysed the creation of GHG markets, and increased investments in low-carbon technologies. Other international agreements and institutions have led to avoided CO₂ emissions from land-use practices, as well as avoided emissions of some non-CO₂ greenhouse gases (*medium confidence*). {14.3, 14.5, 14.6}

New forms of international cooperation have emerged since AR5 in line with an evolving understanding of effective mitigation policies, processes, and institutions. Both new and pre-existing forms of cooperation are vital for achieving climate mitigation goals in the context of sustainable development (*high confidence*). While previous IPCC assessments have noted important synergies between the outcomes of climate mitigation and achieving sustainable development objectives, there now appear to be synergies between the two processes themselves (*medium confidence*). Since AR5, international cooperation has shifted towards facilitating national-level mitigation action through numerous channels, including through processes established under the UNFCCC regime and through regional and sectoral agreements and organisations. {14.2, 14.3, 14.5, 14.6}

Participation in international agreements and transboundary networks is associated with the adoption of climate policies at the national and sub-national levels, as well as by non-state actors (*high confidence*). International cooperation helps countries achieve long-term mitigation targets when it supports development and diffusion of low-carbon technologies, often at the level of individual sectors, which can simultaneously lead to significant benefits in the areas of sustainable development and equity (*medium confidence*). {14.2, 14.3, 14.5, 14.6}

International cooperation under the UN climate regime took an important new direction with the entry into force of the 2015 Paris Agreement, which strengthened the objective of the UN climate regime, including its long-term temperature goal, while adopting a different architecture to that of the Kyoto Protocol (*high confidence*). The core national commitments under the Kyoto Protocol were legally binding quantified emission targets for developed countries tied to well-defined mechanisms for monitoring and enforcement. By contrast, the commitments under the Paris Agreement are primarily procedural, extend to all parties, and are designed to trigger domestic policies and measures, enhance transparency, and stimulate climate investments, particularly in developing countries, and to lead iteratively to rising levels of ambition across all countries. Issues of equity remain of central importance in the UN climate regime, notwithstanding shifts in the operationalisation of 'common but differentiated responsibilities and respective capabilities' from Kyoto to Paris. {14.3}

There are conflicting views on whether the Paris Agreement's commitments and mechanisms will lead to the attainment of

its stated goals (*medium confidence*). Arguments in support of the Paris Agreement are that the processes it initiates and supports will in multiple ways lead, and indeed have already led, to rising levels of ambition over time. The recent proliferation of national mid-century net zero GHG targets can be attributed in part to the Paris Agreement. Moreover, its processes and commitments will enhance countries' abilities to achieve their stated level of ambition, particularly among developing countries. Arguments against the Paris Agreement are that it lacks a mechanism to review the adequacy of individual Parties' Nationally Determined Contributions (NDCs), that collectively current NDCs are inconsistent in their level of ambition with achieving the Paris Agreement's long-term temperature goal, that its processes will not lead to sufficiently rising levels of ambition in the NDCs, and that NDCs will not be achieved because the targets, policies and measures they contain are not legally binding at the international level. To some extent, arguments on both sides are aligned with different analytic frameworks, including assumptions about the main barriers to mitigation that international cooperation can help overcome. The extent to which countries increase the ambition of their NDCs and ensure they are effectively implemented will depend in part on the successful implementation of the support mechanisms in the Paris Agreement, and in turn will determine whether the goals of the Paris Agreement are met (*high confidence*). {14.2, 14.3, 14.4}

International cooperation outside the UNFCCC processes and agreements provides critical support for mitigation in particular regions, sectors and industries, for particular types of emissions, and at the sub- and trans-national levels (*high confidence*). Agreements addressing ozone depletion, transboundary air pollution, and release of mercury are all leading to reductions in the emissions of specific greenhouse gases. Cooperation is occurring at multiple governance levels including cities. Transnational partnerships and alliances involving non-state and sub-national actors are also playing a growing role in stimulating low-carbon technology diffusion and emissions reductions (*medium confidence*). Such transnational efforts include those focused on climate litigation; the impacts of these are unclear but promising. Climate change is being addressed in a growing number of international agreements operating at sectoral levels, as well as within the practices of many multilateral organisations and institutions. Sub-global and regional cooperation, often described as climate clubs, can play an important role in accelerating mitigation, including the potential for reducing mitigation costs through linking national carbon markets, although actual examples of these remain limited. {14.2, 14.4, 14.5, 14.6}

International cooperation will need to be strengthened in several key respects in order to support mitigation action consistent with limiting temperature rise to well below 2°C in the context of sustainable development and equity (*high confidence*). Many developing countries' NDCs have components or additional actions that are conditional on receiving assistance with respect to finance, technology development and transfer, and capacity-building, greater than what has been provided to date. Sectoral and sub-global cooperation is providing critical support, and yet there is room for further progress. In some cases, notably with respect to aviation and shipping, sectoral agreements have adopted climate mitigation goals that fall far short of what would be required to achieve the long-term

temperature goal of the Paris Agreement. Moreover, there are cases where international cooperation may be hindering mitigation efforts, namely evidence that trade and investment agreements, as well as agreements within the energy sector, impede national mitigation efforts (*medium confidence*). International cooperation is emerging but so far fails to fully address transboundary issues associated with solar radiation modification (SRM) and carbon dioxide removal (CDR). {14.2, 14.3, 14.4, 14.5, 14.6, Cross-Working Group Box 4 in Chapter 14}

TS.6.3 Societal Aspects of Mitigation

Social equity reinforces capacity and motivation for mitigating climate change (*medium confidence*). Impartial governance such as fair treatment by law-and-order institutions, fair treatment by gender, and income equity, increases social trust, thus enabling demand-side climate policies. High-status (often high-carbon) item consumption may be reduced by taxing absolute wealth without compromising well-being. {5.2, 5.4.2, 5.6}

Policies that increase the political access and participation of women, racialised, and marginalised groups, increase the democratic impetus for climate action (*high confidence*). Including more differently situated knowledge and diverse perspectives makes climate mitigation policies more effective. {5.2, 5.6}

Greater contextualisation and granularity in policy approaches better addresses the challenges of rapid transitions towards zero-carbon systems (*high confidence*). Larger systems take more time to evolve, grow, and change compared to smaller ones. Creating and scaling up entirely new systems takes longer than replacing existing technologies and practices. Late adopters tend to adopt faster than early pioneers. Obstacles and feasibility barriers are high in the early transition phases. Barriers decrease as a result of technical and social learning processes, network building, scale economies, cultural debates, and institutional adjustments. {5.5, 5.6}

Mitigation policies that integrate and communicate with the values people hold are more successful (*high confidence*). Values differ between cultures. Measures that support autonomy, energy security and safety, equity and environmental protection, and fairness resonate well in many communities and social groups. Changing from a commercialised, individualised, entrepreneurial training model to an education cognisant of planetary health and human well-being can accelerate climate change awareness and action. {5.4.1, 5.4.2}

Changes in consumption choices that are supported by structural changes and political action enable the uptake of low-carbon choices (*high confidence*). Policy instruments applied in coordination can help to accelerate change in a consistent desired direction. Targeted technological change, regulation, and public policy can help in steering digitalisation, the sharing economy, and circular economy towards climate change mitigation. (Boxes TS.12 and TS.14) {5.3, 5.6}

Complementarity in policies helps in the design of an optimal demand-side policy mix (*medium confidence*). In the case of energy efficiency, for example, this may involve CO₂ pricing, standards and norms, and information feedback. {5.3, 5.4, 5.6}

TS.6.4 Investment and Finance

Finance to reduce net GHG emissions and enhance resilience to climate impacts is a critical enabling factor for the low-carbon transition. Fundamental inequities in access to finance as well as finance terms and conditions, and countries' exposure to physical impacts of climate change overall, result in a worsening outlook for a global Just Transition (*high confidence*). Decarbonising the economy requires global action to address fundamental economic inequities and overcome the climate investment trap that exists for many developing countries. For these countries the costs and risks of financing often represent a significant challenge for stakeholders at all levels. This challenge is exacerbated by these countries' general economic vulnerability and indebtedness. The rising public fiscal costs of mitigation, and of adapting to climate shocks, is affecting many countries and worsening public indebtedness and country credit ratings at a time when there were already significant stresses on public finances. The COVID-19 pandemic has made these stresses worse and tightened public finances still further. Other major challenges for commercial climate finance include: the mismatch between capital and investment needs, home bias³¹ considerations, differences in risk perceptions for regions, as well as limited institutional capacity to ensure safeguards are effective (*high confidence*). {15.2, 15.6.3}

Investors, central banks, and financial regulators are driving increased awareness of climate risk. This increased awareness can support climate policy development and implementation (*high confidence*) {15.2, 15.6}. Climate-related financial risks arise from physical impacts of climate change (already relevant in the short term), and from a disorderly transition to a low-carbon economy. Awareness of these risks is increasing, leading also to concerns about financial stability. Financial regulators and institutions have responded with multiple regulatory and voluntary initiatives to assess and address these risks. Yet despite these initiatives, climate-related financial risks remain greatly underestimated by financial institutions and markets, limiting the capital reallocation needed for the low-carbon transition. Moreover, risks relating to national and international inequity – which act as a barrier to the transformation – are not yet reflected in decisions by the financial community. Stronger steering by regulators and policymakers has the potential to close this gap. Despite the increasing attention of investors to climate change, there is limited evidence that this attention has directly impacted emission reductions. This leaves high uncertainty, both near term (2021–30) and longer term (2021–50), on the feasibility of an alignment of financial flows with the Paris Agreement goals (*high confidence*). {15.2, 15.6}

Progress on the alignment of financial flows with low-GHG emissions pathways remains slow. There is a climate financing

31 Most of climate finance stays within national borders, especially private climate flows (over 90%). The reasons for this range from national policy support, differences in regulatory standards, exchange rate, political and governance risks, to information market failures.

gap which reflects a persistent misallocation of global capital (*high confidence*) {15.2, 15.3}. Persistently high levels of both public and private fossil fuel-related financing continue to be of major concern despite promising recent commitments. This reflects policy misalignment, the current perceived risk-return profile of fossil fuel-related investments, and political economy constraints

(*high confidence*). Estimates of climate finance flows³² exhibit highly divergent patterns across regions and sectors and a slowing growth {15.3}. When the perceived risks are too high, the misallocation of abundant savings persists and investors refrain from investing in infrastructure and industry in search of safer financial assets, even earning low or negative real returns (*high confidence*). {15.2, 15.3}

Figure TS.25 | Breakdown of recent average (downstream) mitigation investments and model-based investment requirements for 2020–2030 (USD billion) in scenarios that likely limit warming to 2°C or lower. Mitigation investment flows and model-based investment requirements by sector / segment (energy efficiency in buildings and industry, transport including efficiency, electricity generation, transmission and distribution including electrification, and agriculture, forestry and other land use), by type of economy, and by region (see Annex II Part I Section 1: By region is based on intermediate level (R10) classification scheme, which considers 'North America', 'Europe', and 'Australia, Japan and New Zealand' as developed countries, and the other seven regions as developing countries). Breakdown by sector / segment may differ slightly from sectoral analysis in other contexts due to the availability of investment needs data. The granularity of the models assessed in Chapter 3, and other studies, do not allow for a robust assessment of the specific investment needs of LDCs or SIDSs. Investment requirements in developing countries might be underestimated due to missing data points as well as underestimated technology costs. In modelled pathways, regional investments are projected to occur when and where they are cost-effective to limit global warming. The model quantifications help to identify high-priority areas for cost-effective investments, but do not provide any indication on who would finance the regional investments. Investment requirements and flows covering downstream / mitigation technology deployment only. Data includes investments with a direct mitigation effect, and in the case of electricity, additional transmission and distribution investments. See section 15.4.2 Quantitative assessment of financing needs for detailed data on investment requirements. Data on mitigation investment flows are based on a single series of reports (Climate Policy Initiative, CPI) which assembles data from multiple sources. Investment flows for energy efficiency are adjusted based on data from the International Energy Agency (IEA). Data on mitigation investments do not include technical assistance (i.e., policy and national budget support or capacity building), other non-technology deployment financing. Adaptation only flows are also excluded. Data on mitigation investment requirements for electricity are based on emission pathways C1, C2 and C3 (Table SPM.1). For electricity investment requirements, the upper end refers to the mean of C1 pathways and the lower end to the mean of C3 pathways. Data points for energy efficiency, transport and AFOLU cannot always be linked to C1–C3 scenarios. Data do not include needs for adaptation or general infrastructure investment or investment related to meeting the SDGs other than mitigation, which may be at least partially required to facilitate mitigation. The multiplication factors show the ratio of average annual model-based mitigation investment requirements (2020–2030) and most recent annual mitigation investments (averaged for 2017–2020). The lower and upper multiplication factors refer to the lower and upper ends of the range of investment needs.

Given the multiple sources and lack of harmonised methodologies, the data can only be indicative of the size and pattern of investment gaps. The gap between most recent flows and required investments is only a single indicator. A more comprehensive (and qualitative) assessment is required in order to understand the magnitude of the challenge of scaling up investment in sectors and regions. The analysis also does not consider the effects of misaligned flows. {15.3, 15.4, 15.5, Table 15.2, Table 15.3, Table 15.4}

32 Climate finance flows refers to local, national, or transnational financing from public, private, and alternative sources, to support mitigation and adaptation actions addressing climate change.

Global climate finance is heavily focused on mitigation (more than 90% on average between 2017–2020) (*high confidence*) {15.4, 15.5}. This is despite the significant economic effects of climate change's expected physical impacts, and the increasing awareness of these effects on financial stability. To meet the needs for rapid deployment of mitigation options, global mitigation investments are expected to need to increase by the factor of three to six (*high confidence*). The gaps represent a major challenge for developing countries, especially Least-Developed Countries (LDCs), where flows have to increase by the factor of four to seven for specific sectors such as AFOLU, and for specific groups with limited access to, and high costs of, climate finance (*high confidence*) (Figure TS.25) {15.4, 15.5}. The actual size of sectoral and regional climate financing gaps is only one component driving the magnitude of the challenge. Financial and economic viability, access to capital markets, appropriate regulatory frameworks, and institutional capacity to attract and facilitate investments and ensure safeguards are decisive to scaling-up funding. Soft costs for regulatory environment and institutional capacity, upstream funding needs as well as R&D and venture capital for development of new technologies and business models are often overlooked despite their critical role to facilitate the deployment of scaled-up climate finance (*high confidence*). {15.4.1, 15.5.2}

The relatively slow implementation of commitments by countries and stakeholders in the financial sector to scale up climate finance reflects neither the urgent need for ambitious climate action, nor the economic rationale for ambitious climate action (*high confidence*). Delayed climate investments and financing – and limited alignment of investment activity with the Paris Agreement – will result in significant carbon lock-ins, stranded assets, and other additional costs. This will particularly impact urban infrastructure and the energy and transport sectors (*high confidence*). A common understanding of debt sustainability and debt transparency, including negative implications of deferred climate investments on future GDP, and how stranded assets and resources may be compensated, has not yet been developed (*medium confidence*). {15.6}

There is a mismatch between capital availability in the developed world and the future emissions expected in developing countries (*high confidence*). This emphasises the need to recognise the explicit and positive social value of global cross-border mitigation financing. A significant push for international climate finance access for vulnerable and poor countries is particularly important given these countries' high costs of financing, debt stress and the impacts of ongoing climate change (*high confidence*). {15.2, 15.3.2.3, 15.5.2, 15.6.1, 15.6.7}

Innovative financing approaches could help reduce the systemic under-pricing of climate risk in markets and foster demand for investment opportunities aligned with the Paris Agreement goals. Approaches include de-risking investments, robust 'green' labelling and disclosure schemes, in addition to a regulatory focus on transparency and reforming international monetary system financial sector regulations (*medium confidence*). Green bond markets and markets for sustainable finance products have grown significantly since AR5 and the landscape continues to evolve. Underpinning this evolution

is investors' preference for scalable and identifiable low-carbon investment opportunities. These relatively new labelled financial products will help by allowing a smooth integration into existing asset allocation models (*high confidence*). Green bond markets and markets for sustainable finance products have also increased significantly since AR5, but challenges nevertheless remain, in particular, there are concerns about 'greenwashing' and the limited application of these markets to developing countries (*high confidence*). {15.6.2, 15.6.6}

New business models (e.g., pay-as-you-go) can facilitate the aggregation of small-scale financing needs and provide scalable investment opportunities with more attractive risk-return profiles (*high confidence*). Support and guidance for enhancing transparency can promote capital markets' climate financing by providing quality information to price climate risks and opportunities. Examples include SDG and environmental, social and governance (ESG) disclosure, scenario analysis and climate risk assessments, including the Task Force on Climate-related Financial Disclosures (TCFD). The outcome of these market-correcting approaches on capital flows cannot be taken for granted, however, without appropriate fiscal, monetary and financial policies. Mitigation policies will be required to enhance the risk-weighted return of low-emission and climate-resilient options, accelerate the emergence and support for financial products based on real projects, such as green bonds, and phase-out fossil fuel subsidies. Greater public-private cooperation can also encourage the private sector to increase and broaden investments, within a context of safeguards and standards, and this can be integrated into national climate change policies and plans (*high confidence*). {15.1, 15.2.4, 15.3.1, 15.3.2, 15.3.3, 15.5.2, 15.6.1, 15.6.2, 15.6.6, 15.6.7, 15.6.8}

Ambitious global climate policy coordination and stepped-up public climate financing over the next decade (2021–2030) can help redirect capital markets and overcome challenges relating to the need for parallel investments in mitigation. It can also help address macroeconomic uncertainty and alleviate developing countries' debt burden post-COVID-19 (*high confidence*). Providing strong climate policy signals helps guide investment decisions. Credible signalling by governments and the international community can reduce uncertainty for financial decision-makers and help reduce transition risk. In addition to indirect and direct subsidies, the public sector's role in addressing market failures, barriers, provision of information, and risk-sharing can encourage the efficient mobilisation of private sector finance (*high confidence*) {15.2, 15.6.1, 15.6.2}. The mutual benefits of coordinated support for climate mitigation and adaptation in the next decade for both developed and developing regions could potentially be very high in the post-COVID era. Climate-compatible stimulus packages could significantly reduce the macro-financial uncertainty generated by the pandemic and increase the sustainability of the world economic recovery {15.2, 15.3.2.3, 15.5.2, 15.6.1, 15.6.7}. Political leadership and intervention remain central to addressing uncertainty, which is a fundamental barrier for the redirection of financial flows. Existing policy misalignments – for example, in fossil fuel subsidies – undermine the credibility of public commitments, reduce perceived transition risks and limit financial sector action (*high confidence*). {15.2, 15.3.3, 15.6.1, 15.6.2, 15.6.3}

The greater the urgency of action to remain on a 1.5°C pathway, the greater need for parallel investment decisions in upstream and downstream parts of the value chain (*high confidence*). Greater urgency also reduces the lead times to build trust in regulatory frameworks. Consequently, many investment decisions will need to be made based on the long-term global goals. This highlights the importance of trust in political leadership which, in turn, affects risk perception and ultimately financing costs (*high confidence*). {15.6.1, 15.6.2}

Accelerated international cooperation on finance is a critical enabler of a low-carbon and Just Transition (*very high confidence*). Scaled-up public grants for adaptation and mitigation, and funding for low-income and vulnerable regions, especially in Sub-Saharan Africa, may have the highest returns. Key options include: increased public finance flows from developed to developing countries beyond USD100 billion a year; shifting from a direct lending modality towards public guarantees to reduce risks and greatly leverage private flows at lower cost; local capital markets development; and, changing the enabling operational definitions. A coordinated effort to green the post-pandemic recovery is also essential in countries facing much higher debt costs (*high confidence*). {15.2, 15.6}

TS.6.5 Innovation, Technology Development and Transfer

Innovation in climate mitigation technologies has seen enormous activity and significant progress in recent years. Innovation has also led to, and exacerbated, trade-offs in relation to sustainable development. Innovation can leverage

action to mitigate climate change by reinforcing other interventions. In conjunction with other enabling conditions, innovation can support system transitions to limit warming and help shift development pathways. The currently widespread implementation of solar PV and LED lighting, for instance, could not have happened without technological innovation. Technological innovation can also bring about new and improved ways of delivering services that are essential to human well-being (*high confidence*) {16.1, 16.3, 16.4, 16.6}. At the same time as delivering benefits, innovation can result in trade-offs that undermine both progress on mitigation and progress towards other Sustainable Development Goals (SDGs). Trade-offs include negative externalities – for instance, greater environmental pollution and social inequalities – rebound effects leading to lower net emission reductions or even increases in emissions, and increased dependency on foreign knowledge and providers (*high confidence*). Effective governance and policy have the potential to avoid and minimise such misalignments (*medium evidence, high agreement*). {16.2, 16.3, 16.4, 16.5.1, 16.6}

A systemic view of innovation to direct and organise the processes has grown over the last decade. This systemic view of innovation takes into account the role of actors, institutions, and their interactions, and can inform how innovation systems that vary across technologies, sectors and countries, can be strengthened (*high confidence*) {16.2, 16.3, 16.5}. Where a systemic view of innovation has been taken, it has enabled the development and implementation of indicators that are better able to provide insights in innovation processes. This, in turn, has enabled the analysis and strengthening of innovation systems. Traditional quantitative innovation indicators mainly include R&D investments and patents. Figure TS.26 illustrates that energy-related research, development and demonstration (RD&D) has risen slowly in the last

Figure TS.26 | Fraction of public energy research, development and demonstration (RD&D) spending by technology over time for IEA (largely OECD) countries between 1974 and 2018. {Box 16.3, Figure 1}

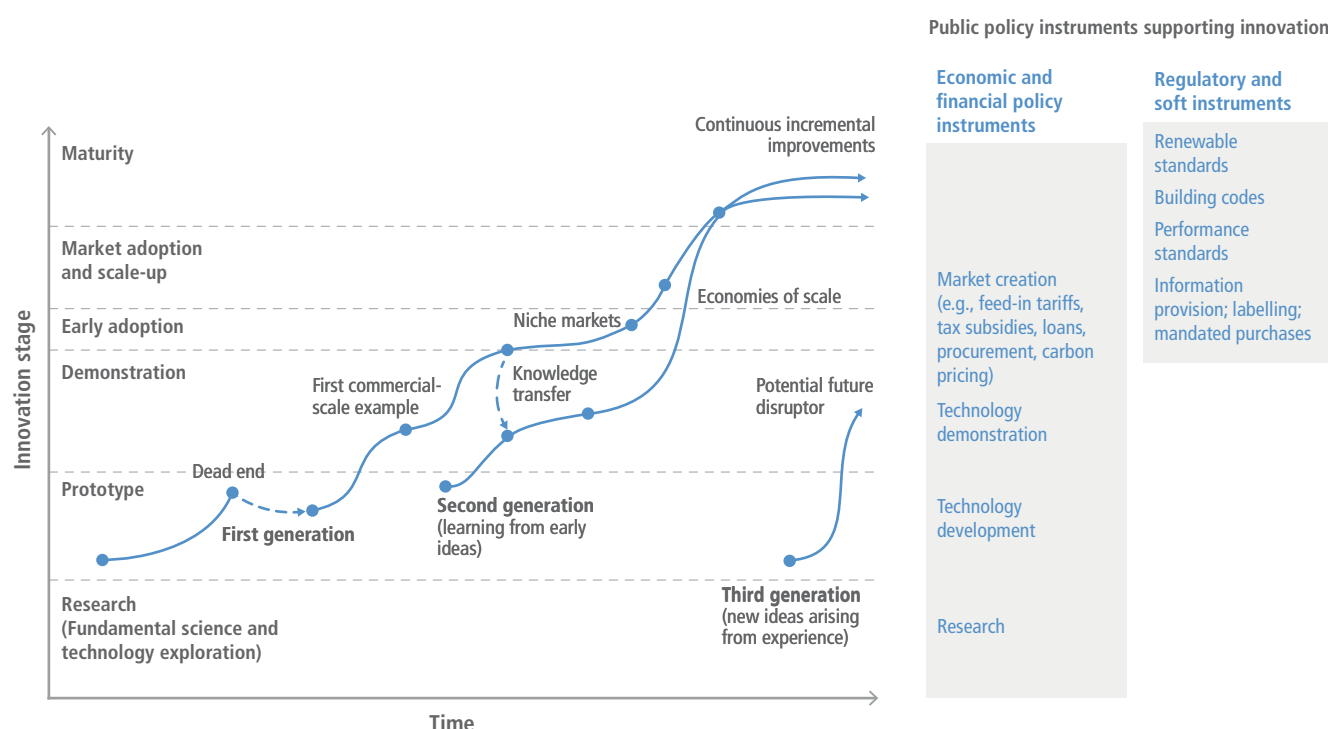

Figure TS.27 | Technology innovation process and the (illustrative) roles of different public policy instruments (on the right-hand side). {Figure 16.1} Note that demand-pull instruments in the regulatory instrument category, for instance, can also shape the early stages of the innovation process. Their position in the latter stages is highlighted in this figure because typically these instruments have been introduced in latter stages of the development of the technology. {16.4.4}

two decades, and that there has been a reorientation of the portfolio of funded energy technologies. Systemic indicators of innovation, however, go well beyond these approaches. They include structural innovation system elements including actors and networks, as well as indicators for how innovation systems function, such as access to finance, employment in relevant sectors, and lobbying activities {16.3.4, Table 16.7}. For example, in Latin America, monitoring systemic innovation indicators for the effectiveness of agroecological mitigation approaches has provided insights on the appropriateness and social alignment of new technologies and practices {Box 16.5}. Climate-energy-economy models, including integrated assessment models (IAMs), generally employ a stylised and necessarily incomplete view of innovation, and have yet to incorporate a systemic representation of innovation systems. {16.2.4, Box 16.1}

A systemic perspective on technological change can provide insights to policymakers supporting their selection of effective innovation policy instruments (high confidence) {16.4, 16.5}. A combination of scaled-up innovation investments with demand-pull interventions can achieve faster technology unit cost reductions and more rapid scale-up than either approach in isolation. These innovation policy instruments would nonetheless have to be tailored to local development priorities, to the specific context of different countries, and to the technology being supported. The timing of interventions and any trade-offs with sustainable development also need to be addressed. Public R&D funding and support, as well as innovation procurement, have shown to be valuable for fostering innovation in small-to-medium clean-tech firms (Figure TS.27) {16.4.4.3}. Innovation outcomes of policy instruments not necessarily aimed at innovation, such as feed-in tariffs, auctions, emissions

trading schemes, taxes and renewable portfolio standards, vary from negligible to positive for climate change mitigation. Some specific designs of environmental taxation can also result in negative distributional outcomes {16.4.4}. Most of the available literature and evidence on innovation systems come from industrialised countries and larger developing countries. However, there is a growing body of evidence from developing countries and Small Island Developing States (SIDS). {16.4, 16.5, 16.7}

Experience and analyses show that technological change is inhibited if technological innovation system functions are not adequately fulfilled; this inhibition occurs more often in developing countries (high confidence). Examples of such functions are knowledge development, resource mobilisation, and activities that shape the needs, requirements and expectations of actors within the innovation system (guidance of the search). Capabilities play a key role in these functions, the buildup of which can be enhanced by domestic measures, but also by international cooperation. For instance, innovation cooperation on wind energy has contributed to the accelerated global spread of this technology. As another example, the policy guidance by the Indian government, which also promoted development of data, testing capabilities and knowledge within the private sector, has been a key determinant of the success of an energy-efficiency programme for air conditioners and refrigerators in India. {16.3, 16.5, 16.6, Cross-Chapter Box 12 in Chapter 16, Box 16.3}

Consistent with innovation system approaches, the sharing of knowledge and experiences between developed and developing countries can contribute to addressing global climate and the SDGs. The effectiveness of such international cooperation arrangements, however, depends on the way they are developed and implemented (*high confidence*). The effectiveness and sustainable development benefits of technology sharing under market conditions appears to be determined primarily by the complexity of technologies, local capabilities and the policy regime. This suggests that the development of planning and innovation capabilities remains necessary, especially in Least-Developed Countries (LDCs) and SIDS. International diffusion of low-emission technologies is also facilitated by knowledge spillovers from regions engaged in clean R&D (*medium confidence*). {16.2}

The evidence on the role of intellectual property rights (IPR) in innovation is mixed. Some literature suggests that it is a barrier while other sources suggests that it is an enabler to the diffusion of climate-related technologies (*medium confidence*). There is agreement that countries with well-developed institutional capacity may benefit from a strengthened IPR regime, but that countries with limited capabilities might face greater barriers to innovation as a consequence. This enhances the continued need for capacity-building. Ideas to improve the alignment of the global IPR regime and addressing climate change include specific arrangements for LDCs, case-by-case decision-making and patent-pooling institutions. {16.2.3, 16.5, Box 16.10}

Although some initiatives have mobilised investments in developing countries, gaps in innovation cooperation remain, including in the Paris Agreement instruments. These gaps could be filled by enhancing financial support for international technology cooperation, by strengthening cooperative approaches, and by helping build suitable capacity in developing countries across all technological innovation system functions (*high confidence*). The implementation of current arrangements of international cooperation for technology development and transfer, as well as capacity-building, are insufficient to meet climate objectives and contribute to sustainable development. For example, despite building a large market for mitigation technologies in developing countries, the lack of a systemic perspective in the implementation of the Clean Development Mechanism (CDM), operational since the mid-2000s, has only led to some technology transfer, especially to larger developing countries, but limited capacity building and minimal technology development (*medium confidence*). In the current climate regime, a more systemic approach to innovation cooperation could be introduced by linking technology institutions, such as the Technology Mechanism, and financial actors, such as the Financial Mechanism. {16.5.3}

Countries are exposed to sustainable development challenges in parallel with the challenges that relate to climate change. Addressing both sets of challenges simultaneously presents multiple and recurrent obstacles that systemic approaches to technological change could help resolve, provided they are well managed (*high confidence*). Obstacles include both entrenched power relations dominated by vested interests that

control and benefit from existing technologies, and governance structures that continue to reproduce unsustainable patterns of production and consumption (*medium confidence*). Studies also highlight the potential of cultural factors to strongly influence the pace and direction of technological change. Sustainable solutions require adoption and mainstreaming of locally novel technologies that can meet local needs, and simultaneously address the SDGs. Acknowledging the systemic nature of technological innovation – which involve many levels of actors, stages of innovation and scales – can lead to new opportunities to shift development pathways towards sustainability. {16.4, 16.5, 16.6}

Strategies for climate change mitigation can be most effective in accelerating transformative change when actions taken to strengthen one set of enabling conditions also reinforce and strengthen the effectiveness of other enabling conditions (*medium confidence*). Applying transition or system dynamics to decisions can help policymakers take advantage of such high-leverage intervention points, address the specific characteristics of technological stages, and respond to societal dynamics. Inspiration can be drawn from the global unit-cost reductions of solar PV, which were accelerated by a combination of factors interacting in a mutually reinforcing way across a limited group of countries (*high confidence*) {Box 16.2, Cross-Chapter Box 12 in Chapter 16}. Transitions can be accelerated by policies appropriately targeted, which may be grouped in different ‘pillars of policy’. The relative importance of different ‘pillars’ differs according to the stage of the transition. (Figure TS.28) {1.2.3}

Better and more comprehensive data on innovation indicators can provide timely insights for policymakers and policy design locally, nationally and internationally, especially for developing countries, where such insights are often missing. Data needed include those that can show the strength of technological, sectoral and national innovation systems. It is also necessary to validate current results and generate insights from theoretical frameworks and empirical studies for developing countries’ contexts. Innovation studies on adaptation and mitigation other than energy and *ex-post* assessments of the effectiveness of various innovation-related policies and interventions, including R&D, would also provide benefits. Furthermore, methodological developments to improve the ability of IAMs to capture energy innovation system dynamics and the relevant institutions and policies (including design and implementation), would allow for more realistic assessment. {16.2, 16.3, 16.7}

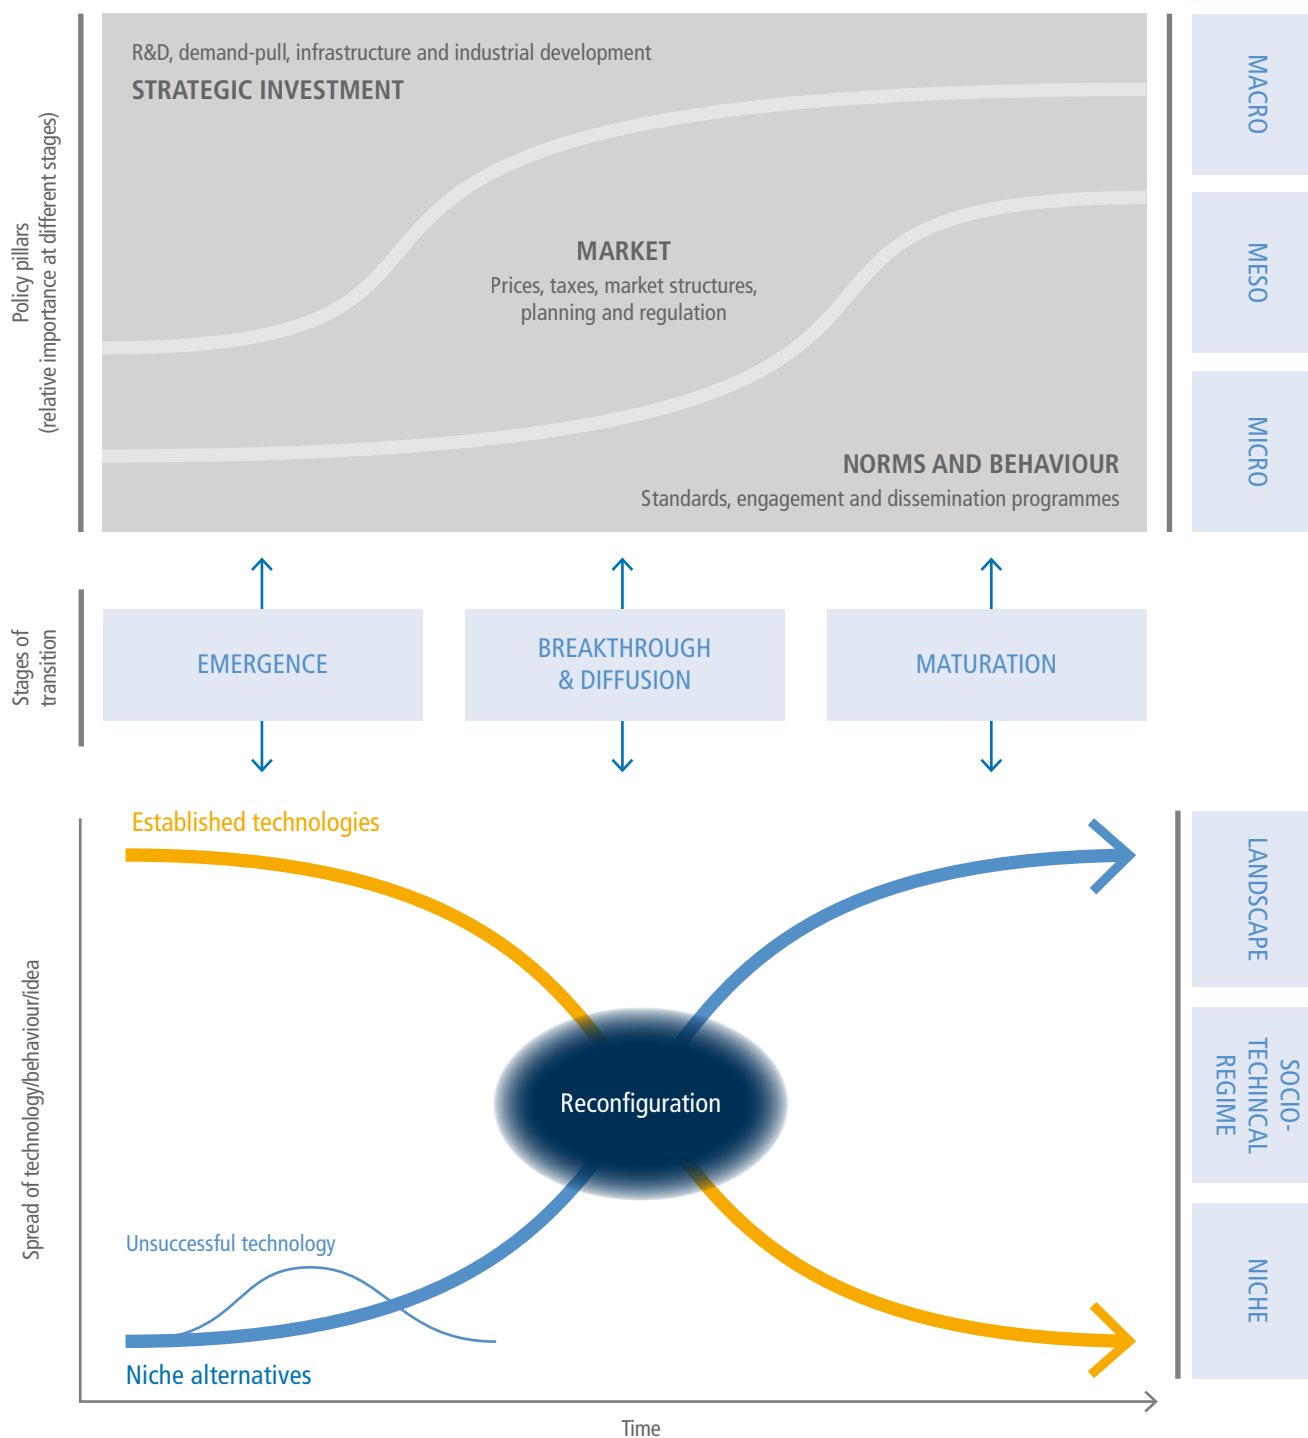

Figure TS.28 | Transition dynamics: levels, policies and processes. {Figure 1.7} The relative importance of different ‘pillars of policy’ differs according to the stage of the transition. The lower panel illustrates growth of innovative technologies or practices, which if successful, emerge from niches into an S-shaped dynamic of exponential growth. The diffusion stage often involves new infrastructure and reconfiguration of existing market and regulatory structures. During the phase of more widespread diffusion, growth levels off to linear, then slows as the industry and market matures. The processes displace incumbent technologies/practices which decline, initially slowly, but then at an accelerating pace. Many related literatures identify three main levels with different characteristics, most generally termed *micro*, *meso* and *macro*.

Box TS.14 | Digitalisation

Digital technologies can promote large increases in energy efficiency through coordination and an economic shift to services, but they can also greatly increase energy demand because of the energy used in digital devices (*high confidence*). {Cross-Chapter Box 11 in Chapter 16, 16.2}

Digital devices, including servers, increase pressure on the environment due to the demand for rare metals and end-of-life disposal. The absence of adequate governance in many countries can lead to harsh working conditions and unregulated disposal of electronic waste. Digitalisation also affects firms' competitiveness, the demand for skills, and the distribution of, and access to resources. The existing digital divide, especially in developing countries, and the lack of appropriate governance of the digital revolution can hamper the role that digitalisation could play in supporting the achievement of stringent mitigation targets. At present, the understanding of both the direct and indirect impacts of digitalisation on energy use, carbon emissions and potential mitigation is limited (*medium confidence*).

The digital transformation is a megatrend that is fundamentally changing all economies and societies, albeit in very different ways depending on the level of development of a given country and on the nature of its economic system. Digital technologies have significant potential to contribute to decarbonisation due to their ability to increase energy and material efficiency, make transport and building systems less wasteful, and improve the access to services for consumers and citizens. Yet, if left unmanaged, the digital transformation will probably increase energy demand, exacerbate inequities and the concentration of power, leaving developing economies with less access to digital technologies behind, raise ethical issues, reduce labour demand and compromise citizens' welfare. Appropriate governance of the digital transformation can ensure that digitalisation works as an enabler, rather than as a barrier and further strain in decarbonisation pathways. Governance can ensure that digitalisation not only reduces GHG emissions intensity but also contributes to reducing absolute GHG emission, constraining run-away consumption. {Cross-Chapter Box 11 in Chapter 16, 16.2}

Digital technologies have the potential to reduce energy demand in all end-use sectors through steep improvements in energy efficiency. This includes material input savings and increased coordination as they allow the use of fewer inputs to perform a given task. Smart appliances and energy management, supported by choice architectures, economic incentives and social norms, effectively reduce energy demand and associated GHG emissions by 5–10% while maintaining equal service levels. Data centres can also play a role in energy-system management, for example by waste-heat utilisation where district heat systems are close by; temporal and spatial scheduling of electricity demand can provide about 6% of the total potential demand response. {5.5, Cross-Chapter Box 11, Table 1 in Chapter 16}

Digital technologies, analytics and connectivity consume large amounts of energy, implying higher direct energy demand and related carbon emissions. Global energy demand from digital appliances reached 7.14 EJ in 2018. The demand for computing services increased by 550% between 2010 and 2018 and is now estimated at 1% of global electricity consumption. Due to efficiency improvements, the associated energy demand increased only modestly, by about 6% from 2000 to 2018. {Box 9.5}

System-wide effects endanger energy and GHG-emission savings. Rising demand can diminish energy savings, and also produce run-away effects associated with additional consumption and GHG emissions if left unregulated. Savings are varied in smart and shared mobility systems, as ride-hailing increases GHG emissions due to deadheading, whereas shared pooled mobility and shared cycling reduce GHG emissions, as occupancy levels and/or weight per person kilometre transported improve. Systemic effects have wider boundaries of analysis and are more difficult to quantify and investigate but are nonetheless very relevant. Systemic effects tend to have negative impacts, but policies and adequate infrastructures and choice architectures can help manage and contain these. {5.3, 5.4, 5.6}

TS.7 Mitigation in the Context of Sustainable Development

Accelerating climate mitigation *in the context of sustainable development* involves not only expediting the pace of change but also addressing the underlying drivers of vulnerability and emissions. Addressing these drivers can enable diverse communities, sectors, stakeholders, regions and cultures to participate in just, equitable and inclusive processes that improve the health and well-being of people and the planet. Looking at climate change from a justice perspective also means placing the emphasis on: (i) the protection of vulnerable populations from the impacts of climate change, (ii) mitigating the effects of low-carbon transformations, and (iii) ensuring an equitable decarbonised world (*high confidence*). {17.1}

The SDG framework³³ can serve as a template to evaluate the long-term implications of mitigation on sustainable development and vice versa (*high confidence*). Understanding the co-benefits and trade-offs associated with mitigation is key to understanding how societies prioritise among the various sectoral policy options (*medium confidence*). Areas with anticipated trade-offs include food and biodiversity, energy affordability/access, and mineral-resource extraction. Areas with anticipated co-benefits include health, especially regarding air pollution, clean energy access and water availability. The possible implementation of the different sectoral mitigation options therefore depends on how societies prioritise mitigation versus other products and services: not least, how societies prioritise food, material well-being, nature conservation and biodiversity protection, as well as considerations such as their future dependence on CDR. Figure TS.29 summarises the assessment of where key synergies and trade-offs exist between mitigation options and the SDGs. (Figures TS.29 and TS.31, Table TS.7) {12.3, 12.4, 12.5, 12.6.1, Figures 3.39 and 17.1}

The beneficial and adverse impacts of deploying climate-change mitigation and adaptation responses are highly context-specific and scale-dependent. There are synergies and trade-offs between adaptation and mitigation as well as synergies and trade-offs with sustainable development (*high confidence*). Strong links also exist between sustainable development, vulnerability and climate risks, as limited economic, social and institutional resources often result in low adaptive capacities and high vulnerability, especially in developing countries. Resource limitations in these countries can similarly weaken the capacity for climate mitigation and adaptation. The move towards climate-resilient societies requires transformational or deep systemic change. This has important implications for countries' sustainable development pathways (*medium evidence, high agreement*). (Box TS.3, Figure TS.29) {4.5, Figure 4.9, 17.3.3}

Many of the potential trade-offs between mitigation and other sustainable development outcomes depend on policy design and can be compensated or avoided with additional policies and investments, or through policies that integrate mitigation with other SDGs (*high confidence*). Targeted SDG

policies and investments, for example, in the areas of healthy nutrition, sustainable consumption and production, and international collaboration, can support climate change mitigation policies and resolve or alleviate trade-offs. Trade-offs can also be addressed by complementary policies and investments, as well as through the design of cross-sectoral policies integrating mitigation with the SDGs, and in particular: good health and well-being (SDG 3), zero hunger and nutrition (SDG 2), responsible consumption and production (SDG 12), reduced inequalities (SDG 10), and life on land (SDG 15). (Figures TS.29 and TS.30) {3.7}

Decent living standards, which encompasses many SDG dimensions, are achievable at lower energy use than previously thought (*high confidence*). Mitigation strategies that focus on lowering demand for energy and land-based resources exhibit reduced trade-offs and negative consequences for sustainable development relative to pathways involving either high emissions and climate impacts or pathways with high consumption and emissions that are ultimately compensated by large quantities of BECCS. Figure TS.30 illustrates how, in the case of pathways limiting warming to 1.5°C (>67%), sustainable development policies can lead to overall benefits compared to mitigation policies alone. (Figures TS.22 and TS.30) {3.7, 5.2}

The timing of mitigation actions and their effectiveness will have significant consequences for broader sustainable development outcomes in the longer term (*high confidence*). Ambitious mitigation can be considered a precondition for achieving the SDGs. {3.7}

Adopting coordinated cross-sectoral approaches to climate mitigation can target synergies and minimise trade-offs, both between sectors and between sustainable development objectives (*high confidence*). This requires integrated planning using multiple-objective-multiple-impact policy frameworks. Strong inter-dependencies and cross-sectoral linkages create both opportunities for synergies and need to address trade-offs related to mitigation options and technologies. This can only be done if coordinated sectoral approaches to climate change mitigation policies are adopted that mainstream these interactions and ensure local people are involved in the development of new products, as well as production and consumption practices. For instance, there can be many synergies in urban areas between mitigation policies and the SDGs but capturing these depends on the overall planning of urban structures and on local integrated policies such as combining affordable housing and spatial planning with walkable urban areas, green electrification and clean renewable energy (*medium confidence*). Integrated planning and cross-sectoral alignment of climate change policies are also particularly evident in developing countries' NDCs under the Paris Agreement, where key priority sectors such as agriculture and energy are closely aligned with the proposed mitigation and adaptation actions and the SDGs. {12.6.2, Supplementary Material Table 17.SM.1, 17.3.3}

33 The 17 SDGs are at the heart of the UN 2030 Agenda for Sustainable Development, adopted by all United Nations Member States in 2015.

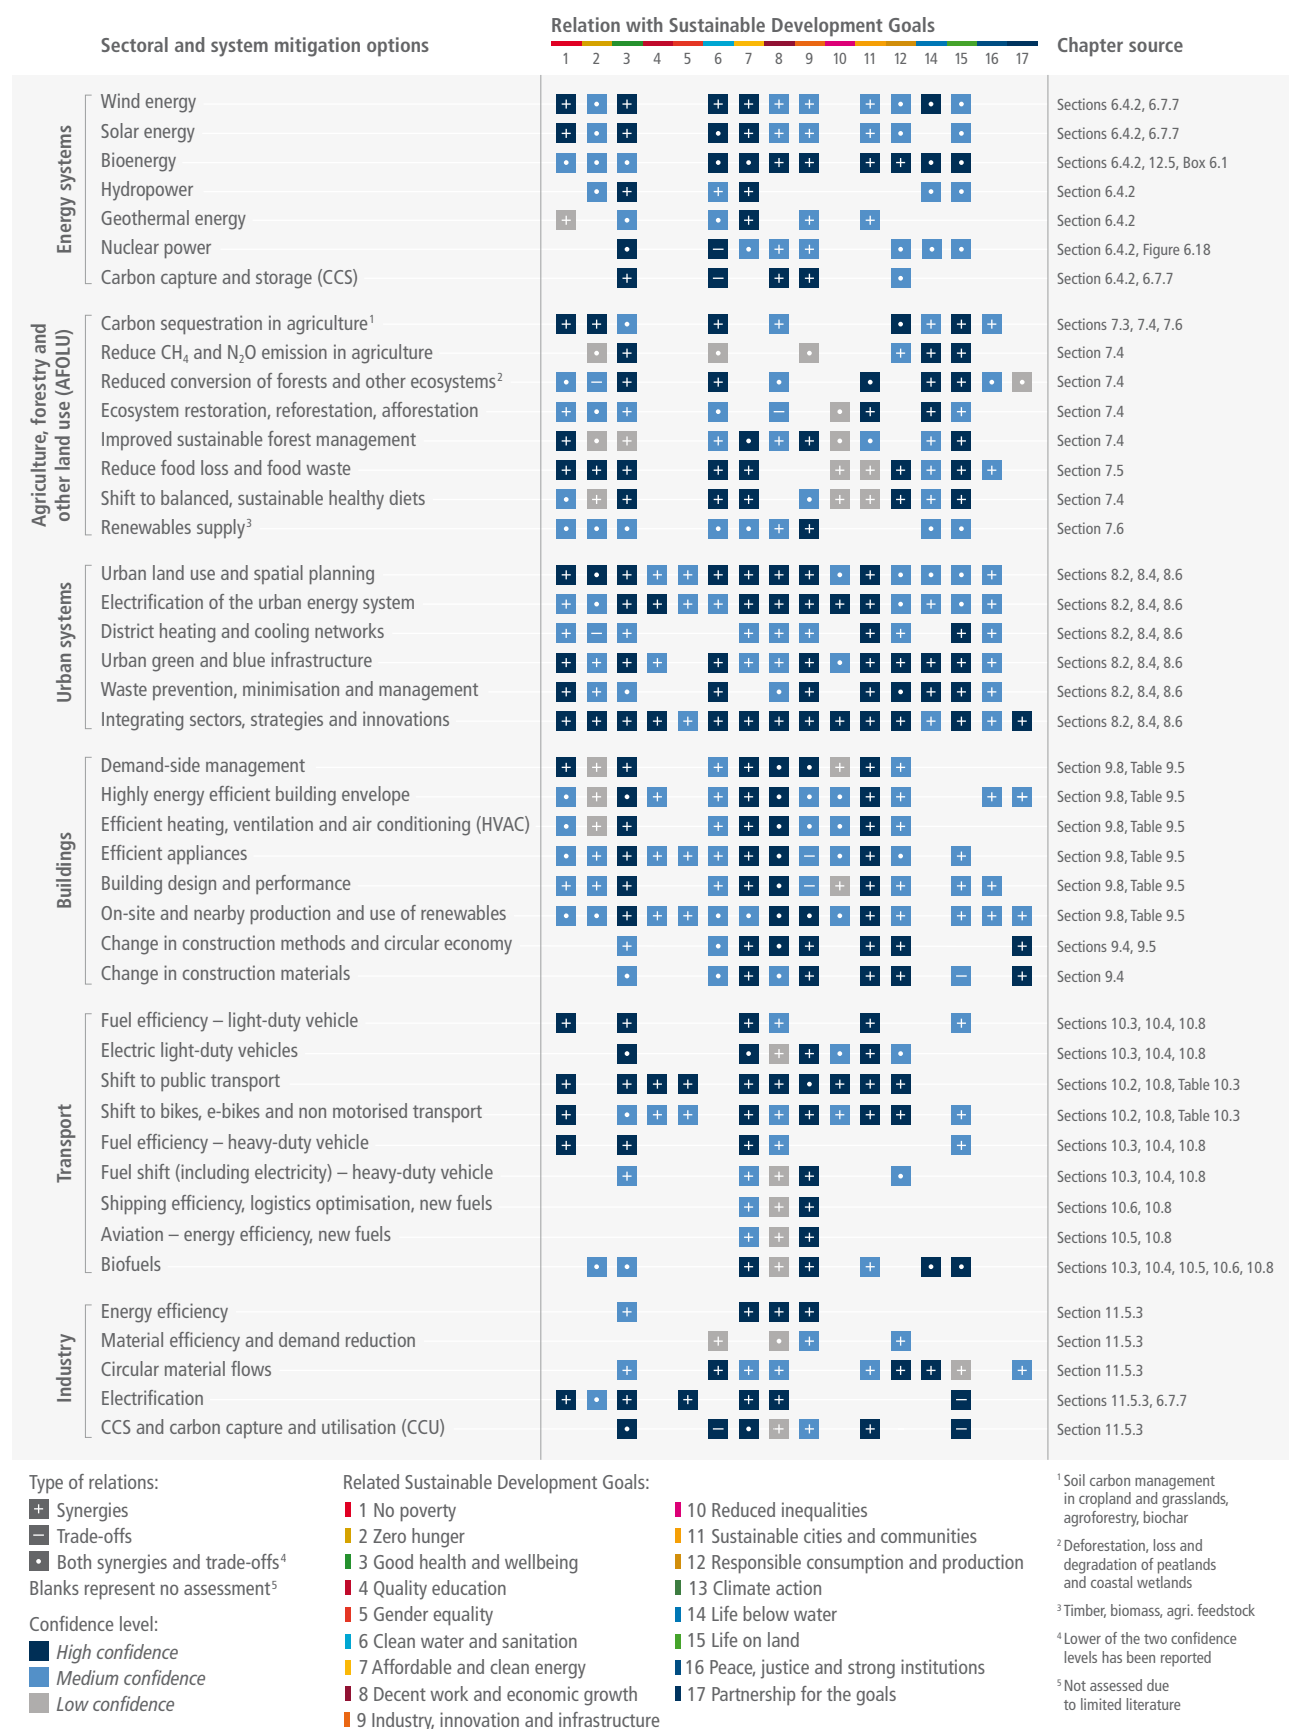

Figure TS.29 | Mitigation options have synergies with many Sustainable Development Goals (SDGs), but there are trade-offs associated with some options especially when implemented at scale.

Figure TS.29 (continued): Mitigation options have synergies with many Sustainable Development Goals (SDGs), but there are trade-offs associated with some options especially when implemented at scale. The synergies and trade-offs vary widely and depend on the context. Figure presents a summary of the chapter-level qualitative assessment of the synergies and trade-offs for selected mitigation options. Overlaps may exist in the mitigation options assessed and presented by sector and system, and interlinkages with the SDGs might differ depending on the application of that option by sector. Interactions of mitigation options with the SDGs are context-specific and dependent on the scale of implementation. For some mitigation options, these scaling and context-specific issues imply that there are both synergies and trade-offs in relation to specific SDGs. The SDGs are displayed as coloured squares. They indicate whether a synergy, trade-off, or both synergies and trade-offs exist between the SDG and the mitigation option. Confidence levels are indicated through the solidity of the squares. A solid square indicates high confidence, a partially filled square indicates medium confidence, and an outlined square indicates low confidence. The final column in the figure provides a line of sight to the chapters that provide details on context-specificity and scale of implementation. {6.3, 6.4, 6.7, 7.3, 7.4, 7.5, 7.6, 8.2, 8.4, 8.6, 9.4, 9.5, 9.8, Table 9.5, 10.3, 10.4, 10.5, 10.6, 10.8, 11.5, Table 10.3, 17.3, Figure 17.1, Supplementary Material Table 17.SM.1, Annex II.IV.12}

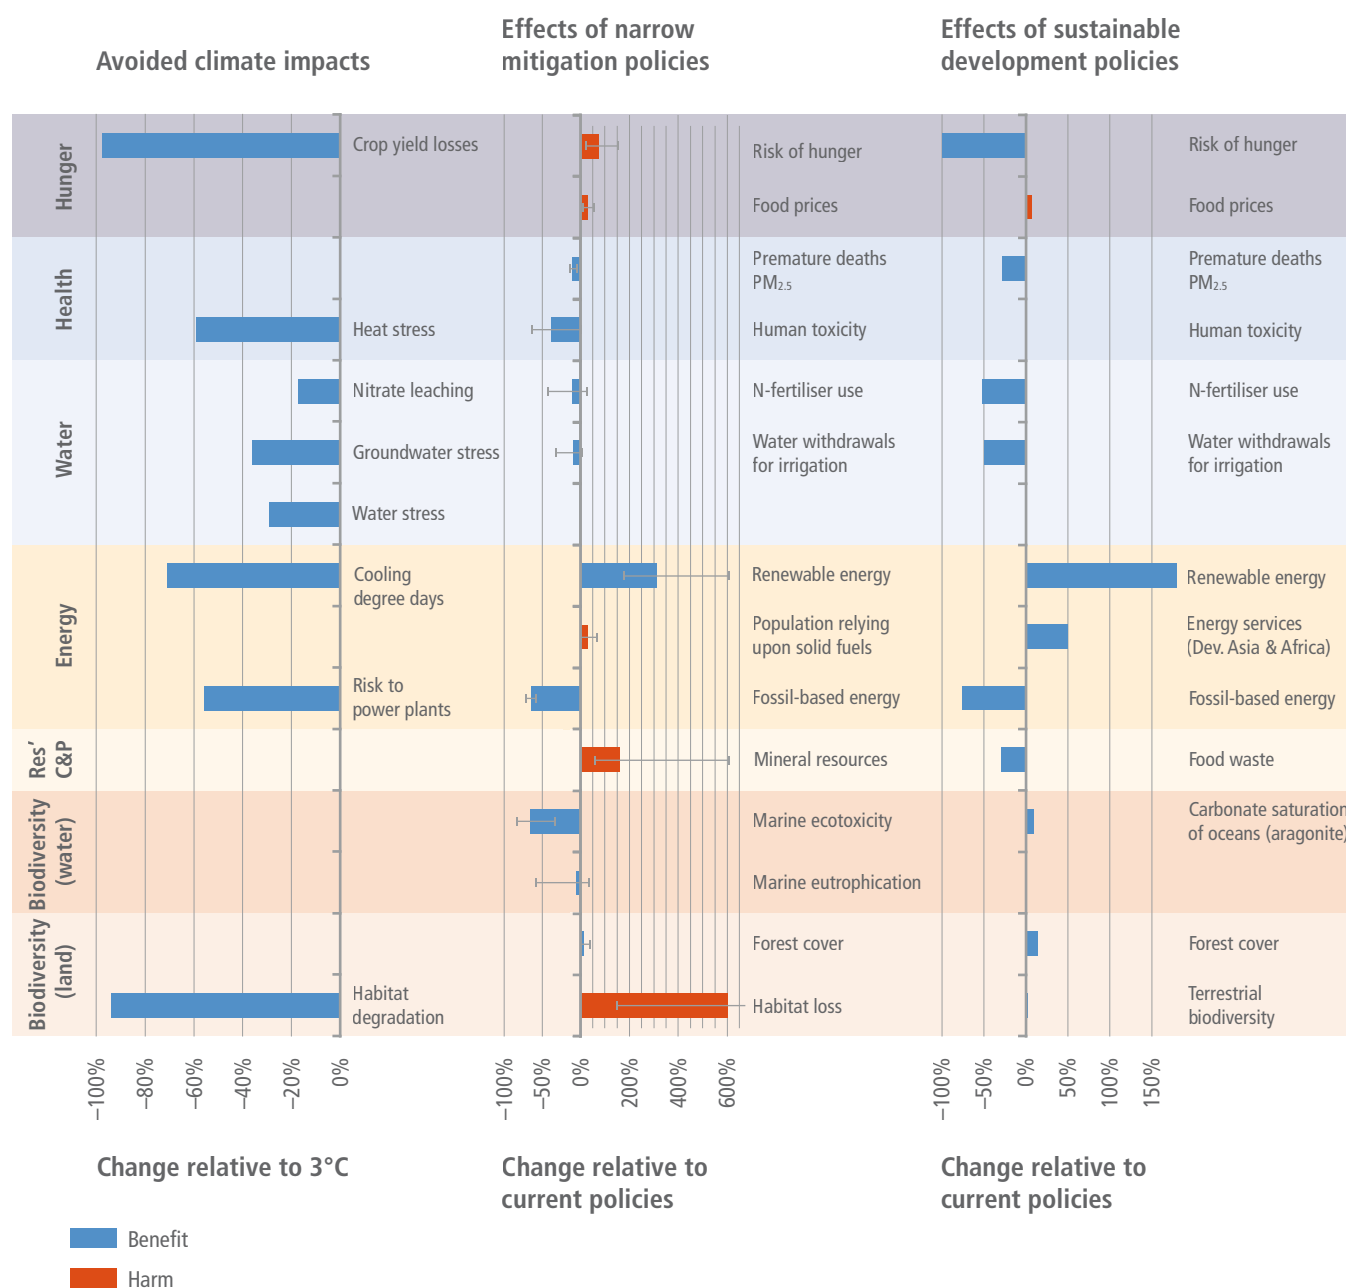

Figure TS.30 | Impacts on SDGs of mitigation limiting warming to 1.5°C (>50%) with narrow mitigation policies vs broader sustainable development policies. **Left:** benefits of mitigation from avoided impacts. **Middle:** sustainability co-benefits and trade-offs of narrow mitigation policies (averaged over multiple models). **Right:** sustainability co-benefits and trade-offs of mitigation policies integrating Sustainable Development Goals. Scale: 0% means no change compared to 3°C (left) or current policies (middle and right). Green values correspond to proportional improvements, red values to proportional worsening. Note: only the left panel considers climate impacts on sustainable development; the middle and right panels do not. 'Res' C&P' stands for Responsible Consumption and Production (SDG 12). {Figure 3.39}

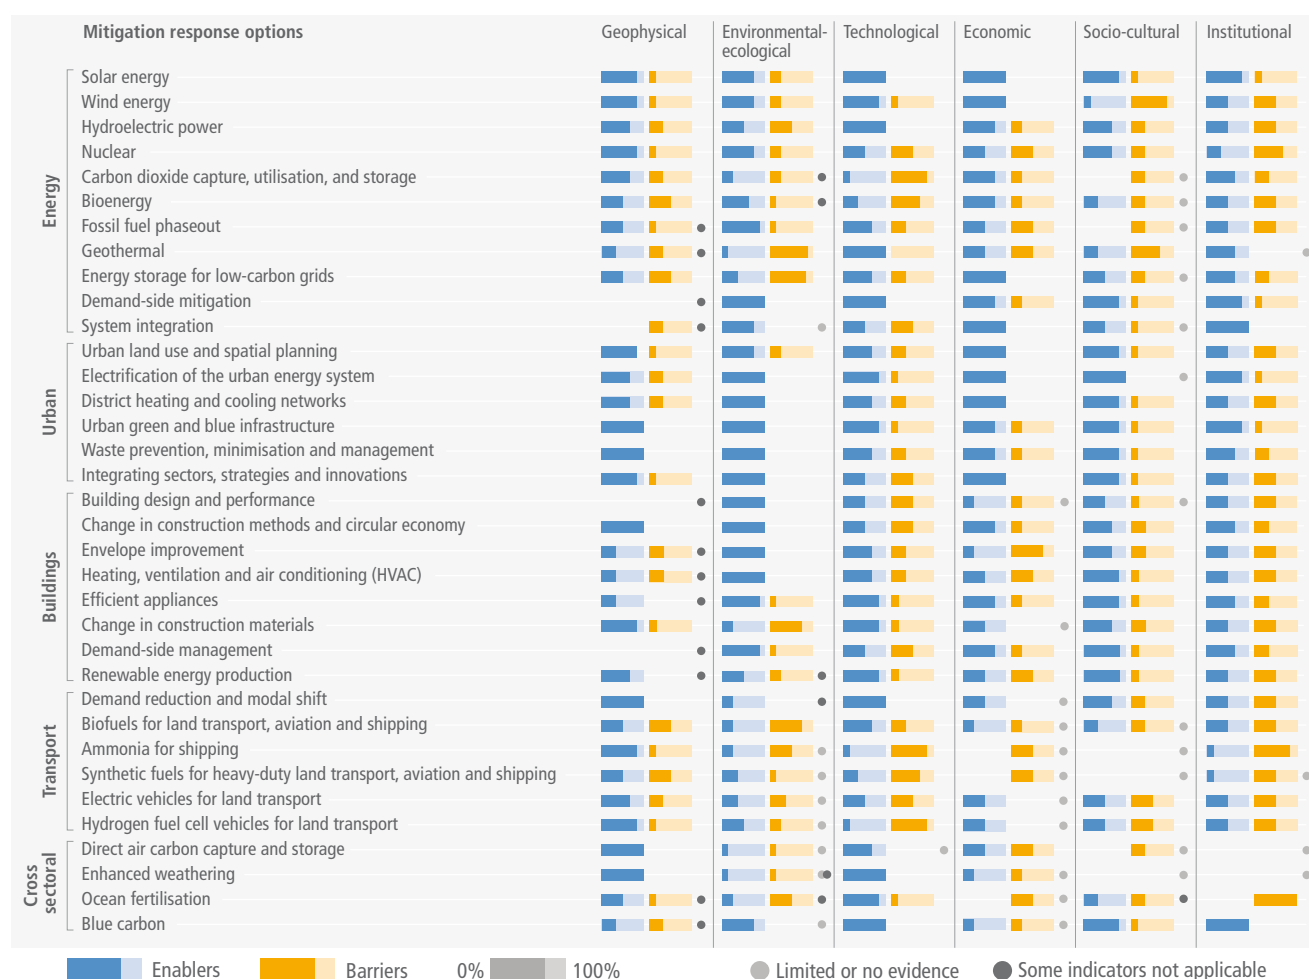

Figure TS.31 | Geophysical, environmental-ecological, technological, economic, socio-cultural and institutional factors can enable or act as barriers to the deployment of response options. Chapter-level assessment for selected mitigation options. Overlaps may exist in the mitigation options assessed and presented by sector and system, and feasibility might differ depending on the demarcation of that option in each sector. Chapters 6, 8, 9, 10, and 12 assess mitigation response options across six feasibility dimensions: *geophysical*, *environmental-ecological*, *technological*, *economic*, *socio-cultural* and *institutional*. AFOLU (Chapter 7) and industry (Chapter 11) are not included because of the heterogeneity of options in these sectors. For each dimension, a set of feasibility indicators was identified. Examples of indicators include impacts on land use, air pollution, economic costs, technology scalability, public acceptance and political acceptance (see Box TS.15, and Annex II.IV.11 for a detailed explanation). An indicator could refer to a barrier or an enabler to implementation, or could refer to both a barrier or an enabler, depending on the context, speed, and scale of implementation. Dark blue bars indicate the extent of enablers to deployment within each dimension. This is shown relative to the maximum number of possible enablers, as indicated by the light blue shading. Dark orange bars indicate the extent of barriers to deployment within each dimension. This is shown relative to the maximum number of possible barriers, as indicated by light orange shading. A light grey dot indicates that there is limited or no evidence to assess the option. A dark grey dot indicates that one of the feasibility indicators within that dimension is not relevant for the deployment of the option. The relevant sections in the underlying chapters include references to the literature on which the assessment is based and indicate whether the feasibility of an option varies depending on context (e.g., region), scale (e.g., small, medium or full scale), speed (e.g., implementation in 2030 versus 2050) and warming level (e.g., 1.5°C versus 2°C). {6.4, 8.5, 9.10, 10.8, 12.3, Annex II.IV.11}

The feasibility of deploying response options is shaped by barriers and enabling conditions across geophysical, environmental-ecological, technological, economic, socio-cultural, and institutional dimensions (high confidence). Accelerating the deployment of response options depends on reducing or removing barriers across these dimensions, as well on establishing and strengthening enabling conditions. Feasibility is context-dependent, and also depends on the scale and the speed of implementation. For example: the institutional, legal and administrative capacity to support deployment varies across countries; the feasibility of options that involve large-scale land-use changes is highly context-dependent; spatial planning has a higher potential in early stages of urban development; the geophysical potential of geothermal is site-

specific; and cultural and local conditions may either inhibit or enable demand-side responses. Figure TS.31 summarises the assessment of barriers and enablers for a broad range of sector-specific, and cross-sectoral response options. (Box TS.15) {6.4, 7.4, 8.5, 9.10, 10.8, 12.3}

Alternative mitigation pathways are also associated with different feasibility challenges (high confidence). These challenges are multi-dimensional, context-dependent, malleable to policy and to technological and societal trends. They can also be reduced by putting in place appropriate enabling conditions. Figure TS.32 highlights the dynamic and transient nature of feasibility risks. These risks are transient and concentrated in the decades before mid-century. Figure TS.32 also illustrates how different

Figure TS.32 | The feasibility of mitigation scenarios. Figure TS.32 shows the proportion of scenarios in the AR6 scenarios database – falling within the warming level classifications C1 and C3 (**C1**: below 1.5°C (>50%), no or limited overshoot; **C3**: below 2°C (>67%)) – that exceed threshold values in 2030, 2050 and 2100 for five dimensions of feasibility (Boxes TS.5 and TS.15). The feasibility dimensions shown are: *geophysical, technological, economic, socio-cultural and institutional*. The thresholds shown are: (i) *plausible* – range of values based on past historical trends or other peer reviewed assessments; (ii) *best-case scenario* – range of values assuming major political support or technological breakthrough; (iii) *unprecedented* – values going beyond those observed or reported in peer-reviewed assessments. Overlaid are the Illustrative Mitigation Pathways consistent with SSP2 (LD, SP, Ren: C1 category; Neg, GS: C3 category). The positioning of the illustrative pathways is simply indicative of the general trade-offs over time and across the feasibility dimensions, it is not determined mathematically. (Box TS.5) [3.8]

feasibility dimensions pose differentiated challenges: for example, institutional feasibility challenges are shown as *unprecedented* for a high proportion of scenarios, in line with the qualitative literature, but moving from 2030 to 2050 and 2100 these challenges decrease.

The feasibility challenges associated with mitigation pathways are predominantly *institutional* and *economic* rather than *technological* and *geophysical* (*medium confidence*). The rapid pace of technological development and deployment in mitigation scenarios is not incompatible with historical records, but rather,

institutional capacity is a key limiting factor for a successful transition. Emerging economies appear to have highest feasibility challenges in the near to mid-term. This suggests a key role of policy and technology as enabling factors. (Figure TS.32) {3.8}

Pathways relying on a broad portfolio of mitigation strategies are more robust and resilient (*high confidence*). Portfolios of technological solutions reduce the feasibility risks associated with the low-carbon transition. (Figures TS.31 and TS.32, Box TS.15) {3.8}

Box TS.15 | A Harmonised Approach to Assessing Feasibility

The assessment of feasibility in this report aims to identify barriers and enablers to the deployment of mitigation options and pathways. The assessment organises evidence to support policy decisions, and decisions on actions, that would improve the feasibility of mitigation options and pathways by removing relevant barriers and by strengthening enablers of change.

The feasibility of mitigation response options

Mitigation response options are assessed against six dimensions of feasibility. Each dimension comprises a key set of indicators that can be evaluated by combining various strands of literature. {Annex II.IV.11, Table 6.1}

The assessment – undertaken by the sectoral chapters in this report – evaluates to what extent each indicator (listed in Box TS.15, Table.1) would be an enabler or barrier to implementation using a scoring methodology (described in detail in Annex II.IV.11). When appropriate, it is also indicated whether the feasibility of an option varies across context, scale, time and temperature goal. The resulting scores provide insight into the extent to which each feasibility dimension enables or inhibits the deployment of the relevant option. It also provides insight into the nature of the effort needed to reduce or remove barriers, thereby improving the feasibility of individual options. {Annex II.IV.11}

Box TS.15, Table.1 | Feasibility dimensions and indicators to assess the barriers and enablers of implementing mitigation options.

Feasibility dimension	Indicators
Geophysical feasibility	Availability of required geophysical resources: – Physical potential – Geophysical resource availability – Land use
Environmental-ecological feasibility	Impacts on environment: – Air pollution – Toxic waste, ecotoxicity and eutrophication – Water quantity and quality – Biodiversity
Technological feasibility	Extent to which the technology can be implemented at scale soon: – Simplicity – Technology scalability – Maturity and technology readiness
Economic feasibility	Financial costs and economic effects: – Costs now, in 2030 and in the long term – Employment effects and economic growth
Socio-cultural feasibility	Public engagement and support, and social impacts: – Public acceptance – Effects on health and well-being – Distributional effects
Institutional feasibility	Institutional conditions that affect the implementation of the response option: – Political acceptance – Institutional capacity and governance, cross-sectoral coordination – Legal and administrative capacity

Box TS.15 (continued)

The feasibility of mitigation scenarios

Scenarios provide internally consistent projections of emission-reduction drivers and help contextualise the scale of deployment and interactions of mitigation strategies. Recent research has proposed and operationalised frameworks for the feasibility assessment of mitigation scenarios. In this report the feasibility assessment of scenarios uses an approach that involves developing a set of multi-dimensional metrics capturing the *timing*, *disruptiveness* and the *scale* of the transformative change within five dimensions: *geophysical*, *technological*, *economic*, *socio-cultural* and *institutional*, as illustrated in Box TS.15, Figure 1.

More than 20 indicators were chosen to represent feasibility dimensions that could be related to scenario metrics. Thresholds of feasibility risks of different intensity were obtained through empirical analysis of historical data and assessed literature. Details of indicators, thresholds, and how they were applied is reported in Annex II.IV.11. {3.8}

Step 1 Feasibility dimensions	Step 2 Indicators	Step 3 Thresholds	Step 4 Aggregation (geometric mean)
Geophysical Technological Economic Institutional Socio-cultural	For each dimension, selection of relevant indicators measuring decadal changes (among indicators available or computable based on scenario set)	Categorisation of level of feasibility concern for each indicator in each decade based on thresholds defined based on the literature and available empirical data – 3 high – 2 medium – 1 low	<div>Aggregation within each dimension → allows assessing tradeoffs among feasibility dimensions</div> <div>Aggregation across dimensions at different points in time → allows assessing the timing and disruptiveness of the transformation</div> <div>Aggregation across dimensions and across time → allows assessing the scale of the transformation</div>

Box TS.15, Figure 1 | Steps involved in evaluating the feasibility of scenarios. {Figure 3.41} Note: in this approach the *environmental-ecological* dimension is captured through different scenarios' categories.

A wide range of factors have been found to enable sustainability transitions, ranging from technological innovations to shifts in markets, and from policies and governance arrangements to shifts in belief systems and market forces (*high confidence*). Many of these factors have come together in a co-evolutionary process that has unfolded globally, internationally and locally over several decades (*low evidence, high agreement*). Those same conditions that may serve to impede the transition (i.e., organisational structure, behaviour, technological lock-in) can also 'flip' to enable both the transition and the framing of sustainable development policies to create a stronger basis for policy support (*high confidence*). It is important to note that strong shocks to these systems, including accelerating climate change impacts, economic crises and political changes, may provide crucial openings for accelerated transitions to sustainable systems. For example, rebuilding more sustainably after an extreme event, or renewed public debate about the drivers of social and economic vulnerability to multiple stressors (*medium confidence*). {17.4}

While transition pathways will vary across countries it is anticipated that they will be challenging in many contexts (*high confidence*). Climate change is the result of decades of unsustainable production and consumption patterns, as well as governance arrangements and political economic institutions that lock-in resource-intensive development patterns (*high confidence*). Resource shortages, social divisions, inequitable distributions of wealth, poor infrastructure and limited access to advanced technologies and skilled human resources can constrain the options

and capacity of developing countries to achieve sustainable and Just Transitions (*medium evidence, high agreement*) {17.1.1}. Reframing development objectives and shifting development pathways towards sustainability can help transform these patterns and practices, allowing space to transform unsustainable systems (*medium evidence, high agreement*). {1.6, Cross-Chapter Box 5 in Chapter 4, 17.1, 17.3}

The landscape of transitions to sustainable development is changing rapidly, with multiple transitions already underway. This creates the room to manage these transitions in ways that prioritise the needs of workers in vulnerable sectors (e.g., land, energy) to secure their jobs and maintain secure and healthy lifestyles (*medium evidence, high agreement*). {17.3.2}

Actions aligning sustainable development, climate mitigation and partnerships can support transitions. Strengthening different stakeholders' 'response capacities' to mitigate and adapt to a changing climate will be critical for a sustainable transition (*high confidence*). {17.1}

Accelerating the transition to sustainability will be enabled by explicit consideration being given to the principles of justice, equality and fairness (*high confidence*). {5.2, 5.4, 5.6, 13.2, 13.6, 13.8, 13.9, 17.4}

Executive Summary

Global greenhouse gas (GHG) emissions continued to rise to 2019: the aggregate reductions implied by current Nationally Determined Contributions (NDCs) to 2030 would still make it impossible to limit warming to 1.5°C with no or limited overshoot, and would only be compatible with *likely limiting warming below 2°C if followed by much steeper decline, hence limiting warming to either level implies accelerated mitigation actions at all scales (robust evidence, high agreement)*. Since the IPCC's Fifth Assessment Report (AR5), important changes that have emerged include the specific objectives established in the Paris Agreement of 2015 (for temperature, adaptation and finance), rising climate impacts, and higher levels of societal awareness and support for climate action. The growth of global GHG emissions has slowed over the past decade, and delivering the updated NDCs to 2030 would turn this into decline, but the implied global emissions by 2030 exceed pathways consistent with 1.5°C by a large margin, and are near the upper end of the range of modelled pathways which keep temperatures *likely* limit warming to 2°C (with >65% probability). Continuing investments in carbon-intensive activities at scale will heighten the multitude of risks associated with climate change and impede societal and industrial transformation towards low-carbon development. Meeting the long-term temperature objective in the Paris Agreement therefore implies a rapid turn to an accelerating decline of GHG emissions towards 'net zero', which is implausible without urgent and ambitious action at all scales. The unprecedented COVID-19 pandemic has had far-reaching impacts on the global economic and social system, and recovery will present both challenges and opportunities for climate mitigation. {1.2, 1.3, 1.5, 1.6, Chapters 3 and 4}

While there are some trade-offs, effective and equitable climate policies are largely compatible with the broader goal of sustainable development and efforts to eradicate poverty as enshrined in the 17 Sustainable Development Goals (SDGs) (*robust evidence, high agreement*). Climate mitigation is one of many goals that societies pursue in the context of sustainable development, as evidenced by the wide range of the SDGs. Climate mitigation has synergies and/or trade-offs with many other SDGs. There has been a strong relationship between development and GHG emissions, as historically both per capita and absolute emissions have risen with industrialisation. However, recent evidence shows countries can grow their economies while reducing emissions. Countries have different priorities in achieving the SDGs and reducing emissions as informed by their respective national conditions and capabilities. Given the differences in GHG emissions contributions, degree of vulnerabilities and impacts, as well as capacities within and between nations, equity and justice are important considerations for effective climate policy and for securing national and international support for deep decarbonisation. Achieving sustainable global development and eradicating poverty as enshrined in the 17 SDGs would involve effective and equitable climate policies at all levels from local to global scale. Failure to address questions of equity and justice over time can undermine social cohesion and stability. International cooperation can enhance efforts to achieve ambitious global climate mitigation in the context of sustainable development. {1.4, 1.6, Chapters 2, 3, 4, 5, 13 and 17}

The transition to a low-carbon economy depends on a wide range of closely intertwined drivers and constraints, including policies and technologies where notable advances over the past decade have opened up new and large-scale opportunities for deep decarbonisation, and for alternative development pathways which could deliver multiple social and developmental goals (*robust evidence, medium agreement*). Drivers for and constraints against low-carbon societal transition comprise *economic and technological* factors (the means by which services such as food, heating and shelter are provided and for whom, the emissions intensity of traded products, finance, and investment), *socio-political issues* (political economy, equity and fairness, social innovation and behaviour change), and *institutional factors* (legal framework and institutions, and the quality of international cooperation). In addition to being deeply intertwined all the factors matter to varying degrees, depending on the prevailing social, economic, cultural and political context. They often exert both push and pull forces at the same time, within and across different scales. The development and deployment of innovative technologies and systems at scale are important for achieving deep decarbonisation. In recent years, the cost of several low-carbon technologies has declined sharply, alongside rapid deployment. Over 20 countries have also sustained emission reductions, and many more have accelerated energy efficiency and/or land-use improvements. Overall, however, the global contribution is so far modest, at a few billion tonnes (tCO₂-eq) of avoided emissions annually. {1.3, 1.4, Chapters 2, 4, 13 and 14}

Accelerating mitigation to prevent dangerous anthropogenic interference within the climate system will require the integration of broadened assessment frameworks and tools that combine multiple perspectives, applied in a context of multi-level governance (*robust evidence, medium agreement*). Analysing a challenge on the scale of fully decarbonising our economies entails integration of multiple analytic frameworks. Approaches to risk assessment and resilience, established across IPCC Working Groups, are complemented by frameworks for probing the challenges in implementing mitigation. *Aggregate frameworks* include cost-effectiveness analysis towards given objectives, and cost-benefit analysis, both of which have been developing to take fuller account of advances in understanding risks and innovation, the dynamics of emitting systems and of climate impacts, and welfare economic theory including growing consensus on long-term discounting. *Ethical frameworks* consider the fairness of processes and outcomes which can help ameliorate distributional impacts across income groups, countries and generations. *Transition and transformation frameworks* explain and evaluate the dynamics of transitions to low-carbon systems arising from interactions amongst levels, with inevitable resistance from established socio-technical structures. *Psychological, behavioural and political frameworks* outline the constraints (and opportunities) arising from human psychology and the power of incumbent interests. A comprehensive understanding of climate mitigation must combine these multiple frameworks. Together with established risk frameworks, collectively these help to explain potential synergies and trade-offs in mitigation, imply a need for a wide portfolio of policies attuned to different

actors and levels of decision-making, and underpin Just Transition strategies in diverse contexts. {1.2.2, 1.7, 1.8}

The speed, direction and depth of any transition will be determined by choices in the, environmental, technological, economic, socio-cultural and institutional realms (*robust evidence, high agreement*). Transitions in specific systems can be gradual or rapid and disruptive. The pace of a transition can be impeded by ‘lock-in’ generated by existing physical capital, institutions, and social norms. The interaction between power, politics and economy is central in explaining why broad commitments do not always translate to urgent action. At the same time, attention to and support for climate policies and low-carbon societal transition has generally increased, as the impacts have become more salient. Both public and private financing and financial structures strongly affect the scale and balance of high- and low-carbon investments. COVID-19 has strained public finances, and integrating climate finance into ongoing recovery strategies, nationally and internationally, can accelerate the diffusion of low-carbon technologies and also help poorer countries to minimise future stranded assets. Societal and behavioural norms, regulations and institutions are essential conditions to accelerate low-carbon transitions in multiple sectors, whilst addressing distributional concerns endemic to any major transition. {1.3.3, 1.4, 1.8, Chapters 2, 4 and 15, and Cross-Chapter Box 1 in this chapter}

Achieving the global transition to a low-carbon, climate-resilient and sustainable world requires purposeful and increasingly coordinated planning and decisions at many scales of governance including local, sub-national, national and global levels (*robust evidence, high agreement*). Accelerating mitigation globally would imply strengthening policies adopted to date, expanding the effort across options, sectors, and countries, and broadening responses to include more diverse actors and societal processes at multiple – including international – levels. Effective governance of climate change entails strong action across multiple jurisdictions and decision-making levels, including regular evaluation and learning. Choices that cause climate change as well as the processes for making and implementing relevant decisions involve a range of non-nation state actors such as cities, businesses, and civil society organisations. At global, national and sub-national levels, climate change actions are interwoven with and embedded in the context of much broader social, economic and political goals. Therefore, the governance required to address climate change has to navigate power, political, economic, and social dynamics at all levels of decision-making. Effective climate-governing institutions, and openness to experimentation on a variety of institutional arrangements, policies and programmes can play a vital role in engaging stakeholders and building momentum for effective climate action. {1.4, 1.9, Chapters 8, 15 and 17}

1.1 Introduction

This report (AR6 WGIII) aims to assess new literature on climate mitigation including implications for global sustainable development. In this Sixth Assessment Cycle the IPCC has also published three Special Reports,¹ all of which emphasise the rising threat of climate change and the implications for more ambitious mitigation efforts at all scales. At the same time, the Paris Agreement (PA) and the UN 2030 Agenda for Sustainable Development with its 17 Sustainable Development Goals (SDGs), both adopted in 2015, set out a globally agreed agenda within which climate mitigation efforts must be located. Along with a better understanding of the physical science basis of climate change (AR6 WGI), and vulnerabilities, impacts, and adaptation (AR6 WGII), the landscape of climate mitigation has evolved substantially since the Fifth Assessment Report (AR5).

Since (IPCC 2014a), climate mitigation policies around the world have grown in both number and shape (Chapter 13). However, while the average rate of annual increase of CO₂ emissions has declined (Section 1.3.2), GHG emissions globally continued to rise, underlining the urgency of the mitigation challenge (Chapters 2 and 3). Over 20 countries have cut absolute emissions alongside sustained economic growth, but the scale of mitigation action across countries remains varied and is generally much slower than the pace required to meet the goals of the Paris Agreement (Sections 1.3.2 and 2.7.2). Per capita GHG emissions between countries even at similar stages of economic development (based on GDP per capita) vary by a factor of three (Figure 1.6) and by more than two on consumption basis (Section 2.3).

The Special Report on Global Warming of 1.5°C (SR1.5) underlined that humanity is now living with the ‘unifying lens of the Anthropocene’ (IPCC 2018a, pp. 52–53), that requires a sharpened focus on the impact of human activity on the climate system and the planet more broadly given ‘planetary boundaries’ (Steffen et al. 2015) including interdependencies of climate change and biodiversity (Dasgupta 2021). Recent literature assessed by Working Groups I and II of this AR6 underlines the urgency of climate action as cumulative CO₂ emissions, along with other greenhouse gases (GHGs), drives the temperature change. Across AR6, global temperature changes are defined relative to the period 1850–1900, as in SR1.5 and collaboration with WGI enabled the use of AR6-calibrated emulators to assure consistency across the three Working Groups. The remaining ‘carbon budgets’ (see Annex I: Glossary) associated with 1.5°C and 2°C temperature targets equate to about one (for 1.5°C) to three (for 2°C) decades of current emissions, as from 2020, but with significant variation depending on multiple factors including other gases (Figure 2.7, and Cross-Working Group Box 1 in Chapter 3). For an outline of the WGIII approach to mitigation scenarios, emission pathways implied by the Paris goals, and the timing of peak and ‘net zero’ (see Glossary and FAQ 1.3), see Section 1.5 and Chapter 3.

Strong differences remain in responsibilities for, and capabilities to, take climate action within and between countries. These differences, as well as differences in the impact of climate change, point to the role of collective action in achieving urgent and ambitious global climate mitigation in the context of sustainable development, with attention to issues of equity and fairness as highlighted in several chapters of the report (Chapters 4, 5, 14, 15 and 17).

Innovation and industrial development of key technologies in several relevant sectors have transformed prospects for mitigation at much lower cost than previously assessed (Chapters 2 and 6–12). Large reductions in the cost of widely available renewable energy technologies, along with energy efficient technologies and behavioural changes (Chapters 5 and 9–11), can enable societies to provide services with much lower emissions. However, there are still significant differences in the ability to access and utilise low-carbon technologies across the world (Chapters 4, 15 and 16). New actors, including cities, businesses, and numerous non-state transnational alliances have emerged as important players in the global effort to tackle climate change (Chapters 13–16).

Along with continued development of concepts, models and technologies, there have been numerous insights from both the successes and failures of mitigation action that can inform future policy design and climate action. However, to date, policies and investments are still clearly inadequate to put the world in line with the PA’s aims (Chapters 13 and 15).

The greater the inertia in emission trends and carbon-intensive investments, the more that CO₂ will continue to accumulate (Hilaire et al. 2019; IPCC 2019a). Overall, the literature points to the need for a more dynamic consideration of intertwined challenges concerning the transformation of key GHG-emitting systems: to minimise the trade-offs, and maximise the synergies, of delivering deep decarbonisation whilst enhancing sustainable development.

This chapter introduces readers to the AR6 WGIII Report and provides an overview of progress and challenges, in three parts. Part A (1.1–1.5) introduces the climate mitigation challenge, provides key findings and developments since previous assessment, and reviews the main drivers for, and constraints against accelerated climate action. Part B (1.6–1.8) provides an assessment of the key frameworks for understanding the climate mitigation challenge covering broad approaches such as sustainable development and more specific economic, political and ethical framings. Part C (1.9–1.12) briefly highlights the role of governance for steering and coordinating efforts to accelerate globally effective and equitable climate mitigation, notes the gaps in knowledge that have been identified in the process of assessment, and provides a road map to the rest of the report.

¹ These are the Special Report on Global Warming of 1.5°C (SR1.5) (IPCC 2018b); the Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC) (IPCC 2019b); and the Special Report on Climate Change and Land (SRCCL) (IPCC 2019c).

1.2 Previous Assessments

1.2.1 Key Findings from Previous Assessment Reports

Successive WGIII IPCC assessments have emphasised the importance of climate mitigation along with the need to consider broader societal goals especially sustainable development. Key insights from AR5 and the subsequent three Special Reports (IPCC 2018b, 2019b, 2019c) are summarised below.

The AR5 projected that in baseline scenarios (i.e., based on prevailing trends without explicit additional mitigation efforts), agriculture, forestry and other land use (AFOLU) would be the only sector where emissions could fall by 2100, with some CO₂ removal (IPCC 2014b, p. 17). Direct CO₂ emissions from energy were projected to double or even triple by 2050 (IPCC 2014b, p. 20) due to global population and economic growth, resulting in global mean surface temperature increases in 2100 from 3.7°C to 4.8°C compared to pre-industrial levels. The AR5 noted that mitigation effort and the costs associated with ambitious mitigation differ significantly across countries, and in ‘globally cost-effective’ scenarios, the biggest reductions (relative to projections) occur in the countries with the highest future emissions in the baseline scenarios (IPCC 2014b, p. 17). Since most physical capital (e.g., power plants, buildings, transport infrastructure) involved in GHG emissions is long-lived, the timing of the shift in investments and strategies will be crucial (IPCC 2014b, p. 18).

A key message from recent Special Reports is the urgency to mitigate GHG emissions in order to avoid rapid and potentially irreversible changes in natural and human systems (IPCC 2018b, 2019b, 2019c). Successive IPCC reports have drawn upon increasing sophistication of modelling tools to project emissions in the absence of ambitious decarbonisation action, as well as the emission pathways that meet long-term temperature targets. The SR1.5 examined pathways limiting warming to 1.5°C, compared to the historical baseline of 1850–1900, finding that ‘in pathways with no or limited overshoot of 1.5°C, global net anthropogenic CO₂ emissions decline by about 45% from 2010 levels by 2030, reaching net zero around 2050’ (2045–2055 interquartile range); with ‘overshoot’ referring to higher temperatures, then brought down by 2100 through ‘net negative’ emissions. It found this would require rapid and far-reaching transitions in energy, land, urban and infrastructure (including transport and buildings), and industrial systems (*high confidence*) (IPCC 2018b).

The SR1.5 found that the Nationally Determined Contributions (NDCs) as declared under the Paris Agreement (PA) would not limit warming to 1.5°C; despite significant updates to NDCs in 2020/21, this remains the case, although delivery of these more ambitious NDCs would somewhat enhance the prospects for staying below 2°C (Section 1.3.3).

The AR5 WGIII and the Special Reports analysed economic costs associated with climate action. The estimates vary widely depending on the assumptions made as to how ordered the transition is, temperature target, technology availability, and the metric or model used, among others (Chapter 6). Modelled direct mitigation costs of pathways to 1.5°C, with no/limited overshoot, span a wide range,

but were typically three to four times higher than in pathways to 2°C (*high confidence*), before taking account of benefits, including significant reduction in loss of life and livelihoods, and avoided climate impacts (IPCC 2018b).

Successive IPCC reports highlight a strong connection between climate mitigation and sustainable development. Climate mitigation and adaptation goals have synergies and trade-offs with efforts to achieve sustainable development, including poverty eradication. A comprehensive assessment of climate policy therefore involves going beyond a narrow focus on specific mitigation and adaptation options to incorporate climate issues into the design of comprehensive strategies for equitable sustainable development. At the same time, some climate mitigation policies can run counter to sustainable development and eradicating poverty, which highlights the need to consider trade-offs alongside benefits. Examples include synergies between climate policy and improved air quality, reducing premature deaths and morbidity (IPCC 2014b, Figure SPM.6) (AR6 WGI Sections 6.6.3 and 6.7.3), but there would be trade-offs if policy raises net energy bills, with distributional implications. The Special Report on Climate Change and Land (SRCL) also emphasises important synergies and trade-offs, bringing new light on the link between healthy and sustainable food consumption and emissions caused by the agricultural sector. Land-related responses that contribute to climate change adaptation and mitigation can also combat desertification and land degradation, and enhance food security (IPCC 2019a).

Previous Assessment Reports (ARs) have detailed the contribution of various sectors and activities to global GHG emissions. When indirect emissions (mainly from electricity, heat and other energy conversions) are included, the four main consumption (end-use) drivers are industry, AFOLU, buildings and transport (Figure 2.14), though the magnitude of these emissions can vary widely between countries. These – together with the energy and urban systems which feed and shape end-use sectors – define the sectoral chapters in this AR6 WGIII report.

Estimates of emissions associated with production and transport of internationally traded goods were first presented in AR5 WGIII, which estimated the ‘embodied emission transfers’ from upper-middle-income countries to industrialised countries through trade at about 10% of CO₂ emissions in each of these groups (IPCC 2014a, Figure TS.5). The literature on this and discussion on their accounting has grown substantially since then (Chapters 2 and 8).

The atmosphere is a shared global resource and an integral part of the ‘global commons’. In the depletion/restoration of this resource, myriad actors at various scales are involved, for instance, individuals, communities, firms and states. *Inter alia*, international cooperation to tackle ozone depletion and acid rain offer useful examples. The AR5 noted that greater cooperation would ensue if policies are perceived as fair and equitable by all countries along the spectrum of economic development – implying a need for equitable sharing of the effort. A key takeaway from AR5 is that climate policy involves value judgement and ethics. (IPCC 2014a Box TS.1: ‘People and countries have rights and owe duties towards each other. These are matters

of justice, equity, or fairness. They fall within the subject matter of moral and political philosophy, jurisprudence, and economics.’ p. 37). International cooperation and collective action on climate change alongside local, national, regional and global policies will be crucial to solve the problem, and this report notes cooperative approaches beyond simple ‘global commons’ framings (Chapters 13 and 14).

The AR5 (all Working Group reports) also underlined that climate policy inherently involves risk and uncertainty (in nature, economy, society and individuals). To help evaluate responses, there exists a rich suite of analytical tools, for example, cost-benefit analysis, cost-effectiveness analysis, multi-criteria analysis, expected utility theory, and catastrophe and risk models. All have pros and cons, and have been further developed in subsequent literature and in AR6 (Sections 1.2.2 and 1.7).

Recent assessments (IPCC 2014a, 2018b) began to consider the role of individual behavioural choices and cultural norms in driving energy and food patterns. Notably, SR1.5 (Section 4.4.3) outlined emerging evidence on the potential for changes in behaviour, lifestyle and culture to contribute to decarbonisation (and lower the cost); for the first time, AR6 devotes a whole chapter (Chapter 5) to consider these and other underlying drivers of energy demand, food choices and social aspects.

1.2.2 Developments in Climate Science, Impacts and Risk

The assessment of the Physical Science Basis (IPCC AR6 WGI) documents sustained and widespread changes in the atmosphere, cryosphere, biosphere and ocean, providing unequivocal evidence of a world that has warmed, associated with rising atmospheric CO₂ concentrations reaching levels not experienced in at least the last 2 million years. Aside from temperature, other clearly discernible, human-induced changes beyond natural variations include declines in Arctic Sea ice and glaciers, thawing of permafrost, and a strengthening of the global water cycle (AR6 WGI SPM A.2, B.3 and B.4). Oceanic changes include rising sea level, acidification, deoxygenation, and changing salinity (WGI SPM B.3). Over land, in recent decades, both frequency and severity have increased for hot extremes but decreased for cold extremes; intensification of heavy precipitation is observed in parallel with a decrease in available water in dry seasons, along with an increased occurrence of weather conditions that promote wildfires.

In defining the objective of international climate negotiations as being to ‘prevent dangerous anthropogenic interference’ (UNFCCC 1992, Art. 2), the UNFCCC underlines the centrality of risk framing in considering the threats of climate change and potential response measures. Against the background of ‘unequivocal’ (AR4) evidence of human-induced climate change, and the growing experience of direct impacts, the IPCC has sought to systematise a robust approach to risk and risk management.

In AR6 the IPCC employs a common risk framing across all three working groups and provides guidance for more consistent and transparent usage (AR6 WGI Cross-Chapter Box 3 in Chapter 1; AR6 WGII Section 1.4.1; IPCC risk guidance). AR6 defines risk as ‘the potential for adverse consequences for human or ecological systems, recognising the diversity of values and objectives associated with such systems’ (Annex I), encompassing risks from both potential impacts of climate change and human responses to it (Reisinger et al. 2020). The risk framing includes steps for identifying, evaluating, and prioritising current and future risks; for understanding the interactions among different sources of risk; for distributing effort and equitable sharing of risks; for monitoring and adjusting actions over time while continuing to assess changing circumstances; and for communications among analysts, decision-makers, and the public.

Climate change risk assessments face challenges including a tendency to mischaracterise risks and pay insufficient attention to the potential for surprises (Weitzman 2011; Aven and Renn 2015; Stoerk et al. 2018). Concepts of resilience and vulnerability provide overlapping, alternative entry points to understanding and addressing the societal challenges caused and exacerbated by climate change (AR6 WGII, Section 1.2.1).

The AR6 WGII devotes a full chapter (Chapter 17) to ‘Decision-Making Options for Managing Risk’, detailing the analytic approaches and drawing upon the *Cynefin* classification of *known*, *knowable*, *complex* and *chaotic* systems (Section 17.3.1). With deep uncertainty, risk management often aims to identify specific combinations of response actions and enabling institutions that increase the potential for favourable outcomes despite irreducible uncertainties (AR6 WGII Chapter 17 Cross-Chapter Box DEEP; also Marchau et al. (2019); Doukas and Nikas (2020)).

Literature trying to quantify the cost of climate damages has continued to develop. Different methodologies systematically affect outcomes, with recent estimates based on empirical approaches – econometric measurements based on actual impacts – ‘categorically higher than estimates from other approaches’ (AR6 WGII, Cross-Working Group Box ECONOMIC in Chapter 16, and Section 16.6.2). This, along with other developments strengthen foundations for calculating a ‘social cost of carbon’. This informs a common metric for comparing different risks and estimating benefits compared to the costs of GHG reductions and other risk-reducing options (Section 1.7.1); emissions mitigation itself also involves multiple uncertainties, which alongside risks can also involve potential opportunities (Section 1.7.3).

Simultaneously, the literature increasingly emphasises the importance of multi-objective risk assessment and management (e.g., representative key risks in AR6 WGII Chapter 16), which may or may not correlate with any single estimate of economic value (AR6 WGII, Section 1.4.1; IPCC risk guidance). Given the deep uncertainties and risks, the goals established (notably in the Paris Agreement and SDGs) reflect negotiated outcomes informed by the scientific assessment of risks.

1.3 The Multilateral Context, Emissions Trends and Key Developments

Since AR5, there have been notable multilateral efforts which help determine the context for current and future climate action. This section summarises key features of this evolving context.

1.3.1 The 2015 Agreements

In 2015 the world concluded four major agreements that are very relevant to climate action. These include: the Paris Agreement under the 1992 United Nations Framework Convention on Climate Change (UNFCCC), the UN agreements on Disaster Risk Reduction (Sendai) and Finance for Development (Addis Ababa), and the Sustainable Development Goals (SDGs).

The Paris Agreement (PA). The Paris Agreement aims to ‘hold the increase in the global average temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the temperature increase to 1.5°C above pre-industrial levels’ (UNFCCC 2015), alongside goals for adaptation (IPCC AR6 WGII), and ‘aligning financial flows’ (see ‘finance goal’, below), so as ‘to strengthen the global response to the threat of climate change, in the context of sustainable development and efforts to eradicate poverty.’

The Paris Agreement is predicated on encouraging progressively ambitious climate action from all countries on the basis of Nationally Determined Contributions (Cléménçon 2016; Rajamani 2016). The NDC approach requires countries to set their own level of ambitions for climate change mitigation but within a collaborative and legally binding process to foster ambition towards the agreed goals (Bodansky 2016; Falkner 2016a). The PA entered into force in November 2016 and as of February 2021 it already had 190 Parties (out of 197 Parties to the UNFCCC).

The PA also underlines ‘the principle of common but differentiated responsibilities and respective capabilities, in the light of different national circumstances’ (PA Art. 2, para. 2), and correspondingly that ‘developed country Parties should continue taking the lead by undertaking economy-wide absolute emission reductions’. It states that developing country Parties should continue enhancing their mitigation efforts, and are encouraged to move over time towards economy-wide emission reduction or limitation targets in the light of different national circumstances.

In order to achieve the its long term temperature goal, the Paris Agreement aims ‘to achieve a balance between anthropogenic emissions by sources and removals by sinks of greenhouse gases in the second half of this century’ (PA Art. 4 para. 1). The PA provides for five-yearly stocktakes in which Parties have to take collective stock on progress towards achieving its purposes and its long-term goal in the light of equity and available best science (PA Art. 14). The first global stocktake is scheduled for 2023 (PA Art. 14, para. 3).

The Paris Agreement’s finance goal aims to make ‘finance flows consistent with a pathway towards low greenhouse gas emissions

and climate-resilient development’ (PA Art. 2.1C). In keeping with the acknowledged context of global sustainable development and poverty eradication, and the corresponding aims of aligning finance and agreed differentiating principles as indicated above, ‘...the developed country parties are to assist developing country parties with financial resources’ (PA Art. 9). The Green Climate Fund (GCF), an operating entity of the UNFCCC Financial Mechanism to finance mitigation and adaptation efforts in developing countries (GCF 2020), was given an important role in serving the Agreement and supporting PA goals. The GCF gathered pledges worth USD10.3 billion, from developed and developing countries, regions, and one city (Paris) (Antimiani et al. 2017; Bowman and Minas 2019). Financing has since increased but remains short of the goal to mobilise USD100 billion by 2020 (Chapter 15).

Initiatives contributing to the Paris Agreement goals include the Non-State Actor Zone for Climate Action (NAZCA: now renamed as Global Climate Action) portal, launched at COP20 (December 2014) in Lima, Peru, to support city-based actions for mitigating climate change (IISD 2015) and Marrakech Partnership for Global Climate Action which is a UNFCCC-backed series of events intended to facilitate collaboration between governments and the cities, regions, businesses and investors that must act on climate change.

Details of the Paris Agreement, evaluation of the Kyoto Protocol, and other key multilateral developments since AR5 that are relevant to climate mitigation including the CORSIA aviation agreement adopted under ICAO, the IMO shipping strategy, and the Kigali Amendment to the Montreal Protocol on hydrofluorocarbons (HFCs), are discussed in Chapter 14.

SDGs. In September 2015, the UN endorsed a universal agenda – ‘Transforming our World: the 2030 Agenda for Sustainable Development’. The agenda adopted 17 non-legally-binding SDGs and 169 targets to support people, peace, prosperity, partnerships and the planet. While climate change is explicitly listed as SDG 13, the pursuit of the implementation of the UNFCCC is relevant for a number of other goals including SDG 7 (clean energy for all), SDG 9 (sustainable industry), and SDG 11 (sustainable cities), SDG 12 (responsible consumption and production) as well as those relating to life below water (SDG 14) and on land (SDG 15) (Biermann et al. 2017). Mitigation actions could have multiple synergies and trade-offs across the SDGs (Pradhan et al. 2017) (Chapter 17) and their net effects depend on the pace and magnitude of changes, the specific mitigation choices and the management of the transition. This suggests that mitigation must be pursued in the broader context of sustainable development as explained in Section 1.6.

Finance. The Paris Agreement’s finance goal (above) reflects a broadened focus, beyond the costs of climate adaptation and mitigation, to recognising that a structural shift towards low-carbon climate-resilient development pathways requires large-scale investments that engage the wider financial system (Sections 15.1 and 15.2.4). The SR1.5 report estimated that 1.5°C pathways would require *increased investment* of 0.5–1% of global GDP between now and 2050, which is up to 2.5% of global savings/investment over the period. For low- and middle-income countries, SDG-compatible

infrastructure investments in the most relevant sectors are estimated to be around 4–5% of their GDP, and ‘infrastructure investment paths compatible with full decarbonisation in the second half of the century need not cost more than more-polluting alternatives’ (Rozenberg and Fay 2019).

The parallel 2015 UN Addis Ababa Conference on Finance for Development, and its resulting Action Agenda, aims to ‘address the challenge of financing ... to end poverty and hunger, and to achieve sustainable development in its three dimensions through promoting inclusive economic growth, protecting the environment, and promoting social inclusion.’ The Conference recognises the significant potential of regional cooperation and provides a forum for discussing the solutions to common challenges faced by developing countries (Section 15.6.4).

Alongside this, private and blended climate finance is increasing but is still short of projected requirements consistent with Paris Agreement goals (Section 15.3.2.1). The financing gap is particularly acute for adaptation projects, especially in vulnerable developing countries. From a macro-regulatory perspective, there is growing recognition that substantial financial value may be at risk from changing regulation and technology in a low-carbon transition, with potential implications for global financial stability (Section 15.6.3). To date, the most significant governance development is the Financial Stability Board’s Task Force on Climate-related Financial Disclosures (TCFD) and its recommendations that investors and companies consider climate change risks in their strategies and capital allocation, so investors can make informed decisions (TCFD 2018), welcomed by over 500 financial institutions and companies as signatories, albeit with patchy implementation (Sections 1.4.4 and 15.6.3).

Talanoa Dialogue and Just Transition. As mandated at Paris COP21 and launched at COP23, the ‘Talanoa Dialogue’ (UNFCCC 2018a) emphasised holistic approaches across multiple economic sectors for climate change mitigation. At COP24 also, the Just Transition Silesia Declaration, focusing on the need to consider social aspects in designing policies for climate change mitigation was signed by 56 heads of state (UNFCCC 2018b). This underlined the importance of aiming for Just Transitions in reducing emissions, at the same time preserving livelihoods and managing economic risks for countries and communities that rely heavily on emissions-intensive technologies for domestic growth (Markkanen and Anger-Kraavi 2019), and for maintaining ecosystem integrity through nature-based solutions.

1.3.2 Global and Regional Emissions

Global GHG emissions have continued to rise since AR5, though the average rate of emissions growth slowed, from 2.4% (from 2000–2010) to 1.3% for 2010–2019 (Figure 1.1). After a period of exceptionally rapid growth from 2000 as charted in AR5, global fossil fuel- and industry-related (FFI) CO₂ emissions almost plateaued between 2014 and 2016 (while the global economy continued to expand (World Bank 2020)), but increased again over 2017–19, the average annual growth rate for all GHGs since 2014 being around 0.8% yr⁻¹ (IPCC/EDGAR emissions database; see also Chapter 11, Figure 11.2)). Important driving factors include population and GDP growth, as illustrated in panels (b) and (c) of Figure 1.1 respectively. The pause in emissions growth reflected the interplay of strong energy efficiency improvements and low-carbon technology deployment, but these did not expand fast enough to offset the continued pressures for overall growth at global level (UNEP 2018a; IEA 2019a). However, since 2013/14, the decline in global emissions intensity (GHG/GDP) has accelerated somewhat, and global emissions growth has averaged slightly slower than population growth (Figure 1.1d), which if sustained would imply a peak of global CO₂ (GHG) emissions per capita, at about 5 tCO₂ per person (7 tCO₂-eq per person) respectively.

Due to its much shorter lifetime, methane has a disproportionate impact on near-term temperature, and is estimated to account for almost a third of the warming observed to date (AR6 WGI SPM; AR6 WGIII Chapter 2, Figure 2.4). Methane reductions could be particularly important in relation to near- and medium-term temperatures, including through counteracting the impact of reducing short-lived aerosol pollutants which have an average cooling effect.²

The land-use component of CO₂ emissions has different drivers and particularly large uncertainties (Figures 2.2 and 2.5), hence is shown separately. Also, compared to AR5, new evidence showed that the AFOLU CO₂ estimates by the global models assessed in this report are not necessarily comparable with national GHG inventories, due to different approaches to estimate the ‘anthropogenic’ CO₂ sink. Possible ways to reconcile these discrepancies are discussed in Chapter 7.

Regional trends have varied. Emissions from most countries continued to grow, but in absolute terms, 32 countries reduced energy and industry CO₂ emissions for at least a decade, and 24 reduced overall GHG (CO₂-eq) emissions over the same period, but only half of them by more than 10% over the period in each case (Chapter 2).³ In total,

² Indeed, cooling effects of anthropogenic aerosols (organic carbon, black carbon, sulphates, nitrates), which are also important components of local air pollution (Myhre et al. 2013) (AR6 WGI SPM D1.7) may in global average be of similar magnitude to warming from methane at present. Mitigation which reduces such aerosol masking could thereby increase global temperatures, and reducing methane emissions would offset this much more rapidly than reducing CO₂ because of its relatively short lifetime, with the combined effects which could counterbalance each other (AR6 WGI SPM D1.7). Methane is thus particularly important in determining whether or when 1.5°C is reached for example.

³ With some exclusions for countries which were very small or undergoing economic collapse: fossil-fuel-and industry (CO₂-FFI) emissions in 2018 were below 2008 levels in 32 developed countries, but only in 24 when including other GHGs. Reductions were by less than 10% in half these countries. Data from Chapter 2: see Section 2.2.3, as analysed in Lamb et al. (2021). An earlier study found 18 developed countries that had reduced CO₂-FFI emissions over 2005–2015 (Le Quéré et al. 2019). Decomposition analysis of national trends in Xia et al. (2021), identified 23 industrialised countries (UNFCCC Annex I) with CO₂-FFI emissions in 2017 lower than in 2000 (Figure 1.3), of which 22 had increased GDP over the period. The previously rising trend of ‘outsourced/embody emissions’ associated with goods imported into developed countries peaked in 2006, but detailed data on this are only available for CO₂-FFI up to 2018 (Section 2.3). See Chapter 3 for reduction rates associated with 1.5°C and 2°C.

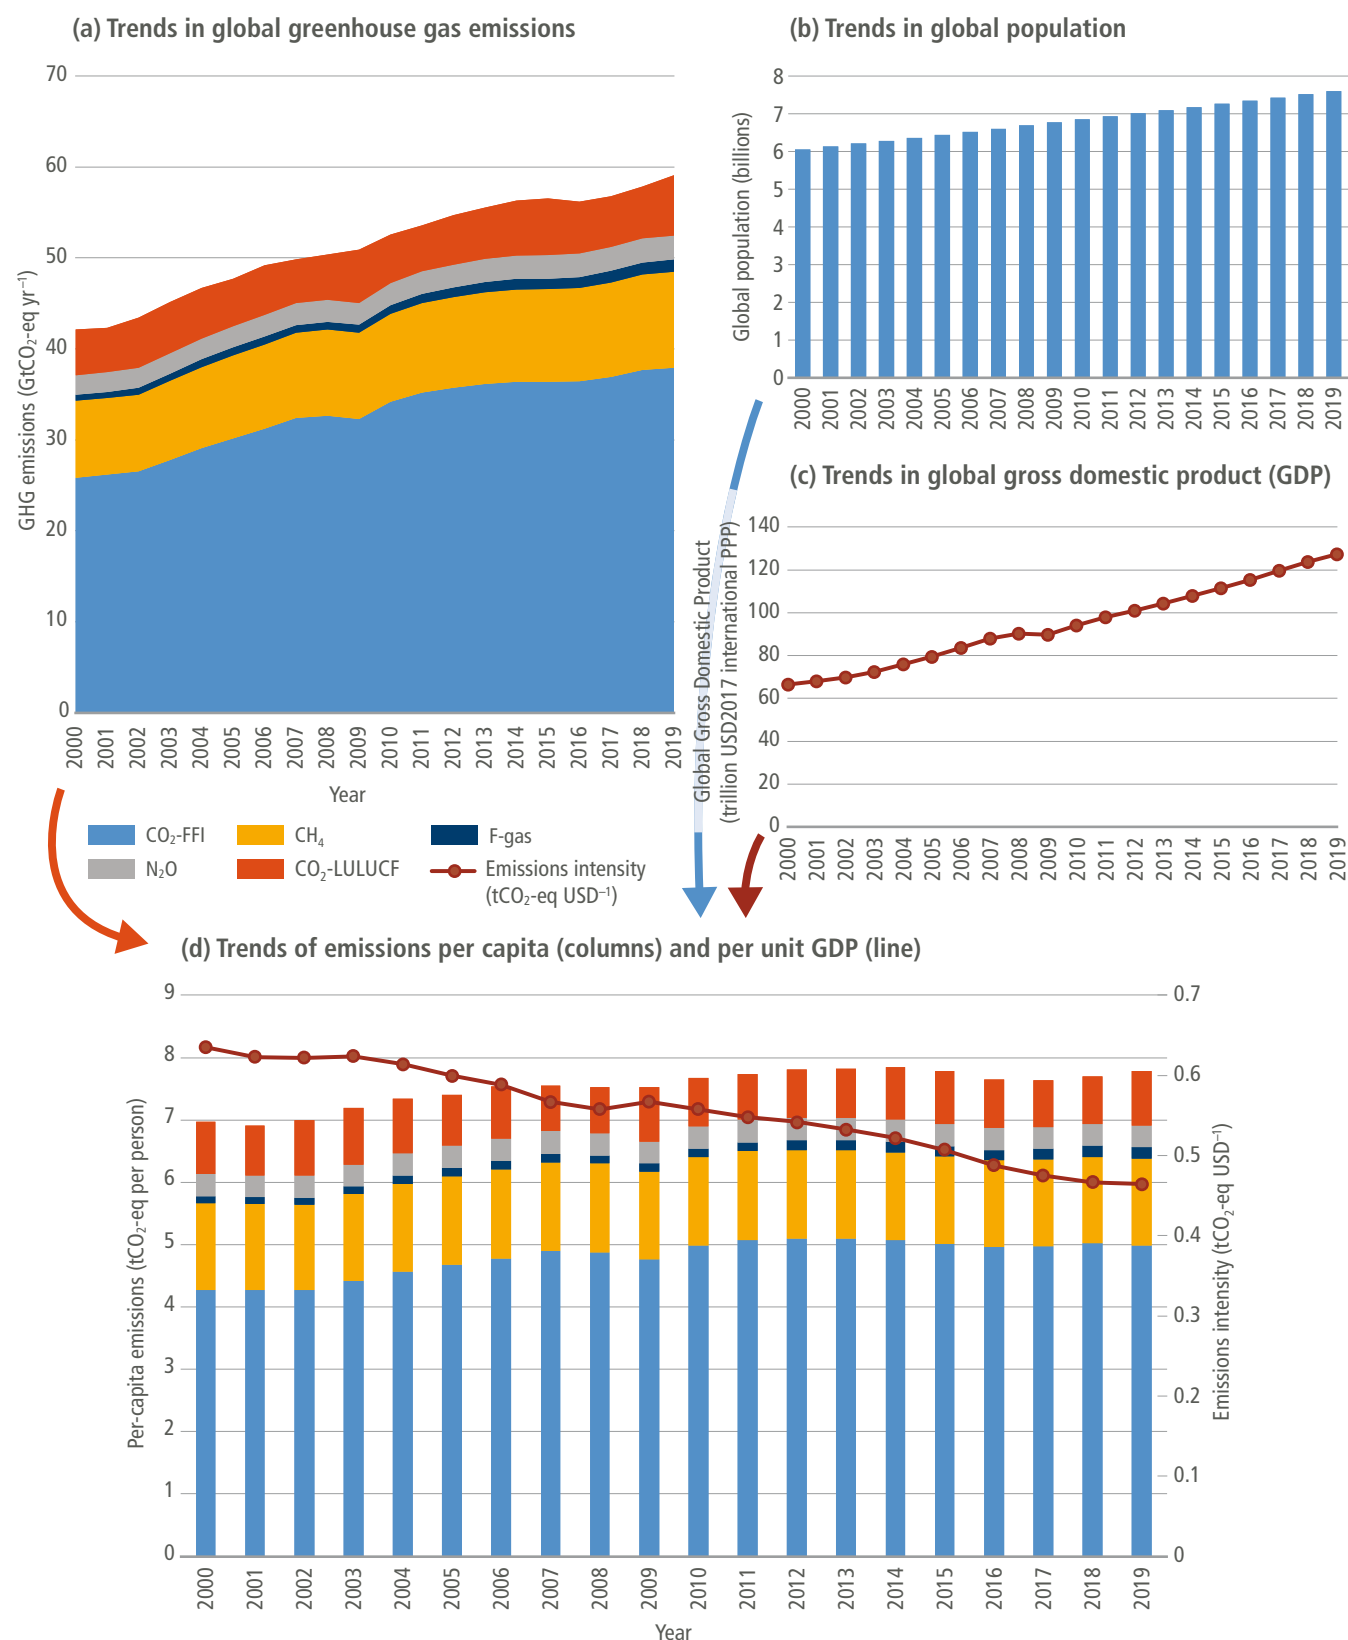

Figure 1.1 | Global emission trends since 2000 by groups of gases: absolute, per capita, and intensity. Note: shows CO₂ from fossil fuel combustion and industrial processes (FFI); CO₂ from agriculture, forestry and other land use (AFOLU); methane (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases). Gases reported in GtCO₂-eq converted based on AR6 global warming potentials with a 100-year time horizon (GWP100).

developed country emissions barely changed from 2010, whilst those from the rest of the world grew.

Figure 1.2 shows the distribution of regional emissions (a) per capita and (b) per GDP based on purchasing power parity (GDP_{PPP}) of different country groupings in 2019. Plotted against population and GDP respectively, the area of each block is proportional to the

1

(a) Distribution of regional emissions (territorial, 2019): CO₂-FFI (bottom-bar above x-axis, darker), plus non-CO₂ GHGs (top bar, lighter), plus CO₂-LULUCF (top-most or below-axis (negative) bars)

(b) Distribution of regional emissions (territorial, 2019): CO₂-FFI (bottom-bar above x-axis, darker), plus non-CO₂ GHGs (top bar, lighter), plus CO₂-LULUCF (top-most or below-axis (negative) bars)

(c) Distribution of regional emissions (consumption-based footprint, 2018): CO₂-FFI only

(d) Distribution of regional emissions (consumption-based footprint, 2018): CO₂-FFI only

Figure 1.2 | Distribution of regional greenhouse gas (GHG) emissions for 10 broad global regions according to territorial accounting (panels (a) and (b), GHG emissions) and consumption-based accounting (panels (c) and (d), CO₂-FFI emissions only). GHG emissions are categorised into: fossil fuel and industry (CO₂-FFI); land use, land-use change and forestry (CO₂-LULUCF); and other greenhouse gases (methane, nitrous oxide and F-gas – converted to 100-year global warming potentials). Per-capita GHGs for territorial (panel a) and CO₂-FFI emissions vs population for consumption-based accounting (panel c). Panels (b) and (d): GHG emissions per unit GDP_{PPP} vs GDP_{PPP} , weighted with purchasing power parity for territorial accounting (panel b), CO₂-FFI emissions per unit GDP_{PPP} for consumption-based accounting (panel d). The area of the rectangles refers to the total emissions for each regional category, with the height capturing per-capita emissions (panels a and c) or emissions per unit GDP_{PPP} (panels (b) and (d)), and the width proportional to the population of the regions and GDP_{PPP} . Emissions from international aviation and shipping (2.4% of the total GHG emissions) are not included.

region's emissions. Compared to the equivalent presentations in 2004 (AR4 WGIII Figure SPM.3) and 2010 (AR5 WGIII Figure 1.8), East Asia now forms substantially the biggest group, whilst at about 8 tCO₂-FFI (/10 tCO₂-eq all GHGs) per person, its emissions per capita remain about half that of North America. In contrast, a third of the world's population, in Southern Asia and Africa, emit on average under 2 (2.5 tCO₂-eq) per person, little more than in the previous assessments. Particularly for these regions, there continue to be substantial differences in GDP, life expectancy and other measures of well-being (Figure 1.6).

Emissions per unit GDP are much less diverse than per capita and have also converged significantly. Poorer countries tend to show higher energy/emissions per unit GDP partly because of higher reliance on basic industries, and this remains the case, though in general their energy/GDP has declined faster.

Many developed country regions are net importers of energy-intensive goods, and emissions are affected by the accounting of such 'embodied emissions'. Panels (c) and (d) show results (only available for CO₂-FFI, to 2018) on the basis of consumption footprints which include emissions embodied in traded goods. This makes modest changes to the relative position of different regions (for further discussion see Section 2.3).

While extreme poverty has fallen in more than half of the world's economies in recent years, nearly one fifth of countries faced poverty rates above 30% in 2015 (below USD1.90 a day), reflecting large income inequality (Laborde Debucquet and Martin 2017; Rozenberg and Fay 2019). Diffenbaugh and Burke (2019) find that global warming already has increased global economic inequality, even if between-country inequalities have decreased over recent decades. The distributional implications between regional groups in the Shared Socio-economic Pathways (SSPs) diverge according to the scenario (Frame et al. 2019).

An important recent development has been commitments by many countries, now covering a large majority of global emissions, to reach net zero CO₂ or greenhouse gas emissions (Chapter 3).⁴ Furthermore, globally, net zero targets (whether CO₂ or GHG) have been adopted by about 823 cities and 101 regions (Chapter 8).

1.3.3 Some Other Key Trends and Developments

The COVID-19 pandemic profoundly impacted economy and human society, globally and within countries. As detailed in Cross-Chapter Box 1 in this chapter, some of its impacts will be long-lasting, permanent even, and there are also lessons relevant to climate change. The direct impact on emissions projected for rest of this decade are modest, but the necessity for economic recovery packages creates a central role for government-led investment, and may change the economic fundamentals involved for some years to come.

The COVID-19 aftermath consequently also changes the economic context for mitigation (Sections 15.2 and 15.4). Many traditional forms of economic analysis (expressed as general equilibrium) assume that available economic resources are fully employed, with limited scope for beneficial economic 'multiplier effects' of government-led investment. After COVID-19 however, no country is in this state. Very low interest rates amplify opportunities for large-scale investments which could bring 'economic multiplier' benefits, especially if they help to build the industries and infrastructures for further clean growth (Hepburn et al. 2020). However, the capability to mobilise low-interest finance varies markedly across countries and large public debts – including bringing some developing countries close to default – undermine both the political appetite and feasibility of large-scale clean investments. In practice the current orientation of COVID-19 recovery packages is very varied, pointing to a very mixed picture about whether or not countries are exploiting this opportunity (Cross-Chapter Box 1 in this chapter).

Cross-Chapter Box 1 | The COVID-19 Crisis: Lessons, Risks and Opportunities for Mitigation

Authors: Diana Ürge-Vorsatz (Hungary), Lilia Caiado Couto (Brazil), Felix Creutzig (Germany), Dipak Dasgupta (India), Michael Grubb (United Kingdom), Kirsten Halsnæs (Denmark), Şiir Kılıç (Turkey), Alexandre Köberle (Brazil/United Kingdom), Silvia Kreibiehl (Germany), Jan Christoph Minx (Germany), Peter Newman (Australia), Chukwumerije Okereke (Nigeria/United Kingdom)

The COVID-19 pandemic triggered the deepest global economic contraction as well as CO₂ emission reductions since the Second World War (Le Quéré et al. 2020b), (AR6 WGI, Box 6.1) (Section 2.2.2.1). While emissions and most economies are expected to rebound in 2021–2022 (IEA 2021), some impacts of the pandemic (e.g., aspects of economy, finance and transport-related emission drivers) may last far longer. COVID-19 pushed more than 100 million people back into extreme poverty, and reversed progress towards some other SDGs including health, life expectancy and child literacy (UN DESA 2021). Health impacts and the consequences of deep economy-wide shocks may last many years even without significant future recurrence (Section 15.6.3). These changes, as well as the pandemic response actions, bring both important risks as well as opportunities for accelerating mitigation (Chapters 1, 5, 10 and 15).

⁴ Continually updated information on net zero commitments is available at <https://www.zerotracker.net>.

Cross-Chapter Box 1 (continued)

Lessons. Important lessons can be drawn from the pandemic to climate change including the value of forward-looking risk management, the role of scientific assessment, preparatory action and international process and institutions (Chapter 5 and Section 1.3). There had been long-standing warnings of pandemic risks and precursors – with both pandemic and climate risks being identified by social scientists as ‘uncomfortable knowledge’ or ‘unknown knowns’, which tend to be marginalised in practical policy (Rayner 2012; Sarewitz 2020). This echoes long-standing climate literature on potential ‘high impact’ events, including those *perceived* as low probability (Dietz 2011; Weitzman 2011). The costs of preparatory action, mainly in those countries that had suffered from earlier pandemics were negligible in comparison, suggesting the importance not just of knowledge but its effective communication and embodiment in society (Chapter 5). Klenert et al. (2020) offer five early lessons for climate policy, concerning: the cost of delay; the bias in human judgement; the inequality of impacts; the need for multiple forms of international cooperation; and finally, ‘transparency in value judgements at the science–policy interface’.

Emissions and behavioural changes. Overall, global CO₂ FFI emissions declined by about 5.8% (5.1–6.3%) from 2019 to 2020, or about 2.2 (1.8–2.4) GtCO₂ in total (Section 2.2.2). Analysis from previous economic crises suggest significant rebound in emissions without policy-induced structural shifts (Jaeger et al. 2020) (Section 2.2.2.1 and Figure 2.5). Initial projections suggest the COVID aftermath may reduce emissions by 4–5% over 2025–2030 (Shan and Et.al 2020; Reilly et al. 2021), below a ‘no-pandemic’ baseline. The long-term impacts on behaviour, technology and associated emissions remain to be seen, but may be particularly significant in transport – lockdowns reduced mobility-related emissions, alongside two major growth areas: electronic communications replacing many work and personal travel requirements (Chapter 10 and Section 4.4.3.4); and revitalised local active transport and e-micromobility (Earley and Newman 2021). Temporary ‘clear skies’ may also have raised awareness of the potential environment and health co-benefits of reduced fossil fuel use particularly in urban areas (Section 8.7), with evidence also indicating that air pollution itself amplified vulnerability to COVID-19 (Gudka et al. 2020; Wu et al. 2020). The significant impacts on passenger aviation are projected to extend not just through behavioural changes, but also fleet changes from retiring older planes, and reduced new orders indicating expectations of reduced demand and associated GHG emissions until 2030 (Sections 5.1.2 and 10.5) (AR6 WGI Box 6.1 in Chapter 6). However, air cargo has recovered more rapidly (IATA 2020), possibly enhanced by online ordering.

Fiscal, growth and inequality impacts. Aspects of the global and regional economic crises from COVID-19 may prevail much longer than the crisis itself, potentially compromising mitigation. Most countries have undertaken unprecedented levels of short-term public expenditures. The International Monetary Fund (IMF) projects sovereign debt to GDP to have increased by 20% in advanced economies and 10% in emerging economies by the end of 2021 (IMF 2020). This is likely to slow economic growth, and may squeeze financial resources for mitigation and relevant investments for many years to come (Sections 15.2.3 and 15.6.3). COVID-19 further lowered interest rates which should facilitate low-carbon investment, but pandemic responses have increased sovereign debt across countries in all income bands (IMF 2021), and, particularly in some developing economies and regions, it has caused debt distress (Bulow et al. 2021), widening the gap in developing countries’ access to capital (Hourcade et al. 2021b) (Section 15.6.3). After decades of global progress in reducing poverty, COVID-19 has pushed hundreds of millions of people below poverty thresholds and raises the spectre of intersecting health and climate crises that are devastating for the most vulnerable (Section 5.1.2 and Box 5.1). Like those of climate change, pandemic impacts fall heavily on disadvantaged groups, exacerbate the uneven distribution of future benefits, amplify existing inequities, and introduce new ones. Increased poverty also hinders efforts towards sustainable low-carbon transitions (Section 1.6).

Impacts on profitability and investment. COVID-19-induced demand reduction in electricity disproportionately affected coal power plants, whilst transport reduction most affected oil (IEA 2020a). This accelerated pre-existing decline in the relative profitability of most fossil fuel industries (Ameli et al. 2021). Renewables were the only energy sector to increase output (IEA 2020a). Within the context of a wider *overall* reduction in energy investment this prompted a substantial *relative* shift towards low-carbon investment particularly by the private sector (IEA 2020b; Rosebloom and Markard 2020) (Sections 15.2.1, 15.3.1 and 15.6.1).

Post-pandemic recovery pathways provide an opportunity to attract finance into accelerated and transformative low-carbon public investment (Sections 15.2 and 15.6.3). In most countries, COVID-19 has increased unemployment and/or state-supported employment. There is a profound difference between short-term ‘bail outs’ to stem unemployment, and the orientation of new public investment. The public debt is mirrored by large pools of private capital. During deep crises like that of COVID-19, economic multipliers of stimulus packages can be high (Hepburn et al., 2020), so much so that fiscal injections can then generate multipliers from 1.5 to 2.5, weakening the alleged crowding-out effect of public stimulus (Auerbach and Gorodnichenko 2012; Blanchard and Leigh 2013) (Section 15.2.3).

Cross-Chapter Box 1 (continued)

Recovery packages are motivated by assessments of the macroeconomic effectiveness ('multipliers') of public spending in ways that can crowd-in and revive private investment (Hepburn et al. 2020). There are clear reasons why a low-carbon response can create more enduring jobs, better aligned to future growth sectors: by also crowding-in and reviving private investment (e.g., from capital markets and institutional investors, including the growing profile of environmental, social and governance (ESG) and green bond markets (Section 15.6)), this can boost the effectiveness of public spending (IMF 2020). Stern and Valero (2021) argue that investment in low-carbon innovation and its diffusion, complemented by investments in sustainable infrastructure, are key to shaping environmentally sustainable and inclusive growth in the aftermath of the COVID-19 pandemic crisis. This would be the case both for high-income economies on the global innovation frontier, and to promote sustainable development in poorer economies.

A study with a global general equilibrium model (Liu et al. 2021) finds that because the COVID-19 economic aftermath combines negative impacts on employment and consumption, a shift from employment and consumption taxes to carbon- or other resource-related taxes would enhance GDP by 1.7% in 2021 relative to 'no policy', in addition to reducing CO₂ and other pollutants. A post-Keynesian model of wider 'green recovery' policies (Pollitt et al. 2021) finds a short-run benefit of around 3.5% GDP (compared to 'no policy'), and even about 1% above a recovery boosted by cuts in consumption taxes, the latter benefit sustained through 2030 – outperforming an equivalent conventional stimulus package while reducing global CO₂ emissions by 12%.

Orientation of recovery packages. The large public spending on supporting or stimulating economies, exceeding USD12 trillion by October 2020, dwarfs clean-energy investment needs and hence could either help to solve the combined crises, or result in high-carbon lock-in (Andrijevic et al. 2020). The short-term 'bail outs' to date do not foster climate-resilient long-term investments and have not been much linked to climate action, (Sections 15.2.3 and 15.6.3): in the G20 countries, 40% of energy-related support spending went to the fossil fuel industry compared to 37% on low-carbon energy (EPT 2020). Recovery packages are also at risk of being 'colourless' (Hepburn et al., 2020), though some countries and regions have prioritised green stimulus expenditures for example as part of a 'Green New Deal' (Rochedo et al. 2021) (Sections 13.9.6 and 15.6.3).

Integrating analyses. The response to COVID-19 also reflects the relevance of combining multiple analytic frameworks spanning economic efficiency, ethics and equity, transformation dynamics, and psychological and political analyses (Section 1.7). As with climate impacts, not only has the global burden of disease been distributed unevenly, but capabilities to prevent and treat disease were asymmetrical and those in greatest vulnerability often had the least access to human, physical, and financial resources (Ruger and Horton 2020). 'Green' versus 'brown' recovery has corresponding distributional consequences between these and 'green' producers, suggesting need for differentiated policies with international coordination (Le Billon et al. 2021). This illustrates the role of Just Transition approaches to global responses including the value of integrated, multi-level governance (Sections 1.7, 4.5 and 17.1).

Crises and opportunities: the wider context for mitigation and transformation. The impacts of COVID-19 have been devastating in many ways, in many countries, and may distract political and financial capacity away from efforts to mitigate climate change. Yet, studies of previous post-shock periods suggest that waves of innovation that are ready to emerge can be accelerated by crises, which may prompt new behaviours, weaken incumbent ('meso-level') systems, and prompt rapid reforms (Roberts and Geels 2019a) (Section 1.6.5). Lessons from the collective effort to 'flatten the curve' during the pandemic, illustrating aspects of science–society interactions for public health in many countries, may carry over to climate mitigation, and open new opportunities (Section 5.1.2). COVID-19 appears to have accelerated the emergence of renewable power, electromobility and digitalisation (Newman 2020) (Sections 5.1.2, 6.3 and 10.2). Institutional change is often very slow but major economic dislocation can create significant opportunities for new ways of financing and enabling 'leapfrogging' investment to happen (Section 10.8). Given the unambiguous risks of climate change, and consequent stranded asset risks from new fossil fuel investments (Box 6.11), the most robust recoveries are likely to be those which emerge on lower carbon and resilient pathways (Obergassel et al. 2021). Noting the critical global post-COVID-19 challenge as the double impact of heightened credit risk in developing countries, along with indebtedness in developed countries, Hourcade et al. (2021a) estimate that a 'multilateral' sovereign guarantee structure to underwrite low-carbon investments could leverage projects up to 15 times its value, contributing to shifting development pathways consistent with the SDGs and Paris goals.

COVID-19 can thus be taken as a reminder of the urgency of addressing climate change, a warning of the risk of future stranded assets (Rempel and Gupta 2021) (Chapter 17), but also an opportunity for a cleaner recovery.

In addition to developments in climate science, emissions, the international agreements in 2015, and the recent impact of COVID-19, a few other key developments have strong implications for climate mitigation.

Cheaper renewable energy technologies. Most striking, the cost of solar photovoltaic (PV) has fallen by a factor of 5 to 10 in the decade since the IPCC Special Report on Renewable Energy (IPCC 2011a) and other data inputting to the AR5 assessments. The SR1.5 reported major cost reductions, the IEA (2020) World Energy Outlook described PV as now ‘the cheapest electricity in history’ for projects that ‘tap low cost finance and high quality resources.’ Costs and deployment both vary widely between different countries (Chapters 6, 9 and 12) but costs are still projected to continue falling (Vartiainen et al. 2020). Rapid technological developments have occurred in many other low-carbon technologies including batteries and electric vehicles (Section 1.4.3), IT and related control systems, with progress also where electrification is not possible (Chapters 2, 6 and 11).

Civil society pressures for stronger action. Civic engagement increased leading up to the Paris Agreement (Bäckstrand and Lövbrand 2019) and after. Youth movements in several countries show young people’s awareness about climate change, evidenced by the school strikes for the climate (Hagedorn et al. 2019; Buettner 2020; Thackeray et al. 2020; Walker 2020). Senior figures across many religions (Francis 2015; IFEEES 2015) stressed the duty of humanity to protect future generations and the natural world, and warned about the inequities of climate change. Growing awareness of local environmental problems such as air pollution in Asia and Africa (Karlsson et al. 2020), and the threat to indigenous people’s rights and existence has also fuelled climate activism (Etchart 2017). Grass-roots movements (Cheon and Urpelainen 2018; Fisher et al. 2019), build political pressure for accelerating climate change mitigation, as does increasing climate litigation (Setzer and Vanhala 2019) (Chapters 13 and 14).

Climate policies also encounter resistance. However, there are multiple sources of resistance to climate action in practice. Corporations and trade associations often lobby against measures they deem detrimental (Section 1.4.6). The emblematic ‘yellow vest’ movement in France was triggered by higher fuel costs as a result of a CO₂ tax hike (Lianos 2019; Driscoll 2021), though it had broader aspect of income inequality and other social issues. There is often a mismatch between concerns on climate change and people’s willingness to pay for mitigation. For example, whilst most Americans believe climate change is happening, 68% said in a survey they would oppose climate policies that added just USD10 per month to electricity bills (EPIC et al. 2019), and worry about energy costs can eclipse those about climate change elsewhere (Poortinga et al. 2018) (Chapter 13).

Global trends contrary to multilateral cooperation. State-centred politics and geopolitical/geo-economic tensions seem to have become more prominent across many countries and issues (WEF 2019). In some cases, multilateral cooperation could be threatened by trends such as rising populism, nationalism, authoritarianism and growing protectionism (Abrahamsen et al. 2019), making it

more difficult to tackle global challenges including protecting the environment (Schreurs 2016; Parker et al. 2017; WEF 2019).

Transnational alliances. Partly countering this trend, cities, businesses and a wide range of other non-state actors also have emerged with important international networks to foster mitigation. City-based examples include the Cities Alliance in addressing climate change, Carbon Neutral Cities Alliance and the Covenant of Mayors (Chapter 8); there are numerous other alliances and networks such as those in finance (Chapter 15) and technology (Chapter 16), amongst many others (Chapters 13 and 14).

Finally, under the Paris Agreement process, during 2020/21, many countries strengthened their Nationally Determined Contributions (NDCs). Including updates until October 2021, these would imply global GHG emissions declining by 2030 to between 1–4% below 2019 levels (unconditional NDCs), or 4–10% (for NDCs conditional on international support) (Table 4.3). This is a significant change but would still not be compatible with 1.5°C pathways, and even if delivered in full, to limit warming to 2°C (>67%), emissions would have to fall very rapidly after 2030 (Section 3.2.5).

Thus, developments since AR5 highlight the complexity of the mitigation challenge. There is no far-sighted, globally optimising decision-maker and indeed climate policymaking at all levels is subject to conflicting pressures in multiple ways. The next section overviews the drivers and constraints.

1.4 Drivers and Constraints of Climate Mitigation and System Transitions/Transformation

This section provides a brief assessment of key factors and dynamics that drive, shape and/or limit climate mitigation in (i) **economic factors**: which include sectors and services, trade and leakage, finance and investment, and technological innovation; (ii) **socio-political issues**: which include political economy, social innovation, and equity and fairness; and (iii) **institutional factors**, which comprise policy, legal frameworks and international cooperation.

The AR5 introduced six ‘enabling conditions’ for shifting development pathways which are presented in Chapter 4 of this report and some of which overlap with the drivers reviewed here. However, the terminology of drivers and constraints have been chosen here to reflect the fact that each of these factors can serve as an enabling condition or a constraint to ambitious climate action depending on the context and how they are deployed. Often one sees the factors exerting both push and pull forces at the same time in the same and across different scales. For example, finance and investments can serve as a barrier or an enabler to climate action (Battiston et al. 2021). Similarly, political economy factors can align in favour of ambitious climate action or act in ways that inhibit strong cooperation and low-carbon transition. The other key insight from the assessment of the system drivers and constraints undertaken below is that none of the factors or conditions by themselves is more or less important than the others. In addition to being deeply intertwined all the factors

matter in different measures with each exacting more or less force depending on the prevailing social, economic, cultural and political context. Often achieving accelerated mitigation would require effort to bring several of the factors in alignment in and across multiple levels of political or governance scales.

1.4.1 Services, Sectors and Urbanisation

Human activities drive emissions primarily through the demand for a wide range of services such as food, shelter, heating/cooling, goods, travel, communication, and entertainment. This demand is fulfilled by various activities often grouped into sectors such as agriculture, industry and commerce. The literature uses a wide range of sectoral definitions to organise data and analysis (Chapter 2). Energy sectors are typically organised into primary energy producers, energy transformation processes (such as power generation and fuel refining), and major energy users such as buildings, industry and transport (Chapters 2 and 5). Other research (Chapter 8) organises data around interacting urban and rural human activities. Land-based activities can be organised into agriculture, forestry and other land-use (AFOLU), or land use, land-use change and forestry (LULUCF) (Chapter 7). Each set of sectoral definitions and analysis offers its own insights.

Sectoral perspectives help to identify and understand the drivers of emissions, opportunities for emissions mitigation, and interactions with resources, other goals and other sectors, including the co-evolution of systems across scales (Kyle et al. 2016; Moss et al. 2016; Mori et al. 2017; IPBES 2019). Interactions between sectors and agents pursuing multiple goals is a major theme pervading this assessment.

The ‘nexus’ between energy, water, and land – all key contributors to human well-being – also helps to provide, regulate and support ecosystem and cultural services (Bazilian et al. 2011; Ringler et al. 2013; Smajgl et al. 2016; Albrecht et al. 2018; Brouwer et al. 2018; D’Odorico et al. 2018; Van Vuuren et al. 2019), with important implications for cities in managing new systems of transformation (Thornbush et al. 2013; Wolfram et al. 2016) (Chapter 8). Other important nexuses shaping our planet’s future (Fajardy et al. 2018) include agriculture, forestry, land use and ecosystem services (Chazdon 2008; Settele et al. 2016; Torralba et al. 2016; Nesshöver et al. 2017; Keesstra et al. 2018).

Historically, energy-related GHG emissions were considered a by-product of the increasing scale of human activity, driven by population size, economic activity and technology. That simple notion has evolved greatly over time to become much more complex and diverse, with increasing focus on the provision of energy services (Cullen and Allwood 2010; Bardi et al. 2019; Brockway et al. 2019; Garrett et al. 2020). The demand for agricultural products has historically driven conversion of natural lands (land-use change). AFOLU along with food processing accounts for 21–37% of total net anthropogenic GHG emissions (SRCL SPM A3).⁵

Continued growth in population and income are expected to continue driving up demand for goods and services (Chapters 2, 3 and 5), with an important role for urbanisation which is proceeding at an unprecedented speed and scale. In the last decade, the urban population grew by 70 million people each year, or about 1.3 million people per week, with urban area expanding by about 102 km² per day (Chapter 8). Urban areas account for most (45–87%) of the global carbon footprint (8.1) and the strong and positive correlation between urbanisation and incomes means higher consumption from urban lifestyles will continue driving direct and indirect GHG emissions. Cities provide a conduit to many of the services such as transportation, housing, water, food, medical care and recreation, and other services and urban carbon emissions are driven not only by population and income but also by the form and structure of urban areas (Sections 8.1 and 8.3–8.6). This creates opportunities for decarbonisation through urban planning and purposeful ‘experimentation’ (Newman et al. 2017) (Chapter 8).

Human needs and wants evolve over time making the transition toward climate and sustainable development goals either more or less difficult. For example, changes in the composition of goods consumed, such as shifting diets toward a more vegetarian balance, can reduce land-use emissions without compromising the quality of life (Stehfest et al. 2009; Gough 2017; van Vuuren et al. 2018; van den Berg et al. 2019; Hargreaves et al. 2021; SRCL SPM B2.3).

Human behaviour and choices, including joint achievement of wider social goals, will play an important part in enabling or hindering climate mitigation and sustainable development (Shi et al. 2016), for example, shifting passenger transportation preferences in ways that combine climate, health and sustainable development goals (Romanello et al. 2021).

1.4.2 Trade, Consumption and Leakage

Emissions associated with international trade account for 20–33 % of global emissions, as calculated using multi-regional input-output analysis (Wiedmann and Lenzen 2018). Whether international trade drives an increase or decrease in global GHG emissions depends on the emissions intensity of traded products as well as the influence of trade on relocation of production, with studies reaching diverse conclusions about the net effect of trade openness on CO₂ emissions (Section 2.4.5). Tariff reduction of low-carbon technologies could facilitate effective mitigation (de Melo and Vijil 2014; Ertugrul et al. 2016; Islam et al. 2016; WTO 2016).

The magnitude of carbon leakage (see Glossary) caused by unilateral mitigation in a fragmented climate policy world depends on trade and substitution patterns of fossil fuels and the design of policies (IPCC 2014a, Box 5.4), but its potential significance in trade-exposed energy-intensive sectors (Bauer et al. 2013; Carbone and Rivers 2017; Naegle and Zaklan 2019) can make it an important constraint on policy. See Section 13.6.6.1 in Chapter 13 for channels and evidence. Akimoto et al. (2018) argue that differences in marginal abatement

⁵ AFOLU accounted for about 13% of CO₂, 44% of CH₄ and 82% of N₂O global anthropogenic GHG emissions in 2007–2016.

costs of NDCs could cause carbon leakage in energy-intensive, trade-exposed sectors, and could weaken effective global mitigation.

Policy responses to cope with carbon leakage include border carbon adjustment (BCAs) and differentiated carbon taxes (Liu et al. 2020). Some BCA options focusing on levelling the cost of carbon paid by consumers on products could be designed in line with the WTO (Ismer et al. 2016), while others may not be (Mehling et al. 2019). All proposals could involve difficulty of tracing and verifying the carbon content of inputs (Onder 2012; Denis-Ryan et al. 2016). An international consensus and certification practice on the carbon content would help to overcome WTO compatibility (Holzer 2014). See Chapter 13 and Mehling et al. (2019) on the context of trade law and the PA.

Official inventories report territorial emissions, which do not consider the impacts embodied in imports of goods. Global supply chains undoubtedly lead to a growth in trade volumes (Federico and Tena-Junguito 2017), alternative methods have been suggested to account for emissions associated with international trade, such as shared responsibility (Lenzen et al. 2007), technology-adjusted consumption-based accounting (Kander et al. 2015), value-added-based responsibility (Piñero et al. 2019) and exergy-based responsibility based on thermodynamics (Khajepour et al. 2019). Consumption-based emissions (i.e., attribution of emissions related to domestic consumption and imports to final destination) are not officially reported in global emissions datasets but data has improved (Tukker and Dietzenbacher 2013; Afionis et al. 2017). This analysis has been used extensively for consumption-based accounting of emissions, and other environmental impacts (Wiedmann and Lenzen 2018; Malik et al. 2019) (Section 2.3).

Increasing international trade has resulted in a general shifting of fossil fuel-driven emissions-intensive production from developed to developing countries (Arto and Dietzenbacher 2014; Malik and Lan 2016), and between developing countries (Zhang et al. 2019). High-income developed countries thus tend to be net importers of emissions, whereas low/middle-income developing countries net exporters (Peters et al. 2011) (Figure 1.2c, d). This trend is shifting, with a growth in trade between non-OECD countries (Meng et al. 2018; Zhang et al. 2019), and a decline in emissions intensity of traded goods (Wood et al. 2020b).

The Paris Agreement primarily deals with national commitments relating to domestic emissions and removals, hence emissions from international aviation and shipping are not covered. Aviation and shipping accounted for approximately 2.7% of greenhouse gas emissions in 2019 (before COVID-19); see Section 10.5.2 for discussion. In addition to CO₂ emissions, aircraft-produced contrail cirrus clouds, and emissions of black carbon and short-lived aerosols (e.g., sulphates) from shipping are especially harmful for the Arctic (Section 10.8 and Box 10.6).

1.4.3 Technology

The rapid developments in technology over the past decade enhance potential for transformative changes, in particular to help deliver climate goals simultaneously with other SDGs.

The fall in renewable energy costs alongside rapid growth in capacity (Figure 1.3; see also Figures 6.8 and 6.11 in Chapter 6) has been accompanied by varied progress in many other technology areas such as electric vehicles, fuel cells for both stationary and mobile applications (Dodds 2019), thermal energy (Chapter 6), and battery and other storage technologies (Freeman et al. 2017) (Chapters 6, 9 and 12; Figure TS.7). Nuclear contributions may be enhanced by new generations of reactors (e.g., Generation III) and small modular reactors (Knapp and Pevac 2018) (Chapter 6).

Large-scale hydrogen developments could provide a complementary energy channel with long-term storage. Like electricity, hydrogen (H₂) is an energy vector with multiple potential applications, including in industrial processes such as steel and non-metallic materials production (Chapter 11), for long-range transportation (Chapter 10), and low-temperature heating in buildings (Chapter 9). Emissions depend on how it is produced, and deploying H₂ delivery infrastructure economically is a challenge when the future scale of hydrogen demand is so uncertain (Chapter 6). H₂ from natural gas with CO₂ capture and storage (CCS) may help to kick-start the H₂ economy (Sunny et al. 2020).

CO₂-based fuels and feedstocks such as synthetic methane, methanol, diesel, jet fuel and other hydrocarbons, potentially from carbon capture and utilisation (CCU), represent drop-in solutions with limited new infrastructure needs (Artz et al. 2018; Bobeck et al. 2019; Yugo and Soler 2019) (Chapter 10). Deployment and development of CCS technologies (with large-scale storage of captured CO₂) have been much slower than projected in previous assessments (IEA 2019b; Page et al. 2019) (Chapter 11).

Potential constraints on new energy technologies may include their material requirements, notably rare earth materials for electronics or lithium for batteries (Wanger 2011; Flexer et al. 2018), stressing the importance of recycling (IPCC 2011b; Rosendahl and Rubiano 2019). Innovation is enabling greater recycling and reuse of energy-intensive materials (Shemi et al. 2018), and introducing radically new and more environmentally friendly materials, however, still not all materials can be recycled (Allwood 2014).

By sequestering carbon in biomass and soils, soil carbon management, and other terrestrial strategies could offset hard-to-reduce emissions in other sectors. However, large-scale bioenergy deployment could increase risks of desertification, land degradation, and food insecurity (IPCC 2019a), and higher water withdrawals (Hasegawa et al. 2018; Fuhrman et al. 2020), though this may be at least partially offset by innovation in agriculture, diet shifts and plant-based proteins contributing to meeting demand for food, feed, fibre and bioenergy (or bioenergy with carbon capture and storage (BECCS) with CCS) (Havlik et al. 2014; Popp et al. 2017; Köberle et al. 2020) (Chapters 5 and 7).

Figure 1.3 | Cost reductions and adoption in solar photovoltaic and wind energy. Fossil fuel Levelised Cost of Electricity (LCOE) is indicated by blue shading at USD50–177 MWh⁻¹ (IRENA 2020b). Source: data from IRENA (2021a,b).

A broad class of more speculative technologies propose to counteract effects of climate change by removing CO₂ from the atmosphere (CDR), or by directly modifying the Earth's energy balance at a large scale (solar radiation modification or SRM). CDR technologies include ocean iron fertilisation, enhanced weathering and ocean alkalisation (Council 2015a), along with direct air carbon capture and storage (DACCS). They could potentially draw down atmospheric CO₂ much faster than the Earth's natural carbon cycle, and reduce reliance on biomass-based removal (Köberle 2019; Realmonde et al. 2019), but some present novel risks to the environment and DACCS is currently more expensive than most other forms of mitigation (Fuss et al. 2018) (Cross-Chapter Box 8 in Chapter 12). Solar radiation modification (SRM) could potentially cool the planet rapidly at low estimated direct costs by reflecting incoming sunlight (Council 2015b), but entails uncertain side effects and thorny international equity and governance challenges (Netra et al. 2018; Florin et al. 2020; National Academies of Sciences 2021) (Chapter 14). Understanding the climate response to SRM remains subject to large uncertainties (AR6 WGI). Some literature uses the term 'geoengineering' for both CDR or SRM when applied at a planetary scale (Shepherd 2009; GESAMP 2019). In this report, CDR and SRM are discussed separately, reflecting their very different geophysical characteristics.

Large improvements in information storage, processing, and communication technologies, including artificial intelligence, will affect emissions. They can enhance energy-efficient control, reduce transaction costs for energy production and distribution, improve demand-side management (DSM) (Raza and Khosravi 2015), and reduce the need for physical transport (Smidfelt Rosqvist and Winslott Hiselius 2016) (Chapters 5, 6 and 9–11). However, data centres and related IT systems (including blockchain), are electricity-

intensive and will raise demand for energy (Avgerinou et al. 2017) – cryptocurrencies may be a major global source of CO₂ if the electricity production is not decarbonised (Mora et al. 2018) – and there is also a concern that Information technologies can compound and exacerbate current inequalities (Chapters 5, 16 and Cross-Chapter Box 11 in Chapter 16). IT may affect broader patterns of work and leisure (Boppart and Krusell 2020), and the emissions intensity of how people spend their leisure time will become more important (Chapters 5 and 9). Because higher efficiency tends to reduce costs, it often involves some 'rebound' offsetting at least some of the emission savings (Sudbury and Hutchinson 2016; Belkhir and Elmehli 2018; Cohen and Cavoli 2019).

Technology can enable both emissions reductions and/or increased emissions (Chapter 16). Governments play an important role in most major innovations, in both 'technology-push' (Mazzucato 2013) and induced by 'demand-pull' (Grubb et al. 2021a), so policy is important in determining its pace, direction and utilisation (Roberts and Geels 2019a) (Sections 1.7.1 and 1.7.3). Overall, the challenge will be to enhance the synergies and minimise the trade-offs and rebounds, including taking account of ethical and distributional dimensions (Gonella et al. 2019).

1.4.4 Finance and Investment

Finance is both an enabler and a constraint on mitigation, and since AR5, attention to the financial sector's role in mitigation has grown. This is partly in the context of the Paris Agreement finance articles and the Green Climate Fund, the pledge to mobilise USD100 billion yr⁻¹ by 2020, and the Addis Ababa Action Agenda (Section 1.3.1).

However, there is a persistent but uncertain gap in mitigation finance (Cui and Huang 2018) (Table 15.15.1), even though tracked climate finance overwhelmingly goes toward mitigation compared to adaptation (UNEP 2020) (Section 15.3; Working Group II). Green bond issuance has increased recently in parallel with efforts to reform the international financial system by supporting development of local capital markets (Section 15.6.4).

Climate finance is a multi-actor, multi-objective domain that includes central banks, commercial banks, asset managers, underwriters, development banks, and corporate planners. Climate change presents both risks and opportunities for the financial sector. The risks include physical risks related to the impacts of climate change itself; transition risks related to the exposure to policy, technology and behavioural changes in line with a low-carbon transition; and liability risks from litigation for climate-related damages (Box 15.2). These could potentially lead to stranded assets (the loss of economic value of existing assets before the end of their useful lifetimes (Bos and Gupta 2019) (Sections 6.7 and 15.6.3). Such risks continue to be underestimated by financial institutions (Section 15.6.1). The continuing expansion of fossil fuel infrastructure and insufficient transparency on how these are valued raises concerns that systemic risk may be accumulating in the financial sector in relation to a potential low-carbon transition that may already be under way (Battiston et al. 2017) (Section 15.6.3). The Financial Stability Board's Taskforce on Climate-related Financial Disclosures' (TCFD) recommendations on transparency aim to ensure that investors and companies consider climate change risks in their strategies and capital allocation (TCFD 2018). This is helping 'investors to reassess core assumptions' and may lead to 'significant' capital reallocation (Fink 2020). However, metrics and indicators of assets risk exposure are inadequate (Monasterolo 2017; Campiglio et al. 2018) and transparency alone is insufficient to drive the required asset reallocation in the absence of clear regulatory frameworks (Ameli et al. 2020; Chenet et al. 2021). A coalition of central banks have formed the Network for Greening the Financial Sector, to support and advance the transformation of the financial system (Allen et al. 2020; NGFS 2020), with some of them conducting climate-related institutional stress tests.

Governments cannot single-handedly fund the transition (Section 15.6.7), least of all in low-income developing countries with large sovereign debt and poor access to global financial markets. Long-term sources of private capital are required to close the financing gap across sectors and geographies (Section 15.6.7). Future investment needs are greatest in emerging and developing economies (Section 15.5.2) which already face higher costs of capital, hindering capacity to finance a transition (Buhr et al. 2018; Ameli et al. 2020). Requisite North–South financial flows are impeded by both geographic and technological risk premiums (Iyer et al. 2015), and the COVID-19 pandemic has further compromised the ability of developing and emerging economies to finance development activities or attract additional climate finance from developed countries (Section 15.6.3, and Cross-Chapter Box 1 in this chapter). Climate-related investments in developing countries also suffer from structural barriers such as sovereign risk and exchange rate volatility (Farooque and Shrimali 2016; Guzman et al. 2018) which affect not

only climate-related investment but investment in general (Yamahaki et al. 2020) including in needed infrastructure development (Gray and Irwin 2003). A Green Climate Fund (GCF) report notes the paradox that USD14 trillion of negative-yielding debt in OECD countries might be expected to flow to much larger low-carbon, climate-resilient investment opportunities in developing countries, but 'this is not happening' (Hourcade et al. 2021b).

There is often a disconnect between stated national climate ambition and finance flows, and overseas direct investment (ODI) from donor countries may be at odds with national climate pledges such as NDCs. One report found funds supported by foreign state-owned enterprises into 56 recipient countries in Asia and Africa in 2014–2017 went mostly to fossil fuel-based projects not strongly aligned with low-carbon priorities of recipient countries' NDCs (Zhou et al. 2018). Similarly, Steffen and Schmidt (2019) found that even within multilateral development banks, 'public- and private-sector branches differ considerably', with public-sector lending used mainly in non-renewable and hydropower projects. Political leadership is therefore essential to steer financial flows to support low-carbon transition (Section 15.6). Voituriez et al. (2019) identify significant mitigation potential if financing countries simply applied their own environmental standards to their overseas investments.

1.4.5 Political Economy

The politics of interest (most especially economic interest) of key actors at sub-national, national and global levels can be important determinants of climate (in)action (O'Hara 2009; Lo 2010; Tanner and Allouche 2011; Sovacool et al. 2015; Lohmann 2017; Clapp et al. 2018; Newell and Taylor 2018; Lohmann 2019). Political economy approaches can be crudely divided into 'economic approaches to politics', and those used by other social scientists (Paterson and P-Laberge 2018). The former shows how electoral concerns lead to weak treaties (Battaglini and Harstad 2016) and when policy negotiations cause status-quo biases and the use of inefficient policy instruments (Austen-Smith et al. 2019) or delays and excessive harmonisation (Harstad 2007). The latter emphasises the central role of structures of power and production, and a commitment to economic growth and capital accumulation in relation to climate action, given the historically central role of fossil fuels to economic development and the deep embedding of fossil energy in daily life (Newell and Paterson 2010; Huber 2012; Di Muzio 2015; Malm 2015).

The economic centrality of fossil fuels raises obvious questions regarding the possibility of decarbonisation. Economically, this is well understood as a problem of decoupling. But the constraint is also political, in terms of the power of incumbent fossil fuel interests to block initiatives towards decarbonisation (Jones and Levy 2009; Newell and Paterson 2010; Geels 2014). The effects of climate policy are key considerations in deciding the level of policy ambition and direction and strategies of states (Lo 2010; Alam et al. 2013; Ibikunle and Okereke 2014), regions (Goldthau and Sitter 2015), and business actors (Wittneben et al. 2012), and there is a widespread cultural assumption that continued fossil fuel use is central to this (Strambo and Espinosa 2020). Decarbonisation strategies are often centred

around projects to develop new sources of economic activity: carbon markets creating new commodities (Newell and Paterson 2010); investment generated in new urban infrastructure (Whitehead 2013); and/or innovations in a range of new energy technologies (Fankhauser et al. 2013; Lachapelle et al. 2017; Meckling and Nahm 2018).

One factor limiting the ambition of climate policy has been the ability of incumbent industries to shape government action on climate change (Newell and Paterson 1998; Jones and Levy 2009; Geels 2014; Breetz et al. 2018). Incumbent industries are often more concentrated than those benefiting from climate policy and lobby more effectively to prevent losses than those who would gain (Meng and Rode 2019). Drawing upon wider networks (Brulle 2014), campaigns by oil and coal companies against climate action in the United States of America and Australia are perhaps the most well known and largely successful of these (Pearse 2017; Brulle et al. 2020; Mildenberger 2020; Stokes 2020), although similar dynamics have been demonstrated in Brazil and South Africa (Hochstetler 2020), Canada (Harrison 2018), and Norway and Germany (Fitzgerald et al. 2019), for example. In other contexts, resistance by incumbent companies is more subtle but nevertheless has weakened policy design on emissions trading systems (Rosembloom and Markard 2020), and limited the development of alternative-fuelled automobiles (Levy and Egan 2003; Wells and Nieuwenhuis 2012).

The interaction of politics, power and economics is central in explaining why countries with higher per-capita emissions, which logically have more opportunities to reduce emissions, in practice often take the opposite stance, and conversely, why some low-emitting countries may find it easier to pursue climate action because they have fewer vested interests in high-carbon economies. These dynamics can arise from the vested interest of state-owned enterprises (SOEs) (Wittneben et al. 2012; Polman 2015; Wright and Nyberg 2017), the alignment and coalitions of countries in climate negotiations (Gupta 2016; Okereke and Coventry 2016), and the patterns of opposition to or support for climate policy among citizens (Baker 2015; Swilling et al. 2016; Heffron and McCauley 2018; Ransan-Cooper et al. 2018; Turhan et al. 2019).

1.4.6 Equity and Fairness

Equity and fairness can serve as both drivers and barriers to climate mitigation at different scales of governance. Literature regularly highlights equity and justice issues as critical components in local politics and international diplomacy regarding all SDGs, such as goals for no poverty, zero hunger, gender equality, affordable clean energy, reducing inequality, but also for climate action (SDG 13) (Marmot and Bell 2018; Spijkers 2018). Equity issues help explain why it has proved hard to reach more substantive global agreements, as it is hard to agree on a level of greenhouse gas (GHG) mitigation (or emissions) and how to distribute mitigation efforts among countries (Kverndokk 2018) for several reasons. First, an optimal trade-off between mitigation costs and damage costs of climate change depends on ethical considerations, and simulations from integrated assessment models using different ethical parameters producing different optimal mitigation paths (IPCC 2018b) (Section 3.6.1.2). Second, treaties that

are considered unfair may be hard to implement (Klinsky et al. 2017; Liu et al. 2017). Lessons from experimental economics show that people may not accept a distribution that is considered unfair, even if there is a cost of not accepting (Gampfer 2014). As equity issues are important for reaching deep decarbonisation, the transition towards sustainable development (Evans and Phelan 2016; Heffron and McCauley 2018; Okereke 2018) depends on taking equity seriously in climate policies and international negotiations (Okereke and Coventry 2016; Klinsky et al. 2017; Martinez et al. 2019).

Climate change and climate policies affect countries and people differently. Low-income countries tend to be more dependent on primary industries (agriculture and fisheries, etc.) than richer countries, and their infrastructure may be less robust to tackle more severe weather conditions. Within a country, the burdens may not be equally distributed either, due to policy measures implemented and from differences in vulnerability and adaptive capacity following from e.g. income and wealth distribution, race and gender. For instance, unequal social structures can result in women being more vulnerable to the effects of climate change compared to men, especially in poor countries (Arora-Jonsson 2011; Jost et al. 2016; Rao et al. 2019). Costs of mitigation also differ across countries. Studies show there are large disparities of economic impacts of NDCs across regions, and also between relatively similar countries when it comes to the level of development, due to large differences in marginal abatement costs for the emission-reduction goal of NDCs (Fujimori et al. 2016; Hof et al. 2017; Akimoto et al. 2018; Evans & Gabbatiss 2019). Equalising the burdens from climate policies may give more support for mitigation policies (Maestre-Andrés et al. 2019).

Taking equity into account in designing an international climate agreement is complicated as there is no single universally accepted equity criterion, and countries may strategically choose a criterion that favours them (Lange et al. 2007, 2010). Still, several studies analyse the consequences of different social preferences in designing climate agreements, such as, for instance, inequality aversion, sovereignty and altruism (Anthoff et al. 2010; Kverndokk et al. 2014).

International transfers from rich to poor countries to support mitigation and adaptation activities may help with equalising burdens, as agreed upon in the UNFCCC (1992) (Chapters 14 and 15), such that they may be motivated by strategic as well as equity reasons (Kverndokk 2018) (Section 1.4.4).

1.4.7 Social Innovation and Behaviour Change

Social and psychological factors affect both perceptions and behaviour (Weber 2015; Whitmarsh et al. 2021). Religion, values, culture, gender, identity, social status and habits strongly influence individual behaviours and choices, and therefore sustainable consumption (Sections 1.6.3.1 and 5.2). Identities can provide powerful attachments to consumption activities and objects that inhibit shifts away from them (Brekke et al. 2003; Bénabou and Tirole 2011; Stoll-Kleemann and Schmidt 2017; Ruby et al. 2020). Consumption is a habit-driven and social practice rather than simply a set of individual decisions, making shifts in consumption

harder to pursue (Evans et al. 2012; Shove and Spurling 2013; Kurz et al. 2015; Warde 2017; Verplanken and Whitmarsh 2021). Finally, shifts towards low-carbon behaviour are also inhibited by social-psychological and political dynamics that cause individuals to ignore the connections from daily consumption practices to climate change impacts (Norgaard 2011; Brulle and Norgaard 2019).

As a notable example, plant-based alternatives to meat could reduce emissions from diets (Eshel et al. 2019; Willett et al. 2019). However, diets are deeply entrenched in cultures and identities, and hard to change (Fresco 2015; Mylan 2018). Changing diets also raises cross-cultural ethical issues, in addition to meat's role in providing nutrition (Plumwood 2004). Henceforth, some behaviours that are harder to change will only be transformed by the transition itself: triggered by policies, the transition will bring about technologies that, in turn, will entrench new sustainable behaviours.

Behaviour can be influenced through a number of mechanisms besides economic policy and regulation, such as information campaigns, advertising and 'nudging'. Innovations and infrastructure also impact behaviour, as with bicycle lanes to reduce road traffic. Wider social innovations also have indirect impacts. Education is increasing across the world, and higher education will have impacts on fertility, consumption and the attitude towards the environment (Osili and Long 2008; Hamilton 2011; McCrary and Royer 2011). Reducing poverty and improvements in health and reproductive choice will also have implications for fertility, energy use and consumption globally. Finally, social capital and the ability to work collectively may have large consequences for mitigation and the ability to adapt to climate change (Adger 2009; IPCC 2014a Section 4.3.5).

1.4.8 Policy Impacts

Transformation to different systems will hinge on conscious policy to change the direction in which energy, land use, agriculture and other key sectors develop (Bataille et al. 2016) (Chapters 13 and 16). Policy plays a central role in in land-related systems (Chapter 7), urban development (Chapter 8), improving energy efficiency in buildings (Chapter 9) and transport/mobility (Chapter 10), and decarbonising industrial systems (Chapter 11).

Policy has been and will be central not only because GHG emissions are almost universally under-priced in market economies (Stern and Stiglitz 2017; World Bank 2019), and because of inadequate economic incentives to innovation (Jaffe et al. 2005), but also due to various delay mechanisms (Karlsson and Gilek 2020) and multiple sources of path-dependence and lock-in to existing systems (Section 1.8.2), including: 'Infrastructure developments and long-lived products that lock societies into GHG-intensive emissions pathways may be difficult or very costly to change, reinforcing the importance of early

action for ambitious mitigation (*robust evidence, high agreement*).'⁶ (AR5 WGIII p.18).

Many hundreds of policies have been introduced explicitly to mitigate GHG emissions, improve energy efficiency or land use, or to foster low-carbon industries and innovation, with demonstrable impact. The role of policy to date has been most evident in energy efficiency (Sections 5.4 and 5.6) and electricity (Chapter 6). The IPCC Special Report on Renewable Energy already found that: 'Government policies play a crucial role in accelerating the deployment of RE technologies' (IPCC 2011a, p. 24). Policy packages since then have driven rapid expansion in renewables capacity and cost reductions (e.g., through the German *Energiewende*), and emission reductions from electricity (most dramatically with the halving of CO₂ emissions from the UK power sector, driven by multiple policy instruments and regulatory changes), as detailed in Chapter 6 (Section 6.7.5).

Chapter 13 charts the international evolution of policies and many of the lessons drawn. Attributing the overall impact on emissions is complex, but an emerging literature of several hundred papers indicates impacts on multiple drivers of emissions. Collectively, policies are likely to have curtailed global emissions growth by several GtCO₂-eq annually already by the mid-2010s (Cross-Chapter Box 10 in Chapter 14). This suggests initial evidence that policy has driven some decoupling (Figure 1.1d) and started to 'bend the curve' of global emissions, but more specific attribution to observed trends is not as yet possible.⁶

However, some policies (e.g., subsidies to fossil fuel production or consumption) increase emissions, whilst others (e.g., investment protection) may constrain efforts at mitigation. Also, wider economic and developmental policies have important direct and indirect impacts on emissions. Policy is thus both a driver and a constraint on mitigation.

Synergies and trade-offs arise partly because of the nexus of GHG emissions with other adverse impacts (e.g., local air pollution) and critical resources (e.g., water and food) (Conway et al. 2015; Andrews-Speed and Dalin 2017), which also imply interacting policy domains.

The literature shows increasing emphasis on policy packages, including those spanning the different levels of niche/behaviour; existing regimes governing markets and public actors; and strategic and landscape levels (Section 1.7.3). Chapters 13, 16 and 17 appraise policies for transformation in the context of sustainable development, indicating the importance of policy as a driver at multiple levels and across many actors, with potential for benefits as well as costs at many levels.

National-level legislation may be particularly important to the credibility and long-term stability of policy to reduce the risks, and hence cost,

⁶ Linking estimated policy impacts to trends is complex, and as yet very tentative. An important factor is that many mitigation policies involve investments in low-carbon or energy-efficient technology, the savings from which persist. As a purely illustrative example: the annual increase in global emissions during 2000–2010 averaged around 1 GtCO₂-eq yr⁻¹, but with large fluctuations. If policies by 2010 reduced the *annual increase* in that year by 100 MtCO₂-eq (0.1 GtCO₂-eq) below what it would otherwise have been, this is hard to discern. But if these savings sustain, and in each subsequent year, policies cut another 100 MtCO₂-eq off the annual increase compared to the previous year, global emissions after a decade would be around 5 GtCO₂-eq yr⁻¹ below what they would have been without any such policies, and on average close to stabilising. However each step would be difficult to discern in the noise of annual fluctuations.

of finance (Chapters 13 and 15), and for encouraging private-sector innovation at scale (Chapter 16), for example, if it offers greater stability and mid-term predictability for carbon prices; Nash and Steurer (2019) find that seven national climate change acts in European countries all act as 'living policy processes, though to varying extents'.

The importance of policy at multiple levels does not lessen the importance of international policy, for reasons including long-term stability, equity, and scope, but examples of effective implementation policy at international levels remain fewer and governance weaker (Chapter 14).

1.4.9 Legal Framework and Institutions

Institutions are rules and norms held in common by social actors that guide, constrain and shape human interaction (IPCC 2018b). Institutions can be formal, such as laws and policies, or informal, such as norms and conventions. Institutions can both facilitate or constrain climate policymaking and implementation in multiple ways. Institutions set the economic incentives for action or inaction on climate change at national, regional and individual levels (Dorsch and Flachsland 2017; Sullivan 2017).

Institutions entrench specific political decision-making processes, often empowering some interests over others, including powerful interest groups who have vested interests in maintaining the current high-carbon economic structures (Okereke and Russel 2010; Wilhite 2016; Engau et al. 2017); see also Section 1.4.6 and Chapter 13 on the sub-national and national governance challenges including coordination, mediating politics and strategy setting.

Some suggest that societal transformation towards a low-carbon future requires new politics that involves thinking in intergenerational time horizons, as well as new forms of partnerships between private and public actors (Westman and Broto 2018), and associated institutions and social innovations to increase involvement of non-state actors in climate governance (Fuhr et al. 2018). However literature is divided as to how much democratisation of climate politics, with greater emphasis on equity and community participation, would advance societal transformation in the face of climate change (Stehr 2005), or may actually hinder radical climate action in some circumstances (Povitkina 2018).

Since 2016, the number of climate litigation cases has increased rapidly. The UN Environment Programme's Global Climate Litigation Report: 2020 Status Review (UNEP 2020) noted that between March 2017 and 1 July 2020, the number of cases nearly doubled with at least 1550 climate cases filed in eight countries. Several important cases such as *Urgenda Foundation vs The State of the Netherlands* ('Urgenda') and *Juliana et al. vs United States* ('Juliana') have had ripple effects, inspiring other similar cases (Lin and Kysar 2020).

Numerous international climate governance initiatives engage national and sub-national governments, NGOs and private corporations, constituting a 'regime complex' (Raustiala and Victor 2004; Keohane and Victor 2011). They may have longer-run and

second-order effects if commitments are more precise and binding (Kahler 2017). However, without targets, incentives, defined baselines or monitoring, reporting, and verification, they are not likely to fill the 'mitigation gap' (Michaelowa and Michaelowa 2017).

1.4.10 International Cooperation

Tackling climate change is often mentioned as an important reason for strong international cooperation in the 21st century (Falkner 2016; Keohane and Victor 2016; Bodansky et al. 2017; Cramton et al. 2017b). Mitigation costs are borne by countries taking action, while the benefits of reduced climate change are not limited to them, being in economic terms 'global and non-excludable'. Hence anthropogenic climate change is typically seen as a global commons problem (Falkner 2016; Wapner and Elver 2017). Moreover, the belief that mitigation will raise energy costs and may adversely affect competitiveness creates incentives for free riding, where states avoid taking their fair share of action (Barrett 2005; Keohane and Victor 2016). International cooperation has the potential to address these challenges through collective action (Tulkens 2019) and international institutions offer the opportunity for actors to engage in meaningful communication and exchange of ideas about potential solutions (Cole 2015). International cooperation is also vital for the creation and diffusion of norms and the framework for stabilising expectations among actors (Pettenger 2016).

Some key roles of the UNFCCC have been detailed by its former heads (Kinley et al. 2021). In addition to specific agreements (most recently the PA) it has enhanced transparency through reporting and data, and generated or reinforced several important norms for global climate action including the principles of equity, common but differentiated responsibility and respective capabilities, and the precautionary principles for maintaining global cooperation among states with unevenly distributed emissions sources, climate impacts, and varying mitigation costs across countries (Keohane and Victor, 2016). In addition to formal negotiations, the annual Conference of the Parties (COPs) have increased awareness, and motivated more ambitious actions, sometimes through the formation of 'coalitions of the willing', for example. It provides a structure for measuring and monitoring action towards a global goal (Milkoreit and Haapala 2019). International cooperation (including the UNFCCC) can also promote technology development and transfer and capacity building; mobilise finance for mitigation and adaptation; and help address concerns on climate justice (Okereke and Coventry 2016; Chan et al. 2018) (Chapters 14–16).

A common criticism of international institutions is their limited (if any) powers to enforce compliance (Zahar 2017). As a global legal institution, the PA has little enforcement mechanism (Sindico 2015), but enforcement is not a necessary condition for an instrument to be legally binding (Bodansky 2016; Rajamani 2016). In reality implementation of specific commitments tends to be high once countries have ratified and a treaty or an agreement is in force (Bodansky 2016; Rajamani 2016). Often, the problem is not so much of 'power to enforce compliance or sanction non-compliance', but the level of ambition (Chapter 14).

However, whilst in most respects a driver, international cooperation has also been characterised as ‘organised hypocrisy’ where proclamations are not matched with corresponding action (Egnell 2010). Various reasons for inadequate progress after 30 years of climate negotiations, have been identified (Stoddard et al. 2021). International cooperation can also seem to be a barrier to ambitious action when negotiation is trapped in ‘relative-gains’ calculus, in which countries seek to game the regime or gain leverage over one another (Purdon 2017), or where states lower ambition to the ‘least common denominator’ to accommodate participation of the least ambitious states (Falkner 2016). Geden (2016) and Dubash (2020) offer more nuanced assessments.

International collaboration works best if an agreement can be made self-reinforcing with incentives for mutual gains and joint action (Barrett 2016; Keohane and Victor 2016), but the structure of the climate challenge makes this hard to achieve. The evidence from the Montreal Protocol on ozone-depleting substances and from the Kyoto Protocol on GHGs, is that legally binding targets have been *effective* in that participating Parties complied with them (Shishlov et al. 2016; Albrecht and Parker 2019), and (for Kyoto) these account for most of the countries that have sustained emission reductions for at least the past 10 to 15 years (Sections 1.3.2 and 2.2). However, such binding commitments may deter *participation* if there are no clear incentives to sustain participation and especially if other growing emitters are omitted by design, as with the Kyoto Protocol. Consequently the USA refused to ratify (and Canada withdrew), particularly on the grounds that developing countries had no targets; with participation in Kyoto’s second period commitments declining further, the net result was limited global progress in emissions under Kyoto (Bodansky 2016; Okereke and Coventry 2016; Scavenius and Rayner 2018) despite full legal compliance in both commitment periods (Chapter 14).

The negotiation of the Paris Agreement was thus done in the context of serious questions about how best to structure international climate cooperation to achieve better results. This new agreement is designed to sidestep the fractious bargaining which characterised international climate cooperation (Marcu 2017). It contains a mix of hard, soft and non-obligations, the boundaries between which are blurred, but each of which plays a distinct and valuable role (Rajamani 2016). The provisions of the PA could encourage flexible responses to changing conditions, but limit assurances of ambitious national commitments and their fulfilment (Pickering et al. 2018). The extent to which this new arrangement will drive ambitious climate policy in the long run remains to be seen (Chapter 14).

Whilst the PA abandoned common accounting systems and time frames, outside of the UNFCCC many other platforms and metrics for comparing mitigation efforts have emerged (Aldy 2015). Countries may assess others’ efforts in determining their actions through multiple platforms including the Climate Change Cooperation Index (C3-I), Climate Change Performance Index (CCPI), Climate Laws, Institutions and Measures Index (CLIMI) (Bernauer and Böhmelt 2013) and Energy Transition Index (Singh et al. 2019). International cooperative initiatives between and among non-state (e.g., business, investors and civil society) and sub-national (e.g., city and state) actors have also been emerging, taking the forms of public-private partnerships,

private-sector governance initiatives, NGO transnational initiatives, and sub-national transnational initiatives (Bulkeley and Schroeder 2012; Hsu et al. 2018). Literature is mostly positive about the role of these transnational initiatives in facilitating climate action across scales although criticism and caution about their accountability and effectiveness remain (Chan et al. 2016; Michaelowa and Michaelowa 2017; Roger et al. 2017; Widerberg and Pattberg 2017) (Chapter 14).

1.5 Emissions Scenarios and Illustrative Mitigation Pathways (IMPs)

Scenarios are a powerful tool for exploring an uncertain future world against the background of alternative choices and development. Scenarios can be constructed using both narrative and quantitative methods. When these two methods are combined they provide complementary information and insights. Quantitative and narrative models are frequently used to represent scenarios to explore choices and challenges. The IPCC has a long history of assessing scenarios (Nakicenovic et al. 2000; van Vuuren et al. 2011, 2014) (see also AR6 WGI Section 1.6 for a history of scenarios within the IPCC). This WGIII assessment employs a wide range of qualitative and quantitative scenarios including quantitative scenarios developed through a wide and heterogeneous set of tools ranging from spreadsheets to complex computational models (Annex III: Scenarios and Modelling Methods provides further discussion and examples of computational models).

The concept of an **illustrative pathway (IP)** was introduced in the IPCC Special Report on Global Warming of 1.5°C (IPCC 2018b) to highlight a subset of the quantitative scenarios, drawn from a larger pool of published literature, with specific characteristics that would help represent some of the key findings emerging from the assessment in terms of different strategies, ambitions and options available to achieve the Paris goals.

Integrated assessment models (IAMs) are the primary tools for quantitatively evaluating the technological and macroeconomic implications of decarbonisation, particularly for global long-term pathways. They broadly divide into ‘stylised aggregate benefit-cost models’, and more complex ‘detailed process’ IAMs (Weyant 2017), often mirroring the benefit-cost and cost-effective approaches outlined in Section 1.7.1, with more detailed classification in, for example, Nikas et al. (2019). IAMs embody a number of structural and socio-demographic assumptions and include multiple modelling approaches, ranging from economic optimising behaviour to simulation (see Annex III). Detailed process models can include energy system models used to analyse decarbonisation and ‘net zero’ scenarios by international agencies (e.g., IEA 2020a).

Calculating cost-effective trajectories towards given goals typically involves detailed process IAMs. Often these calculate the dynamic portfolio of technologies consistent with a given climate target. Some track records of technology forecasting in IAMs are outlined in Section 2.5.4, and Box 16.1. Climate targets may be imposed in models in a variety of ways that include, but are not limited to, constraints on emissions or cumulated emissions (carbon budgets), and the pricing of emissions. The time-path of mitigation costs

calculated through these models may be translated into 'shadow prices' that (like the social cost of carbon; SCC) offer a benchmark to assess the cost-effectiveness of investments, as used by some governments and companies (Section 1.8.2).

Scenarios in the IPCC and AR6. For AR6, WGIII received submissions of more than 2500 model-based scenarios published in the scientific literature. Such scenarios, which explore different possible evolutions of future energy and land use (with or without climate policy) and associated emissions, are made available through an interactive AR6 scenario database. The main characteristics of pathways in relation to 'net zero' emissions and remaining 'carbon budgets' are summarised in Box 3.5 in Chapter 3. The warming contribution of CO₂ is very closely related to cumulative CO₂ emissions, but the remaining 'carbon budget' for a given warming depends strongly *inter alia* on emissions of other GHGs; for targets below 2°C this may affect the corresponding 'carbon budget' by about ±220 GtCO₂, compared to central estimates of around 500 GtCO₂ (for 1.5°C) and 1350 GtCO₂ (for 2°C) (AR6 WGI, Table SPM.2) (Cross-Working Group Box 1 in Chapter 3).

Pathways and 'net zero'. The date at which the world needs aggregate emissions to reach net zero for Paris-consistent temperature goals depends both on progress in reducing non-CO₂ GHG emissions and near-term progress in reducing CO₂ emissions. Faster progress in the near term extends the date at which net zero must be reached, while conversely, slower near-term progress brings the date even closer to the present. Some of the modelled 1.5°C pathways with limited overshoot cut global CO₂ emissions in half until 2030, which allows for a more gradual decline thereafter, reaching net zero CO₂ after 2050; also, net zero GHGs occurs later,

with remaining emissions of some non-CO₂ GHGs compensated by 'net negative' CO₂ (see Glossary and FAQ 1.3, and Cross-Chapter Box 3 in Chapter 3).

Drawing from the scenarios database, five **Illustrative Mitigation Pathways (IMPs)** were defined for this report (Figure 3.5 and Table 1.1). These are introduced here, with a more complete description and discussion provided in Section 3.2.5. These IMPs were chosen to illustrate key themes with respect to mitigation strategies across the entire WGIII assessment. The IMPs embody both a storyline, which describes in narrative form the key socio-economic characteristics of that scenario, and a quantitative illustration providing numerical values that are internally consistent and comparable across chapters of this report. Quantitative IMPs can be associated directly with specific human activities and provide a quantitative point of reference that links activities in different parts of socio-economic systems. Some parts of the report draw on these quantitative scenarios, whilst others use only the narratives. No assessment of the likelihood of each IMP has been made (as they reflect both human choice and deep uncertainty).

The IMPs are organised around two dimensions: the *level of ambition* consistent with meeting Paris goals, and the scenario features (Figure 1.4). The IMPs explore different pathways potentially consistent with meeting the long-term temperature goals of the Paris Agreement. As detailed in Section 3.2.5 and in Chapter 4, a pathway of Gradual Strengthening of current policies (**IMP-GS**) to 2030, if followed by very fast reductions, may stay below 2°C. The **IMP-NEG** pathway, with somewhat deeper emission cutbacks to 2030, might enable 1.5°C to be reached but only after significant overshoot, through the subsequent extensive use of CDR in the energy and

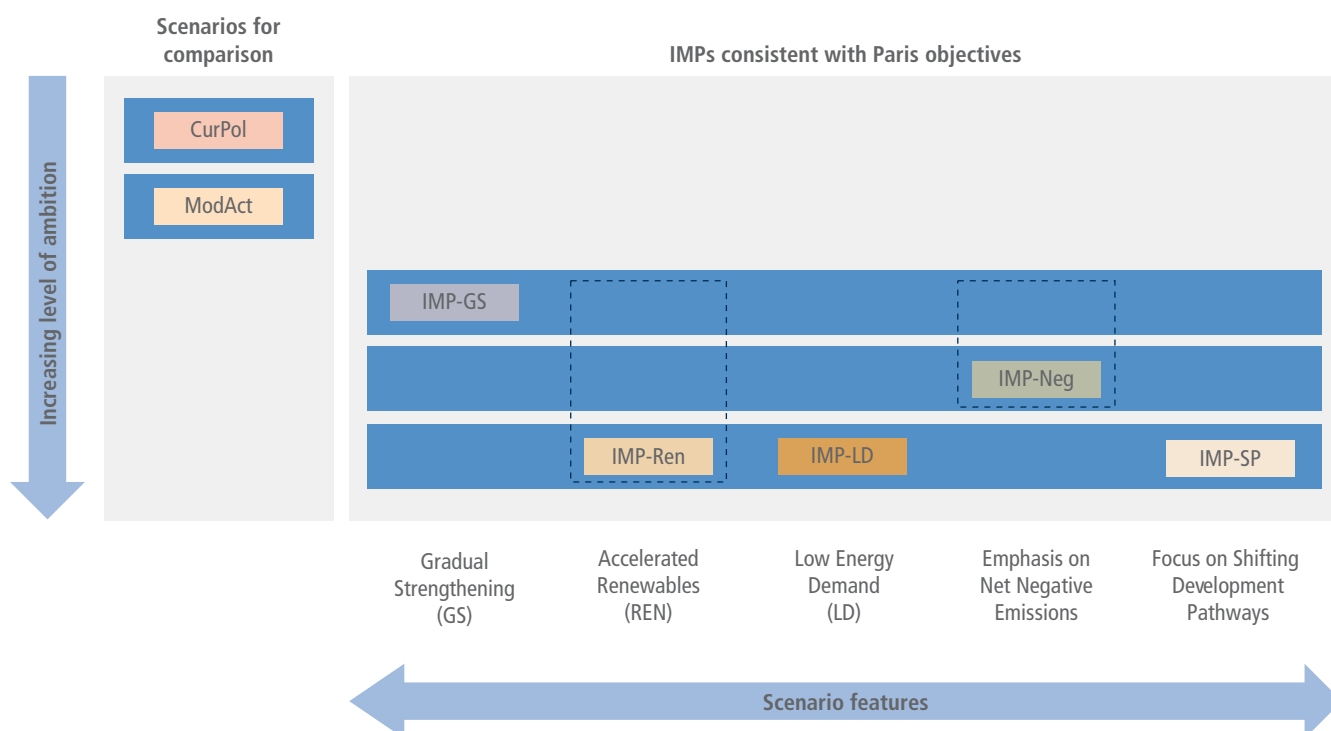

Figure 1.4 | Illustrative Mitigation Pathways (IMPs) used in AR6: illustration of key features and levels of ambition.

Table 1.1 | Illustrative Mitigation Pathways used in AR6.

Scenarios			Full name	Main policy characteristics
CurPol			Current Policies	Implementation of current climate <i>policies</i> (mostly as reported in Nationally Determined Contributions (NDCs)), neglecting stated subsequent goals and objectives (e.g., for 2030); only Gradual Strengthening after 2030; grey COVID recovery.
ModAct			Moderate Action	Implementation of current policies <i>and</i> achievement of 2030 NDCs, with further strengthening post-2030. Similarly to the situation implied by the diversity of NDCs (both policies and pledges), a fragmented policy landscape remains; mixed COVID recovery.
IMPs	1.5°C/ <2°C	GS	Gradual Strengthening	Until 2030, primarily current NDCs are implemented; after that a strong universal regime leads to coordinated and rapid decarbonisation actions.
		Neg	Net Negative Emissions	Successful international climate policy regime reduces emissions below ModAct or GS to 2030, but with a focus on the long-term temperature goal, negative emissions kick in at growing scales thereafter, so that mitigation in all sectors also includes a growing and ultimately large reliance on negative emissions, with large 'net global negative' after 2050 to meet 1.5°C after significant overshoot.
		Ren	Renewables	Successful international climate policy regime with immediate action, particularly policies and incentives (including international finance) favouring renewable energy; less emphasis on negative-emission technologies. Rapid deployment and innovation of renewables and systems; electrification of all end use.
		LD	Low Demand	Successful international climate policy regime with immediate action on the demand side; policies and financial incentives favouring reduced demand that in turn leads to early emission reductions; this reduces the decarbonisation effort on the supply side.
		SP	Shifting Pathways	Successful international climate policy regime with a focus on additional SDG policies aiming, for example, at poverty reduction and broader environmental protection. Major transformations shift development towards sustainability and reduced inequality, including deep GHG emissions reduction.

the industry sectors to achieve net negative global emissions, as discussed in Chapters 3, 6, 7, 10 and 12.

Three other IMPs illustrate different features of technology scenarios with more short-term rapid emission reductions, which could deliver outcomes compatible with the temperature range in the Paris Agreement without large overshoot. Based on the assessment in Section 5.3.3, one key mitigation strategy would be to rely on the opportunities for reducing demand (**IMP-LD**). Chapters 6 and 7–11 show how energy systems based on accelerated deep renewable energy penetration and electrification can also provide a pathway to deep mitigation (**IMP-REN**). Chapters 3, 4 and 17 provide insights into how shifting development pathways can lead to deep emission reductions and achieve sustainable development goals (**IMP-SP**).

These pathways can be implemented with different levels of ambition, that can be measured through the classes (C) of temperature levels from the scenarios database, see Chapter 3 (Table 3.2). In the IMP framework, Section 3.2.5 presents and explores quantitative scenarios that can limit warming to 1.5°C (with a probability of 50% or greater, i.e., C1 for the illustrated quantification of LD, SP and REN, and C2 for NEG scenario), along with other GS pathways which keep warming below 2°C with a probability of 67% or greater (C3). In addition to these primary IMPs, the full scenario database contains sensitivity cases that explore alternative warming levels.

In addition to the IMPs two additional scenarios were selected, which illustrate the consequences of current policies and pledges. Current Policies (**CurPol**) explores the consequences of continuing along the path of implemented climate policies in 2020 and only a Gradual Strengthening after that, drawing on numerous such scenarios in the literature. Moderate Action (**ModAct**) explores the impact of implementing NDCs to 2030, but without further strengthening:

both result in global mean temperature above 2°C. They provide benchmarks against which to compare the IMPs.

Table 1.1 summarises the main storyline elements of the reference scenarios and each IMP.

What the IMPs do and don't do. The IMPs are, as their name implies, a set of scenarios meant to illustrate some important themes that run through the entire WGIII assessment. They illustrate that the climate outcomes that individuals and society will face in the century ahead depend on individual and societal choices. In addition, they illustrate that there are multiple ways to successful achievement of Paris long-term temperature goals.

IMPs are not intended to be comprehensive. They are not intended to illustrate all possible themes in this report. They do not, for example, attempt to illustrate the range of alternative socio-economic pathways against which efforts to implement Paris goals may be set, or to reflect variations in potential regional development pathways. They do not explore issues around income distribution or environmental justice, but assume implicitly that *where* and *how* action occurs can be separated from *who* pays, in ways to adequately address such issues. They are essentially pathways of technological evolution and demand shifts reflecting broad global trends in social choice. The IMPs do not directly assess issues of realisation linked to the 'drivers and constraints' summarised in our previous section, and the quantifications use, for the most part, models that are grounded mainly in the Aggregate Economics Frameworks (Section 7.1). As such they reflect primarily the geophysical, economic and technological Dimensions of Assessment, but can be assessed in relation to the full set of Feasibility criteria (Section 1.8.1).

Together the IMPs provide illustrations of potential future developments that can be shaped by human choices, including:

Where are current policies and pledges leading? What is needed to reach specific temperature goals under varying assumptions? What are the consequences of different strategies to meet climate targets (i.e., demand-side strategy, a renewable energy strategy or a strategy with a role for net negative emissions)? What are the consequences of delay? What are the implications for other SDGs of various climate mitigation pathways?

1.6 Achieving Mitigation in the Context of Sustainable Development

This chapter now sets out approaches to understanding the mitigation challenge, working from its broad location in the context of wider aspirations for sustainable development, then identifying specific analytic approaches, before summarising the corresponding main dimensions used for the assessment of options and pathways in much of the report.

1.6.1 The Climate Change and Development Connection

Climate change mitigation is one of many goals that societies pursue in the context of sustainable development, as evidenced by the wide range of the Sustainable Development Goals (SDGs). Climate change and sustainable development, as well as development more broadly, are interwoven along multiple and complex lines of relationship (Okereke et al. 2009; Fankhauser and McDermott 2016; Okereke and Massaquoi 2017; Gomez-Echeverri 2018a), as highlighted in several previous IPCC reports (IPCC 2007, 2011a, 2014a, 2018b, 2019a). With its significant negative impact on natural systems, food security and infrastructure, loss of lives and territories, species extinction, conflict health, among several other risks, climate change poses a serious threat to development and wellbeing in both rich and poor countries (IPCC 2007, 2011a, 2014a, 2018b, 2019b). Without serious efforts at mitigation and adaptation, climate change could push millions further into poverty and limit the opportunities for economic development (Chapters 4 and 17). It follows that ambitious climate mitigation is necessary to secure a safe climate within which development and well-being can be pursued and sustained.

At the same time, rapid and large-scale economic development (which has in the past driven climate change through land-use change and dependence on fossil fuels), is widely seen as needed to improve global well-being and lift millions especially in low- and middle-income countries out of poverty (Chen et al. 2017; Mugambiwa and Tirivangasi 2017; Lu et al. 2019; Baarsch et al. 2020) (Figure 1.6). This strand of literature emphasises the importance of economic growth including for tackling climate change itself, pointing to the relationship between economic development and climate resilience as well as the role of industry-powered technologies such as electric vehicles in reducing GHG levels and promoting well-being (Heinrichs et al. 2014; Kasztelan 2017). Yet, others argue that the character of social and economic development produced by the nature of capitalist society (Pelling and Manuel-Navarrete 2011; Koch 2012; Malm 2016) is ultimately unsustainable.

There are at least two major implications of the very close link between climate change and development as outlined above. The first is that the choice of development paths made by countries and regions have significant consequences for GHG emissions and efforts to combat climate change (Chapters 2, 3, 4, 5 and 14). The second is that climate mitigation at local, national and global levels cannot be effectively achieved by a narrow focus on 'climate-specific' sectors, actors and policies, but rather through a much broader attention to the mix of development choices and the resulting development paths and trajectories (O'Neill et al. 2014) (Chapters 4, 6 and 10).

As a key staple of IPCC reports and the global climate policy landscape (IPCC 2007, 2014b; van Vuuren et al. 2017; Gidden et al. 2019; Quilcaille et al. 2019) (Chapter 2), integrated assessment models and global scenarios (such as the Shared Socio-economic Pathways – SSPs) highlight the interaction between development paths, climate change and emission stabilisation (Section 3.6). The close links are also recognised in the PA (Section 1.3.1).

The impact of climate change in limiting well-being is most acutely felt by the world's poorest people, communities, and nations, who have the smallest carbon footprint, constrained capacity to respond and limited voice in important decision-making circles (Okereke and Ehresman 2015; Tosam and Mbih 2015; Mugambiwa and Tirivangasi 2017). The wide variation in the contribution to, and impact of climate change within and across countries makes equity, inequality, justice, and poverty eradication, inescapable aspects of the relationship between sustainable development and climate change (Okereke and Coventry 2016; Klinsky et al. 2017; Reckien et al. 2017; Bos and Gupta 2019; Kayal et al. 2019; Dffenbaugh and Burke 2019; Baarsch et al. 2020). This underpins the conclusion, as commonly expressed, that climate action needs to be pursued in the context of sustainable development, equity and poverty eradication (Smit et al. 2001; Tschakert and Olsson 2005; IPCC 2014a, 2018b; Klinsky and Winkler 2014).

1.6.2 Concepts and Frameworks for Integrating Climate Mitigation and Development

At one level, sustainable development can be seen as a meta framework for integrating climate action with other global sustainability goals (Casadio Tarabusi and Guarini 2013; Antal and Van Den Bergh 2016). Fundamentally, the concept of sustainable development underscores the interlinkages and interdependence of human and natural systems and the need to balance economic, social, and environmental (including climate pollution) aspects in development planning and processes (Nunan 2017; Gomez-Echeverri 2018b; Zhenmin and Espinosa 2019).

Despite the appeal of the concept, tensions remain over the interpretation and practical application, with acute disagreements regarding what the balancing entails in real life, how to measure well-being, which goals to set, and the means through which such goals might be pursued (Arrow et al. 2011; Dasgupta et al. 2015; Michelsen et al. 2016; Okereke and Massaquoi 2017; UNEP 2018b; Haberl et al. 2019; Shang et al. 2019; Sugiawan et al. 2019).

Moreover, countries differ enormously in their respective situation regarding their development path – a condition which affects their capability, goals, priorities and approach to the pursuit of sustainability (Shi et al. 2016; Ramos-Mejía et al. 2018; Okereke et al. 2019). Most of the literature recognises that despite its limitations, sustainable development with its emphasis on integrating social, economic and environmental goals, provides a more comprehensive approach to the pursuit of planetary health and human well-being. Sustainable development is then not a static objective but a dynamic framework for measuring human progress (Costanza et al. 2016; Fotis and Polemis 2018), relevant for all countries even if different groups of nations experience the challenge of sustainability in different ways.

Much like sustainable development, concepts like low-carbon development (Mulugetta and Urban 2010; Yuan et al. 2011; Wang et al. 2017; Tian et al. 2019), climate-compatible development (CCD) (Mitchell and Maxwell 2010; Tompkins et al. 2013; Stringer et al. 2014; Bickersteth et al. 2017) and more recently climate-resilient development (CRD) (Fankhauser and McDermott 2016; Henly-Shepard et al. 2018; IPCC 2018b) have all emerged as ideas, tools and frameworks, intended to bring together the goals of climate mitigation and the SDGs, as well as development more broadly. Figure 1.5 suggests that the prospects for realising a climate-resilient and equitable world are enhanced by a process of transformation and development trajectories that seek to limit global warming while also achieving the SDGs. The SDGs represent medium-term goals, and long-term sustainability requires continued

effort to keep the world along a climate-resilient development path. A key feature of development or transformation pathways that achieve a climate-resilient world is that they maximise the synergies and minimise the trade-offs between climate mitigation and other sustainable development goals (Klausbrückner et al. 2016; Thornton and Comberti 2017; Wüstemann et al. 2017; Dagnachew et al. 2018; Fuso Nerini et al. 2018; Mainali et al. 2018). Crucially, the nature of trade-offs and timing of related decisions will vary across countries depending on circumstances including the level of development, capability and access to resources (Cross-Chapter Box 5, Shifting Development Paths to Increase Sustainability, in Chapter 4).

Other concepts such as ‘Doughnut Economics’ (Raworth 2018), ecological modernisation, and mainstreaming are also used to convey ideals of development pathways that take sustainability, climate mitigation, and environmental limits seriously (Dale et al. 2015a). Mainstreaming focuses on incorporating climate change into national development activities, such as the building of infrastructure (Wamsler and Pauleit 2016; Runhaar et al. 2018). The ‘green economy’ and green growth – growth without undermining ecological systems, partly by gaining economic value from cleaner technologies and systems and is inclusive and equitable in its outcomes – has gained popularity in both developed and developing countries as an approach for harnessing economic growth to address environmental issues (Bina 2013; Georgeson et al. 2017; Capasso et al. 2019; Song et al. 2020; Hao et al. 2021). However, critics argue that green economy ultimately emphasises economic growth to the detriment of other important aspects of human welfare such as social

Figure 1.5 | A climate-resilient and equitable world requires limiting global warming while achieving the Sustainable Development Goals (SDGs).
Source: IPCC (2018b).

justice (Death 2014; Adelman 2015; Kamuti 2015), and challenge the central idea that it is possible to decouple economic activity and growth (measured as GDP increment) from increasing use of biophysical resources (raw materials, energy) (Jackson and Victor 2019; Parrique et al. 2019; Haberl et al. 2020; Hickel and Kallis 2020; Vadén et al. 2020).

Literature on degrowth, post growth, and post development questions the sustainability and imperative of more growth especially in already industrialised countries and argues that prosperity and the 'Good Life' are not immutably tied to economic growth (Asara et al. 2015; Escobar 2015; Latouche 2018; Kallis 2019) (Section 5.2.1). The concept of Just Transition also stresses the need to integrate justice concerns so as to not impose hardship on already marginalised populations within and between countries (Evans and Phelan 2016; Goddard and Farrelly 2018; Heffron and McCauley 2018; Smith, Jackie and Patterson 2018; McCauley and Heffron 2018) (Section 1.7.2). The key insight is that pursuing climate goals in the context of sustainable development requires holistic thinking including on how to measure well-being, serious consideration of the notion of ecological limits, at least some level of decoupling and certainly choices and decision-making approaches that exploit and maximise the synergy and minimise the trade-off between climate mitigation and other sustainable development goals. It also requires consideration of equity and justice within and between countries. However, ideas of a synergistic relationship between development and climate mitigation can sometimes offer limited practical guidelines for reconciling the tensions that are often present in practical policymaking (Ferguson et al. 2014; Dale et al. 2015b; Kasztelan 2017; Kotzé 2018).

1.6.3 Climate Mitigation, Equity and the Sustainable Development Goals (SDGs)

Climate action can be conceptualised as both a stand-alone and cross-cutting issue in the 2030 SDGs (Makomere and Liti Mbeva 2018), given that several of the other goals such as ending poverty (SDG 1), zero hunger (SDG 2), good health and well-being (SDG 3), and affordable and clean energy (SDG 7), among many others, are related to climate change (Figure 3.39).

In addition to galvanising global collective action, the SDGs provide concrete themes, targets and indicators for measuring human progress to sustainability (Kanie and Biermann 2017). The SDGs also provide a basis for exploring the synergies and trade-offs between sustainable development and climate change mitigation (Pradhan et al. 2017; Fuso Nerini et al. 2018; Mainali et al. 2018; Makomere and Liti Mbeva 2018). Progress to date (Sachs et al. 2016) shows fulfilling SDGs is a challenge for all groups of countries – developed

and developing – even though the challenge differs between countries and regions (Pradhan et al. 2017).

Historically, the industrialisation associated with economic development has involved a strong relationship with GHG emissions (Section 5.2.1). Figure 1.6 shows per-capita GHG emissions on the vertical axis and Historical Index of Human Development (HIHD) levels (Prados de la Escosura 2015) on the horizontal axis.⁷ The grey line shows historic global average GHG emissions per capita and levels of human development over time, from 1870 to 2014. The current positions of different regions are shown by bubbles, with sizes representing total GHG emissions. Figure 1.6 also shows the estimated position of the SDGs zone for the year 2030, and a 'sustainable development corridor' as countries reach towards higher HDI and lower emissions. To fulfil the SDGs, including SDG 13 (climate action), the historic relationship needs to change.

The top of the SDG zone is situated around the global per-capita GHG emissions level of 5 tCO₂-eq required for the world to be path towards fulfilling the Paris Agreement.⁸ The horizontal position of the SDG zone is estimated based on the HIHD levels (Prados de la Escosura 2015) of countries that have been shown to either have achieved, or have some challenges, when it comes to SDG 3, SDG 4 and SDG 8 (Sachs et al. 2016), as these SDGs are related to the constituent parts of the HIHD. Beyond 2030, the sustainable development corridor allows for increasing levels of human development while lowering per-capita GHG emissions.

Figure 1.6 shows that at present, regions with HIHD levels of around 0.5 all have emissions at or above about 5 tCO₂-eq per capita (even more so on a consumption footprint basis; see Figure 1.1c,d), but there are wide variations within this. Indeed, there are regions with HIHD levels above 0.8 which have GHG per-capita emissions lower than several with HIHD levels of around 0.5. The mitigation challenge involves countries at many different stages of development seeking paths towards higher welfare with low emissions.

From Figure 1.6, there are two distinct dimensions to sustainable development pathways for fulfilling the SDGs. In terms of per-capita GHG emissions (the vertical), some regions have such low levels that they could increase and still be below the global average required in 2030 for the world to be on path to fulfil the Paris Agreement. Meanwhile, other regions with high per-capita GHG emissions would require a rapid transformation in technologies and practices. It is against this background that Dubash (2019) emphasises placing the need for urgent action on climate change in the context of domestic political priorities and the institutions within which national frameworks are crystallised.

⁷ The Historical Index of Human Development (HIHD) emulates the widely used Human Development Index (HDI) as they both summarise in indexes the key human development dimensions consisting of a healthy life, knowledge and a decent standard of living. HDI is based on: life expectancy, expected years of schooling of children, the mean years of schooling of the adult population, and gross national income (GNI) per capita adjusted for purchasing power; the HIHD is based on: life expectancy at birth, adult literacy rates, educational enrolment rates, and GDP per capita, and is used in Figure 1.6 because it is available for a longer time series (Prados de la Escosura 2015).

⁸ Based on global population projections of between 8 and 8.5 billion people in 2030, and GHG emissions levels from the C1, C2 and C3 categories of scenarios in Table 3.2 and Box 3.7.

Figure 1.6 | Sustainable development pathways towards fulfilling the Sustainable Development Goals (SDGs). The graph shows global average per-capita GHG emissions (vertical axis) and relative 'Historic Index of Human Development' (HIHD) levels (horizontal) have increased globally since the industrial revolution (grey line). The bubbles on the graph show regional per-capita GHG emissions and human development levels in the year 2015, illustrating large disparities. Pathways towards fulfilling the Paris Agreement (and SDG 13) involve global average per-capita GHG emissions below about 5 tCO₂-eq by 2030. Likewise, to fulfil SDGs 3, 4 and 8, HIHD levels (see footnote 7) need to be at least 0.5 or greater. This suggests a 'sustainable development zone' for year 2030 (in pale brown); the in-figure text also suggests a 'sustainable development corridor', where countries limit per-capita GHG emissions while improving levels of human development over time. The emphasis of pathways into the sustainable development zone differ (dashed brown arrows), but in each case transformations are needed in how human development is attained while limiting GHG emissions.

Concerns over equity in the context of growing global inequality and very tight remaining global carbon budgets have motivated an emphasis on equitable access to sustainable development (Peters et al. 2015; Kartha et al. 2018b; Matthews et al. 2019; van den Berg et al. 2019). This literature emphasises the need for less developed countries to have sufficient room for development while addressing climate change (Winkler et al. 2013; Pan et al. 2014; Gajevic Sayegh 2017; Robinson and Shine 2018; Warlenius 2018). Meanwhile, many

countries reliant on fossil fuels, related technologies and economic activities, are eager to ensure tax revenues are maintained, workers and industries have income and justice is embedded in the economic transformations required to limit GHG emissions (Cronin et al. 2021).

Correlation between CO₂ emission intensity, or absolute emission and gross domestic product growth, is not rigid, unambiguous and deterministic (Ojekunle et al. 2015), but the extent to which SDGs

and economic growth expectations can be fulfilled while decoupling GHG emissions remains a concern (Haberl et al. 2020; Hickel and Kallis 2020). Below some thresholds of absolute poverty, more consumption is necessary for development to lead to well-being (Section 5.2.1.1), which may not be the case at higher levels of consumption (Lamb and Steinberger 2017; Steinberger et al. 2020) (Section 1.7.2).

In conclusion, achieving climate stabilisation in the context of sustainable development and efforts to eradicate poverty requires collective action and exploiting synergies between climate action and sustainable development, while minimising the impact of trade-offs (Najam 2005; Okereke and Massaquoi 2017; Makomere and Liti Mbeva 2018; Dooley et al. 2021). It also requires a focus on equity considerations to avoid climate-induced harm, as well as unfairness that can result from urgent actions to cut emissions (Pan et al. 2014; Robiou du Pont et al. 2017; Kartha et al. 2018a). This is ever more important as the diminishing carbon budget has intensified debates on which countries should have the greatest claim to the 'remaining space' for emissions (Raupach et al. 2014) or production (McGlade and Ekins 2015), amplified by persistent concerns over the insufficiency of support for means of implementation, to support ambitious mitigation efforts (Pickering et al. 2015; Weikmans and Roberts 2019).

1.7 Four Analytic Frameworks for Understanding Mitigation Response Strategies

Climate change is unprecedented in its scope (sectors, actors and countries), depth (major transformations) and time scales (over generations). As such, it creates unique challenges for analysis. It has been called 'the greatest market failure in history' (Stern 2007); the 'perfect moral storm' (Gardiner 2006) and a 'super wicked problem' (Lazarus 2009; Levin et al. 2012) – one which appears difficult to solve through the traditional tools and assumptions of social organisation and analysis.

To complement the extensive literature on risks and decision-making under uncertainty reviewed in AR6 WGII (notably, Chapter 19), this section summarises insights and developments in key analytic frameworks and tools particularly relevant to understanding specific mitigation strategies, policies and other actions, including explaining the observed if limited progress to date. Organised partly as reflected in the quotes above, these include *aggregated* (principally, economic) frameworks to evaluate system-level choices; *ethical* perspectives on values and equity including stages of development and distributional concerns; and *transition* frameworks which focus on the processes and actors involved in major technological and social transitions. These need to be complemented by a fourth set of approaches which shine more light on *psychological/behavioural and political* factors. All these frameworks are relevant, and together they point to the multiple perspectives and actions required if the positive drivers of emission reduction summarised in Section 4 are to outweigh the barriers and overcome the constraints.

1.7.1 Aggregated Approaches: Economic Efficiency and Global Dynamics of Mitigation

Some of the most established and influential approaches to understanding the *aggregate* causes and consequences of climate change and mitigation across societies, draw upon economic theories and modelling to generate global emission pathways in the absence of climate policies and to study alternative mitigation pathways (described in detail in Section 3.2.5, and Appendix 3). The underlying economic concepts aggregate wealth or other measures of welfare based on utilitarian ethical foundations, and in most applications, a number of additional assumptions detailed in AR5 (Chapters 2 and 3).

1.7.1.1 Cost-benefit Analysis and Cost-effectiveness Analysis

Such global aggregate economic studies coalesce around two main questions. One, as pioneered by Nordhaus (1992, 2008) attempts to monetise overall climate damages and mitigation costs so as to strike a 'cost-benefit optimum' pathway. More detailed and empirically-grounded 'cost-effectiveness analysis' explores pathways that would minimise mitigation costs (Ekholm 2014; IPCC 2014a Section 2.5; Weyant 2017) for given targets (e.g., as agreed in international negotiations, see Section 3.2 in Chapter 3). Both approaches recognise that resources are limited and climate change competes with other priorities in government policymaking, and are generally examined with some form of Integrated Assessment Model (IAM) (Section 1.5 and Appendix III). Depending on the regional disaggregation of the modelling tools used and on the scope of the analyses, these studies may or may not address distributional aspects within and across nations associated with climate policies (Bauer et al. 2020).

For at least 10 to 15 years after the first computed global cost-benefit estimate (Nordhaus 1992), the dominant conclusions from these different approaches seemed to yield very different recommendations, with cost-benefit studies suggesting lenient mitigation compared to the climate targets typically recommended from scientific risk assessments (Weyant 2017). Over the past 10 to 15 years, literature has made important strides towards reconciling these two approaches, both in the analytic methods and the conclusions arising.

Damages and risks. Incorporating impacts which may be extremely severe but are uncertain (known as 'fat tails' (Weitzman 2009, 2011)), strengthens the economic case for ambitious action to avoid risks of extreme climate impacts (Ackerman et al. 2010; Fankhauser et al. 2013; Dietz and Stern 2015). The salience of risks has also been amplified by improved understanding of climate 'tipping points' (Lontzek et al. 2015; Lenton et al. 2019); valuations should reflect that cutting emissions reduces not only average expected damages, but also the risk of catastrophic events (IWG 2021).

Discounting. The role of time discounting in weighting future climate change impacts against today's costs of mitigating emissions has been long recognised (Weitzman 1994, 2001; Nordhaus 2007; Stern 2007; Dasgupta 2008). Its importance is underlined in analytical Integrated Assessment Models (IAMs) (Golosov et al. 2014; van den Bijgaart et al. 2016; van der Ploeg and Rezai 2019) (Annex III). Economic

literature suggests applying risk-free, public, and long-term interest rates when evaluating overall climate strategy (Weitzman 2001; Dasgupta 2008; Arrow et al. 2013; Groom and Hepburn 2017). Expert elicitations indicate values around 2% (majority) to 3% (Drupp et al. 2018). This is lower than in many of the studies reviewed in earlier IPCC assessments, and many IAM studies since, and by increasing the weight accorded to the future would increase current 'optimal effort'. The US Interagency Working Group on the Social Cost of Carbon used 3% as its central value (IAWG 2016; Li and Pizer 2018; Adler et al. 2017). Individual projects may require specific risk adjustments.

Distribution of impacts. The economic damages from climate change at the nationally aggregated and sub-national level are very diverse (Moore et al. 2017; Ricke et al. 2018; Carleton et al. 2020). A 'global damage function' necessarily implies aggregating impacts across people and countries with different levels of income, and over generations, a process which obscures the strategic considerations that drive climate policymaking (Keohane and Oppenheimer 2016). Economics acknowledges there is no single, objectively defined 'social welfare function' (IPCC 1995, 2014a). This applies also to the distribution of responses: both underline the relevance of equity (next section) and global negotiations to determine national and collective objectives.

Obvious limitations arise from these multiple difficulties in assessing an objective, globally acceptable single estimate of climate change damages (e.g., Arrow et al. 2013; Pindyck 2013; Auffhammer 2018; Stern et al. 2021), with some arguing that agreement on a specific value can never be expected (Rosen and Guenther 2015; Pezzey 2018). A new generation of cost-benefits analysis, based on projections of actual observed damages, results in stronger mitigation efforts as optimal (Glanemann et al. 2020; Hänsel et al. 2020). Overall, the combination of improved damage functions with the wider consensus on low discount rates (as well as lower mitigation costs due to innovation) has increasingly yielded 'optimal' results from benefit-cost studies in line with the range established in the Paris Agreement (Cross-Working Group Box 1 in Chapter 3).

Hybrid cost-benefit approaches that extend the objective of the optimisation beyond traditional welfare, adding some form of temperature targets as in Llavador et al. (2015) and Held (2019) also represent a step in bridging the gap between the two approaches and result in proposed strategies much more in line with those coming from the cost-effectiveness literature. Approaching from the opposite side, cost-effectiveness studies have looked into incorporating benefits from avoided climate damages, to improve the assessment of net costs (Drouet et al. 2021).

Cost-benefit IAMs utilise damage functions to derive a social cost of CO₂ emissions' (SCC – the additional cost to society of a pulse of CO₂ emissions). One review considered that 'the best estimate' of the optimal (near-term) level 'still ranges from a few tens to a few hundreds of dollars per ton of carbon' (Tol 2018), with various recent studies in the hundreds, taking account of risks (Taconet et al. 2019), learning (Ekholm 2018) and distribution (Ricke et al. 2018). In addition to the importance of uncertainty/risk, aggregation, and realistic damage functions as noted, on which some progress has been made,

some reviews additionally critique how IAMs represent abatement costs in terms of energy efficiency and innovation (e.g., Farmer et al. 2015; Rosen and Guenther 2015; Keen 2021) (Sections 1.7.3 and 1.7.4). IAMs may better reflect associated 'rebound' at system level (Saunders et al. 2021), and inefficient implementation would raise mitigation costs (Homma et al. 2019); conversely, *co-benefits* – most extensively estimated for air quality, valued at a few tens of USD per tCO₂-eq across 16 studies (Karlsson et al. 2020) – complement global with additional local benefits (Table 1.2).

Whereas many of these factors affect primarily cost-benefit evaluation, discounting also determines the cost-effective trajectory: Emmerling et al. (2019) find that, for a remaining budget of 1000 GtCO₂, reducing the discount rate from 5% to 2% would more than double current efforts, limit 'overshoot', greatly reduce a late rush to negative emissions, and improve intergenerational justice by more evenly distributing policy costs across the 21st century.

1.7.1.2 Dynamic Efficiency and Uncertainty

Care is required to clarify what is optimised (Dietz and Venmans 2019). Optimising a path towards a given temperature goal *by a fixed date* (e.g., 2100) gives time-inconsistent results backloaded to large, last-minute investment in carbon dioxide removal (CDR). 'Cost-effective' optimisations generate less initial effort than *equivalent* cost-benefit models (Dietz and Venmans 2019; Gollier 2021) as they do not incorporate benefits of reducing impacts earlier.

'Efficient pathways' are affected by inertia and innovation. Inertia implies amplifying action on long-lived investments and infrastructure that could otherwise lock-in emissions for many decades (Vogt-Schilb et al. 2018; Baldwin et al. 2020). Chapter 3 (Section 3.5) discusses interactions between near-, medium- and long-term actions in global pathways, particularly vis-à-vis inertia. Also, to the extent that early action induces low-carbon innovation, it 'multiplies' the optimal effort (for given damage assumptions), because it facilitates subsequent cheaper abatement. For example, a 'learning-by-doing' analysis concludes that early deployment of expensive PV was of net global economic benefit, due to induced innovation (Newbery 2018).

Research thus increasingly emphasises the need to understand climate transformation in terms of dynamic, rather than static, efficiency (Gillingham and Stock 2018). This means taking account of inertia, learning and various additional sources of 'path-dependence'. Including induced innovation in stylised IAMs can radically change the outlook (Acemoglu et al. 2012, 2016), albeit with limitations (Pottier et al. 2014); many more detailed-process IAMs now do include endogenous technical change (as reviewed in Yang et al. 2018 and Grubb et al. 2021b) (Annex III).

These dynamic and uncertainty effects typically justify greater upfront effort (Kalkuhl et al. 2012; Bertram et al. 2015), including accelerated international diffusion (Schultes et al. 2018), and strengthen optimal initial effort in cost-benefit models (Baldwin et al. 2020; Grubb et al. 2021b). Approaches to risk premia common in finance would similarly amplify the initial mitigation effort, declining as uncertainties reduce (Daniel et al. 2019).

1.7.1.3 Disequilibrium, Complex Systems and Evolutionary Approaches

Other approaches to aggregate evaluation draw on various branches of intrinsically non-equilibrium theories (e.g., Chang 2014). These including long-standing theories from the 1930s (e.g., Schumpeter 1934; Keynes 1936) to understand situations of structurally underemployed resources, potential financial instabilities (Minsky 1986), and related economic approaches which emphasise time dimensions (e.g., recent reviews in Legrand and Hagemann 2017; Stern 2018). More recently developing have been formal economic theories of endogenous growth building on, for example, Romer (1986), and developments of Schumpeterian creative destruction (Aghion et al. 2021) and evolutionary economic theories which abandon any notion of full or stable resource utilisation even as a reference concept (Nelson and Winter 1982; Freeman and Perez 1988; Carlsson and Stankiewicz 1991; Freeman and Louçã 2001; Perez 2001).

The latter especially are technically grounded in complex system theories (e.g., Arthur 1989, 1999; Beinhocker 2007; Hidalgo and Hausmann 2009). These take inherently dynamic views of economies as continually evolving systems with continuously unfolding and path-dependent properties, and emphasise uncertainty in contrast to any predictable or default optimality. Such approaches have been variously applied in policy evaluation (Walton 2014; Moore et al. 2018), and specifically for global decarbonisation (e.g., Barker and Crawford-Brown 2014) using global simulation models. Because these have no natural reference 'least lost' trajectory, they illustrate varied and divergent pathways and tend to emphasise the diversity of possibilities and relevant policies, particularly linked to innovation and potentially 'sensitive intervention points' (Farmer et al. 2019) (Section 1.7.3). They also illustrate that different representations of innovation and financial markets together can explain why estimated impacts of mitigation on GDP can differ very widely (potentially even in sign), between different model types (Chapter 15, Section 15.6.3 and Box 15.7).

1.7.2 Ethical Approaches

Gardiner's (2011) book on climate change as 'The Perfect Moral Storm' identified three 'tempests'. Its *global* dimension, in a world of sovereign states which have only fragmentary responsibility and control, makes it 'difficult to generate the moral consideration and necessary political will'. Its impacts are *intergenerational* but future generations have no voice in contemporary affairs, the usual mechanism for addressing distributional injustices, amplified by the intrinsic inequity of wealthy big emitters impacting particularly poorer victims. He argues that these are exacerbated by a third, *theoretical* failure to acknowledge a central need for 'moral sensitivity, compassion, transnational and transgenerational care, and other forms of ethical concern to rise to the surface' to help guide effective climate action. As noted in Section 1.4.6, however, equity and ethics are both a driver of and constraint on mitigation.

1.7.2.1 Ethics and Values

A large body of literature examines the critical role of values, ethics, attitudes, and behaviours as foundational frames for understanding and assessing climate action, sustainable development and societal transformation (IPCC 2014a Chapter 3). Most of this work is offered as a counterpoint or critique to mainstream literature's focus on the safeguarding of economic growth of nations, corporations and individuals (Castree 2017; Gunster 2017). These perspectives highlight the dominance of economic utilitarianism in western philosophical thought as a key driver for unsustainable consumption and global environmental change (Hoeing et al. 2015; Popescu 2016).

Entrenching alternative values that promote deep decarbonisation, environmental conservation and protection across all levels of society is then viewed as foundational component of climate-resilient and sustainable development and for achieving human rights, and a safe climate world (Evensen 2015; Jolly et al. 2015; Popescu 2016; Tàbara et al. 2019). The UN Human Rights Office of the High Commissioner has highlighted the potentially crucial role of human rights in relation to climate change (UNHCR 2018). While acknowledging the role of policy, technology, and finance, the 'managerialist' approaches, that emphasise 'technical governance' and fail to challenge the deeper values that underpin society, may not secure the deep change required to avert dangerous climate change and other environmental challenges (Hartzell-Nichols 2014; Steinberger et al. 2020).

Social justice perspectives emphasise the distribution of responsibilities, rights, and mutual obligations between nations in navigating societal transformations (Gawel and Kuhlicke 2017; Leach et al. 2018; Patterson et al. 2018). Current approaches to climate action may fail to match what is required by science because they tend to circumvent constraints on human behaviour, especially constraints on economic interest and activity. Related literature explores governance models that are centred on environmental limits, planetary boundaries and the moral imperative to prioritise the poor in earth systems governance (Carley and Konisky 2020; Kashwan et al. 2020), with emphasis on trust and solidarity as foundations for global cooperation on climate change (Jolly et al. 2015). A key obstacle is that the economic interests of states tend to be stronger than the drivers for urgent climate action (Bain 2017).

Short-term interests of stakeholders are acknowledged to impede the reflection and deliberation needed for climate mitigation and adaptation planning (Hackmann 2016; Sussman et al. 2016; Schlosberg et al. 2017; Herrick 2018). Situationally appropriate mitigation and adaptation policies at both national and international level may require more ethical self-reflection (Herrick 2018), including self-transcendent values such as universalism and benevolence, and moderation which are positively related to pro-environmental behaviours (Jonsson and Nilsson 2014; Katz-Gerro et al. 2015; Braito et al. 2017; Howell and Allen 2017).

Another strong theme in the literature concerns recognition of interdependence including the intimate relationship between humans and the non-human world (Hannis 2016; Gupta and Racherla 2018; Howell and Allen 2017), with such ecological interdependence

offered as an organising principle for enduring transformation to sustainability. A key policy implication of this is moving away from valuing nature only in market and monetary terms to strongly incorporating existential and non-material value of nature in natural-resource accounting (Neuteleers and Engelen 2015; Shackleton et al. 2017; Himes-Cornell et al. 2018). There has been increasing attention on ways to design climate policy frameworks to help reconcile ecological virtue (with its emphasis on the collective) with individual freedoms and personal autonomy (Kasperbauer 2016; Nash et al. 2017; Xiang et al. 2019). In such a framework, moderation, fairness, and stewardship are all understood and promoted as directly contributing to the 'good life'. Such approaches are deemed vital to counteract tendencies to 'free ride', and to achieve behavioural changes often associated with tackling climate change (Section 5.2.1).

Some literature suggests that attention to emotions, especially with regards to climate communication, could help societies and individuals act in ways that focus less on monetary gain and more on climate and environmental sustainability (Bryck and Ellis 2016; Chapman et al. 2017; Nabi et al. 2018; Zummo et al. 2020).

1.7.2.2 Equity and Representation: International Public Choice Across Time and Space

Equity perspectives highlight three asymmetries relevant for climate change (Okereke and Coventry 2016; Okereke 2017) (Section 1.4.6). *Asymmetry in contribution* highlights different contributions to climate change both in historical and current terms, and applies both within and between states as well as between generations (Caney 2016; Heyward and Roser 2016). *Asymmetry in impacts* highlights the fact that the damages will be borne disproportionately across countries, regions, communities, individuals and gender; moreover, it is often those that have contributed the least that stand to bear the greatest impact of climate change (IPCC 2014a; Shi et al. 2016). *Asymmetry in capacity* highlights differences of power between groups and nations to participate in climate decision and governance, including the capacity to implement mitigation and adaptation measures.

If attention is not paid to equity, efforts designed to tackle climate change may end up exacerbating inequities among communities and between countries (Heffron and McCauley 2018). The implication is that to be sustainable in the long run, mitigation involves a central place for consideration of justice, both within and between countries (Chapters 4 and 14). Arguments that the injustices following from climate change are symptomatic of a more fundamental structural injustice in social relations, are taken to imply a need to address the deeper inequities within societies (Routledge et al. 2018).

Climate change and climate policies affect countries and people differently, with the poor likely to be more affected (Section 1.6.1). Ideas of Just Transitions (outlined in Section 1.8.2.) often have a national focus in the literature, but also imply that mitigation should not increase the asymmetries between rich and poor countries, implying a desire for transitions which seek to reduce (or at least avoid adverse) distributional affects. Thus, it comes into play in the timing of zero emissions (Chapters 3 and 14). International climate finance in which rich countries finance mitigation and adaptation in

poor countries is also essential for reducing the asymmetries between rich and poor countries (Section 1.6.3 and Chapter 15).

Equity across generations – the distribution between the present and future generations – also matters. One aspect is discounting (Section 1.7.1). Another approach has been to study the burdens on each generation following from the transition to low-carbon economies (IPCC 2014a Chapter 3) (Cross-Working Group Box 3 in Chapter 12). Suggestions include shifting more investments into 'natural capital', so that future generations will inherit less physical capital but a better environment, or financing mitigation efforts today using governmental debt redeemed by future generations (Heijdra et al. 2006; Broome 2012; Karp and Rezai 2014; Hoel et al. 2019).

1.7.3 Transition and Transformation Processes

This report uses the term *transition* as the process, and *transformation* as the overall change or outcome, of large-scale shifts in technological, economic and social systems, called socio-technical systems in the innovation literature. Typically, new technologies, ideas and associated systems initially grow slowly in absolute terms, but may then 'take-off' in a phase of exponential growth as they emerge from a position of niche into mainstream diffusion, as indicated by the 'S-curve' growth in Figure 1.7 (lower panel). These dynamics arise from interactions between innovation (in technologies, companies and other organisations), markets, infrastructure and institutions, at multiple levels (Geels et al. 2017; Kramer 2018). Consequently, interdisciplinary perspectives are needed (Turnheim et al. 2015; Geels et al. 2016; Hof et al. 2020). Beyond aggregated economic perspectives on dynamics (Section 1.7.1.2), these emphasise the multiple actors and processes involved.

Technological Innovation Systems (TIS) frameworks (Section 16.4) focus on processes and policies of early innovation and 'emergence', which combine experimentation and commercialisation, involving *Strategic Niche Management* (Rip and Kemp 1998; Geels and Raven 2006). Literatures on the wider processes of transition highlight different stages (e.g., Cross-Chapter Box 12 in Chapter 16) and scales across three main levels, most generally termed *micro*, *meso* and *macro* (Rotmans et al. 2001).

The widely-used *Multi-Level Perspective* or MLP (Geels 2002) identifies the meso level as the established 'socio-technical (ST) regime', a set of interrelated sub-systems which define rules and regulatory structures around existing technologies and practices. The micro level is an ecosystem of varied niche alternatives, and overlaying the ST regime is a macro 'landscape' level. Transitions often start with niche alternatives (Grin et al. 2010; Köhler et al. 2019), which may break through to wider diffusion (second stage in Figure 1.8), especially if external landscape developments 'create pressures on the regime that lead to cracks, tensions and windows of opportunity' (Rotmans et al. 2001; Geels 2010); an example is climate change putting sustained pressure on current regimes of energy production and consumption (Kuzemko et al. 2016). There are continual interactions between landscape, regime and niches, with varied implications for *Transition Management* (Rotmans et al. 2001; Loorbach 2010).

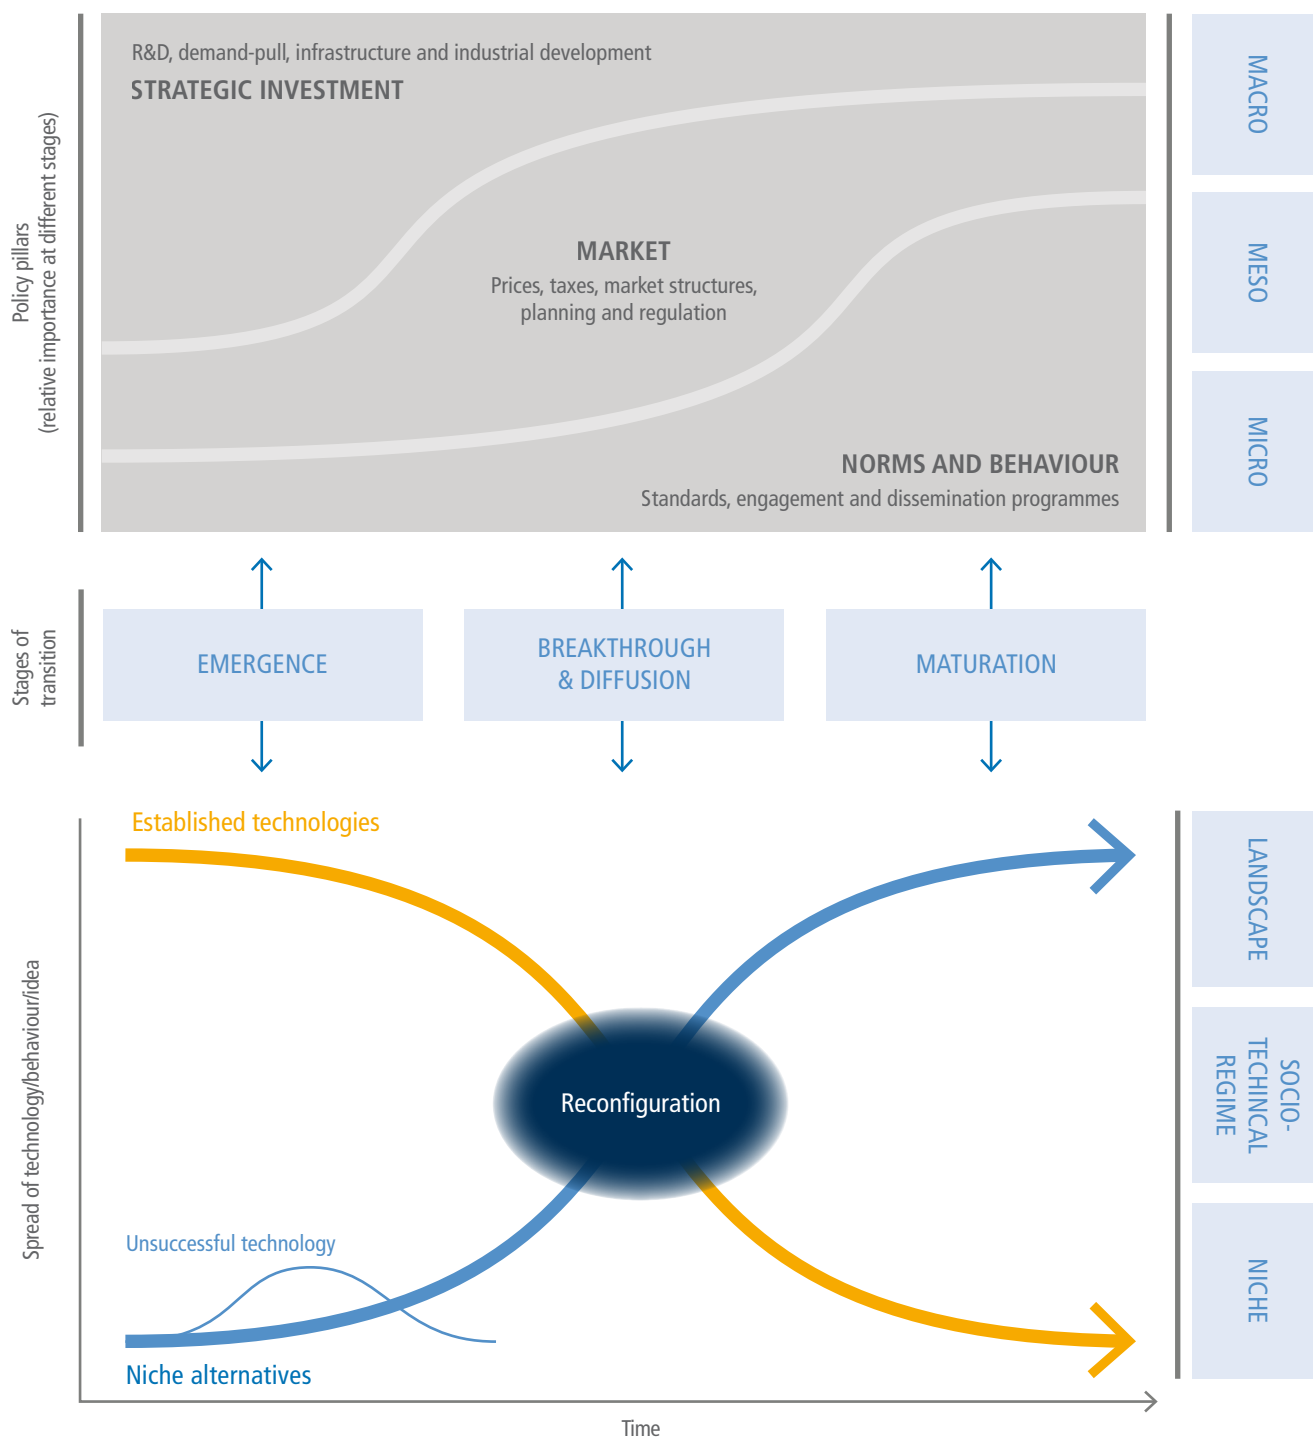

Figure 1.7 | Transition dynamics: levels, policies and processes. Note: the lower panel illustrates growth of innovative technologies or practices, which if successful emerge from niches into an S-shape dynamic of exponential growth. The diffusion stage often involves new infrastructure and reconfiguration of existing market and regulatory structures (known in the literature as the 'socio-technical regime'). During the phase of more widespread diffusion, growth levels off to linear, then slows as the industry and market matures. The processes displace incumbent technologies/practices which decline, initially slowly but then at an accelerating pace. Many related literatures identify three main levels with different characteristics, most generally termed micro, meso and macro. Transitions can be accelerated by policies appropriately targeted, which may be similarly grouped and sequenced (upper panel) in terms of three corresponding pillars of policy (Section 1.7.3): generally all are relevant, but their relative importance differs according to the stage of the transition.

In contrast to standard economic metrics of marginal or smooth change (e.g., elasticities), transition theories emphasise interdisciplinary approaches and the non-linear dynamics, social, economic and environmental aspects of transitions to sustainability (Cherp et al. 2018; Köhler et al. 2018). This may explain persistent tendencies to underestimate the exponential pace of change now being observed in renewable electricity (Chapters 2 and 6) and emerging in mobility (Chapter 10).

Recent decades have seen parallel broadening of economic perspectives and theories. Building also on the New Institutional Economics literatures, Building on the New Institutional Economics literature (Williamson 2000), Grubb et al. (2014, 2015) classify these into three 'domains of economic decision-making' associated with different branches of economic theory, respectively (i) *behavioural and organisational*; (ii) *neoclassical and welfare*; and (iii) *evolutionary and institutional*. Like MLP, these are related to different social and temporal scales, as applied also in studying the 'adaptive finance' in UK electricity transition (Hall et al. 2017). There are significant differences but these approaches all point to understanding the characteristics of different actors, notably, individuals/local actors; larger corporate organisations (public or private); and (mainly) public authorities, each with different decision-making characteristics.

Sustainability may require purposeful actions at the different levels to foster the growth of sustainable technologies and practices, including support for niche alternatives (Grin et al. 2010). The middle level (established 'socio-technical regime') tends to resist major change, reforms generally involve pressures from the other two levels. Thus, transitions can be accelerated by policies appropriately targeting relevant actors at the different levels (Köhler et al. 2019), the foundations for 'three pillars of policy' (Grubb et al. 2014), which logically evolve in the course of transition (Figure 2.6a). Incumbent industries have to adapt if they are to thrive within the growth of new systems. Policy may need to balance existing socio-technical systems with strategic investment and institutional development of the emerging niches (e.g., the maintenance of energy provision and energy security with the development of renewables), and help manage declining industries (Koasidis et al. 2020).

There is usually a social dimension to such transitions. Key elements include capacity to transform (Folke et al. 2010), planning, and interdisciplinarity (Woiwode 2013). The Second World War demonstrated the extent to which crises can motivate (sometimes positive) change across complex social and technical systems, including industry, and agriculture which then doubled its productivity over 15 years (Roberts and Geels 2019b). In practice, climate change may involve a combination of (reactive) transformational adaptation, and (proactive) societal transformation (Feola 2015), the latter seen as reorientation (including values and norms) in a sustainable direction (Section 5.4), including, for example, 'democratisation' in energy systems (Sorman et al. 2020). Business change management principles could be relevant to support positive social change (Stephan et al. 2016). Overall, effective transitions rest on appropriate enabling conditions, which can also link socio-technical transitions to broader development pathways (Cross-Chapter Box 12 in Chapter 16).

Transition theories tend to come from very different disciplines and approaches compared to either economics or other social sciences, with less quantification, notwithstanding evolutionary and complex system models (Section 1.7.1.3). However, a few distinct types of quantitative models of 'socio-technical energy transition' (Li et al. 2015) have emerged. For policy evaluation, transitions can be viewed as processes in which dynamic efficiency (Section 1.7.2) dominates over static allocative efficiency, with potential 'positive intervention points' (Farmer et al. 2019). Given inherent uncertainties, there are obvious risks (e.g., Alic and Sarewitz 2016). All this may make an evaluation framework of *risks and opportunities* more appropriate than traditional cost-benefit (Mercure et al. 2021), and (drawing on lessons from renewables and electric vehicles) create foundations for sector-based international 'positive sum cooperation' in climate mitigation (Sharpe and Lenton 2021).

1.7.4 Approaches From Psychology and Politics of Changing Course

The continued increase in global emissions to 2019, despite three decades of scientific warnings of ever-greater clarity and urgency, motivates growing attention in the literature to the psychological 'faults of our rationality' (Bryck and Ellis 2016), and the political nature of climate mitigation.

1.7.4.1 Psychological and Behavioural Dimensions

The AR5 emphasised that decision processes often include both deliberate ('calculate the costs and benefits') and intuitive thinking, the latter utilising emotion- and rule-based responses that are conditioned by personal past experience, social context, and cultural factors (e.g., Kahneman 2003), and that laypersons tend to judge risks differently than experts – for example, 'intuitive' reactions are often characterised by biases to the status quo and aversion to perceived risks and ambiguity (Kahneman and Tversky 1979). Many of these features of human reasoning create 'psychological distance' from climate change (Spence et al. 2012; Marshall 2014). These can impede adequate personal responses, in addition to the collective nature of the problem, where such problems can take the form of 'uncomfortable knowledge', neglected and so becoming 'unknown knowns' (Sarewitz 2020). These decision processes, and the perceptions that shape them, have been studied through different lenses from psychology (Weber 2016) to sociology (Guilbeault et al. 2018), and media studies (Boykoff 2011). Karlsson and Gilek (2020) identify science denialism and 'decision thresholds' as key mechanisms of delay.

Experimental economics (Allcott 2011) also helps explain why cost-effective energy efficiency measures or other mitigation technologies are not taken up as fast or as widely as the benefits might suggest, including procrastination and inattention, as 'we often resist actions with clear long-term benefits if they are unpleasant in the short run' (Allcott and Mullainathan 2010). Incorporating behavioural and social dynamics in models is required particularly to better represent the demand side (Nikas et al. 2020), for example, Safarzyńska (2018) demonstrates how behavioural

factors change responses to carbon pricing relative to other instruments. A key perspective is to eschew ‘either/or’ between economic and behavioural frameworks, as the greatest effects often involve combining behavioural dimensions (e.g., norms, social influence networks, convenience and quality assurance) with financial incentives and information (Stern et al. 2010). Randomised, controlled field trials can help predict the effects of behavioural interventions (Levitt and List 2009; McRae and Meeks 2016; Gillan 2017). Chapter 5 explores both positive and negative dimensions of behaviour in more depth, including the development of norms and interactions with the wider social context, with emphasis upon the services associated with human well-being, rather than the economic activities per se.

1.7.4.2 Socio-political and Institutional Approaches

Political and institutional dynamics shape climate change responses in important ways, not least because incumbent actors have frequently blocked climate policy (Section 1.4.5). Institutional perspectives probe networks of opposition (Brulle 2019) and emphasise that their ability to block – as well as the ability of others to foster low-carbon transitions – are structured by specific institutional forms across countries (Lamb and Minx 2020). National institutions have widely been developed to promote traditionally fossil fuel-based sectors like electricity and transport as key to economic development, contributing to carbon lock-in (Seto et al. 2016) and inertia (Rosenschöld et al. 2014).

The influence of interest groups on policymaking varies across countries. Comparative political economy approaches tend to find that countries where interests are closely coordinated by governments (‘coordinated market economies’) have been able to generate transformative change more than those with a more arms-length, even combative relationship between interest groups and governments (‘liberal market economies’) (Lachapelle and Paterson 2013; Četković and Buzogány 2016; Zou et al. 2016; Meckling 2018). ‘Developmental states’ often have the capacity for strong intervention but any low-carbon interventions may be overwhelmed by other pressures and very rapid economic growth (Wood et al. 2020a).

Institutional features affecting climate policy include levels and types of democracy (Povitkina 2018), electoral systems, or levels of institutional centralisation (federal vs unitary states, presidential vs parliamentary systems) (Lachapelle and Paterson 2013; Steurer and Clar 2018; Clulow 2019). Countries that have constructed an overarching architecture of climate governance institutions (e.g., cross-department and multi-level coordination, and semi-autonomous climate agencies), are more able to develop the strategic approaches to climate governance needed to foster transformative change (Dubash 2021).

Access of non-governmental organisations (NGOs) to policy processes enables new ideas to be adopted, but too close an NGO-government relation may stifle innovation and transformative action (Dryzek et al. 2003). NGO campaigns on fracking (Neville et al. 2019) or divestment (Mangat et al. 2018) have raised attention to ideas such as ‘stranded assets’ in policy arenas (Green 2018; Piggot

2018; Newell et al. 2020; Paterson 2021). Attempts to depoliticise climate change may narrow the space for democratic participation and contestation, thus impacting policy responses (Swyngedouw 2010, 2011; Kenis and Lievens 2014). Some institutional innovations have more directly targeted enhanced public deliberation and participation, notably in citizens’ climate assemblies (Howarth et al. 2020) and in the use of legal institutions to litigate against those opposing climate action (Peel and Osofsky 2020). This literature shows that transformative pathways are possible within a variety of institutional settings, although institutional innovation will be necessary everywhere to pursue zero carbon transitions (Section 4.4, Chapter 13 and Cross-Chapter Box 12).

Balancing the forces outlined in Section 4.6 in Chapter 4 typically involves building coalitions of actors who benefit economically from climate policy (Levin et al. 2012). Policy stability is critical to enabling long-term investments in decarbonisation (Rietig and Laing 2017; Rosenbloom et al. 2018). Policy design can encourage coalitions to form that sustain momentum by supporting further policy development to accelerate decarbonisation (Roberts et al. 2018), for example, by generating concentrated benefits to coalition members (Bernstein and Hoffmann 2018; Meckling 2019; Millar et al. 2020), as with renewable feed-in tariffs (FiTs) in Germany (Michaelowa et al. 2018). Coalitions may also be sustained by overarching framings, especially to involve actors (e.g., NGOs) for whom the benefits of climate policy are not narrowly economic. However, policy design can also provoke coalitions to oppose climate policy, as in the FiT programme in Ontario (Stokes 2013; Raymond 2020) or the yellow vest protests against carbon taxation in France (Berry and Laurent 2019). The Just Transitions frame can thus also be understood in terms of coalition-building, as well as ethics, as the pursuit of low-carbon transitions which spread the economic benefits broadly, through ‘green jobs’, and the redistributive policies embedded in them both nationally and globally (Healy and Barry 2017; Winkler 2020). Appropriate policy design will be different at different stages of the transition process (Meckling et al. 2017; Breetz et al. 2018).

Integration. Politics is ultimately the way in which societies make decisions – which in turn, reflect diverse forces and assumed frameworks. Effective policy requires understandings which combine economic efficiency, ethics and equity, the dynamics and processes of large-scale transitions, and the role of psychology and politics. No one framework is adequate to such a broad-ranging goal, nor are single tools. Chapter 13 (Figure 13.6) presents a ‘framing’ table for policy instruments depending on the extent to which they focus on mitigation per se or wider socio-economic development, and whether they aim to shift marginal incentives or drive larger transitions. Holistic analysis needs to bridge modelling, qualitative transition theories illuminated by case studies, and practice-based action research (Geels et al. 2016).

These analytic frameworks also point to arenas of potential synergies and trade-offs (when broadly known), and opportunities and risks (when uncertainties are greater), associated with mitigation. This offers theoretical foundations for mitigation strategies which can also generate co-benefits. Climate policy may help to motivate policies with beneficial synergies (such as

Table 1.2 | Potential for net co-benefits arising from synergies and trade-offs, opportunities and risks.

	Positives	Negatives
Broadly known (e.g., air pollution, distributional).	Synergies	Trade-offs
Deep uncertainties (e.g., radical innovations).	Opportunities	Risks
	Select options with maximum synergies, and foster and exploit opportunities.	Ameliorate trade-offs (e.g., revenue redistribution), and minimise or allocate risks appropriately.
Net co-benefits from appropriate mitigation choices		

the consumer cost savings from energy efficiency, better forest management, transitions to cleaner vehicles) and opportunities (such as stimulating innovation), by focusing on options for which the positives outweigh the negatives, or can be made to be, through smart policy (e.g., Karlsson et al. 2020). More broadly, climate concerns may help to attract international investment, and help overcoming bureaucratic or political obstacles to better policy, and support synergies between mitigation, adaptation, and other SDGs, a foundation for shifting development pathways towards sustainability (Chapter 17 and Section 1.6.1).

- *Institutional and political*, including political acceptability, legal and administrative feasibility, and the capacity and governance requirements at different levels to deliver sustained mitigation in the wider context of sustainable development.

The AR6 emphasises that all pathways involve different challenges and require choices to be made. Continuing ‘business as usual’ is still a choice, which in addition to the obvious geophysical risks, involves not making the best use of new technologies, risks of future stranded assets, greater local pollution, and multiple other environmental threats.

1.8 Feasibility and Multi-dimensional Assessment of Mitigation

1.8.1 Building on the SR1.5 Assessment Framework: Feasibility and Enabling Conditions

While previous ARs dealt with the definition of alternative mitigation pathways mostly exploring the technological potentials, the latest research focused on what kind of mitigation pathways are feasible in a broader sense, underlining the multi-dimensional nature of the mitigation challenge. Building on frameworks introduced by Majone (1975) and Gilabert and Lawford-Smith (2012), SR1.5 introduced multi-dimensional approaches to analysing ‘feasibility’ and ‘enabling conditions’, which AR6 develops and applies broadly in relation to six ‘dimensions of feasibility assessment’ (Figure 1.8). Two reflect the physical environment:

- *Geophysical*, not only the global risks from climate change but also, for technology assessment, the global availability of critical resources.
- *Environmental and ecological*, including local environmental constraints and co-benefits of different technologies and pathways.

The other four dimensions correspond broadly to the four analytic frameworks outlined in Section 1.7:

- *Economic*, particularly aggregate economic and financial indicators, and SDGs reflecting different stages and goals of economic development.
- *Socio-cultural*, including particularly ethical and justice dimensions, and social and cultural norms.
- *Technological*, including innovation needs and transitional dynamics associated with new and emergent technologies and associated systems.

The dimensions as listed provide a basis for this assessment both in the sectoral chapters (6–11), providing a common framework for cross-sectoral assessment detailed further in Chapter 12, and in the evaluation of global pathways (Section 3.2). More specific indicators under each of these dimensions offer consistency in assessing the challenges, choices, and enabling requirements facing different aspects of mitigating climate change.

Figure 1.8 also illustrates variants on these dimensions appropriate for evaluating domestic and international policies (Chapters 13 and 14). The SR1.5 (Section 4.4) also introduced a framework of ‘Enabling Conditions for systemic change’, which as illustrated also has key dimensions in common with those of our feasibility assessment. In AR6 these enabling conditions are applied particularly in the context of shifting development pathways (Chapter 4.4).

Some fundamental criteria may span across several dimensions. Most obviously, issues of ethics and equity are intrinsic to the economic, socio-cultural (values, including intergenerational justice) and institutional (e.g., procedural justice) dimensions. Geopolitical issues could also clearly involve several dimensions, for example, concerning the politics of international trade, finance and resource distribution (economic dimension); international versus nationalistic identity (socio-cultural); and multilateral governance (institutional).

In this report, chapters with a strong demand-side dimension also suggest a simple policy hierarchy, reflecting that avoiding wastage – demands superfluous to human needs and wants – can carry benefits across multiple indicators. Consequently, Chapters 5 and 10 organise key actions in a hierarchy of **Avoid** (unnecessary demand) – **Shift** (to less resource-intensive modes) – **Improve** (technologies for existing modes), with a closely-related policy hierarchy in Chapter 9 (buildings).

Figure 1.8 | Feasibility and related dimensions of assessment.

1.8.2 Illustrations of Multi-dimensional Assessment: Lock-in, Policies and 'Just Transition'

The rest of this section illustrates briefly how such multi-dimensional assessment, utilising the associated analytic frameworks, can shed light on a few key issues which arise across many chapters of this assessment.

Carbon Lock-in. The continued rise of global emissions reflects in part the strongly *path-dependent* nature of socio-economic systems, which implies a historic tendency to 'carbon lock-in' (Unruh 2000). An interdisciplinary review (Seto et al. 2016) identifies a dozen main components organised into four types, across the relevant dimensions of assessment as summarised in Table 1.3.

Along with the long lifetime of various physical assets detailed in AR5, AR6 underlines the exceptional degree of path-dependence in urban systems (Chapter 8) and associated buildings (Chapter 9) and transport (Chapter 10) sectors, but it is a feature across almost all the major emitting sectors. The (typically expected) operating lifetimes of existing carbon-emitting assets would involve anticipated emissions (often but inaccurately called 'committed' emissions in the literature), substantially exceeding the remaining carbon budgets associated with 1.5°C pathways (Chapter 2.7). Ongoing GHG-intensive investments, including those from basic industrialisation in poorer countries, are adding to this.

The fact that investors anticipate a level of fossil fuel use that is not compatible with severe climate constraints creates a clear risk of '*stranded assets*' facing these investors (Box 6.2), and others who depend on them, which itself raises issues of equity. A multi-dimensional/multi-framework assessment helps to explain why such investments have continued, even in rich countries, and the consequent risks, and the complexity of shifting such investments in all countries. It may also inform approaches that could exploit path-dependence in clean energy systems, if there is sufficient investment in building up the low-GHG industries, infrastructures and networks required.

Carbon pricing. Appraisal of policy instruments also requires such multi-dimensional assessment. Stern's (2007) reference to climate change as 'the greatest market failure in history' highlights that damages inflicted by climate change are not properly costed in most economic decision-making. Economic perspectives emphasise the value of removing fossil fuel subsidies, and pricing emissions to 'internalise' in economic decision-making the 'external' damages imposed by GHG emissions, and/or to meet agreed goals. Aggregate economic frameworks generally indicate carbon pricing (on principles which extend to other gases) as the most cost-effective way to reduce emissions, notwithstanding various market failures which complicate this logic.⁹ The High-Level Commission on carbon pricing (Stern and Stiglitz 2017) estimated an appropriate range as USD40–80 tCO₂ in 2020, rising steadily thereafter. In practice the extent and level of carbon pricing implemented to date is far lower than this or

⁹ Beyond GHG externalities, Stern (2015) lists such market failures as: inadequate R&D; failures in risk/capital markets; network effects creating coordination failures; wider information failures; and co-benefits.

Table 1.3 | Carbon lock-in – types and key characteristics. Source: adapted from Seto et al. (2016).

Lock-in type	Key characteristics
Economic	<ul style="list-style-type: none"> – Large investments with long lead times and sunk costs, made on the basis of anticipated use of resources, capital, and equipment to pay back the investment and generate profits. – Initial choices account for private but not social costs and benefits.
Socio-cultural, equity and behaviour	<ul style="list-style-type: none"> – Lock-in through social structure (e.g., norms and social processes). – Lock-in through individual decision-making (e.g., psychological processes). – Single, calculated choices become a long string of non-calculated and self-reinforcing habits. – Interrupting habits is difficult but possible (e.g., family size, thermostat setting) to change. – Individuals and communities become dependent on the fossil fuel economy, meaning that change may have adverse distributional impacts.
Technology and infrastructure	<ul style="list-style-type: none"> – Learning-by-doing and scale effects, including the cumulative nature of innovation, reinforces established technologies. – Interaction of technologies and networks (physical, organisational, financial) on which they depend. – Random, unintentional events including network and learning-effect final outcomes (e.g., lock-in to the QWERTY keyboard).
Institutional and political	<ul style="list-style-type: none"> – Powerful economic, social, and political actors seek to reinforce the status quo that favours their interests. – Laws and Institutions, including regulatory structures, are designed to stabilise and lock-in a desired trajectory, and also to provide long-term predictability (socio-technical regimes in transition theories). – Beneficial and intended outcomes for some actors. – Not random chance but intentional choice (e.g., support for renewable electricity in Germany) can develop political consistencies that reinforce a direction of travel.

than most economic analyses now recommend (Section 3.6.1), and nowhere is carbon pricing the only instrument deployed.

A socio-cultural and equity perspective emphasises that the faith in and role of markets varies widely between countries – many energy systems do not in fact operate on a basis of competitive markets – and that because market-based carbon pricing involves large revenue transfers, it must also contend with major distributional effects and political viability (Prinn et al. 2017; Klenert et al. 2018), both domestic (Chapter 13) and international (Chapter 14). A major review (Maestre-Andrés et al. 2019) finds persistent distributional concerns (rich incumbents have also been vocal in using arguments about impacts on the poor (Rennkamp 2019)), but suggests these may be addressed by combining redistribution of revenues with support for low-carbon innovation. Measures could include redistributing the tax revenue to favour of low-income groups or differentiated carbon taxes (Metcalf 2009; Klenert and Mattauch 2016; Stiglitz 2019), including ‘dual track’ approaches (van den Bergh et al. 2020). To an extent though, all these depend on levels of trust, and institutional capacity.

Technological and transitions perspectives in turn find carbon-pricing incentives may only stimulate incremental improvements, but other instruments may be much more effective for driving deeper innovation and transitions (Chapters 14, 15 and 16), whilst psychological and behavioural studies emphasise many factors beyond only pricing (Sections 5.4.1 and 5.4.2). In practice, a wide range of policy instruments are used (Chapter 13).

Finally, in economic theory, negotiations on a common carbon price (or other common policies) may have large benefits (less subject to ‘free riding’) compared to a focus on negotiating national targets (Cramton et al. 2017a). The fact that this has never even been seriously considered (outside some efforts in the EU) may reflect the exceptional sovereignty sensitivities around taxation and cultural differences around the role of markets. However, carbon-pricing concepts can be important outside of the traditional market (‘tax or trading’) applications. A ‘social cost of carbon’ can be used to

evaluate government and regulatory decisions, to compensate for inadequate carbon prices in actual markets, and by companies to reflect the external damage of their emissions and strategic risks of future carbon controls (Zhou and Wen 2020). An agreed ‘social value of mitigation activities’ could form a basic index for underwriting risks in low-carbon investments internationally (Hourcade et al. 2021a).

Thus, practical assessment of carbon pricing inherently needs multi-dimensional analysis. The realities of political economy and lobbying have to date severely limited the implementation of carbon pricing (Mildenberger 2020), leading some social scientists to ask ‘Can we price carbon?’ (Rabe 2018). Slowly growing adoption (World Bank 2019) suggests ‘yes’, but only through complex evolution of efforts: a study of 66 implemented carbon-pricing policies show important effects of regional clustering, international processes, and seizing political windows of opportunity (Skovgaard et al. 2019).

Just Transitions. Finally, whilst ‘transition’ frameworks may explain potential dynamics that could transform systems, a multi-dimensional/multi-framework assessment underlines the motivation for Just Transitions (Sections 1.6.2.3 and 4.5). This can be defined as a transition from a high-carbon to a low-carbon economy which is considered sufficiently equitable for the affected individuals, workers, communities, sectors, regions and countries (Jasanoff 2018; Newell and Mulvaney 2013). As noted, sufficient equity is not only an ethical issue but an enabler of deeper ambition for accelerated mitigation (Klinsky and Winkler 2018; Urpelainen and Van de Graaf 2018; Hoegh-Guldberg et al. 2019). Perception of fairness influences the effectiveness of cooperative action (Winkler et al. 2018), and this can apply to affected individuals, workers, communities, sectors, regions and countries (Newell and Mulvaney 2013; Jasanoff 2018).

A Just Transitions framing can also enable coalitions which integrate low-carbon transformations with concerns for climate adaptation (Patterson et al. 2018). All this explains the emergence of ‘Just Transition Commissions’ in several of the more ambitious developed countries and complex social packages for coal phase-out in Europe

(Sovacool et al. 2019; Green and Gambhir 2020) (Section 4.5), as well as reference to the concept in the PA and its emphasis in the Talanoa Dialogue and Silesia Declaration (Section 1.2.2).

Whilst the broad concepts of Just Transitions have roots going back decades, its specific realisation in relation to climate change is of course complex: Section 4.5 identifies at least eight distinct elements proposed in the literature, even before considering the international dimensions.

1.9 Governing Climate Change

Previous sections have highlighted the multiple factors that drive and constrain climate action, the complex interconnection between climate mitigation and other societal objectives, and the diversity of analytical frames for interpreting these connections. Despite the complexities, there are signs of progress including increased societal awareness, change in social attitudes, policy commitments by a broad range of actors and sustained emission reductions in some jurisdictions. Nevertheless, emission trends at the global level remains incompatible with the goals agreed in the Paris Agreement. Fundamentally, the challenge of how best to urgently scale up and speed up the climate-mitigation effort at all scales – from local to global – to the pace needed to address the climate challenge is that of governance understood as ‘modes and mechanisms to steer society’ (Jordan et al. 2015). The concept of governance encompasses the ability to plan and create the organisations needed to achieve a desired goal (Güney 2017) and the process of interaction among actors involved in a common problem for making and implementing decisions (Kooiman 2003; Huft 2012).

Climate change governance has been projected as conscious transformation at unprecedented scale and speed involving a contest of ideas and experimentation across scales of authority and jurisdiction (Hildén et al. 2017; Kivimaa et al. 2017; Laakso et al. 2017; Gordon 2018; van der Heijden 2018). Yet, there remains a sense that achieving the urgent transition to a low-carbon, climate-resilient and sustainable world requires significant innovation in governance (Hoffmann 2011; Stevenson and Dryzek 2013; Aykut 2016).

Starting from an initial focus on multilateral agreements, climate change governance has long evolved into a complex polycentric structure that spans from the global to national and sub-national levels, with ‘multiple parallel initiatives involving a range of actors at different levels of governance’ (Okereke et al. 2009) and relying on both formal and informal networks and policy channels (Bulkeley et al. 2014; Jordan et al. 2015). At the international level, implementation of the Paris Agreement and the UNFCCC more broadly is proceeding in parallel with other activities in an increasingly diverse landscape of loosely coordinated institutions, constituting ‘regime complex’ (Keohane and Victor 2011), and new cooperative efforts demonstrate an evolution in the shifting authority given to actors at different levels of governance (Chan et al. 2018).

Multi-level governance has been used to highlight the notion that the processes involved in making and implementing decisions on climate

change are no longer the exclusive preserve of government actors but rather involve a range of non-nation state actors such as cities, businesses, and civil society organisations (IPCC 2014a; Bäckstrand et al. 2017; Jordan et al. 2018) (Chapter 13, and Sections 13.3.1 and 13.5.2). Increased multi-level participation of sub-national actors, along with a diversity of other transnational and non-state actors has helped to facilitate increased awareness, experimentation, innovation, learning and achieving benefits at multiple scales. Multi-level participation in governance systems can help to build coalitions to support climate change mitigation policies (Roberts et al. 2018) and fragmentation has the potential to take cooperative and even synergistic forms (Biermann et al. 2009).

However, there is no guarantee that multi-level governance can successfully deal with complex human-ecological systems (York et al. 2005; Biermann et al. 2017; Di Gregorio et al. 2019). Multi-level governance can contribute to an extremely polarised discussion and policy blockage rather than enabling policy innovation (Fisher and Leifeld 2019). A fragmented governance landscape may lead to coordination and legitimacy gaps undermining the regime (Nasiritousi and Bäckstrand 2019). The realities of the ‘drivers and constraints’ detailed in Section 4, the ‘glocal’ nature of climate change, the divided authority in world politics, diverse preferences of public and private entities across the spectrum, and pervasive suspicions of free riding, imply the challenge as how to incrementally deepen cooperation in a polycentric global system, rather than seeking a single, integrated governance (Keohane and Victor 2016).

Crucially, climate governance takes place in the context of embedded power relations, operating in global, national and local contexts. Effective rules and institutions to govern climate change are more likely to emerge where and when power structures and interests favour action. However widespread and enduring cooperation can only be expected when the benefits outweigh the cost of cooperation and when the interests of key actors are sufficiently aligned (Barrett 1994; Finus and Rübelke 2008; Victor 2011; Mainali et al. 2018; Tulkens 2019). Investigating the distribution and role of hard and soft power resources, capacities and power relations within and across different jurisdictional levels is therefore important to uncover hindrances to effective climate governance (Marquardt 2017). Institutions at international and national levels are also critical as they have the ability to mediate the power and interest of actors, and sustain cooperation based on equity and fair rules and outcomes. Governance, in fact, helps to align and moderate the interests of actors as well as to shift perceptions, including the negative, burden-sharing narratives that often accompany discussion about climate action, especially in international negotiations. It is also useful for engaging the wider public and international networks in imagining low-carbon societies (e.g., Levy and Spicer 2013; Milkoreit 2017; Nikoleris et al. 2017; Wapner and Elver 2017; Bengtsson Sonesson et al. 2019; Fatemi et al. 2020). Experimentation also represents an important source of governance innovation and capability formation, linked to global knowledge and technology flows, which could reshape emergent socio-technical regimes and so contribute to alternative development pathways (Berkhout et al. 2010; Roberts et al. 2018; Turnheim et al. 2018; Lo and Castán Broto 2019).

1.10 Conclusions

Global conditions have changed substantially since the IPCC's Fifth Assessment Report in 2014. The Paris Agreement and the SDGs provided a new international context, but global intergovernmental cooperation has been under intense stress. Growing direct impacts of climate change are unambiguous and movements of protest and activism – in countries and transnational organisations at many levels – have grown. Global emissions growth had slowed but not stopped up to 2018/19, albeit with more diverse national trends. Growing numbers of countries have adopted 'net zero' CO₂ and/or GHG emission goals and decarbonisation or low-carbon growth strategies, but the current NDCs to 2030 collectively would barely reduce global emissions below present levels (Section 1.3.3). An unfolding technology revolution is making significant contributions in some countries, but as yet its global impact is limited. Global climate change can only be tackled within, and if integrated with, the wider context of sustainable development, and related social goals including equity concerns. Countries and their populations have many conflicting priorities. Developing countries in particular have multiple urgent needs associated with earlier stages of sustainable development as reflected in the non-climate SDGs. Developed countries are amongst the most unsustainable in terms of overall consumption, but also face social constraints particularly arising from distributional impacts of climate policies.

The assessment of the key drivers for, and barriers against mitigation undertaken in this chapter underscore the complexity and multi-dimensional nature of climate mitigation. Historically, much of the academic analysis of mitigating climate change, particularly global approaches, has focused on modelling costs and pathways, and discussion about 'optimal' policy instruments. Developments since AR5 have continued to highlight the role of a wide range of factors intersecting the political, economic, social and institutional domains. Yet despite such complexities, there are signs of progress emerging from years of policy effort in terms of technology, social attitudes, and emission reductions in some countries, with tentative signs of impact on the trajectory of global emissions. The challenge remains how best to urgently scale up and speed up the climate mitigation effort at all scales – from local to global – to achieve the level of mitigation needed to address the problem as indicated by climate science. A related challenge is how to ensure that mitigation effort and any associated benefits of action are distributed fairly within and between countries and aligned to the overarching objective of global sustainable development. Lastly, globally effective and efficient mitigation will require international cooperation especially in the realms of finance and technology.

Multiple frameworks of analytic assessment, adapted to the realities of climate change mitigation, are therefore required. We identified four main groups. *Aggregate economic* frameworks – including environmental costs or goals, and with due attention to implied behavioural, distributional and dynamic assumptions – can provide insights about trade-offs, cost-effectiveness and policies for delivering agreed goals. *Ethical frameworks* are equally essential to inform both international and domestic discourse and decisions, including the relationship with international (and intergenerational)

responsibilities, related financial systems, and domestic policy design in all countries. Explicit frameworks for analysing *transition and transformation* across multiple sectors need to draw on both socio-technical transition literatures, and those on social transformation. Finally, literatures on *psychology, behaviour and political sciences* can illuminate obstacles that have impeded progress to date and suggest ways to overcome them.

No single analytical framework, or single discipline, on its own can offer a comprehensive assessment of climate change mitigation. Together they point to the relevance of growing literatures and discourses on Just Transitions, and the role of governance at multiple levels. Ultimately all these frameworks are needed to inform the decisions required to deepen and connect the scattered elements of progress to date, and hence accelerate progress towards agreed goals and multiple dimensions of climate change mitigation in the context of sustainable development.

1.11 Knowledge Gaps

Despite huge expansion in the literature (Callaghan et al. 2020), knowledge gaps remain. Modeling still struggles to bring together detailed physical and economic climate impacts and mitigation, with limited representation of financial and distributional dynamics. There are few interdisciplinary tools which apply theories of transition and transformation to questions of economic and social impacts, compounded by remaining uncertainties concerning the role of new technological sets, international instruments, policy and political evaluation.

One scan of future research needs suggests three priority areas (Roberts et al. 2020): (i) human welfare-focused development (e.g., reducing inequality); (ii) how the historic position of states within international power relations conditions their ability to respond to climate change; (iii) transition dynamics and the flexibility of institutions to drive towards low-carbon development pathways. There remain gaps in understanding how international dynamics and agreements filter down to affect constituencies and local implementation. Literature on the potential for supply-side agreements, in which producers agree to restrict the supply of fossil fuels (e.g., Asheim et al. 2019) is limited but gaining increasing academic attention.

Nature is under pressure both at land and at sea, as demonstrated by declining biodiversity (IPBES 2019). Climate policies could increase the pressure on land and oceans (IPCC 2019c,b), with insufficient attention to relationships between biodiversity and climate agreements and associated policies. IPBES aims to coordinate with the IPCC more directly, but literature will be required to support these reports.

Compounding these gaps is the fact that socially oriented, agriculture-related options, where human and non-human systems intersect most obviously, remain under-researched (e.g., Balasubramanya and Stifel 2020). Efforts to engage with policies here, especially framed around ecosystem services, have often neglected their 'practical fitness' in

favour of focusing on their ‘institutional fitness’, which needs to be addressed in future research (Stevenson et al. 2021).

The relative roles of short-term mitigation policies and long-term investments, including government and financial decision-making tools, remains inadequately explored. Strategic investments may include city planning, public transport, EV-charging networks, and CCU/CCS. Understanding how international treaties can increase incentives to make such investments is all the more salient in the aftermath of COVID-19, on which research is necessarily young but rapidly growing. Finally, the economic, institutional and political strategies to close the gap between NDCs, actual implementation, and mitigation goals – informed by the PA and the UNFCCC Global Stocktake – require much further research.

1.12 Roadmap to the Report

This Sixth Assessment Report covers mitigation in five main parts (Figure 1.9), namely: introduction and frameworks; emission trends, scenarios and pathways; sectors; institutional dimensions including national and international policy, financial and technological mitigation drivers; and conclusions.

Chapters 2 to 5 cover the big picture trends, drivers and projections at national and global levels. Chapter 2 analyses emission trends and drivers to date. Chapter 3 presents long-term global scenarios, including the projected economic and other characteristics of mitigation through to the balancing of sources and sinks through the second half of this century, and the implications for global temperature change and risks. Chapter 4 explores the shorter-term prospects including NDCs, and the possibilities for accelerating mitigation out to 2050 in the context of sustainable development at the national, regional and international scales. Chapter 5, a new chapter for IPCC Assessments, focuses upon the role of services and derived demand for energy and land use, and the social dimensions.

Chapters 6 to 12 examine sectoral contributions and possibilities for mitigation. Chapter 6 summarises characteristics and trends in the energy sector, specifically supply, including the remarkable changes in the cost of some key technologies since AR5. Chapter 7 examines the roles of AFOLU, drawing upon and updating the recent Special Report, including the potential tensions between the multiple uses of land. Chapter 8 presents a holistic view of the trends and pressures of urban systems, as both a challenge and an opportunity for mitigation. Chapters 9 and 10 then examine two sectors which entwine with, but go well beyond, urban systems: buildings (Chapter 9) including construction materials and zero-carbon buildings; and transport (Chapter 10), including shipping and aviation and a wider look at mobility as a general service. Chapter 11 explores the contribution of industry, including supply chain developments, resource efficiency/circular economy, and the cross-system implications of decarbonisation for industrial systems. Finally, Chapter 12 takes a cross-sectoral perspective and explores cross-cutting issues like the interactions of biomass energy, food and land, and carbon dioxide removal.

Four chapters then review thematic issues in implementation and governance of mitigation. Chapter 13 explores national and sub-national policies and institutions, bringing together lessons of policies examined in the sectoral chapters, as well as insights from service and demand-side perspectives (Chapter 5), along with governance approaches and capacity-building, and the role and relationships of sub-national actors. Chapter 14 then considers the roles and status of international cooperation, including the UNFCCC agreements and international institutions, sectoral agreements and multiple forms of international partnerships, and the ethics and governance challenges of solar radiation modification. Chapter 15 explores investment and finance, including current trends, the investment needs for deep decarbonisation, and the complementary roles of public and private finance. This includes climate-related investment opportunities and risks (e.g., ‘stranded assets’), linkages between finance and investments in adaptation and mitigation; and the impact of COVID-19. A new chapter on innovation (Chapter 16) looks at technology development, accelerated deployment and global diffusion as systemic issues that hold potential for transformative changes, and the challenges of managing such changes at multiple levels including the role of international cooperation.

Finally, Chapter 17 considers accelerating the transition in the context of sustainable development, including practical pathways for joint responses to climate change and sustainable development challenges. This includes major regional perspectives, mitigation-adaptation interlinkages, and enabling conditions including the roles of technology, finance and cooperation for sustainable development.

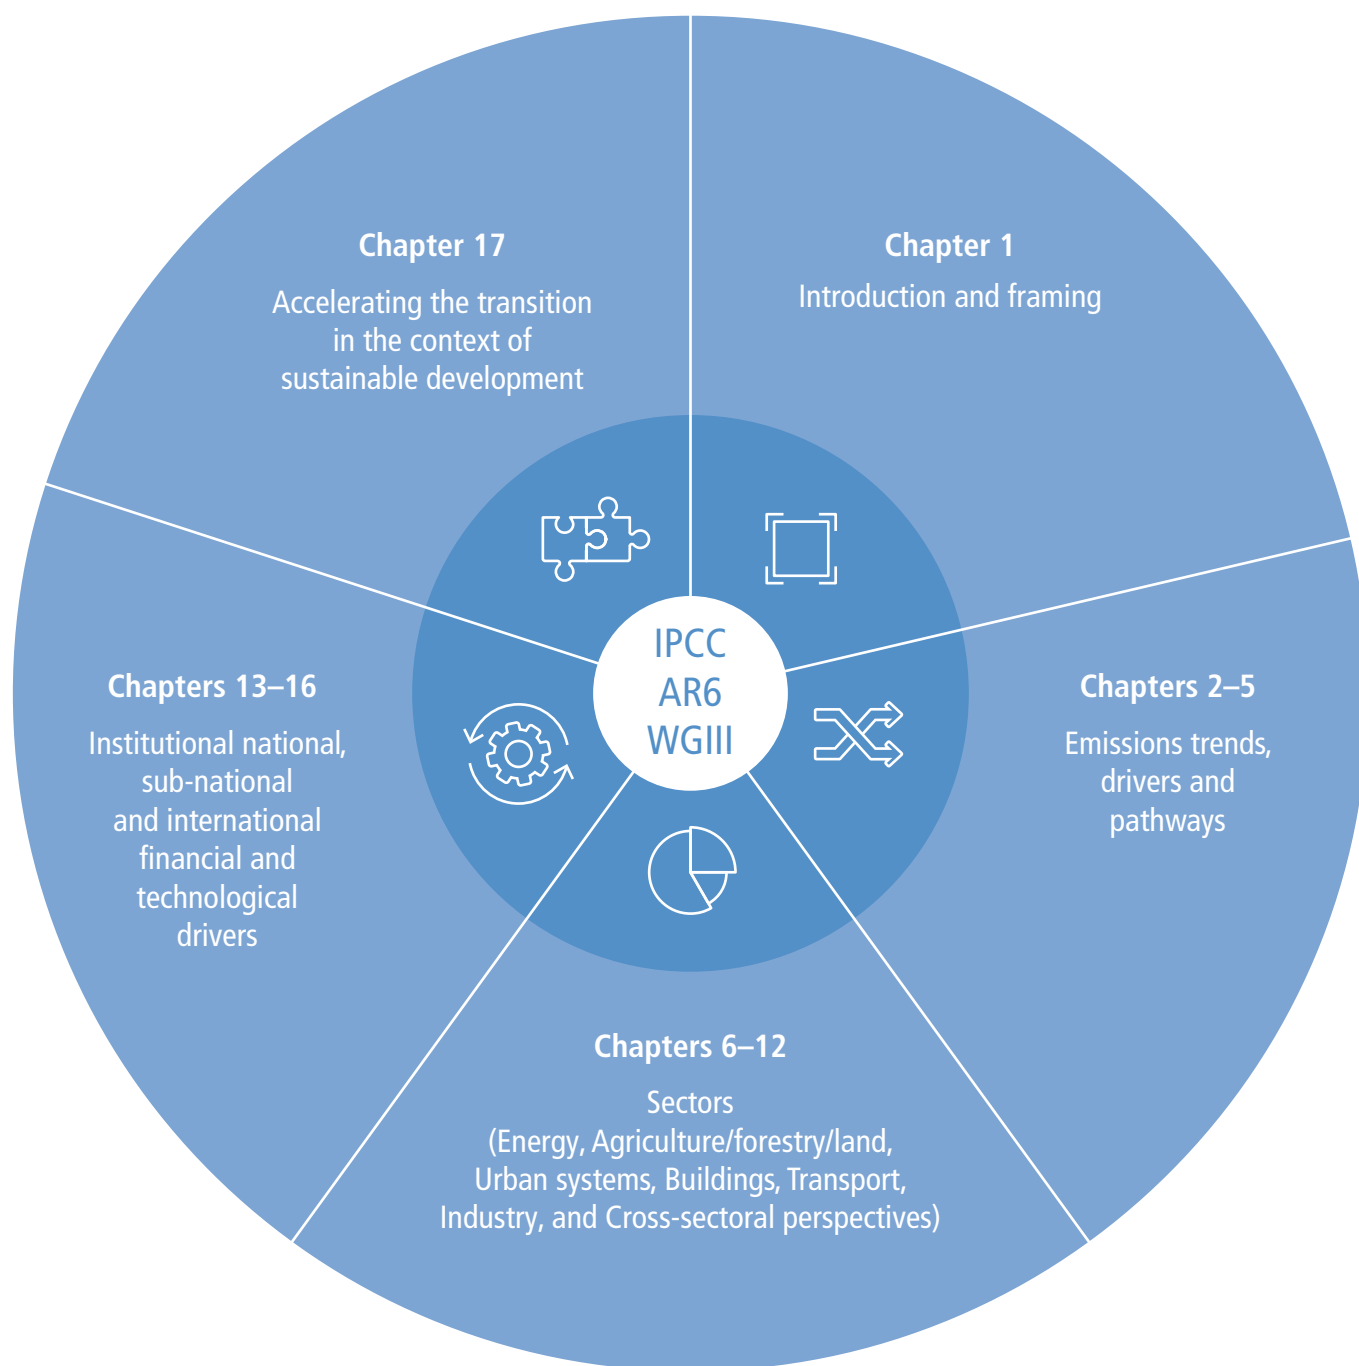

Figure 1.9 | The structure of the AR6 mitigation report.

Frequently Asked Questions (FAQs)

FAQ 1.1 | What is climate change mitigation?

Climate change mitigation refers to actions or activities that limit emissions of greenhouse gases (GHGs) from entering the atmosphere and/or reduce their levels in the atmosphere. Mitigation includes reducing the GHGs emitted from energy production and use (e.g., that reduces use of fossil fuels), and land use, and methods to mitigate warming, for example, by carbon sinks which remove emissions from the atmosphere through land-use or other (including artificial) mechanisms (Sections 12.3 and 14.4.5; see AR6 WGI for physical science, and WGIII Chapter 7 for AFOLU mitigation).

The ultimate goal of mitigation is to preserve a biosphere which can sustain human civilisation and the complex of ecosystem services which surround and support it. This means reducing anthropogenic GHG emissions towards net zero to limit the warming, with global goals agreed in the Paris Agreement. Effective mitigation strategies require an understanding of mechanisms that underpin release of emissions, and the technical, policy and societal options for influencing these.

FAQ 1.2 | Which greenhouse gases (GHGs) are relevant to which sectors?

Anthropogenic GHGs such as carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and fluorinated gases (e.g., hydrofluorocarbons, perfluorocarbons, sulphur hexafluoride) are released from various sources. CO₂ makes the largest contribution to global GHG emissions, but some have extremely long atmospheric lifetimes extending to tens of thousands of years, such as F-gases (Chapter 2).

Different combinations of gases are emitted from different activities. The largest source of CO₂ is combustion of fossil fuels in energy conversion systems like boilers in electric power plants, engines in aircraft and automobiles, and in cooking and heating within homes and businesses (approximately 64% of emissions, Figure SPM.2). Fossil fuels are also a major source of methane (CH₄), the second biggest contributor to global warming. While most GHGs come from fossil fuel combustion, about one quarter comes from land-related activities like agriculture (mainly CH₄ and N₂O) and deforestation (mainly CO₂), with additional emissions from industrial processes (mainly CO₂, N₂O and F-gases), and municipal waste and wastewater (mainly CH₄) (Chapter 2). In addition to these emissions, black carbon – an aerosol that is, for example, emitted during incomplete combustion of fossil fuels – contributes to warming of the Earth's atmosphere, whilst some other short-lived pollutants temporarily cool the surface (IPCC AR6 WGI Section 6.5.4.3).

FAQ 1.3 | What is the difference between 'net zero emissions' and 'carbon neutrality'?

Annex I (Glossary) states that 'carbon neutrality and net zero CO₂ emissions are overlapping concepts' which 'can be applied at the global or sub-global scales (e.g., regional, national and sub-national)'. At the global scale the terms are equivalent. At sub-global scales, net zero CO₂ typically applies to emissions under direct control or territorial responsibility of the entity reporting them (e.g., a country, district or sector); while carbon neutrality is also applied to firms, commodities and activities (e.g., a service or an event) and generally includes emissions and removals beyond the entity's direct control or territorial responsibility, termed 'Scope 3' or 'value chain emissions' (Bhatia et al. 2011).

This means the emissions and removals that should be included are wider for 'neutrality' than for net zero goals, but also that offset mechanisms could be employed to help achieve neutrality through abatement beyond what is possible under the direct control of the entity. Rules and environmental integrity criteria are intended to ensure additionality and avoid double counting of offsets consistent with 'neutrality' claims (see 'carbon neutrality' and 'offset' in Glossary, for detail and a list of criteria).

While the term 'carbon' neutrality in this report is defined as referring specifically to CO₂ neutrality, use of this term in practice can be ambiguous, as some users apply it to neutrality of all GHG emissions. GHG neutrality means an entity's gross emissions of all GHG must be balanced by the removal of an equivalent amount of CO₂ from the atmosphere. This requires the selection of a suitable metric that aggregates emissions from non-CO₂ gases, such as the commonly used GWP100 metric (for a discussion of GHG metrics, see AR6 WGI Box 1.3 and Cross-Chapter Box 2 in Chapter 2 of this report).

Emissions Trends and Drivers

Coordinating Lead Authors:

Shobhakar Dhakal (Nepal/Thailand), Jan Christoph Minx (Germany), Ferenc L. Toth (Austria/Hungary)

Lead Authors:

Amr Abdel-Aziz (Egypt), Maria Josefina Figueroa Meza (Venezuela/Denmark), Klaus Hubacek (the Netherlands/the United States of America), Inge G.C. Jonckheere (Italy/Belgium), Yong-Gun Kim (Republic of Korea), Gregory F. Nemet (the United States of America/Canada), Shonali Pachauri (India), Xianchun C. Tan (China), Thomas Wiedmann (Australia/Germany)

Contributing Authors:

Alaa Al Khourdajie (United Kingdom/Syria), Robbie M. Andrew (Norway), Giovanni Baiocchi (the United States of America/Italy), Igor A. Bashmakov (the Russian Federation), Alexandre Bizeul (France), Kornelis Blok (the Netherlands), Lazarus Chapungu (Zimbabwe), Harry Clark (New Zealand), William Collins (United Kingdom), Annette Cowie (Australia), Monica Crippa (Italy), Hancheng Dai (China), Steven J. Davis (the United States of America), Stéphane de la Rue du Can (the United States of America), Niklas Döbbeling (Germany), Kuishuang Feng (the United States of America), Vivien Fisch-Romito (France), Piers M. Forster (United Kingdom), Jan S. Fuglestad (Norway), Victor García Tapia (Spain), Oliver Geden (Germany), Yong Geng (China), Veronika Ginzburg (the Russian Federation), Giacomo Grassi (Italy/European Union), Baihe Gu (China), Céline Guivarch (France), Diego Guizzardi (Italy), Joanna I. House (United Kingdom), Suzana Kahn Ribeiro (Brazil), Smail Khennas (Algeria/United Kingdom), William F. Lamb (Germany/United Kingdom), Gunnar Luderer (Germany), Giulio Mattioli (Germany/Italy), Francesco Mattion (Italy), Rachid Mrabet (Morocco), Gert-Jan Nabuurs (the Netherlands), Jos Olivier (the Netherlands), Anne Owen (United Kingdom), Glen P. Peters (Norway/Australia), Julia Pongratz (Germany), Roberta Quadrelli (Italy), Andy Reisinger (New Zealand), Keywan Riahi (Austria), Matt Rigby (United Kingdom), Joeri Rogelj (Belgium/United Kingdom), Yamina Saheb (France/Algeria), Marielle Sauniois (France), Roberto Schaeffer (Brazil), Karen C. Seto (the United States of America), Yuli Shan (China), Raphael Slade (United Kingdom), Steven J. Smith (the United States of America), Efisio Solazzo (Italy), Jan Steckel (Germany), Anders Hammer Strømman (Norway), Laixiang Sun (the United States of America), Pouya Taghavi-Moharamli (Canada), Hanqin Tian (the United States of America), Detlef P. van Vuuren (the Netherlands), Dominik Wiedenhofer (Austria)

Review Editors:

Barbara Amon (Germany), David I. Stern (Australia)

Chapter Scientists:

Lazarus Chapungu (Zimbabwe), William F. Lamb (Germany/United Kingdom)

Executive Summary

Global net anthropogenic greenhouse gas (GHG) emissions during the last decade (2010–2019) were higher than at any previous time in human history (*high confidence*). Since 2010, GHG emissions have continued to grow, reaching 59 ± 6.6 GtCO₂-eq in 2019,¹ but the average annual growth in the last decade (1.3%, 2010–2019) was lower than in the previous decade (2.1%, 2000–2009) (*high confidence*). Average annual GHG emissions were 56 ± 6.0 GtCO₂-eq yr⁻¹ for the decade 2010–2019 growing by about 9.1 GtCO₂-eq yr⁻¹ from the previous decade (2000–2009) – the highest decadal average on record (*high confidence*). {2.2.2, Table 2.1, Figure 2.2, Figure 2.5}

Emissions growth has varied, but persisted across all groups of GHGs (*high confidence*). The average annual emission levels of the last decade (2010–2019) were higher than in any previous decade for each group of GHGs (*high confidence*). In 2019, CO₂ emissions were 45 ± 5.5 GtCO₂,² CH₄ 11 ± 3.2 GtCO₂-eq, N₂O 2.7 ± 1.6 GtCO₂-eq and fluorinated gases (F-gases: HFCs, PFCs, SF₆, NF₃) 1.4 ± 0.41 GtCO₂-eq. Compared to 1990, the magnitude and speed of these increases differed across gases: CO₂ from fossil fuel and industry (FFI) grew by 15 GtCO₂-eq yr⁻¹ (67%), CH₄ by 2.4 GtCO₂-eq yr⁻¹ (29%), F-gases by 0.97 GtCO₂-eq yr⁻¹ (254%), and N₂O by 0.65 GtCO₂-eq yr⁻¹ (33%). CO₂ emissions from net land use, land-use change and forestry (LULUCF) have shown little long-term change, with large uncertainties preventing the detection of statistically significant trends. F-gases excluded from GHG emissions inventories such as *chlorofluorocarbons* and *hydrochlorofluorocarbons* are about the same size as those included (*high confidence*). {2.2.1, 2.2.2, Table 2.1, Figures 2.2, 2.3 and 2.5}

Globally, gross domestic product (GDP) per capita and population growth remained the strongest drivers of CO₂ emissions from fossil fuel combustion in the last decade (*robust evidence, high agreement*). Trends since 1990 continued in the years 2010 to 2019 with GDP per capita and population growth increasing emissions by 2.3% and 1.2% yr⁻¹, respectively. This growth outpaced the reduction in the use of energy per unit of GDP (–2% yr⁻¹, globally) as well as improvements in the carbon intensity of energy (–0.3% yr⁻¹) (*high confidence*). {2.4.1, Figure 2.16}

The global COVID-19 pandemic led to a steep drop in CO₂ emissions from fossil fuel and industry (*high confidence*). Global CO₂-FFI emissions dropped in 2020 by about 5.8% (5.1–6.3%) or about 2.2 (1.9–2.4) GtCO₂ compared to 2019. Emissions, however, have rebounded globally by the end of December 2020 (*medium confidence*). {2.2.2, Figure 2.6}

Cumulative net CO₂ emissions of the last decade (2010–2019) are about the same size as the remaining carbon budget for keeping warming to 1.5°C (*medium confidence*). Cumulative net CO₂ emissions since 1850 are increasing at an accelerating rate: about 62% of total cumulative CO₂ emissions from 1850 to 2019 occurred since 1970 (1500 ± 140 GtCO₂); about 43% since 1990 (1000 ± 90 GtCO₂); and about 17% since 2010 (410 ± 30 GtCO₂). For comparison, the remaining carbon budget for keeping warming to 1.5°C with a 67% (50%) probability is about 400 (500) ± 220 GtCO₂ (*medium confidence*). {2.2.2, Figure 2.7; AR6 WGI 5.5; AR6 WGI Table 5.8}

A growing number of countries have achieved GHG emission reductions longer than 10 years – a few at rates that are broadly consistent with climate change mitigation scenarios that limit warming to well below 2°C (*high confidence*). There are at least 18 countries that have reduced CO₂ and GHG emissions for longer than 10 years. Reduction rates in a few countries have reached 4% in some years, in line with rates observed in pathways that limit warming to 2°C (>67%). However, the total reduction in annual GHG emissions of these countries is small (about 3.2 GtCO₂-eq yr⁻¹) compared to global emissions growth observed over the last decades. Complementary evidence suggests that countries have decoupled territorial CO₂ emissions from GDP, but fewer have decoupled consumption-based emissions from GDP. This decoupling has mostly occurred in countries with high per capita GDP and high per capita CO₂ emissions. {2.2.3, 2.3.3, Figure 2.11, Table 2.3, Table 2.4}

Consumption-based CO₂ emissions in Developed Countries and the Asia and Pacific region are higher than in other regions (*high confidence*). In Developed Countries, consumption-based CO₂ emissions peaked at 15 GtCO₂ in 2007, declining to about 13 GtCO₂ in 2018. The Asia and Pacific region, with 52% of current global population, has become a major contributor to consumption-based CO₂ emission growth since 2000 (5.5% yr⁻¹ for 2000–2018); it exceeded the Developed Countries region, which accounts for 16% of current global population, as the largest emitter of consumption-based CO₂. {2.3.2, Figure 2.14}

Carbon intensity improvements in the production of traded products have led to a net reduction in CO₂ emissions embodied in international trade (*robust evidence, high agreement*). A decrease in the carbon intensity of traded products has offset increased trade volumes between 2006 and 2016. Emissions embodied in internationally traded products depend on the composition of the global supply chain across sectors and countries and the respective carbon intensity of production processes (emissions per unit of economic output). {2.3, 2.4}

¹ Emissions of GHGs are weighed by global warming potentials with a 100-year time horizon (GWP100) from the Sixth Assessment Report (Forster et al. 2021). GWP100 is commonly used in wide parts of the literature on climate change mitigation and is required for reporting emissions under the United Nations Framework Convention on Climate Change (UNFCCC). All metrics have limitations and uncertainties. (Cross-Chapter Box 2 in Chapter 2 and Annex II, Part II, Section 8).

² In 2019, CO₂ from fossil fuel and industry (FFI) were 38 ± 3.0 Gt, CO₂ from net land use, land-use change and forestry (LULUCF) 6.6 ± 4.6 Gt.

Developed Countries tend to be net CO₂ emission importers, whereas developing countries tend to be net emission exporters (*robust evidence, high agreement*). Net CO₂ emission transfers from developing to Developed Countries via global supply chains have decreased between 2006 and 2016. Between 2004 and 2011, CO₂ emission embodied in trade between developing countries have more than doubled (from 0.47 to 1.1 Gt) with the centre of trade activities shifting from Europe to Asia. {2.3.4, Figure 2.15}

Emissions from developing countries have continued to grow, starting from a low base of per capita emissions and with a lower contribution to cumulative emissions than Developed Countries (*robust evidence, high agreement*). Average 2019 per capita CO₂-FFI emissions in three developing regions – Africa (1.2 tCO₂ per capita), Asia and Pacific (4.4 tCO₂ per capita), and Latin America and Caribbean (2.7 tCO₂ per capita) – remained less than half that of Developed Countries (9.5 tCO₂ per capita) in 2019. CO₂-FFI emissions in the three developing regions together grew by 26% between 2010 and 2019, compared to 260% between 1990 and 2010, while in Developed Countries emissions contracted by 9.9% between 2010 and 2019, and by 9.6% between 1990 and 2010. Historically, the three developing regions together contributed 28% to cumulative CO₂-FFI emissions between 1850 and 2019, whereas Developed Countries contributed 57% and Least-Developed Countries contributed 0.4%. {2.2.3, Figures 2.9 and 2.10}

Globally, GHG emissions continued to rise across all sectors and subsectors; most rapidly in transport and industry (*high confidence*). In 2019, 34% (20 GtCO₂-eq) of global GHG emissions came from the energy sector, 24% (14 GtCO₂-eq) from industry, 22% (13 GtCO₂-eq) from agriculture, forestry and other land use (AFOLU), 15% (8.7 GtCO₂-eq) from transport and 5.6% (3.3 GtCO₂-eq) from buildings. Once indirect emissions from energy use are considered, the relative shares of industry and buildings emissions rise to 34% and 16%, respectively. Average annual GHG emissions growth during 2010 to 2019 slowed compared to the previous decade in energy supply (from 2.3% to 1.0%) and industry (from 3.4% to 1.4%, direct emissions only), but remained roughly constant at about 2% per year in the transport sector (*high confidence*). Emission growth in AFOLU is more uncertain due to the high share of CO₂-LULUCF emissions (*medium confidence*). {2.4.2, Figure 2.13, Figures 2.16 to 2.21}

Average annual growth in GHG emissions from energy supply decreased from 2.3% for 2000–2009 to 1.0% for 2010–2019 (*high confidence*). This slowing of growth is attributable to further improvements in energy efficiency (annually, 1.9% less energy per unit of GDP was used globally between 2010 and 2019). Reductions in global carbon intensity by $-0.2\% \text{ yr}^{-1}$ contributed further – reversing the trend during 2000 to 2009 ($+0.2\% \text{ yr}^{-1}$) (*medium confidence*). These carbon intensity improvements were driven by fuel switching from coal to gas, reduced expansion of coal capacity, particularly in Eastern Asia, and the increased use of renewables. {2.2.4, 2.4.2.1, Figure 2.17}

GHG emissions in the industry, buildings and transport sectors continue to grow, driven by an increase in the global demand for products and services (*high confidence*). These final demand sectors make up 44% of global GHG emissions, or 66% when the emissions from electricity and heat production are reallocated as indirect emissions to related sectors, mainly to industry and buildings. Emissions are driven by the large rise in demand for basic materials and manufactured products, a global trend of increasing floor space per capita, building energy service use, travel distances, and vehicle size and weight. Between 2010 and 2019, domestic and international aviation were particularly fast growing at average annual rates of +3.3% and +3.4%. Global energy efficiencies have improved in all three demand sectors, but carbon intensities have not. {2.2.4; Figures 2.18 to 2.20}

Providing access to modern energy services universally would increase global GHG emissions by, at most, a few percent (*medium confidence*). The additional energy demand needed to support decent living standards³ for all is estimated to be well below current average energy consumption (*medium evidence, high agreement*). More equitable income distributions can reduce carbon emissions, but the nature of this relationship can vary by level of income and development (*limited evidence, medium agreement*). {2.4.3}

Evidence of rapid energy transitions exists, but only at sub-global scales (*medium evidence, medium agreement*). Emerging evidence since the Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC AR5) on past energy transitions identifies a growing number of cases of accelerated technology diffusion at sub-global scales and describes mechanisms by which future energy transitions may occur more quickly than those in the past. Important drivers include technology transfer and cooperation, intentional policy and financial support, and harnessing synergies among technologies within a sustainable energy system perspective (*medium evidence, medium agreement*). A fast global low-carbon energy transition enabled by finance to facilitate low-carbon technology adoption in developing, and particularly in least-developed countries, can facilitate achieving climate stabilisation targets (*robust evidence, high agreement*). {2.5.2, Table 2.5}

Multiple low-carbon technologies have shown rapid progress since AR5 – in cost, performance, and adoption – enhancing the feasibility of rapid energy transitions (*robust evidence, high agreement*). The rapid deployment and cost decrease of modular technologies like solar, wind, and batteries have occurred much faster than anticipated by experts and modelled in previous mitigation scenarios (*robust evidence, high agreement*). The political, economic, social, and technical feasibility of solar energy, wind energy and electricity storage technologies has improved dramatically over the past few years. In contrast, the adoption of nuclear energy and carbon capture and storage (CCS) in the electricity sector has been slower than the growth rates anticipated in stabilisation scenarios. Emerging evidence since AR5 indicates that small-scale technologies (e.g., solar, batteries) tend to improve faster and be adopted more

³ Decent Living Standards (DLS) – a benchmark of material conditions for human well-being – overlaps with many Sustainable Development Goals (SDGs). Minimum requirements of energy use consistent with enabling well-being for all is between 20 and 50 GJ per capita yr^{-1} depending on the context. {5.2.2, 5.2.2, Box 5.3, Figure 5.6}

quickly than large-scale technologies (nuclear, CCS) (*medium evidence, medium agreement*). {2.5.3, 2.5.4, Figures 2.22 and 2.23}

Robust incentives for investment in innovation, especially incentives reinforced by national policy and international agreements, are central to accelerating low-carbon technological change (*robust evidence, medium agreement*). Policies have driven innovation, including instruments for technology push (e.g., scientific training, research and development) and demand pull (e.g., carbon pricing, adoption subsidies), as well as those promoting knowledge flows and especially technology transfer. The magnitude of the scale-up challenge elevates the importance of rapid technology development and adoption. This includes ensuring participation of developing countries in an enhanced global flow of knowledge, skills, experience, and equipment. Also, technology itself requires strong financial, institutional, and capacity-building support (*robust evidence, high agreement*). {2.5.4, 2.5, 2.8}

The global wealthiest 10% contribute about 36–45% of global GHG emissions (*robust evidence, high agreement*). The global 10% wealthiest consumers live in all continents, with two-thirds in high-income regions and one-third in emerging economies (*robust evidence, medium agreement*). The lifestyle consumption emissions of the middle-income and poorest citizens in emerging economies are between 5 and 50 times below their counterparts in high-income countries (*medium evidence, medium agreement*). Increasing inequality within a country can exacerbate dilemmas of redistribution and social cohesion, and affect the willingness of rich and poor to accept lifestyle changes for mitigation and policies to protect the environment (*medium evidence, medium agreement*) {2.6.1, 2.6.2, Figure 2.25}

Estimates of future CO₂ emissions from existing fossil fuel infrastructures already exceed remaining cumulative net CO₂ emissions in pathways limiting warming to 1.5°C with no or limited overshoot (*high confidence*). Assuming variations in historical patterns of use and decommissioning, estimated future CO₂ emissions from existing fossil fuel infrastructure alone are 660 (460–890) GtCO₂ and from existing and currently planned infrastructure 850 (600–1100) GtCO₂. This compares to overall cumulative net CO₂ emissions until reaching net zero CO₂ of 510 (330–710) Gt in pathways that limit warming to 1.5°C with no or limited overshoot, and 890 (640–1160) Gt in pathways that limit warming to 2°C (<67%) (*high confidence*). While most future CO₂ emissions from existing and currently planned fossil fuel infrastructure are situated in the power sector, most remaining fossil fuel CO₂ emissions in pathways that limit warming to 2°C (<67%) and below are from non-electric energy – most importantly from the industry and transportation sectors (*high confidence*). Decommissioning and reduced utilisation of existing fossil fuel installations in the power sector as well as cancellation of new installations are required to align future CO₂ emissions from the power sector with projections in these pathways (*high confidence*). {2.7.2, 2.7.3, Figure 2.26, Table 2.6, Table 2.7}

A broad range of climate policies, including instruments like carbon pricing, play an increasing role in GHG emissions reductions. The literature is in broad agreement, but the magnitude of the reduction rate varies by the data and methodology used, country, and sector (*robust evidence, high agreement*). Countries with a lower carbon pricing gap (higher carbon price) tend to be less carbon intensive (*medium confidence*). {2.8.2, 2.8.3}

Climate-related policies have also contributed to decreasing GHG emissions. Policies such as taxes and subsidies for clean and public transportation, and renewable policies have reduced GHG emissions in some contexts (*robust evidence, high agreement*). Pollution control policies and legislations that go beyond end-of-pipe controls have also had climate co-benefits, particularly if complementarities with GHG emissions are considered in policy design (*medium evidence, medium agreement*). Policies on AFOLU and sector-related policies such as afforestation can have important impacts on GHG emissions (*medium evidence, medium agreement*). {2.8.4}

2.1 Introduction

As demonstrated by the contribution of Working Group I to the Sixth Assessment Report of the Intergovernmental Panel on Climate Change (AR6 WGI) (IPCC 2021a), greenhouse gas⁴ (GHG) concentrations in the atmosphere and annual anthropogenic GHG emissions continue to grow and have reached a historic high, driven mainly by continued fossil fuels use (Jackson et al. 2019; Friedlingstein et al. 2020; Peters et al. 2020). Unsurprisingly, a large volume of new literature has emerged since AR5 on the trends and underlying drivers of anthropogenic GHG emissions. This chapter provides a structured assessment of this new literature and establishes the most important thematic links to other chapters in this report.

While AR5 has mostly assessed GHG emissions trends and drivers between 1970 and 2010, this assessment focuses on the period 1990–2019 with the main emphasis on changes since 2010. Compared to Chapter 5 in the contribution of WG III to AR5 (Blanco et al. 2014), the scope of the present chapter is broader. It presents the historical background of global progress in climate change mitigation for the rest of the report and serves as a starting point for the assessment of long-term as well as near- and medium-term mitigation pathways in Chapters 3 and 4, respectively. It also provides a systemic perspective on past emissions trends in different sectors of the economy (Chapters 6–12), and relates GHG emissions trends to past policies (Chapter 13) and observed technological development (Chapter 16). There is also a greater focus on the analysis of consumption-based sectoral emissions trends, empirical

Figure 2.1 | Chapter 2 road map and linkages to other chapters. Black arrows show the causal chain driving emissions. Blue lines indicate key linkages to other chapters in this report.

⁴ Greenhouse gases are gaseous constituents of the atmosphere that absorb and emit radiation at specific wavelengths within the spectrum of radiation emitted by the Earth's surface, by the atmosphere itself, and by clouds. This property causes the greenhouse effect. Water vapour (H₂O), carbon dioxide (CO₂), nitrous oxide (N₂O), methane (CH₄), and ozone (O₃) are the primary GHGs in the Earth's atmosphere. Human-made GHGs include sulphur hexafluoride (SF₆), hydrofluorocarbons (HFCs), chlorofluorocarbons (CFCs), and perfluorocarbons (PFCs); see Annex I: Glossary.

evidence of emissions consequences of behavioural choices and lifestyles, and the social aspects of mitigation (Chapter 5). Finally, a completely new section discusses the mitigation implications of existing and planned long-lived infrastructure and carbon lock-in.

Figure 2.1 presents the road map of this chapter. It is a simplified illustration of the causal chain driving emissions along the black arrows. It also highlights the most important linkages to other chapters in this volume (blue lines). The logic of the figure is that the main topic of this chapter is GHG emissions trends (discussed only in this chapter at such level of detail), hence they are at the top of the figure in grey-outlined boxes. The secondary theme is the drivers behind these trends, depicted in the second line of grey-outlined boxes. Four categories of drivers highlight key issues and guide readers to chapters in which more details are presented. Finally, in addition to their own motivations and objectives, climate and non-climate policies and measures shape the aspirations and activities of actors in the main driver categories, as shown in the grey-outlined box below.

Accordingly, the grey-outlined boxes at the top of Figure 2.1 show that the first part of the chapter presents GHG emissions from two main perspectives: their geographical locations; and the places where goods are consumed and services are utilised. A complicated chain of drivers underlie these emissions. They are linked across time, space, and various segments of the economy and society in complex non-linear relationships. Sections shown in the second row of grey-outlined boxes assess the latest literature and improve the understanding of the relative importance of these drivers in mitigating GHG emissions. A huge mass of physical capital embodying immense financial assets and potentially operating over a long lifetime produces vast GHG emissions. This long-lived infrastructure can be a significant hindrance to fast and deep reductions of emissions; it is therefore also shown as an important driver. A large range of economic, social, environmental, and other policies has been shaping these drivers of GHG emissions in the past and are anticipated to influence them in the future, as indicated by the grey-outlined policies box and its manifold linkages. As noted, blue lines show linkages of sections to other chapters that discuss these drivers and their operating mechanisms in detail.

2.2 Past and Present Trends of Territorial GHG Emissions

Total anthropogenic greenhouse gas (GHG) emissions as discussed in this chapter comprise CO₂ emissions from fossil fuel combustion and industrial (FFI) processes,⁵ net CO₂ emissions from land use, land-use change, and forestry (CO₂-LULUCF) (often named FOLU – forestry and other land-use – in previous IPCC reports), methane (CH₄), nitrous oxide (N₂O) and fluorinated gases (F-gases) comprising hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆) as well as nitrogen trifluoride (NF₃). There are other major sources of F-gas emissions that are regulated under the Montreal Protocol such as chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) that also have considerable warming impacts (Figure 2.4), however they are not considered

here. Other substances, including ozone and aerosols, that further contribute climate forcing are only treated very briefly, but a full chapter is devoted to this subject in the Working Group I contribution to AR6 (Szopa et al. 2021a; 2021b).

A growing number of global GHG emissions inventories have become available since AR5 (Minx et al. 2021). However, only a few are comprehensive in their coverage of sectors, countries and gases – namely EDGAR (Emissions Database for Global Atmospheric Research) (Crippa et al. 2021), PRIMAP (Potsdam Real-time Integrated Model for probabilistic Assessment of emissions Paths) (Gütschow et al. 2021a), CAIT (Climate Analysis Indicators Tool) (WRI 2019) and CEDS (A Community Emissions Data System for Historical Emissions) (Hoesly et al. 2018). None of these inventories presently cover CO₂-LULUCF, while CEDS excludes F-gases. For individual gases and sectors, additional GHG inventories are available, as shown in Figure 2.2, but each has varying system boundaries leading to important differences between their respective estimates (Section 2.2.1). Some inventories are compiled bottom-up, while others are produced synthetically and are dependent on other inventories. A more comprehensive list and discussion of different datasets is provided in the Chapter 2 Supplementary Material (2.SM.1) and in Minx et al. (2021).

Across this report, version 6 of EDGAR (Crippa et al. 2021) provided by the Joint Research Centre of the European Commission, is used for a consistent assessment of GHG emissions trends and drivers. It covers anthropogenic releases of CO₂-FFI, CH₄, N₂O, and F-gas (HFCs, PFCs, SF₆, NF₃) emissions by 228 countries and territories and across five sectors and 27 subsectors. EDGAR is chosen because it provides the most comprehensive global dataset in its coverage of sources, sectors and gases. For transparency, and as part of the uncertainty assessment, EDGAR is compared to other global datasets in Section 2.2.1 as well as in the Chapter 2 Supplementary Material (2.SM.1). For individual country estimates of GHG emissions, it may be more appropriate to use inventory data submitted to the United Nations Framework Convention on Climate Change (UNFCCC) under the common reporting format (CRF) (UNFCCC 2021). However, these inventories are only up to date for Annex I countries and cannot be used to estimate global or regional totals. As part of the regional analysis, a comparison of EDGAR and CRF estimates at the country-level is provided, where the latter is available (Figure 2.9).

Net CO₂-LULUCF estimates are added to the dataset as the average of estimates from three bookkeeping models of land-use emissions (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020) following the Global Carbon Project (Friedlingstein et al. 2020). This is different to AR5, where land-based CO₂ emissions from forest fires, peat fires, and peat decay, were used as an approximation of the net-flux of CO₂-LULUCF (Blanco et al. 2014). Note that the definition of CO₂-LULUCF emissions by global carbon cycle models, as used here, differs from IPCC definitions (IPCC 2006) applied in national greenhouse gas inventories (NGHGI) for reporting under the climate convention (Grassi et al. 2018, 2021) and, similarly, from estimates by the Food and Agriculture Organization of the United Nations (FAO) for carbon fluxes on forest land (Tubiello et al. 2021). The conceptual

⁵ Industrial processes relate to CO₂ releases from fossil fuel oxidation and carbonate decomposition.

difference in approaches reflects different scopes. We use the global carbon cycle models' approach for consistency with Working Group I (Canadell et al. 2021) and to comprehensively distinguish natural from anthropogenic drivers, while NGHGI generally report as anthropogenic all CO₂ fluxes from lands considered managed (Section 7.2.2). Finally, note that the CO₂-LULUCF estimate from bookkeeping models as provided in this chapter is indistinguishable from the CO₂ from agriculture, forestry and other land use (AFOLU) as reported in Chapter 7, because the CO₂ emissions component from agriculture is negligible.

The resulting synthetic dataset used here has undergone additional peer review and is publicly available (Minx et al. 2021). Comprehensive information about the dataset as well as underlying uncertainties (including a comparison with other datasets) can be found in the Supplementary Material to this chapter and in Minx et al. (2021).

In this chapter and the report as a whole, different GHGs are frequently converted into common units of CO₂ equivalent (CO₂-eq) emissions using 100-year global warming potentials (GWP100) from AR6 WGI (Forster et al. 2021a). This reflects the dominant use in the scientific literature and is consistent with decisions made by Parties to the Paris Agreement for reporting and accounting of emissions and removals (UNFCCC 2019). Other GHG emissions metrics exist, all of which, like GWP100, are designed for specific purposes and have limitations and uncertainties. The appropriate choice of GHG emissions metrics depends on policy objective and context (Myhre et al. 2013; Kolstad et al. 2015). A discussion of GHG metrics is provided in a Cross-Chapter Box later in the chapter (Cross-Chapter Box 2) and at length in the Chapter 2 Supplementary Material. Throughout the chapter GHG emissions are reported (in GtCO₂-eq) at two significant digits to reflect prevailing uncertainties in emissions estimates. Estimates are subject to uncertainty, which we report for a 90% confidence interval.

2.2.1 Uncertainties in GHG Emissions

Estimates of historical GHG emissions – CO₂, CH₄, N₂O and F-gases – are uncertain to different degrees. Assessing and reporting uncertainties is crucial in order to understand whether available estimates are sufficiently robust to answer policy questions – for example, if GHG emissions are still rising, or if a country has achieved an emission reduction goal (Marland 2008). These uncertainties can be of scientific nature, such as when a process is not sufficiently understood. They also arise from incomplete or unknown parameter information (e.g., activity data, or emission factors), as well as estimation uncertainties from imperfect modelling techniques. There are at least three major ways to examine uncertainties in emission estimates (Marland et al. 2009): (i) by comparing estimates made by independent methods and observations (e.g., comparing atmospheric measurements with bottom-up emissions inventory estimates) (Saunio et al. 2020; Petrescu et al. 2020a and 2020b; Tian et al. 2020); (ii) by comparing estimates from multiple sources and understanding sources of variation (Macknick 2011; Andres et al. 2012; Andrew 2020; Ciais et al. 2021); and (iii) by evaluating estimates from a single source (Hoesly and Smith 2018), for instance via statistical sampling

across parameter values (e.g., Monni et al. 2007; Robert J. Andres et al. 2014; Tian et al. 2019; Solazzo et al. 2021).

Uncertainty estimates can be rather different depending on the method chosen. For example, the range of estimates from multiple sources is bounded by their interdependency; they can be lower than true structural plus parameter uncertainty, or than estimates made by independent methods. In particular, it is important to account for potential bias in estimates, which can result from using common methodological or parameter assumptions, or from missing sources (systemic bias). It is further crucial to account for differences in system boundaries – that is, which emissions sources are included in a dataset and which are not, otherwise direct comparisons can exaggerate uncertainties (Macknick 2011; Andrew 2020). Independent top-down observational constraints are, therefore, particularly useful to bound total emission estimates, but are not yet capable of verifying emission levels or trends (Petrescu et al. 2021a, 2021b). Similarly, uncertainties estimates are influenced by specific modelling choices. For example, uncertainty estimates from studies on the propagation of uncertainties associated with key input parameters (activity data, emissions factors) following the IPCC Guidelines (IPCC 2006) are strongly determined by assumptions on how these parameters are correlated between sectors, countries, and regions (Janssens-Maenhout et al. 2019; Solazzo et al. 2021). Assuming (full) covariance between source categories, and therefore dependence between them, increases uncertainty estimates. Estimates allowing for some covariance as in Solazzo et al. (2021) also tend to yield higher estimates than the range of values from ensemble of dependent inventories (Saunio et al. 2016, 2020).

For this report, a comprehensive assessment of uncertainties is provided in the Supplementary Material (2.SM.2) to this chapter based on Minx et al. (2021). The uncertainties reported here combine statistical analysis, comparisons of global emissions inventories and an expert judgement of the likelihood of results lying outside a defined confidence interval, rooted in an understanding gained from the relevant literature. This literature has improved considerably since AR5, with a growing number of studies that assess uncertainties based on multiple lines of evidence (Saunio et al. 2016, 2020; Tian et al. 2020; Petrescu et al. 2021a, 2021b).

To report the uncertainties in GHG emissions estimates, a 90% confidence interval (5th–95th percentile) is adopted – that is, there is a 90% likelihood that the true value will be within the provided range if the errors have a Gaussian distribution, and no bias is assumed. This is in line with previous reporting in IPCC AR5 (Blanco et al. 2014; Ciais et al. 2014). Note that national emissions inventory submissions to the UNFCCC are requested to report uncertainty using a 95% confidence interval. The use of this broader uncertainty interval implies, however, a relatively high degree of knowledge about the uncertainty structure of the associated data, particularly regarding the distribution of uncertainty in the tails of the probability distributions. Such a high degree of knowledge is not present over all regions, emission sectors and species considered here.

Based on the assessment of relevant uncertainties above, a constant, relative, global uncertainty estimates for GHGs are applied at a 90%

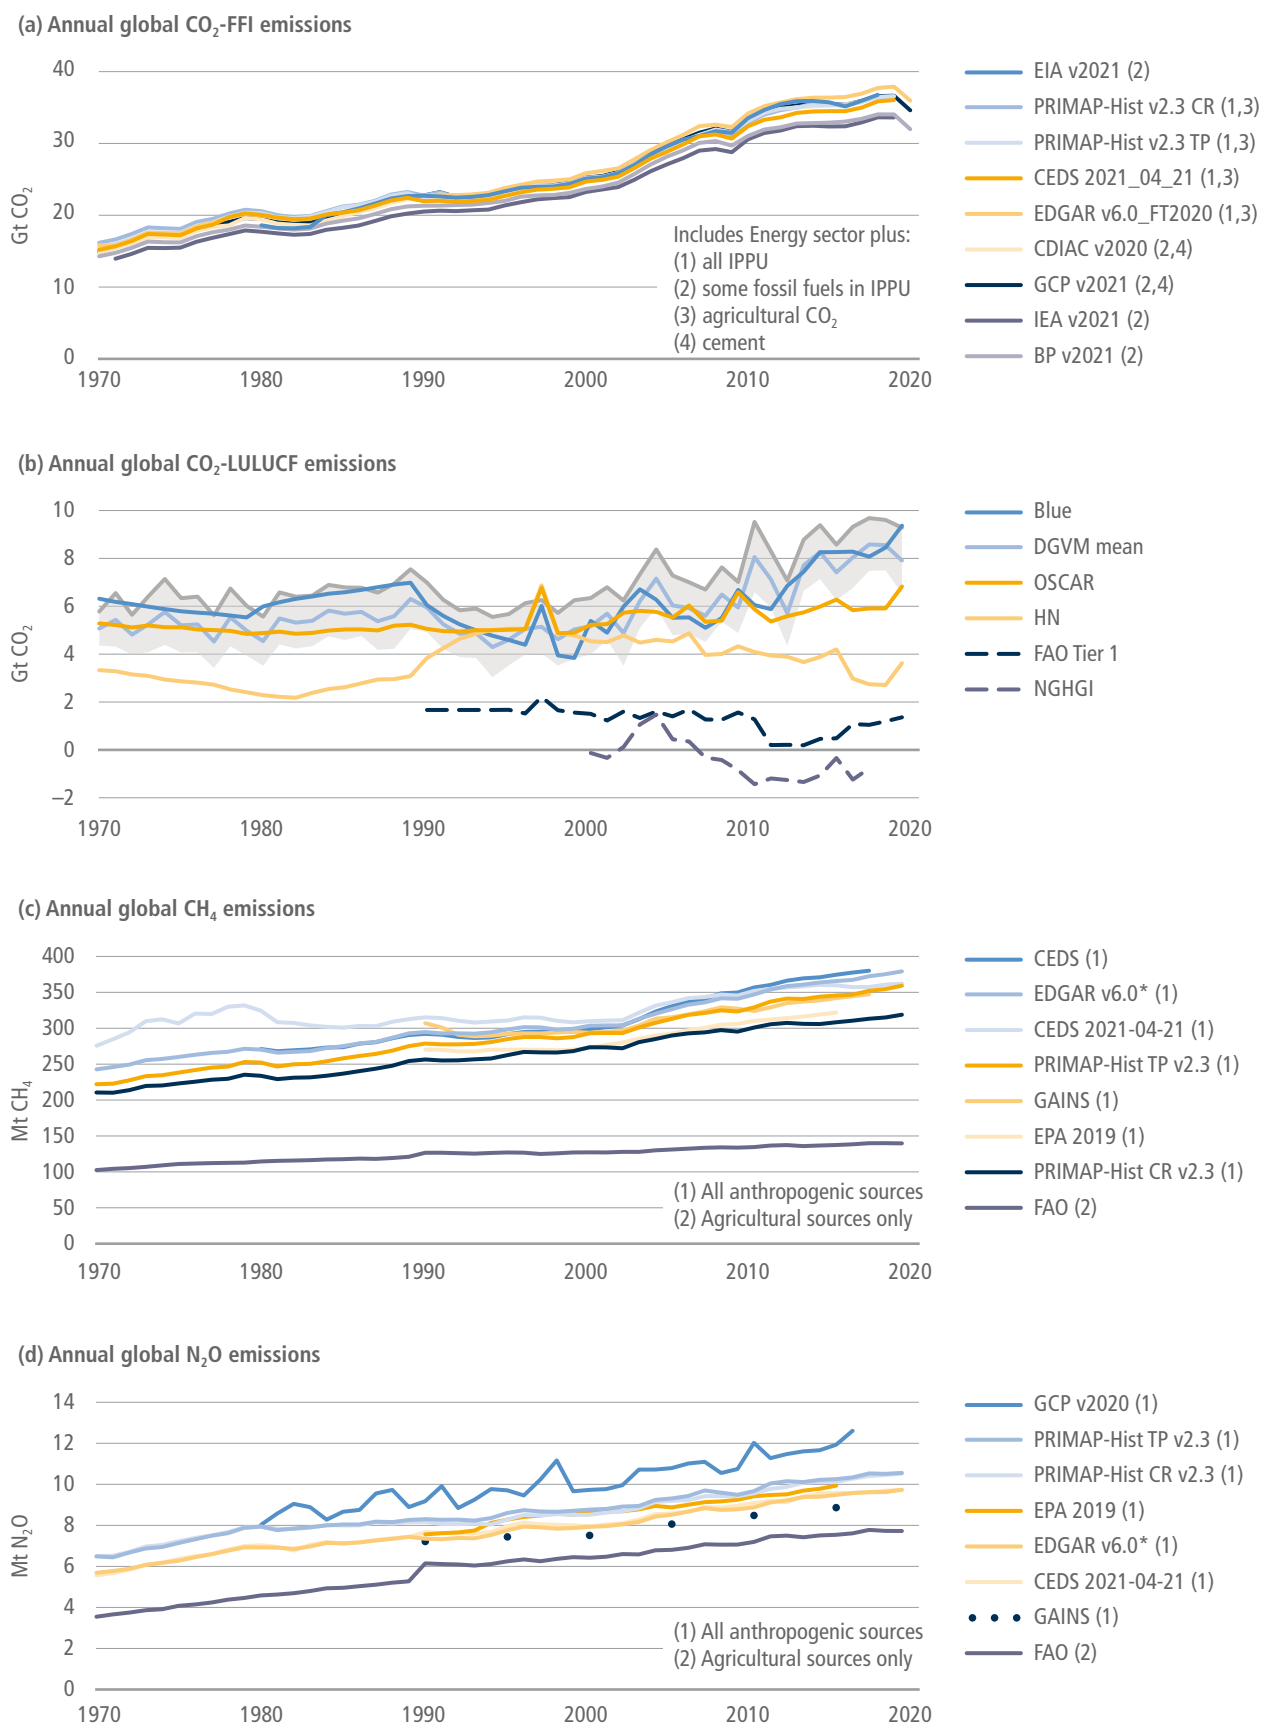

Figure 2.2 | Estimates of global anthropogenic greenhouse gas emissions from different data sources 1970–2019.

Figure 2.2 (continued): Estimates of global anthropogenic greenhouse gas emissions from different data sources 1970–2019. **Panel (a):** CO₂ FFI emissions from: EDGAR – Emissions Database for Global Atmospheric Research (this dataset) (Crippa et al. 2021); GCP – Global Carbon Project (Friedlingstein et al. 2020; Andrew and Peters 2021); CEDS – Community Emissions Data System (Hoesly et al. 2018; O'Rourke et al. 2021); CDIAC Global, Regional, and National Fossil-Fuel CO₂ Emissions (Gilfillan et al. 2020); PRIMAP-hist – Potsdam Real-time Integrated Model for probabilistic Assessment of emissions Paths (Gütschow et al. 2016, 2021b); EIA – Energy Information Administration International Energy Statistics (EIA 2021); BP – BP Statistical Review of World Energy (BP 2021); IEA – International Energy Agency (IEA 2021a, 2021b); IPPU refers to emissions from industrial processes and product use. **Panel (b):** Net anthropogenic CO₂-LULUCF emissions from: BLUE – Bookkeeping of land-use emissions (Hansis et al. 2015; Friedlingstein et al. 2020); DGVM-mean – multi-model mean of CO₂-LULUCF emissions from dynamic global vegetation models (Friedlingstein et al. 2020); OSCAR – an earth system compact model (Friedlingstein et al. 2020; Gasser et al. 2020); HN – Houghton and Nassikas Bookkeeping Model (Houghton and Nassikas 2017; Friedlingstein et al. 2020); for comparison, the net CO₂ flux from FAOSTAT (FAO Tier 1) is plotted, which comprises net emissions and removals on forest land and from net forest conversion (FAOSTAT 2021; Tubiello et al. 2021), emissions from drained organic soils under cropland/grassland (Conchedda and Tubiello 2020), and fires in organic soils (Prosperi et al. 2020), as well as a net CO₂ flux estimate from National Greenhouse Gas Inventories (NGHGI) based on country reports to the UNFCCC, which include land-use change, and fluxes in managed lands (Grassi et al. 2021). **Panel (c):** Anthropogenic CH₄ emissions from: EDGAR (above); CEDS (above); PRIMAP-hist (above); GAINS – The Greenhouse gas – Air pollution Interactions and Synergies Model (Höglund-Isaksson et al. 2020); EPA-2019: Greenhouse gas emission inventory (US-EPA, 2019); FAO – FAOSTAT inventory emissions (Tubiello et al. 2013; Tubiello 2018; FAOSTAT 2021); **Panel (d):** Anthropogenic N₂O emissions from: GCP – global nitrous oxide budget (Tian et al. 2020); CEDS (above); EDGAR (above); PRIMAP-hist (above); GAINS (Winiwarter et al. 2018); EPA-2019 (above); FAO (above). Differences in emissions across different versions of the EDGAR dataset are shown in the Supplementary Material (Figure 2.SM.2). Source: Minx et al. (2021).

2

confidence interval that range from relatively low values for CO₂-FFI ($\pm 8\%$), to intermediate values for CH₄ and F-gases ($\pm 30\%$), to higher values for N₂O ($\pm 60\%$) and CO₂-LULUCF ($\pm 70\%$). Uncertainties for aggregated total GHG emissions in terms of CO₂-eq emissions are calculated as the square root of the squared sums of absolute uncertainties for individual gases (taking F-gases together), using GWP100 to weight emissions of non-CO₂ gases but excluding uncertainties in the metric itself.

This assessment of uncertainties is broadly in line with AR5 WGIII (Blanco et al. 2014), but revises individual uncertainty judgements

in line with the more recent literature (Saunois et al. 2016, 2020; Janssens-Maenhout et al. 2019; Friedlingstein et al. 2020; Tian et al. 2020; Solazzo et al. 2021) as well as the underlying synthetic analysis provided here (e.g., Figures 2.2 and 2.3 in this chapter; and Minx et al. 2021). As such, reported changes in these estimates do not reflect changes in the underlying uncertainties, but rather a change in expert judgement based on an improved evidence base in the scientific literature. Uncertainty estimates for CO₂-FFI and N₂O remain unchanged compared to AR5. The change in the uncertainty estimates for CH₄ from 20% to 30% is justified by larger uncertainties reported for EDGAR emissions (Janssens-Maenhout et al. 2019; Solazzo et al.

Figure 2.3 | Comparison between top-down estimates and bottom-up EDGAR inventory data on GHG emissions for 1980–2016. **Left panel:** Total GWP100-weighted emissions based on IPCC AR6 (Forster et al. 2021a) of F-gases in Olivier and Peters (2020) [EDGARv5FT] (dark-red dotted line, excluding C₄F₁₀, C₅F₁₂, C₆F₁₄ and C₇F₁₆) and EDGARv6 (bright red dashed line) compared to top-down estimates based on AGAGE and NOAA data from WMO (2018) (blue lines; Engel and Rigby (2018); Montzka and Velders (2018)). **Right panel:** Top-down aggregated emissions for the three most abundant CFCs (–11, –12 and –113) and HCFCs (–22, –141b, –142b) not covered in bottom-up emissions inventories are shown in dark blue and yellow. For top-down estimates the shaded areas between two respective lines represent 1 σ uncertainties. Source: Minx et al. (2021).

2021) as well as the wider literature (Kirschke et al. 2013; Tubiello et al. 2015; Saunio et al. 2016, 2020). As AR6 – in contrast to AR5 – uses CO₂-LULUCF data from global bookkeeping models, the respective uncertainty estimate is based on the reporting in the underlying literature (Friedlingstein et al. 2020) as well as Working Group I (Canadell et al. 2021). The 70% uncertainty value is at the higher end of the range considered in AR5 (Blanco et al. 2014).

Finally, for F-gas emissions top-down atmospheric measurements from the 2018 World Meteorological Organization's (WMO) Scientific Assessment of Ozone Depletion (Engel and Rigby 2018; Montzka and Velders 2018) are compared to the data used in this report (Crippa et al. 2021; Minx et al. 2021) as shown in Figure 2.3. Due to the general absence of natural F-gas fluxes, there is a sound understanding of global and regional F-gas emissions from top-down estimates of atmospheric measurements with small and well-understood measurement, lifetime and transport model uncertainties (Engel and Rigby 2018; Montzka and Velders 2018). However, when species are aggregated into total F-gas emissions, EDGARv6.0 emissions are around 10% lower than the WMO 2018 values throughout, with larger differences for individual F-gas species, and further discrepancies when comparing to older EDGAR versions. Based on this, the overall uncertainties for aggregate

F-gas emissions is judged conservatively at 30% – 10 percentage points higher than in AR5 (Blanco et al. 2014).

Aggregate uncertainty across all GHGs is approximately $\pm 11\%$ depending on the composition of gases in a particular year. AR5 applied a constant uncertainty estimates of $\pm 10\%$ for total GHG emissions. The upwards revision applied to the uncertainties of CO₂-LULUCF, CH₄ and F-gas emissions therefore has a limited overall effect on the assessment of GHG emissions.

GHG emissions metrics such as GWP100 have their own uncertainties, which has been largely neglected in the literature so far. Minx et al. (2021) report the uncertainty in GWP100 metric values as $\pm 50\%$ for methane and other short-lived climate forcers (SLCFs), and $\pm 40\%$ for non-CO₂ gases with longer atmospheric lifetimes (specifically, those with lifetimes longer than 20 years). If uncertainties in GHG metrics are considered, and are assumed independent (which may lead to an underestimate) the overall uncertainty of total GHG emissions in 2019 increases from $\pm 11\%$ to $\pm 13\%$. Metric uncertainties are not further considered in this chapter, but are referred to in Cross-Chapter Box 2 in this chapter, and Chapter 2 Supplementary Material on GHG metrics (2.SM.3).

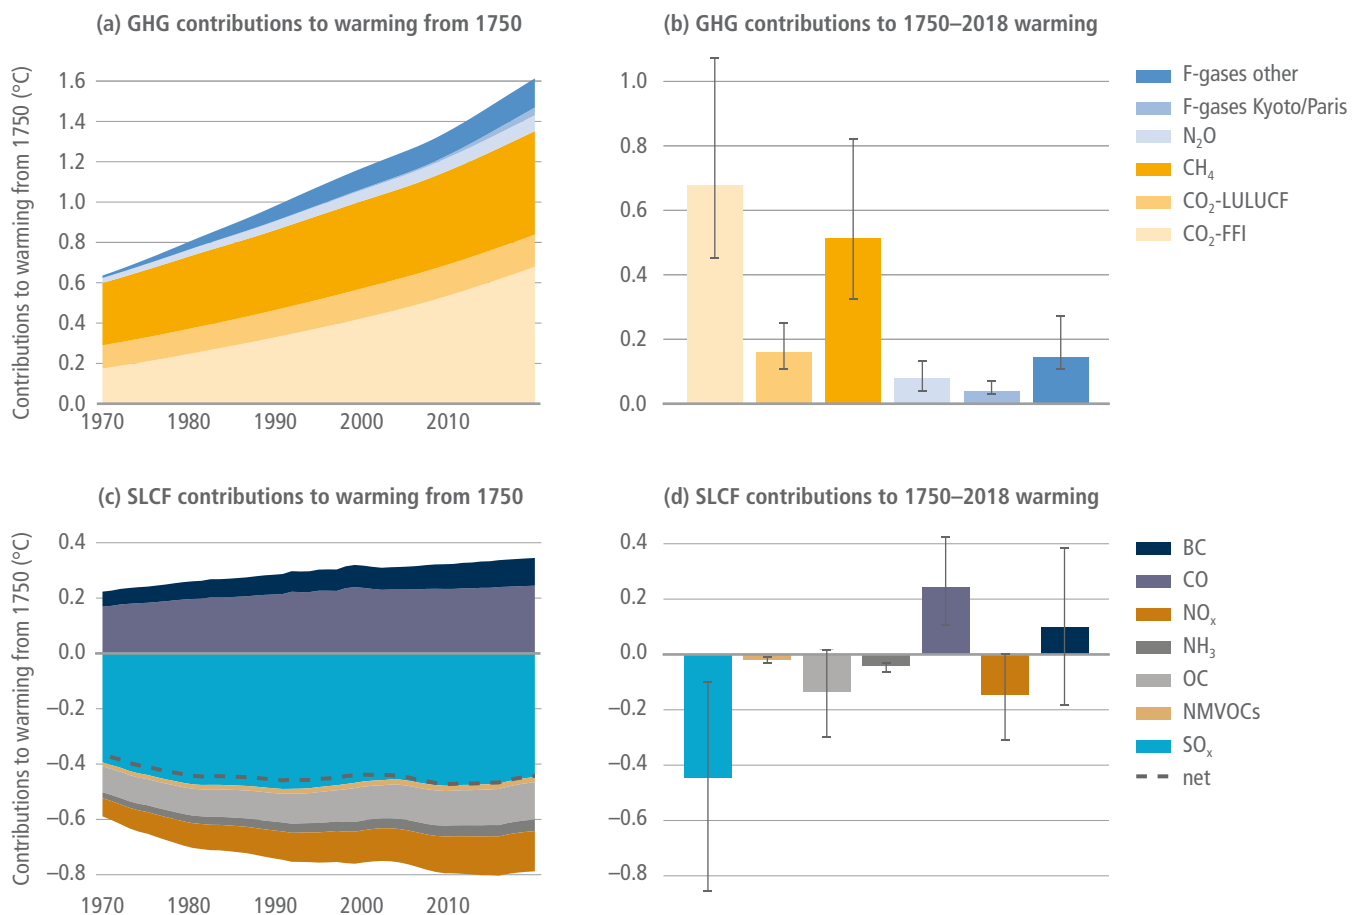

Figure 2.4 | Contribution of different GHGs to global warming over the period 1750 to 2018. Top row: contributions estimated with the FaIR reduced-complexity climate model. Major GHGs and aggregates of minor gases as a timeseries in (a) and as a total warming bar chart with 90% confidence interval added in (b). Bottom row: contribution from short-lived climate forcers as a time series in (c) and as a total warming bar chart with 90% confidence interval added in (d). The dotted line in (c) gives the net temperature change from short-lived climate forcers other than CH₄. F-Kyoto/Paris includes the gases covered by the Kyoto Protocol and Paris Agreement, while F-other includes the gases covered by the Montreal Protocol but excluding the HFCs. Source: Minx et al. (2021).

The most appropriate metric to aggregate GHG emissions depends on the objective (Cross-Chapter Box 2). One such objective can be to understand the contribution of emissions in any given year to warming, while another can be to understand the contribution of cumulative emissions over an extended time period to warming. In Figure 2.4 the modelled warming from emissions of each gas or group of gases is also shown – calculated using the reduced-complexity climate model Finite Amplitude Impulse Response (FaIR) model v1.6, which has been calibrated to match several aspects of the overall WGI assessment (Forster et al. 2021a; specifically Cross-Chapter Box 7 in Chapter 10 therein). Additionally, its temperature response to emissions with shorter atmospheric lifetimes such as aerosols, methane or ozone has been adjusted to broadly match those presented in Szopa et al. (2021a). There are some differences in actual warming compared to the GWP100 weighted emissions of each gas (Figure 2.4), in particular a greater contribution from CH₄ emissions to historical warming. This

is consistent with warming from CH₄ being short-lived and hence having a more pronounced effect in the near-term during a period of rising emissions. Nonetheless, Figure 2.4 highlights that emissions weighted by GWP100 do not provide a fundamentally different information about the contribution of individual gases than modelled actual warming over the historical period, when emissions of most GHGs have been rising continuously, with CO₂ being the dominant and CH₄ being the second most important contributor to GHG-induced warming. Other metrics such as GWP* (or GWP star) (Cain et al. 2019) offer an even closer resemblance between cumulative CO₂-eq emissions and temperature change. Such a metric may be more appropriate when the key objective is to track temperature change when emissions are falling, as in mitigation scenarios.

Cross-Chapter Box 2 | GHG Emissions Metrics

Authors: Andy Reisinger (New Zealand), Alaa Al Khourdajie (United Kingdom/Syria), Kornelis Blok (the Netherlands), Harry Clark (New Zealand), Annette Cowie (Australia), Jan S. Fuglestad (Norway), Oliver Geden (Germany), Veronika Ginzburg (the Russian Federation), Céline Guivarch (France), Joanna I. House (United Kingdom), Jan Christoph Minx (Germany), Rachid Mrabet (Morocco), Gert-Jan Nabuurs (the Netherlands), Glen P. Peters (Norway/Australia), Keywan Riahi (Austria), Roberto Schaeffer (Brazil), Raphael Slade (United Kingdom), Anders Hammer Strømman (Norway), Detlef P. van Vuuren (the Netherlands)

Comprehensive mitigation policy relies on consideration of all anthropogenic forcing agents, which differ widely in their atmospheric lifetimes and impacts on the climate system. GHG emission metrics⁶ provide simplified information about the effects that emissions of different GHGs have on global temperature or other aspects of climate, usually expressed relative to the effect of emitting CO₂ (see emission metrics in Annex I: Glossary). This information can inform prioritisation and management of trade-offs in mitigation policies and emission targets for non-CO₂ gases relative to CO₂, as well as for baskets of gases expressed in CO₂-eq. This assessment builds on the evaluation of GHG emission metrics from a physical science perspective by WGI (Forster et al. 2021b). For additional details and supporting references, see Chapter 2 Supplementary Material (2.SM.3) and Annex II.8.

The global warming potential (GWP) and the global temperature change potential (GTP) were the main metrics assessed in AR5 (Myhre et al. 2013; Kolstad et al. 2014). The GWP with a lifetime of 100 years (GWP100) continues to be the dominant metric used in the scientific literature on mitigation assessed by WGIII. The assessment by WGI (Forster et al. 2021) includes updated values for these metrics based on updated scientific understanding of the response of the climate system to emissions of different gases, including changing background concentrations. It also assesses new metrics published since AR5. Metric values in AR6 include climate-carbon cycle feedbacks by default; this provides an important update and clarification from AR5 which reported metric values both with and without such feedbacks.

The choice of metric, including time horizon, should reflect the policy objectives for which the metric is applied (Plattner et al. 2009). Recent studies confirm earlier findings that the GWP is consistent with a cost-benefit framework (Kolstad et al. 2014), which implies weighting each emission based on the economic damages that this emission will cause over time, or conversely, the avoided damages from avoiding that emission. The GWP time horizon can be linked to the discount rate used to evaluate economic damages from each emission. For methane, GWP100 implies a social discount rate of about 3–5% depending on the assumed damage function, whereas GWP20 implies a much higher discount rate, greater than 10% (*medium confidence*) (Mallapragada and Mignone 2019; Sarofim and Giordano 2018). The dynamic GTP is aligned with a cost-effectiveness framework, as it weights each emission based on its contribution to global warming in a specified future year (e.g., the expected year of peak warming for a given temperature goal). This implies a shrinking time horizon and increasing relative importance of SLCF emissions as the target year is approached (Johansson 2011; Aaheim and Mideksa 2017). The GTP with a static time horizon (e.g., GTP100) is not well-matched to either a cost-benefit or a cost-effectiveness framework, as the year for which the temperature outcome is evaluated would not match the year of peak warming, nor the overall damages caused by each emission (Edwards and Trancik 2014; Strefler et al. 2014; Mallapragada and Mignone 2017).

⁶ Emission metrics also exist for aerosols, but these are not commonly used in climate policy. This assessment focuses on GHG emission metrics only.

Cross-Chapter Box 2 (continued)

A number of studies since AR5 have evaluated the impact of various GHG emission metrics and time horizons on the global economic costs of limiting global average temperature change to a pre-determined level (e.g. Streffer et al. 2014; Harmsen et al. 2016; Tanaka et al. 2021) (see 2.SM.3 for additional detail). These studies indicate that, for mitigation pathways that limit warming to 2°C (<67%) above pre-industrial levels or lower, using GWP100 to inform cost-effective abatement choices between gases would achieve such long-term temperature goals at close to least global cost within a few percent (*high confidence*). Using the dynamic GTP instead of GWP100 could reduce global mitigation costs by a few percent in theory (*high confidence*), but the ability to realise those cost savings depends on the temperature limit, policy foresight and flexibility in abatement choices as the weighting of SLCF emissions increases over time (*medium confidence*) (van den Berg et al. 2015; Huntingford et al. 2015). Similar benefits as for the dynamic GTP might be obtained by regularly reviewing and potentially updating the time horizon used for GWP in light of actual emissions trends compared to climate goals (Tanaka et al. 2020).

The choice of metric and time horizon can affect the distribution of costs and the timing of abatement between countries and sectors in cost-effective mitigation strategies. Sector-specific lifecycle assessments find that different emission metrics and different time horizons can lead to divergent conclusions about the effectiveness of mitigation strategies that involve reductions of one gas but an increase of another gas with a different lifetime (e.g., Tanaka et al. 2019). Assessing the sensitivity of conclusions to different emission metrics and time horizons can support more robust decision-making (Levasseur et al. 2016; Balcombe et al. 2018) (see 2.SM.3 for details). Sectoral and national perspectives on GHG emission metrics may differ from a global least-cost perspective, depending on other policy objectives and equity considerations, but the literature does not provide a consistent framework for assessing GHG emission metrics based on equity principles.

Literature since AR5 has emphasised that the GWP100 is not well-suited to estimating the warming effect at specific points in time from sustained SLCF emissions (e.g., Allen et al. 2016; Cain et al. 2019; Collins et al. 2019). This is because the warming caused by an individual SLCF emission pulse diminishes over time and hence, unlike CO₂, the warming from SLCF emissions that are sustained over multiple decades to centuries depends mostly on their ongoing rate of emissions rather than their cumulative emissions. Treating all gases interchangeably based on GWP100 within a stated emissions target therefore creates ambiguity about actual global temperature outcomes (Fuglestad et al. 2018; Denison et al. 2019). Supplementing economy-wide emission targets with information about the expected contribution from individual gases to such targets would reduce the ambiguity in global temperature outcomes.

Recently developed step/pulse metrics such as the combined global temperature change potential (CGTP) (Collins et al. 2019) and GWP* (Allen et al. 2018; Cain et al. 2019) recognise that a sustained increase/decrease in the rate of SLCF emissions has a similar effect on global surface temperature over multiple decades as a one-off pulse emission/removal of CO₂. These metrics use this relationship to calculate the CO₂ emissions or removals that would result in roughly the same temperature change as a sustained change in the rate of SLCF emissions (CGTP) over a given time period, or as a varying time series of CH₄ emissions (GWP*). From a mitigation perspective, these metrics indicate greater climate benefits from rapid and sustained methane reductions over the next few decades than if such reductions are weighted by GWP100, while conversely, sustained methane increases have greater adverse climate impacts (Collins et al. 2019; Lynch et al. 2020). The ability of these metrics to relate changes in emission rates of short-lived gases to cumulative CO₂ emissions makes them well-suited, in principle, to estimating the effect on the remaining carbon budget from more, or less, ambitious SLCF mitigation over multiple decades compared to a given reference scenario (*high confidence*) (Collins et al. 2019; Forster et al. 2021).

The potential application of GWP* in wider climate policy (e.g., to inform equitable and ambitious emission targets or to support sector-specific mitigation policies) is contested, although relevant literature is still limited (Rogelj and Schleussner 2019, 2021; Schleussner et al. 2019; Allen et al. 2021; Cain et al. 2021). Whereas GWP and GTP describe the marginal effect of each emission relative to the absence of that emission, GWP* describes the equivalent CO₂ emissions that would give the same temperature change as an emissions trajectory of the gas considered, starting at a (user-determined) reference point. The warming based on those cumulative CO₂-equivalent emission at any point in time is relative to the warming caused by emissions of that gas before the reference point. Because of their different focus, GWP* and GWP100 can equate radically different CO₂ emissions to the same CH₄ emissions: rapidly declining CH₄ emissions have a negative CO₂-warming-equivalent value based on GWP* (rapidly declining SLCF emissions result in declining temperature, relative to the warming caused by past SLCF emissions at a previous point in time) but a positive CO₂-equivalent value based on GWP or GTP (each SLCF emission from any source results in increased future radiative forcing and global average temperature than without this emission, regardless of whether the rate of SLCF emissions is rising or declining). The different focus in these metrics can have important distributional consequences, depending on how they are used to inform emission targets (Lynch et al. 2021; Reisinger et al. 2021), but this has only begun to be explored in the scientific literature.

Cross-Chapter Box 2 (continued)

A key insight from WGI is that, for a given emissions scenario, different metric choices can alter the time at which net zero GHG emissions are calculated to be reached, or whether net zero GHG emissions are reached at all (2.SM.3). From a mitigation perspective, this implies that changing GHG emission metrics but retaining the same numerical CO₂-equivalent emissions targets would result in different climate outcomes. For example, achieving a balance of global anthropogenic GHG emissions and removals, as stated in Article 4.1 of the Paris Agreement could, depending on the GHG emission metric used, result in different peak temperatures and in either stable, or slowly or rapidly declining temperature after the peak (Allen et al. 2018; Fuglestedt et al. 2018; Tanaka and O'Neill 2018; Schleussner et al. 2019). A fundamental change in GHG emission metrics used to monitor achievement of existing emission targets could therefore inadvertently change their intended climate outcomes or ambition, unless existing emission targets are re-evaluated at the same time (*very high confidence*).

The WGIII contribution to AR6 reports aggregate emissions and removals using updated GWP100 values from AR6 WGI unless stated otherwise. This choice was made on both scientific grounds (the alignment of GWP100 with a cost-benefit perspective under social discount rates and its performance from a global cost-effectiveness perspective) and for procedural reasons, including continuity with past IPCC reports and alignment with decisions under the Paris Agreement Rulebook (Annex II.8). A key constraint in the choice of metric is also that the literature assessed by WGIII predominantly uses GWP100 and often does not provide sufficient detail on emissions and abatement of individual gases to allow translation into different metrics. Presenting such information routinely in mitigation studies would enable the application of more diverse GHG emission metrics in future assessments to evaluate their contribution to different policy objectives.

All metrics have limitations and uncertainties, given that they simplify the complexity of the physical climate system and its response to past and future GHG emissions. No single metric is well-suited to all applications in climate policy. For this reason, the WGIII contribution to AR6 reports emissions and mitigation options for individual gases where possible; CO₂-equivalent emissions are reported in addition to individual gas emissions where this is judged to be policy-relevant. This approach aims to reduce the ambiguity regarding mitigation potentials for specific gases and actual climate outcomes over time arising from the use of any specific GHG emission metric.

2.2.2 Trends in the Global GHG Emissions Trajectories and Short-lived Climate Forcers

2.2.2.1 Anthropogenic Greenhouse Gas Emissions Trends

Global GHG emissions continued to rise since AR5, but the rate of emissions growth slowed (*high confidence*). GHG emissions reached 59 ± 6.6 GtCO₂-eq in 2019 (Table 2.1 and Figure 2.5). In 2019, CO₂ emissions from the FFI were $38 (\pm 3.0)$ Gt, CO₂ from LULUCF 6.6 ± 4.6 Gt, CH₄ 11 ± 3.2 GtCO₂-eq, N₂O 2.7 ± 1.6 GtCO₂-eq and F-gases 1.4 ± 0.41 GtCO₂-eq. There is *high confidence* that average annual GHG emissions for the last decade (2010–2019) were the highest on record in terms of aggregate CO₂-eq emissions, but *low confidence* for annual emissions in 2019 as uncertainties are large considering the size and composition of observed increases in the most recent years (UNEP 2020a; Minx et al. 2021).

GHG emissions levels in 2019 were higher compared to 10 and 30 years earlier (*high confidence*): about 12% (6.5 GtCO₂-eq) higher than in 2010 (53 ± 5.7 GtCO₂-eq) (the last year of AR5 reporting) and about 54% (21 GtCO₂-eq) higher than in 1990 (38 ± 4.8 GtCO₂-eq) (the baseline year of the Kyoto Protocol and frequent nationally determined contribution (NDC) reference). GHG emissions growth slowed compared to the previous decade (*high confidence*): From 2010 to 2019, GHG emissions grew on average by about 1.3% per year compared to an average annual growth of

2.1% between 2000 and 2009. Nevertheless the absolute increase in average annual GHG emissions for 2010–2019 compared to 2000–2009 was 9.1 GtCO₂-eq and, as such, the largest observed in the data since 1970 (Table 2.1) – and most likely in human history (Friedlingstein et al. 2020; Gütschow et al. 2021b). Decade-by-decade growth in average annual GHG emissions was observed across all (groups of) gas as shown in Table 2.1, but for N₂O and CO₂-LULUCF emissions this is much more uncertain.

Reported total annual GHG emission estimates differ between the WGIII contributions in AR5 (Blanco et al. 2014) and AR6 (this chapter) mainly due to differing global warming potentials (*high confidence*). For the year 2010, total GHG emissions were estimated at 49 ± 4.9 GtCO₂-eq in AR5 (Blanco et al. 2014), while we report 53 ± 5.7 GtCO₂-eq here. However, in AR5 total GHG emissions were weighted based on GWP100 values from IPCC's Second Assessment Report. Applying those GWP values to the 2010 emissions from AR6 yields 50 GtCO₂-eq (Forster et al. 2021a). Hence, observed differences are mainly due to the use of most recent GWP values, which have higher warming potentials for methane (29% higher for biogenic and 42% higher for fugitive methane) and 12% lower values for nitrous oxide (Cross-Chapter Box 2 in this chapter).

Emissions growth has been persistent but varied in pace across gases. The average annual emission levels of the last decade (2010–2019) were higher than in any previous decade for each group of GHGs:

Table 2.1 | Total anthropogenic GHG emissions (GtCO₂-eq yr⁻¹) 1990–2019. CO₂ from fossil fuel combustion and industrial processes (FFI); CO₂ from Land Use, Land Use Change and Forestry (LULUCF); methane (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases: HFCs, PFCs, SF₆, NF₃). Aggregate GHG emissions trends by groups of gases reported in GtCO₂-eq converted based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report (AR6). Uncertainties are reported for a 90% confidence interval. Source: Minx et al. (2021).

	Average annual emissions (GtCO ₂ -eq)					
	CO ₂ FFI	CO ₂ LULUCF	CH ₄	N ₂ O	Fluorinated gases	GHG
2019	38 ± 3.0	6.6 ± 4.6	11 ± 3.2	2.7 ± 1.6	1.4 ± 0.41	59 ± 6.6
2010–2019	36 ± 2.9	5.7 ± 4.0	10 ± 3.0	2.6 ± 1.5	1.2 ± 0.35	56 ± 6.0
2000–2009	29 ± 2.4	5.3 ± 3.7	9.0 ± 2.7	2.3 ± 1.4	0.81 ± 0.24	47 ± 5.3
1990–1999	24 ± 1.9	5.0 ± 3.5	8.2 ± 2.5	2.1 ± 1.2	0.49 ± 0.15	40 ± 4.9
1990	23 ± 1.8	5.0 ± 3.5	8.2 ± 2.5	2.0 ± 1.2	0.38 ± 0.11	38 ± 4.8

CO₂, CH₄, N₂O, and F-gases (*high confidence*). Since 1990, CO₂-FFI have grown by 67% (15 GtCO₂-eq), CH₄ by 29% (2.4 GtCO₂-eq), and N₂O by 33% (0.65 GtCO₂-eq), respectively (Figure 2.5). Growth in fluorinated gases (F-gas) has been by far the highest with about 254% (1.0 GtCO₂-eq), but it occurred from low levels. In 2019, total F-gas levels were no longer negligible with a share of 2.3% of global GHG emissions. Note that the F-gases reported here do not include CFCs and HCFCs, which are groups of substances regulated

under the Montreal Protocol. The aggregate CO₂-eq emissions of HFCs, HCFCs and CFCs were each approximately equal in 2016, with a smaller contribution from PFCs, SF₆, NF₃ and some more minor F-gases. Therefore, the GWP-weighted F-gas emissions reported here (HFCs, PFCs, SF₆, NF₃), which are dominated by the HFCs, represent less than half of the overall CO₂-eq F-gas emissions in 2016 (Figure 2.3).

Emissions of greenhouse gases have continued to increase since 1990, at varying rates

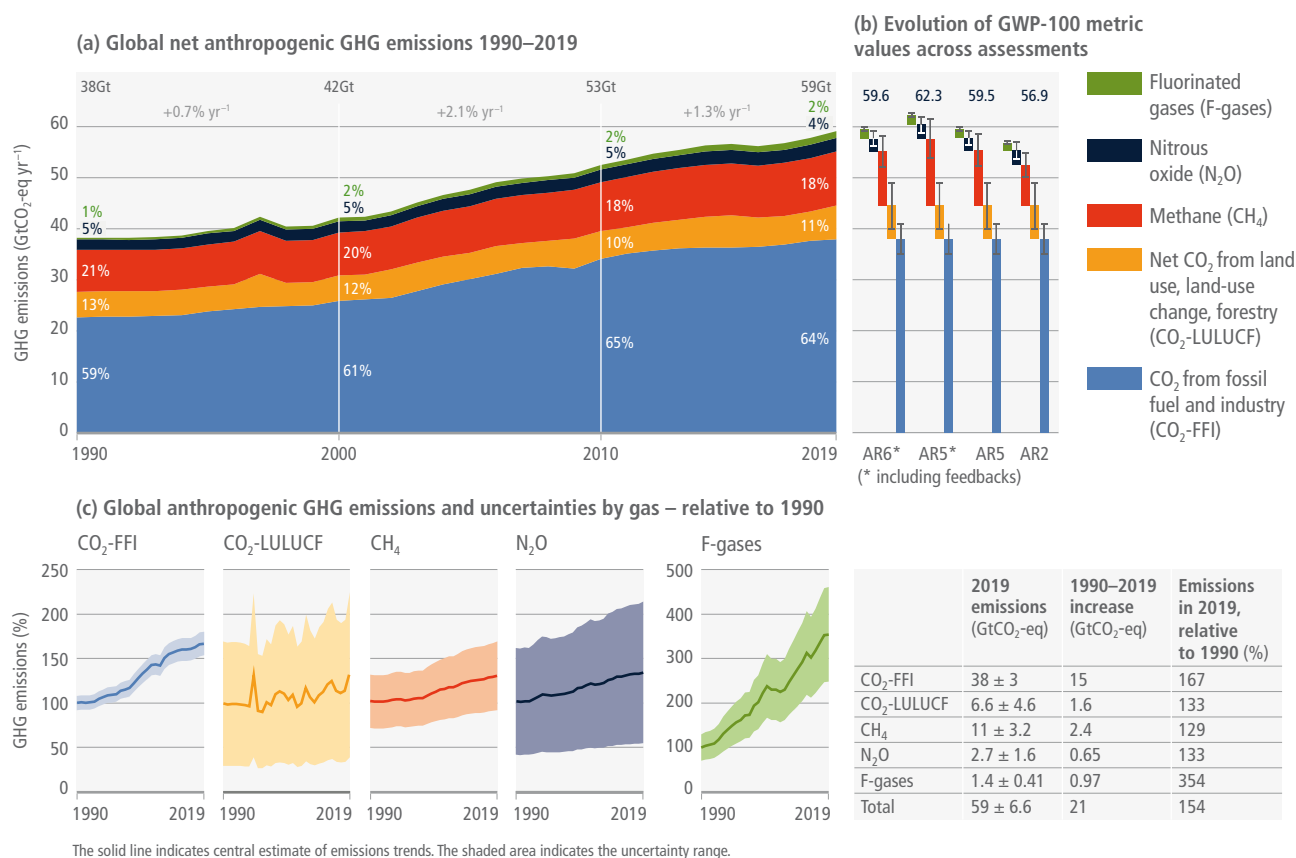

Figure 2.5 | Total anthropogenic GHG emissions (GtCO₂-eq yr⁻¹) 1990–2019. CO₂ from fossil fuel combustion and industrial processes (FFI); net CO₂ from land use, land use change and forestry (LULUCF); methane (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases: HFCs, PFCs, SF₆, NF₃). **Panel (a):** Aggregate GHG emissions trends by groups of gases reported in GtCO₂-eq converted based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report. **Panel (b):** Waterfall diagrams juxtaposes GHG emissions for the most recent year (2019) in CO₂ equivalent units using GWP100 values from the IPCC's Second, Fifth, and Sixth Assessment Reports, respectively. Error bars show the associated uncertainties at a 90% confidence interval. **Panel (c):** individual trends in CO₂-FFI, CO₂-LULUCF, CH₄, N₂O and F-gas emissions for the period 1990–2019, normalised to 1 in 1990. Source: data from Minx et al. (2021).

The only exception to these patterns of GHG emissions growth is net anthropogenic CO₂-LULUCF emissions, where there is no statistically significant trend due to high uncertainties in estimates (Figures 2.2 and 2.5; Chapter 2 Supplementary Material). While the average estimate from the bookkeeping models report a slightly increasing trend in emissions, NGHGI and FAOSTAT estimates show a slightly decreasing trend, which diverges in recent years (Figure 2.2). Similarly, trends in CO₂-LULUCF estimates from individual bookkeeping models differ: while two models (BLUE and OSCAR) show a sustained increase in emissions levels since the mid-1990s, emissions from the third model (Houghton and Nassikas (HN)) declined (Figure 2.2 in this chapter; Friedlingstein et al. 2020). Differences in accounting approaches and their impacts CO₂ emissions estimates from land use is covered in Chapter 7 and in the Chapter 2 Supplementary Material (2.SM.2). Note that anthropogenic net emissions from bioenergy are covered by the CO₂-LULUCF estimates presented here.

The CO₂-FFI share in total CO₂-eq emissions has plateaued at about 65% in recent years and its growth has slowed considerably since AR5 (*high confidence*). The CO₂-FFI emissions grew at 1.1% during the 1990s and 2.5% during the 2000s. For the last decade (2010s) – not covered by AR5 – this rate dropped to 1.2%. This included a short period between 2014 and 2016 with little or no growth in CO₂-FFI emissions, mainly due to reduced emissions from coal combustion

(Jackson et al. 2016; Qi et al. 2016; Peters et al. 2017a; Canadell et al. 2021). Subsequently, CO₂-FFI emissions started to rise again (Peters et al. 2017b; Figueres et al. 2018; Peters et al. 2020).

Starting in the spring of 2020 a major break in global emissions trends was observed due to lockdown policies implemented in response to the COVID-19 pandemic (*high confidence*) (Forster et al. 2020; Le Quéré et al. 2020, 2021; Z. Liu et al. 2020b; Bertram et al. 2021). Overall, global CO₂-FFI emissions are estimated to have declined by 5.8% (5.1%–6.3%) in 2020, or about 2.2 (1.9–2.4) GtCO₂ in total (Friedlingstein et al. 2020; Z. Liu et al. 2020b; BP 2021; Crippa et al. 2021; IEA 2021a). This exceeds any previous global emissions decline since 1970, both in relative and absolute terms (Figure 2.6). Daily emissions, estimated based on activity and power-generation data, declined substantially compared to 2019 during periods of economic lockdown, particularly in April 2020 – as shown in Figure 2.6 – but rebounded by the end of 2020 (*medium confidence*) (Le Quéré et al. 2020, 2021; Z. Liu et al. 2020b). Impacts were differentiated by sector, with road transport and aviation particularly affected. Inventories estimate the total power sector CO₂ reduction from 2019 to 2020 at 3% (IEA 2021a) and 4.5% (Crippa et al. 2021). Approaches that predict near real-time estimates of the power sector reduction are more uncertain and estimates range more widely, between 1.8%

Figure 2.6 | Global CO₂ emissions from fossil fuel combustion and industry (FFI) in 2020 and the impact of COVID-19. Panel (a) depicts CO₂-FFI emissions over the past five decades (GtCO₂ yr⁻¹). The single year declines in emissions following major economic and geopolitical events are shown, as well as the decline recorded in five different datasets for emissions in 2020 (COVID-19) compared to 2019 (no COVID-19). Panel (b) depicts the change in global daily carbon emissions (MtCO₂ per day) in 2020 compared to 2019, showing the impact of COVID-19 lockdown policies. Source: Friedlingstein et al. (2020), Le Quéré et al. (2020), Carbon Monitor (Liu et al. 2020b), BP (2021), Crippa et al. (2021), IEA (2021a).

(Le Quéré et al. 2020, 2021), 4.1% (Z. Liu et al. 2020b) and 6.8% (Bertram et al. 2021); the latter taking into account the over-proportional reduction of coal generation due to low gas prices and merit order effects. Due to the very recent nature of this event, it remains unclear what the exact short- and long-term impacts on future global emissions trends will be.

From 1850 until around 1950, anthropogenic CO₂ emissions were mainly (>50%) from land use, land-use change and forestry (Figure 2.7). Over the past half-century CO₂ emissions from LULUCF have remained relatively constant around 5.1 ± 3.6 GtCO₂ but with a large spread across estimates (Le Quéré et al. 2018a; Friedlingstein et al. 2019, 2020). By contrast, global annual FFI-CO₂ emissions have continuously grown since 1850, and since the 1960s from a decadal average of 11 ± 0.9 GtCO₂ to 36 ± 2.9 GtCO₂ during 2010–2019 (Table 2.1).

Cumulative CO₂ emissions since 1850 reached 2400 ± 240 GtCO₂ in 2019 (*high confidence*).⁷ More than half (62%) of total emissions from 1850 to 2019 occurred since 1970 (1500 ± 140 GtCO₂), about 42% since 1990 (1000 ± 90 GtCO₂) and about 17% since 2010 (410 ± 30 GtCO₂) (Friedlingstein et al. 2019; Friedlingstein et al. 2020; Canadell et al. 2021) (Figure 2.7). Emissions in the last decade are about the same size as the remaining carbon budget of 400 ± 220 (500, 650) GtCO₂ for limiting global warming to 1.5°C and between one-third and half the 1150 ± 220 (1350, 1700) GtCO₂ for limiting global warming below 2°C with a 67% (50%, 33%) probability, respectively (*medium confidence*) (Canadell et al. 2021).

At current (2019) levels of emissions, it would only take 8 (2–15) and 25 (18–35) years to emit the equivalent amount of CO₂ for a 67th percentile 1.5°C and 2°C remaining carbon budget, respectively. Related discussions of carbon budgets, short-term ambition in the context of Nationally Determined Contributions (NDCs), pathways to limiting warming to well below 2°C and carbon dioxide removals are mainly discussed in Chapters 3, 4, and 12, but also Section 2.7 of this chapter.

Even when taking uncertainties into account, historical emissions between 1850 and 2019 constitute a large share of total carbon budgets from 2020 onwards for limiting warming to 1.5°C with a 50% probability as well as for limiting warming to 2°C with a 67% probability. Based on central estimates only, historical cumulative net CO₂ emissions between 1850–2019 amount to about four fifths of the total carbon budget for a 50% probability of limiting global warming to 1.5°C (central estimate about 2900 GtCO₂), and to about two thirds of the total carbon budget for a 67% probability to limit global warming to 2°C (central estimate about 3550 GtCO₂). The carbon budget is the maximum amount of cumulative net global anthropogenic CO₂ emissions that would result in limiting global warming to a given level with a given likelihood, taking into account the effect of other anthropogenic climate forcers. This is referred to as the total carbon budget when expressed starting from the pre-industrial period, and as the remaining carbon budget when expressed from a recent specified date. The total carbon budgets reported here are the sum of historical emissions from 1850 to 2019 and the remaining carbon budgets from 2020 onwards, which extend

Figure 2.7 | Historic anthropogenic CO₂ emission and cumulative CO₂ emissions (1850–2019) as well as remaining carbon budgets for limiting warming to 1.5°C and 2°C. Panel (a) shows historic annual anthropogenic CO₂ emissions (GtCO₂ yr⁻¹) by fuel type and process. Panel (b) shows historic cumulative anthropogenic CO₂ emissions for the periods 1850–1989, 1990–2009, and 2010–2019 as well as remaining future carbon budgets as of 1 January 2020 to limit warming to 1.5°C and 2°C at the 67th percentile of the transient climate response to cumulative CO₂ emissions. The whiskers indicate a budget uncertainty of ± 220 GtCO₂-eq for each budget and the aggregate uncertainty range at one standard deviation for historical cumulative CO₂ emissions, consistent with Working Group 1. Sources: Friedlingstein et al. (2020) and Canadell et al. (2021).

⁷ For consistency with WGI, uncertainties in this paragraph are reported at a 68% confidence interval. This reflects the difficulty in the WGI context of characterising the uncertainty in the CO₂ fluxes between the atmosphere and the ocean and land reservoirs individually, particularly on an annual basis, as well as the difficulty of updating the emissions from land-use change.

until global net zero CO₂ emissions are reached. Uncertainties for total carbon budgets have not been assessed and could affect the specific calculated fractions (IPCC 2021 [Working Group 1 SPM], Canadell et al., 2021 [Working Group 1 Ch5]).

Comparisons between historic GHG emissions and baseline projections provide increased evidence that global emissions are not tracking high-end scenarios (Hausfather and Peters 2020), and rather followed 'middle-of-the-road' scenario narratives in the earlier series, and by combinations of 'global-sustainability' and 'middle-of-the-road' narratives in the most recent series (IPCC Special Report on Emissions Scenarios (SRES) and Shared Socioeconomic Pathways (SSP)-baselines) (Pedersen et al. 2020; Strandsbjerg Tristan Pedersen et al. 2021). As countries increasingly implement climate policies and technology costs continue to evolve, it is expected that emissions will continually shift away from scenarios that assume no climate policy but remain insufficient to limit warming to below 2°C (Vrontisi et al. 2018; Hausfather and Peters 2020; Roelfsema et al. 2020; UNEP 2020b).

The literature since AR5 suggests that compared to historical trends baseline scenarios might be biased towards higher levels of fossil fuel use compared to what is observed historically (Cross-Chapter Box 1 in Chapter 1; Ritchie and Dowlatabadi 2017, 2018; Ritchie 2019; Creutzig et al. 2021;). Ritchie and Dowlatabadi (2017) show that per-capita primary energy consumption in baseline scenarios

tends to increase at rates faster than those observed in the long-term historical evidence – particularly in terms of coal use. For example, SSP5 envisions a six-fold increase in per capita coal use by 2100 – against flat long-term historical observations – while the most optimistic baseline scenario SSP1-Sustainability is associated with coal consumption that is broadly in line with historical long-term trends (Ritchie and Dowlatabadi 2017). In contrast, models have struggled to reproduce historical upscaling of wind and solar and other granular energy technologies (Wilson et al. 2013; van Sluisveld et al. 2015; Creutzig et al. 2017; Shiraki and Sugiyama 2020; Sweerts et al. 2020; Wilson et al. 2020b).

2.2.2.2 Other Short-lived Climate Forcers (SLCFs)

There are other emissions with shorter atmospheric lifetimes that contribute to climate changes. Some of them (aerosols, sulphur emissions or organic carbon) reduce forcing, while others – such as black carbon, carbon monoxide or non-methane volatile organic compounds (NMVOC) – contribute to warming (Figure 2.4) as assessed in WGI (Forster et al. 2021c; Szopa et al. 2021a). Many of these other SLCFs are co-emitted during combustion processes in power plants, cars, trucks, airplanes, but also during wildfires and household activities such as traditional cooking with open biomass burning. As these co-emissions have implications for net warming, they are also considered in long-term emission reduction scenarios as covered in the literature (Harmsen et al. 2020; Rauner et al. 2020b;

Figure 2.8 | Air pollution emissions by major sectors from CEDS (1970–2019) and EDGAR (1970–2015) inventories. Source: Crippa et al. (2019a, 2018); O'Rourke et al. (2020); McDuffie et al. (2020).

Smith et al. 2020; Vandyck et al. 2020) as well as Chapter 3 of this report. These air pollutants are also detrimental to human health (e.g., Lelieveld et al. 2015, 2018; Vohra et al. 2021). For example, Lelieveld et al. (2015) estimate a total of 3.3 (1.6–4.8) million premature deaths in 2010 from outdoor air pollution. Reducing air pollutants in the context of climate policies therefore leads to substantial co-benefits of mitigation efforts (Von Stechow et al. 2015; Rao et al. 2017; Lelieveld et al. 2019; Rauner et al. 2020a). Here we briefly outline the major trends in emissions of SLCFs.

Conventional air pollutants that are subject to significant emission controls in many countries include sulphur dioxide (SO₂), nitrogen oxides (NO_x), black carbon (BC) and carbon monoxide (CO). From 2015 to 2019, global SO₂ and NO_x emissions declined, mainly due to reductions in energy systems (Figure 2.8). Reductions in BC and CO emissions appear to have occurred over the same period, but trends are less certain due to the large contribution of emissions from poorly quantified traditional biofuel use. Emissions of CH₄, OC and NMVOC have remained relatively stable in the past five years. OC and NMVOC may have plateaued, although there is additional uncertainty due to sources of NMVOCs that may be missing in current inventories (McDonald et al. 2018).

2.2.3 Regional GHG Emissions Trends

Regional contributions to global GHG emissions have shifted since the beginning of the international climate negotiations in the 1990s (*high confidence*). As shown in Figure 2.9, developed countries (North America, Europe, and Australia, Japan, New Zealand) as a group have not managed to reduce GHG emissions substantially, with fairly stable levels at about 15 GtCO₂-eq yr⁻¹ between 1990 and 2010, while countries in Asia and Pacific (Eastern Asia, Southern Asia, and South-East Asia and Pacific) have rapidly increased their share of global GHG emissions – particularly since the 2000s (Jackson et al. 2019; Peters et al. 2020; UNEP 2020c; Crippa et al. 2021; IEA 2021b).

Most global GHG emission growth occurred in Asia and Pacific, which accounted for 77% of the net 21 GtCO₂-eq increase in GHG emissions since 1990, and 83% of the net 6.5 GtCO₂-eq increase since 2010.⁸ Africa contributed 11% of GHG emissions growth since 1990 (2.3 GtCO₂-eq) and 10% (0.7 GtCO₂-eq) since 2010. The Middle East contributed 10% of GHG emissions growth since 1990 (2.1 GtCO₂-eq) and also 10% (0.7 GtCO₂-eq) since 2010. Latin America and the Caribbean contributed 11% of GHG emissions growth since 1990 (2.2 GtCO₂-eq), and 5% (0.3 GtCO₂-eq) since 2010. Two regions, Developed Countries, and Eastern Europe and West Central Asia, reduced emissions overall since 1990, by –1.6 GtCO₂-eq and –0.8 GtCO₂-eq, respectively. However, emissions in the latter started to grow again since 2010, contributing to 5% of the global GHG emissions change (0.3 GtCO₂-eq).

Average annual GHG emission growth across all regions slowed between 2010 and 2019 compared to 1990–2010, with the exception of Eastern Europe and West Central Asia. Global emissions changes tend to be driven by a limited number of countries, principally the G20 Group (Friedlingstein et al. 2020; UNEP 2020c; Xia et al. 2021). For instance, the slowing of global GHG emissions between 2010 and 2019, compared to the previous decade, was primarily triggered by substantial reductions in GHG emissions growth in China. Ten countries jointly contributed about 75% of the net 6.5 GtCO₂-eq yr⁻¹ increase in GHG emissions during 2010–2019, of which two countries contributed more than 50% (Figure 2.9) (see also Minx et al., 2021; Crippa et al., 2021).

GHG and CO₂-FFI levels diverge starkly between countries and regions (*high confidence*) (Jackson et al. 2019; Friedlingstein et al. 2020; UNEP 2020c; Crippa et al. 2021). Developed Countries sustained high levels of per capita CO₂-FFI emissions at 9.5 tCO₂ per capita in 2019 (but with a wide range of 1.9–16 tCO₂ per capita). This is more than double that of three developing regions: 4.4 (0.3–12.8) tCO₂ per capita in Asia and Pacific; 1.2 (0.03–8.5) tCO₂ per capita in Africa; and 2.7 (0.3–24) tCO₂ per capita in Latin America.⁹ Per capita CO₂-FFI emissions were 9.9 (0.89–15) tCO₂ per capita in Eastern Europe and West Central Asia, and 8.6 (0.36–38) tCO₂ per capita in the Middle East. CO₂-FFI emissions in the three developing regions together grew by 26% between 2010 and 2019, compared to 260% between 1990 and 2010, while in Developed Countries emissions contracted by 9.9% between 2010–2019 and by 9.6% between 1990–2010.

Least-Developed Countries and Small Island Developing States contributed only a negligible proportion of historic GHG emissions growth and have the lowest per capita emissions. As of 2019 Least Developed Countries contribute 3.3% of global GHG emissions, excluding LULUCF CO₂, despite making up 13% of the global population. Small Island Developing States contributed 0.6% of global GHG emissions in 2019, excluding LULUCF CO₂, with 0.9% of the global population. Since the start of the industrial revolution in 1850 up until 2019, Least Developed Countries contributed 0.4% of total cumulative CO₂ emissions, while Small Island Developing States contributed 0.5% (Figure 2.10). Conversely, Developed Countries have the highest share of historic cumulative emissions (Rocha et al. 2015; Gütschow et al. 2016; Matthews 2016), contributing approximately 57% (Figure 2.10), followed by Asia and Pacific (21%), Eastern Europe and West Central Asia (9%), Latin America and the Caribbean (4%), the Middle East (3%), and Africa (3%). Developed Countries still have the highest share of historic cumulative emissions (45%) when CO₂-LULUCF emissions are included, which typically account for a higher proportion of emissions in developing regions (Figure 2.10).

⁸ Note that GHG emissions from international aviation and shipping could not be attributed to individual regions, while CO₂ emissions from AFOLU could not be attributed to individual countries. Change in GHG emissions that can be easily assigned to regions is 20.3 of 20.8 GtCO₂-eq for 1990–2019 and 6.3 of 6.5 GtCO₂-eq for 2010–2019.

⁹ In all cases, constraining countries within the emissions range to those larger than 1 million population.

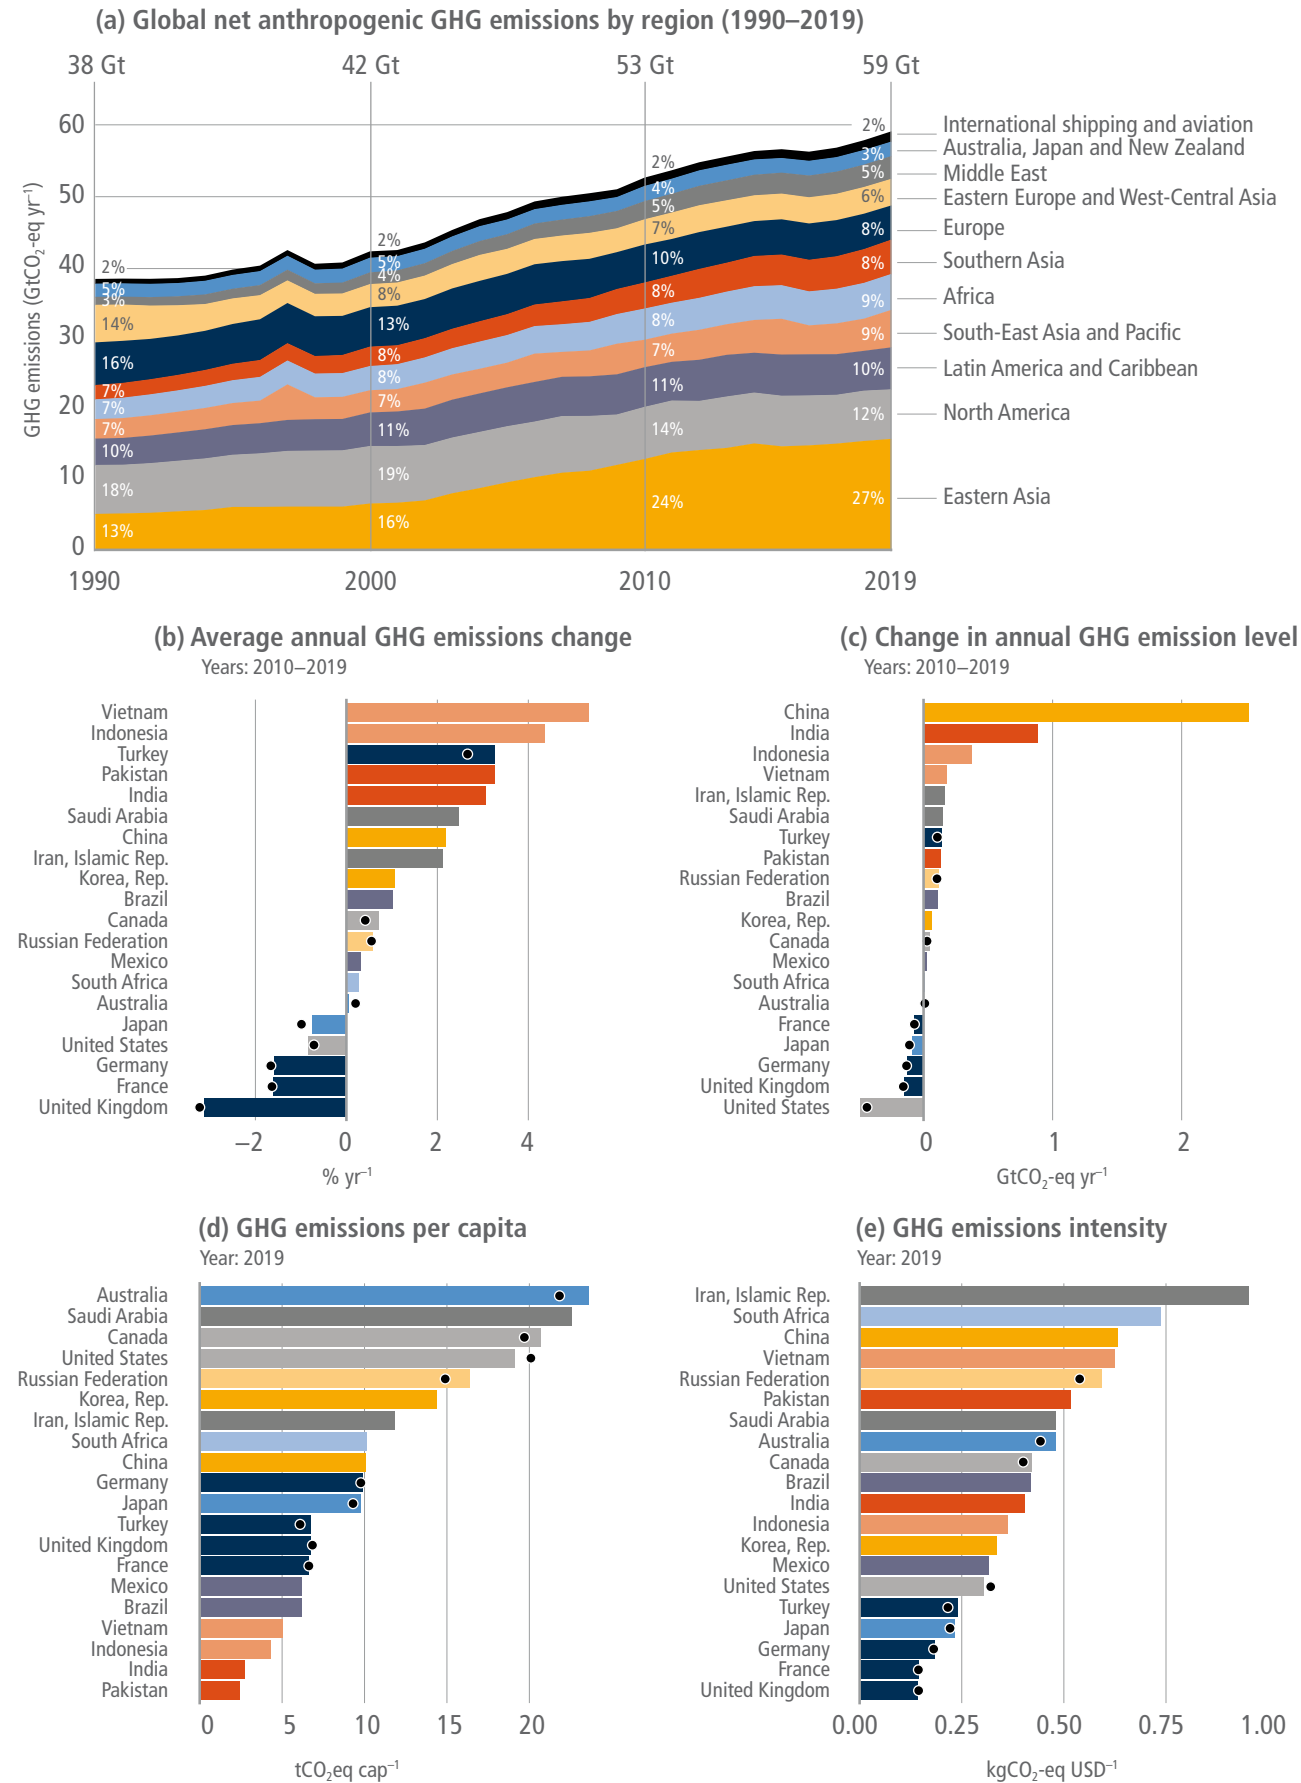

Figure 2.9 | Change in regional GHGs from multiple perspectives and their underlying drivers.

Figure 2.9 (continued): Change in regional GHGs from multiple perspectives and their underlying drivers. Panel (a): Regional GHG emissions trends (in GtCO₂-eq yr⁻¹) for the time period 1990–2019. GHG emissions from international aviation and shipping are not assigned to individual countries and shown separately. **Panels (b) and (c):** Changes in GHG emissions for the 20 largest emitters (as of 2019) for the post-AR5 reporting period 2010–2019 in relative (% annual change) and absolute terms (GtCO₂-eq). **Panels (d) and (e):** GHG emissions per capita and per GDP in 2019 for the 20 largest emitters (as of 2019). GDP estimated using constant international purchasing power parity (USD2017). Emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report (Forster et al. 2021a). The black dots represent the emissions data from UNFCCC-CRFs (2021) that were accessed through Gütschow et al. (2021a). Net LULUCF CO₂ emissions are included in panel (a), based on the average of three bookkeeping models (Section 2.2), but are excluded in panels (b–e) due to a lack of country resolution.

Figure 2.10 | Different perspectives on historic emissions and equity. Panel (a) shows the regional proportion (%) of total global population or emissions in 2018 or 2019, for five categories: population (persons); consumption-based CO₂-FFI emissions (GtCO₂); production-based CO₂-FFI emissions (GtCO₂); production-based GHG emissions excluding CO₂-LULUCF (GtCO₂-eq); and production-based GHG emissions including CO₂-LULUCF (GtCO₂-eq). **Panel (b)** shows the regional proportion (%) of total cumulative production-based CO₂ emissions from 1850 to 2019, including and excluding CO₂-LULUCF (GtCO₂). In the lower panels, the proportion of each population or emissions category attributable to Least-Developed Countries and Small Island Developing States (SIDS) are shown, where available (CO₂-LULUCF data is not available for these regions). GHG emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report (Forster et al. 2021a). Source: data from Friedglinstein et al. (2020).

Figure 2.11 | Recent average annual GHG emissions changes of countries (left panel) versus rates of reduction in 1.5°C and 2°C mitigation scenarios. Scenario data is taken from Chapter 3 of this report with the scenario categories defined and summarised in Table 3.2 in Chapter 3. Emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report (Forster et al. 2021a). Circles indicate countries (left panel) or individual scenarios (right panel), the former scaled by total emissions in 2019. Horizontal lines indicate the region average emissions change (left panel), or scenario category average emissions change (right panel). Source: data from Minx et al. (2021).

A growing number of countries have reduced CO₂ and GHG emissions for longer than 10 years (*high confidence*) (Le Quéré et al. 2019; Burck et al. 2021; Lamb et al. 2021a; Wu et al. 2021). Data up to 2018 indicates that about 24 countries have reduced territorial CO₂ and GHG emissions (excluding LULUCF CO₂), as well as consumption-based CO₂ emissions, for at least 10 years (Lamb et al. 2021a). Uncertainties in emissions levels and changes over time prevents a precise assessment of reductions in some cases. Of these 24 countries, 12 peaked emissions in the 2000s; six have sustained longer reductions since the 1970s; and six are former members of the Eastern Bloc, where emissions dropped rapidly in the 1990s and continued declining at a slower pace thereafter. Country emissions reductions have been driven by both climate and non-climate policies and factors, including structural changes. To date, most territorial emissions reductions were realised in the electricity and heat sector, followed by industry and buildings, while in many cases transport emissions have increased since countries reached their overall emissions peak (Climate Transparency 2021; Lamb et al. 2021a). One estimate of the total reduction in annual GHG emissions – from peak years to 2018 – sums to 3.2 GtCO₂-eq across all decarbonising countries (Lamb et al. 2021a). These reductions have therefore been far outweighed by recent emissions growth. However, climate policy related reductions may be even larger when compared against a counterfactual case of emissions growth across different sectors (Eskander and Fankhauser 2020) (Cross-Chapter Box 1 in Chapter 1; Section 2.8).

The recent (2010–2019) emissions changes of some countries are in line with pathways that limit warming to below 2°C (<67%) (e.g., –4% average annual reductions) (Figure 2.10). Overall, there are first country cases emerging that highlight the feasibility of sustained emission reductions outside of periods of economic disruption (Lamb et al. 2021a). However, such pathways will need to be taken

by many more countries to keep the goals of the Paris Agreement in reach (Höhne et al. 2020; Roelfsema et al. 2020; Kriegler et al. 2018a; den Elzen et al. 2019) as analysed by Chapter 4 of this report. Moreover, observed reductions are not yet consistent and long-term, nor achieved across all sectors, nor fully aligned with country NDC targets (Le Quéré et al. 2019; Lamb et al. 2021a; den Elzen et al. 2019; Burck et al. 2021; Climate Transparency 2021).

2.2.4 Sectoral GHG Emissions Trends

In 2019, 34% (20 GtCO₂-eq) of the 59 GtCO₂-eq GHG emissions came from the energy sector, 24% (14 GtCO₂-eq) from industry, 22% (13 GtCO₂-eq) from AFOLU, 15% (8.7 GtCO₂-eq) from transport and 6% (3.3 GtCO₂-eq) from buildings (Figure 2.12). The relative size of each sector depends on the exact definition of sector boundaries (de la Rue du Can et al. 2015; Lamb et al. 2021b). The largest individual subsector contributing to global GHG emissions in 2019 was electricity and heat generation at 14 GtCO₂-eq. This subsector can be reallocated to consuming sectors as indirect (scope 2) emissions to emphasise the role of final energy demand and demand-side solutions in climate change mitigation (Creutzig et al. 2018) (Chapter 5). This increases the emission share of the industry sector to 34% and of the buildings sector to 16%.

Average annual GHG emissions growth has been fastest in the transport sector with about 1.8% for the most recent period 2010–2019, followed by direct emissions in the industry sector (1.4%) and the energy sector (1%) (Figure 2.13). This is different to growth patterns observed in the previous decade as reported in AR5 (IPCC 2014a; Blanco et al. 2014). Between 2000 and 2009 fastest GHG emissions growth was observed for industry with 3.4% followed by

Direct emissions by sector (59 GtCO₂-eq)Direct+indirect emissions by sector (59 GtCO₂-eq)

Figure 2.12 | Total anthropogenic direct and indirect GHG emissions for the year 2019 (in GtCO₂-eq) by sector and subsector. Direct emissions estimates assign emissions to the sector in which they arise (scope 1 reporting). Indirect emissions – as used here – refer to the reallocation of emissions from electricity and heat to the sector of final use (scope 2 reporting). Note that cement refers to process emissions only, as a lack of data prevents the full reallocation of indirect emissions to this sector. More comprehensive conceptualisations of indirect emissions including all products and services (scope 3 reporting) are discussed in Section 2.3 of this chapter. Emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report. Percentages may not add up to 100 across categories due to rounding at the second significant digit. Source: based on Lamb et al. (2021b); data: Minx et al. (2021).

the energy sector with 2.3%. GHG emissions growth in the transport sector has been stable across both periods at about 1.8%, while direct building emissions growth averaged below 1% during 2010–2019. Ranking of high-emitting subsectors by direct emissions highlights the importance of CO₂ emissions from LULUCF (6.6 GtCO₂-eq; but with low confidence in magnitude and trend), road transport (6.1 GtCO₂-eq), metals (3.1 GtCO₂-eq), and other industry (4.4 GtCO₂-eq). Overall, some of the fastest growing sources of subsector emissions from 2010 to 2019 have been international aviation (+3.4%),¹⁰ domestic aviation (+3.3%), inland shipping (+2.9%), metals (+2.3%), international shipping (+1.7%), and road transport (+1.7%).

¹⁰ Note that this does not include the additional warming impacts from aviation due to short-lived climate forcers, which are assessed in Chapter 10 (Section 10.5).

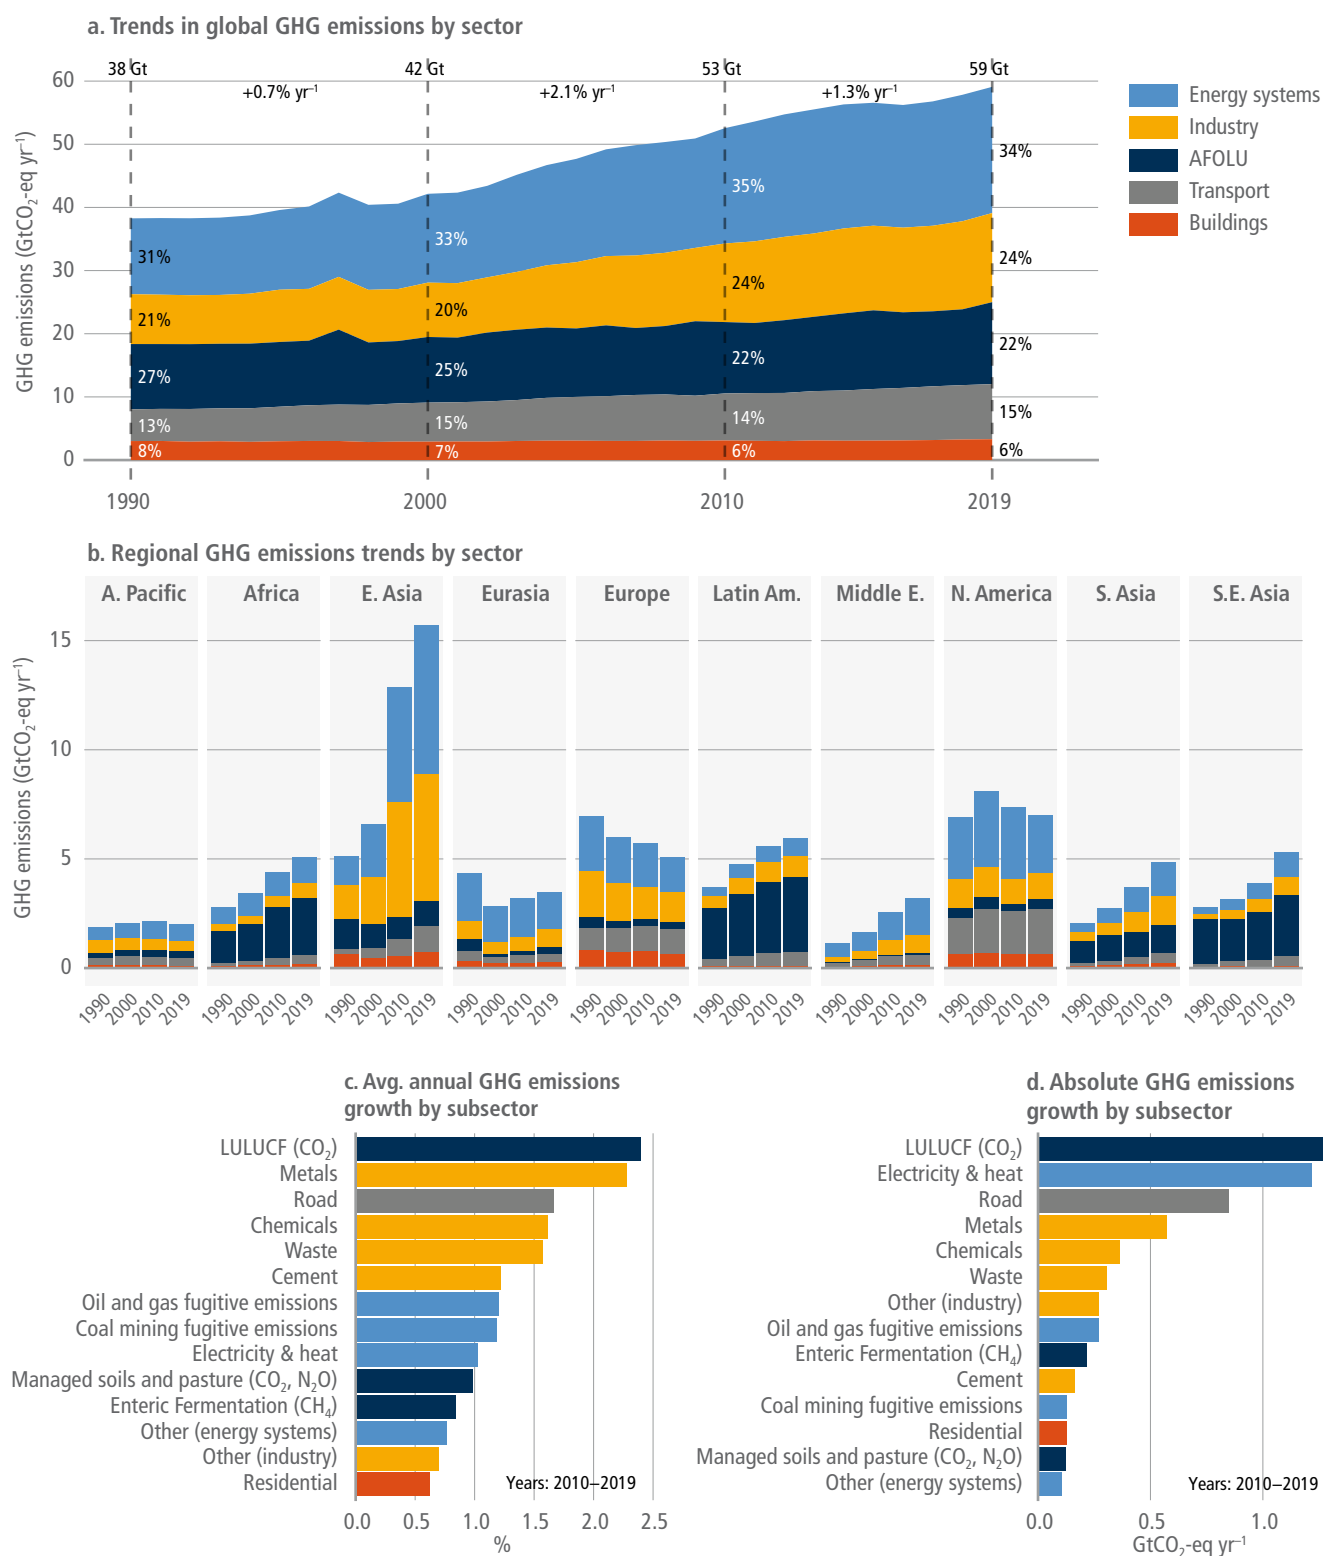

Figure 2.13 | Total annual anthropogenic GHG emissions by major economic sector and their underlying trends by region. Panel (a): Trends in total annual anthropogenic GHG emissions (in GtCO₂-eq yr⁻¹) by major economic sector. **Panel (b):** Trends in total annual anthropogenic GHG emissions (in GtCO₂-eq yr⁻¹) by major economic sector and region. Panels c and d: Largest subsectoral changes in GHG emissions for the reporting period 2010–2019 in relative (% annual change) and absolute terms (GtCO₂-eq yr⁻¹). Emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report. Source: based on Lamb et al. (2021b); Data: Crippa et al. (2021); Minx et al. (2021).

2.3 Past and Present Trends of Consumption-based CO₂ Emissions (CBEs) and Emissions Embodied in Trade

2.3.1 Scope, Variability and Uncertainty of CBEs

Consumption is increasingly met by global supply chains often involving large geographical distances and causing emissions in producing countries (Hubacek et al. 2014, 2016; Wiedmann and Lenzen 2018). Therefore, accounting for emissions from production along the entire supply chain to fulfil final demand, – so-called consumption-based emissions (CBEs), – is necessary to understand why emissions occur and to what extent consumption choices and associated supply chains contribute to total emissions, and ultimately how to influence consumption to achieve climate mitigation targets and environmental justice (Vasconcellos 2020).

Production-based emissions (PBEs) and territorial emissions resulting from the production and consumption of goods and services within a region (for both domestic use and export) are often used by authorities to report carbon emissions (Peters 2008) (Section 2.2). PBEs also include emissions from international activities (e.g., international aviation/shipping and non-resident activities), which are excluded from territorial emissions (Karstensen et al. 2018; Shan et al. 2018). In contrast, CBEs refer to emissions along the entire supply chains induced by consumption, irrespective of the place of production (Liu et al. 2015b). This reflects a shared understanding that a wider system boundary going beyond territorial emissions is important to avoid outsourcing of pollution and to achieve global decarbonisation. CBEs allow for the identification of new policy levers through information on a country's trade balance of embodied emissions, households' carbon implications of their lifestyle choices, companies' upstream emissions as input for supply

chain management, and cities' footprints outside their administrative boundaries (Davis and Caldeira 2010; Feng et al. 2013). Kander et al. (2015) proposed a technology-adjusted consumption-based emission accounting (TCBA) approach to address the issue of carbon intensity in exports. TCBA incorporates emissions embodied in trade but also adjusted for differences in carbon efficiency in exports of different countries. Unlike PBEs, there are no internationally agreed approaches to calculate CBEs, making it a major drawback for mainstreaming the use of this indicator in policymaking.

There are other proposed emission accounting approaches used in different circumstances. Historical cumulative emissions (HCEs) are used when analysing countries' historic contribution to emissions and responsibility for emission reduction. HCEs account for a country's cumulative past emissions, which may be different from the country's current annual emissions (Botzen et al. 2008; Ritchie 2019), but are sensitive to the choice of cut-off period. For example, the USA and EU-27 countries plus the UK contributed respectively 13.3% and 8.7% to global PBEs in 2019 (Crippa et al. 2020), however, they emitted around 25% and 22% of global historical PBEs since 1751 (Ritchie 2019). Extraction-based emissions (EBEs) accounting allocates all emissions from burning fossil fuels throughout the supply chains to the country where the fuels were extracted (Steininger and Schinko 2015). EBEs can be calculated by multiplying primary energy extraction of fossil fuels with their respective carbon content (Erickson and Lazarus 2013). Another approach for accounting emissions is income-based emission (IBE), which traces emissions throughout all supply chains and allocates emissions to primary inputs (e.g., capital and labour). In other words, IBEs investigate a country's direct and indirect downstream GHG emissions enabled by its primary inputs (Liang et al. 2017a). All these approaches provide complementary information and different angles to assigning responsibility for emissions reductions.

Box 2.1 | Policy Applications of Consumption-based Emissions

Consumption-based emissions provide additional or complementary information to production-based emissions that can be used for a variety of policy applications. These include:

- Complementary national-level emissions accounting and target or budget setting
- Raising awareness and increasing understanding of the GHG effects of consumption
- Accounting for and understanding of distributional and responsibility issues in GHG emissions mitigation, both nationally and internationally
- Incentives to change consumption patterns or reduce consumption (e.g., through taxation policies)
- Accounting for and understanding of carbon leakage and emissions embodied in trade*
- International emissions trading schemes or linked national schemes
- Trade policies addressing emissions embodied in trade and international supply chains (e.g., border tax adjustments and clean technology transfers, carbon offsetting or financing, etc.)
- Including embodied emissions in product performance standards and labelling
- Policies of public and private procurement
- Agreements with international suppliers
- Discussing the climate impacts of lifestyles and inequalities in consumption and associated emissions.

Box 2.1 (continued)

The points above are based on a synopsis of studies (Steining et al. 2014; Afionis et al. 2017; Hubacek et al. 2017b; Wang and Zhou 2018; Bolea et al. 2020).

* Note, however, that comparing embodied emissions in trade between countries is further complicated by the fact that emission intensities differ across countries. Approaches to adjust for these differences and facilitate comparisons have been suggested (Kander et al. 2015; Baumert et al. 2019; Dietzenbacher et al. 2020; Jakob 2021). Many different approaches on how to share responsibility between producers and consumers have been proposed in designing effective integrated global climate policies (Liu and Fan 2017; Khajepour et al. 2019; Jakob et al. 2021). Ultimately, assigning responsibility is normative.

Table 2.2 | Features of six global datasets for consumption-based emissions accounts.

Name of consumption-based account datasets (and references)	Years available	Number of countries/regions	Number of sectors
Eora (Lenzen et al. 2013); (https://worldmrio.com)	1990–2015	190	Varies from 25 to >500
EXIOBASE (Stadler et al. 2018); (https://www.exiobase.eu)	1995–2016	49	200 products and 163 industries
GTAP (Peters, et al. 2011b; Aguiar et al. 2019); (https://www.gtap.agecon.purdue.edu)	2004, 2007, 2011, 2014	140	57
OECD/ICIO (Yamano and Guilhoto, 2020); (http://oe.cd/io-co2)	1995–2015	67	36
WIOD (Dietzenbacher et al. 2013; Timmer et al. 2015); (http://wiod.org)	2000–2014	44	56
Global Carbon Budget (Friedlingstein et al. 2020)	1990–2018	118	N/A

The dominant method for calculating nations' CBEs is global multi-region input-output (GMRIO) analysis (Wiedmann and Lenzen 2018). Other frequently used approaches include analysing bilateral trade flows of products and their lifecycle emission factors (Sato 2014). Generally, the uncertainties associated with CBEs depends on the choice of the dataset/model used for calculation, which differs according to: (i) the national economic and trade data used; (ii) the emissions data used; (iii) the sector or product-level aggregation; (iv) the regional aggregation; (v) the conceptual scope (e.g., residential vs territorial accounting principle); and (vi) the model construction techniques, which include table-balancing algorithms and ways of dealing with missing or conflicting data (Moran and Wood 2014; Owen, 2017; Wieland et al. 2018; Wood et al. 2018, 2019). When excluding systematic error sources, research has shown that the stochastic relative standard deviation (RSD) of total national CBEs is not significantly different to that from PBEs accounts and in the region of 5–15% (Wood et al. 2018, 2019).

Six global accounts for consumption-based GHG emissions at the country level are widely used (Table 2.2). Each dataset has been constructed by different teams of researchers, covering different time periods and containing CBEs estimates for different sets of countries and regions (Owen 2017).

Wood et al. (2019) present a comprehensive and systematic model intercomparison and find a variation of 5–10% for both PBE and CBE accounts of major economies and country groups (e.g., EU-28, OECD). The estimates for the USA were the most closely aligned, with 3.7% RSD. For smaller countries, variability is in the order of 20–30% and can reach more than 40% in cases of very small, highly trade-exposed countries such as Singapore and Luxembourg

(Wood et al. 2019). It is recommended that CBEs results for such countries be interpreted with care.

Overall, production accounts showed a slightly higher convergence (8% average of RSD) than consumption-based accounts (12%). The variation across model results can be approximately halved, when normalising national totals to one common value for a selected base year. The difference between PBEs result variation (4% average RSD after normalisation) and CBEs results (7%) remains after normalisation.

In general, the largest contributors to uncertainty of CBEs results are – in descending order of priority – the total of territorial GHG emission accounts, the allocation of emissions to economic sectors, the total and composition of final demand, and lastly the structure of the economy. Harmonising territorial emissions across GMRIO datasets is the single most important factor that reduces uncertainty by about 50% (Tukker et al. 2020). More work is required to optimise or even institutionalise the compilation of multi-region input-output data and models to enhance the accuracy of consumption-based accounting (Tukker et al. 2018; Wood et al. 2018).

2.3.2 Trends in Global and Regional CBEs Trajectories

In comparison to territorial emissions discussed in Section 2.2, Figure 2.14 shows the trends of global and regional CBEs from 1990 to 2018. This section uses the PBEs and CBEs data from the Global Carbon Budget 2020 (Friedlingstein et al. 2020), which are slightly different from the PBEs used in Section 2.2. The Global Carbon Budget only includes CO₂ emissions from fossil fuels and cement production.

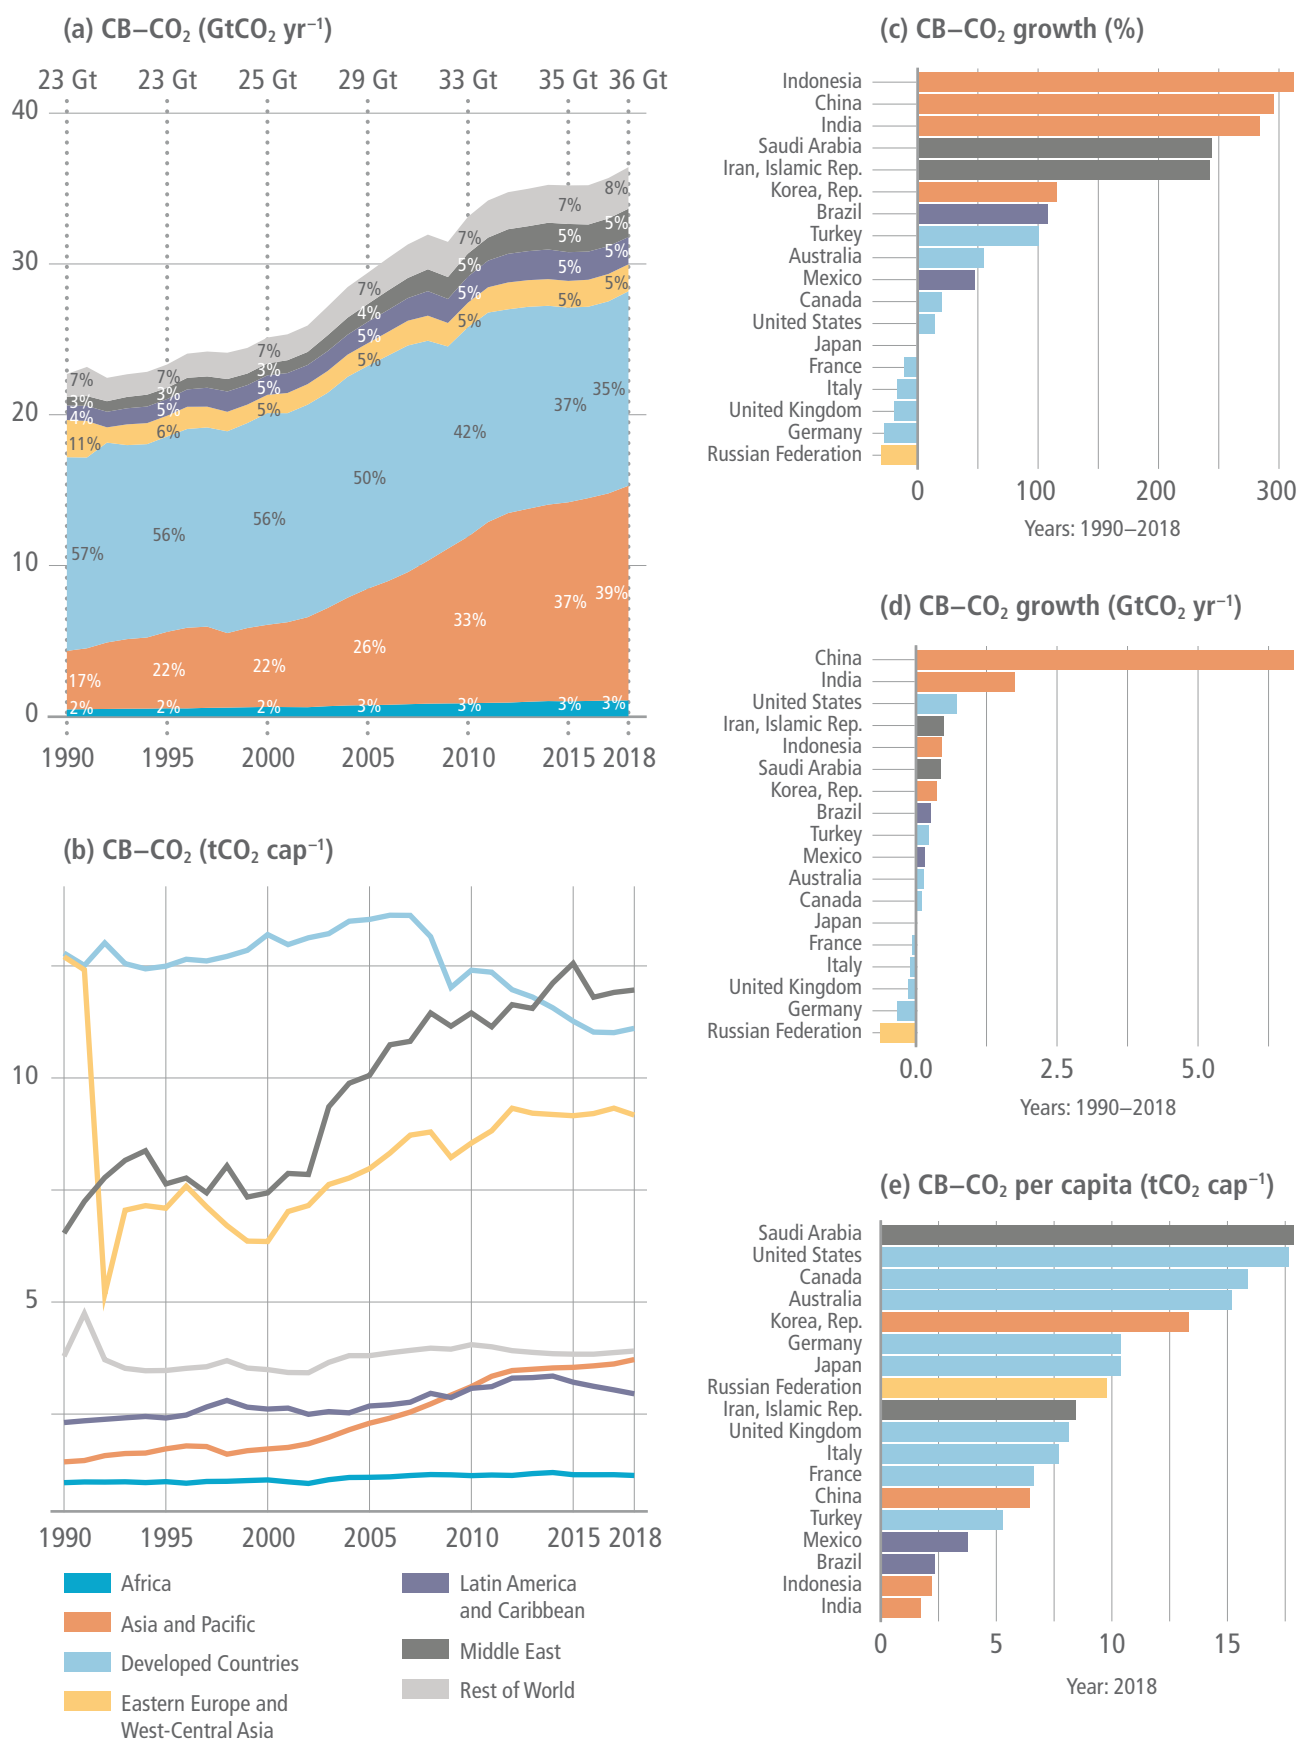

Figure 2.14 | Consumption-based CO₂ emissions trends for the period 1990–2018. The CBEs of countries are collected from the Global Carbon Budget 2020 (Friedlingstein et al. 2020). Source: this figure is modified based on Hubacek et al. (2021).

The two panels at left in Figure 2.14 show total and per capita CBEs for six regions. The three panels on the right show additional information for the 18 top-emitting countries with the highest CBEs in 2018. In Developed Countries, consumption-based CO₂ emissions peaked at 15 GtCO₂ in 2007 with a subsequent 16% decline until 2016 (to 12.7 GtCO₂) and a slight rebound of 1.6% until 2018 (to 12.9 GtCO₂). Asia and Pacific has been a major contributor to consumption-based CO₂ emissions growth since 2000 and exceeded Developed Countries as the global largest emissions source in 2015. From 1990 to 2018, the average growth rate of Asia and Pacific was 4.8% per year, while in other regions emissions declined by –1.1%–4.3% per year on average. In 2018, 35% of global consumption-based CO₂ emissions were from Developed Countries and 39% from Asia and Pacific, 5% from Latin American and Caribbean, 5% from Eastern Europe and West Central Asia, 5% from Middle East, and 3% from Africa (Hubacek et al. 2021). Global CBEs kept growing over the period with a short-lived decline in 2008 due to the global financial crisis. In 2020, lockdowns associated with COVID-19 significantly reduced global emissions (Section 2.2.2), including CBEs (Shan et al. 2021a).

2.3.3 Decoupling of Emissions from Economic Growth

There has been a long-standing discussion on whether environmental impacts such as carbon emissions and use of natural resources can be decoupled from economic growth. It is controversial whether absolute decoupling can be achieved at a global scale (Ward et al. 2016; Hickel and Kallis 2020; Haberl et al. 2020). However, a number of studies found that it is feasible to achieve decoupling at the national level, and they have explored the reasons for such decoupling (Schandl et al. 2016; Ward et al. 2016; Deutch 2017; Roinioti and Koroneos 2017; Vadén et al. 2020; Habimana Simbi et al. 2021; Shan et al. 2021b).

Table 2.3 shows the extent of decoupling of CBEs and GDP of countries based on CBEs from the Global Carbon Budget (Friedlingstein et al. 2020) and GDP data from the World Bank. Table 2.4 also presents countries' degree of decoupling of PBEs and GDP. These data allow a comparison of decoupling between GDP and both PBEs and CBEs.

Table 2.3 | Country groups with different degree of CBE–GDP decoupling from 2015 to 2018.

Number of countries		Absolute decoupling	Relative decoupling	No decoupling	Economic recession
		23	67	19	6
CBEs (gigatonnes)	Total	5.40	25.33	1.93	0.85
	Global share	16.1%	75.6%	5.8%	2.5%
PBEs (gigatonnes)	Total	4.84	25.73	2.16	0.84
	Global share	14.4%	76.6%	6.4%	2.5%
Population (million)	Total	625	5195	768	270
	Global share	9.1%	75.7%	11.2%	3.9%
GDP (billion)	Total	19,891	54,240	2300	2997
	Global share	25.0%	68.3%	2.9%	3.8%
Per capita GDP (1000 USD2010)	Average	31.45	16.29	6.57	17.78
	Median	23.55	8.03	2.56	13.12
	Max	110.70	79.23	63.93	33.11
	Min	1.31	0.49	0.52	5.80
Per capita CBEs (tonnes)	Average	10.27	5.30	4.47	12.55
	Median	8.87	4.13	1.67	11.33
	Max	37.95	17.65	25.35	23.21
	Min	0.64	0.09	0.18	2.33
CBE intensity (tonnes per 1000 USD2010)	Average	0.45	0.50	0.93	0.66
	Median	0.36	0.42	0.62	0.69
	Max	1.16	2.41	4.10	1.22
	Min	0.11	0.10	0.28	0.21
Per capita PBEs (tonnes)	Average	8.20	4.36	5.32	14.15
	Median	6.79	3.02	1.19	13.22
	Max	19.58	20.13	39.27	27.24
	Min	0.49	0.09	0.08	2.23
PBE intensity (tonnes per 1000 USD2010)	Average	0.42	0.40	0.94	0.75
	Median	0.28	0.31	0.58	0.68
	Max	1.57	1.47	4.83	1.80
	Min	0.10	0.05	0.16	0.20

Note: CBEs are obtained from the Global Carbon Budget 2020 (Friedlingstein et al. 2020), GDP and population are from the World Bank. One country (Venezuela) does not have GDP data after 2015, so the degree of decoupling was only calculated for 115 countries. This table is modified from Hubacek et al. (2021).

Absolute decoupling refers to a decline of emissions in absolute terms or as being stable while GDP grows (i.e., a decoupling index¹¹ greater than 1); relative decoupling refers to growth of emissions being lower than growth of GDP (a decoupling index between 0 and 1); and no decoupling, which refers to a situation where emissions grow to the same extent or faster than GDP (a decoupling index of less than 0) (Wu et al. 2018).

During the most recent three-year period from 2015 to 2018, 23 countries (or 20% of the 116 sample countries) have achieved absolute decoupling of CBEs and GDP, while 32 countries (or 28%) achieved absolute decoupling of PBEs and GDP: 14 of them (e.g., the UK, Japan,

and the Netherlands) also decoupled PBEs and GDP. Countries with absolute decoupling of CBEs tend to achieve decoupling at relatively high levels of economic development and high per capita emissions. Most of EU and North American countries are in this group. Decoupling was not only achieved by outsourcing carbon-intensive production, but also improvements in production efficiency and energy mix, leading to a decline of emissions. Structural Decomposition Analysis shows that the main driver for decoupling has been a reduction in carbon intensity (i.e., change in energy mix and energy efficiency) from both domestic production and imports (Hubacek et al. 2021). Similarly, Wood et al. (2020b) found that EU countries have reduced their overall consumption-based GHG emissions by 8% between 1995 and 2016,

Table 2.4 | Country groups with different degree of PBE–GDP decoupling from 2015 to 2018.

Number of countries		Absolute decoupling	Relative decoupling	No decoupling	Economic recession
		32	41	36	6
CBEs (gigatonnes)	Total	6.41	23.43	2.83	0.85
	Global share	19.1%	69.9%	8.4%	2.5%
PBEs (gigatonnes)	Total	5.33	24.36	3.04	0.84
	Global share	15.9%	72.6%	9.1%	2.5%
Population (million)	Total	857	4518	1213	270
	Global share	12.5%	65.9%	17.7%	3.9%
GDP (billion)	Total	27091	45255	4086	2997
	Global share	34.1%	57.0%	5.1%	3.8%
Per capita GDP (1000 USD2010)	Average	28.83	19.53	6.00	17.78
	Median	26.36	12.04	3.64	13.12
	Max	79.23	110.70	63.93	33.11
	Min	1.09	0.57	0.49	5.80
Per capita CBEs (tonnes)	Average	7.70	6.98	3.99	12.55
	Median	6.78	6.00	1.95	11.33
	Max	23.22	37.95	25.35	23.21
	Min	0.43	0.09	0.18	2.33
CBEs intensity (tonnes per 1000 USD2010)	Average	0.41	0.50	0.77	0.66
	Median	0.31	0.44	0.52	0.69
	Max	2.41	1.68	4.10	1.22
	Min	0.12	0.10	0.20	0.21
Per capita PBEs (tonnes)	Average	6.02	5.69	4.33	14.15
	Median	5.36	4.88	1.67	13.22
	Max	20.13	16.65	39.27	27.24
	Min	0.30	0.09	0.01	2.23
PBEs intensity (tonnes per 1000 USD2010)	Average	0.33	0.45	0.71	0.75
	Median	0.20	0.31	0.44	0.68
	Max	1.47	1.76	4.83	1.80
	Min	0.05	0.10	0.13	0.20

Note: CBEs are obtained from the Global Carbon Budget 2020 (Friedlingstein et al. 2020), GDP and population are from the World Bank. One country (Venezuela) does not have GDP data after 2015, so the degree of decoupling was only calculated for 115 countries. In order to be consistent with the results of CBEs, we calculate the decoupling of PBE until 2018.

¹¹ The decoupling index can be calculated based on changes of a country's GDP and CO₂ emissions (Akizu-Gardoki et al. 2018; Wu et al. 2018). See the equation below. *DI* refers to decoupling index; *G*₁ refers to the GDP of reporting year while *G*₀ refers to the base year; *E*₁ refers to emissions of the reporting year while *E*₀ refers to emissions of the base year.

$$DI = \frac{\Delta G\% - \Delta E\%}{\Delta G\%} = \left(\frac{G_1 - G_0}{G_0} - \frac{E_1 - E_0}{E_0} \right) / \frac{G_1 - G_0}{G_0}$$

mainly due to the use of more efficient technology. The literature also shows that changes in the structure of economy with a shift to tertiary sectors of production may contribute to such decoupling (Kanitkar et al. 2015; Jiang et al. 2021).

A total of 67 (or 58%) countries, including China and India, have relatively decoupled GDP and CBEs between 2015 and 2018, reflecting a slower growth in emissions than GDP. It is worth noting that the USA shows relative decoupling of emissions (both CBEs and PBEs) and GDP over the most recent period, although it strongly decoupled economic growth from emissions between 2005 and 2015. Thus decoupling can be temporary and countries' emissions may again increase after a period of decoupling.

Another 19 (or 16%) countries, such as South Africa and Nepal, have experienced no decoupling between GDP and CBEs from 2015 to 2018, meaning the growth of their GDP is closely tied with the consumption of emission-intensive goods. As a result, a further increase of GDP in these countries will likely lead to higher emissions, if they follow the historical trend without substantive improvement in efficiency of production and energy use.

It is important to note that a country's degree of decoupling changes over time. For example, 32 countries achieved absolute decoupling from 2010 to 2015 but only 10 of them remained decoupled over the next three years. More importantly, although absolute decoupling has reduced annual emissions, the remaining emissions are still contributing to an increase in atmospheric carbon concentration. Absolute

decoupling is not sufficient to avoid consuming the remaining CO₂ emission budget under the global warming limit of 1.5°C or 2°C and to avoid climate breakdown (Stoknes and Rockström 2018; Hickel and Kallis 2020). Even if all countries decouple in absolute terms this might still not be sufficient and thus can only serve as one of the indicators and steps toward fully decarbonising the economy and society.

2.3.4 Emissions Embodied in Trade (EET)

As global trade patterns have changed over recent decades, so have emissions embodied in trade (EET) (Jiang & Green 2017). EET refers to emissions associated with production of traded goods and services and is equal to the difference between PBEs and CBEs (Wiebe and Yamano 2016). EET includes two parts: emissions embodied in imports (EEI); and emissions embodied in exports (EEE). For a given country or region with CBEs higher than PBEs, it is a net importer with a higher EEI than EEE, and vice versa.

EET have been rising faster since the 1980s due to an increase in trade volume (Xu and Dietzenbacher 2014; Wood et al. 2018). CO₂ emissions from the production of internationally traded products peaked in 2006 at about 26% of global CO₂ emissions. Since then, international CO₂ emissions transfers declined but are likely to remain an important part of the climate policy agenda (Wood et al. 2020a). About 24% of global economic output and 25% of global CO₂ emissions are embodied in the international trade of goods and services as of 2014 (Hubacek et al. 2021).

Figure 2.15 | Total annual CO₂ emissions for 116 countries by global region based on consumption- and production-based emissions. The shaded areas are the net CO₂ trade balances (differences) between each of the regions. Yellow shading indicates that the region is a net importer of embodied CO₂ emissions, leading to consumption-based emission estimates that are higher than traditional territorial emission estimates. Blue shading indicates the reverse. Production-based emissions are collected from EDGAR and consumption-based emissions from the Global Carbon Budget 2020 (Friedlingstein et al. 2020). Source: this figure is modified based on Hubacek et al. (2021).

2.3.4.1 Net Emission Transfers

Located downstream in global supply chains, developed countries (mostly in Western Europe and North America) tend to be net emission importers, that is, EEI are larger than EEE. For example, over 40% of national CO₂ footprints in France, Germany, Italy, and Spain are from imports (Fan et al. 2017). Developing countries tend to be net emission exporters with higher PBEs than their CBEs (Peters et al. 2011a), especially for Asia and Pacific (as shown in Figure 2.15). That is to say, there is a net emission transfer and outsourcing of carbon-intensive production from developed to developing economies via global trade (Jiang et al. 2018), mainly caused by cheap labour costs (Tate and Bals 2017) and cheap raw materials (Mukherjee 2018). Increasing openness to trade (Fernández-Amador et al. 2016) and less stringent environmental legislation (acting as so-called pollution havens) are also possible reasons (Hoekstra et al. 2016; Malik and Lan 2016; Banerjee and Murshed 2020).

Net emissions transferred between developing and developed countries peaked at 7.3% of global CO₂ emissions in 2006 and then subsequently declined (Wood et al. 2020a). The main reason for the decline was an improvement in the carbon intensity of traded products, rather than a decline in trade volume (Wood et al. 2020a). Despite continued improvements, developing economies tend to have higher emission intensity than developed economies due to less efficient technologies and a carbon-intensive fuel mix (Jiang and Guan 2017).

2.3.4.2 Geographical Shifts of Emissions Embodied in Trade

With the rapid growth of developing countries, the geographical centre of global trade as well as emissions embodied in trade is changing. The fast growth of Asian countries is shifting the global trade centre from Europe to Asia (Zhang et al. 2019). Asian exports in monetary units increased by 235% from 1996 to 2011, and its share in global exports increased from 25% to 46%, whereas Europe's share in global exports decreased from 51% in 1996 to 39% in 2011. After 2011, global trade has stalled, but Asia's share of global exports further increased to 42% in 2020 (UNCTAD 2021).

In addition to changes in trade volume, trading patterns have also been changing significantly in Asian countries. These countries are replacing traditional trading hubs (such as Russia and Germany) due to the fast growth in trade flows, especially with countries of the Global South (Zhang et al. 2019). The largest geographical shifts in trade-embodied emissions between 1995 and 2011 occurred in high-tech, electronics, and machinery (Malik and Lan 2016; Jiang et al. 2018). For example, China is shifting its exports to include more low-carbon and higher value-added goods and services. As a result, China's exported emissions declined by 20% from 2008 to 2015 (Mi et al. 2018).

Developing countries are increasingly playing an important role in global trade. EET between developing countries, so-called South-South trade, has more than doubled between 2004 (0.47 Gt) and 2011 (1.11 Gt), which is seen as a reflection of a new phase

of globalisation (Meng et al. 2018). Developing countries, therefore, have gained importance as global suppliers of goods and services and have also become more relevant as global consumers as they grow their domestic demand (Fernández-Amador et al. 2016). Since 2014, CO₂ emission transfer between developing countries has plateaued and then slightly declined and seems to have stabilised at around the same level of transfers between non-OECD and OECD countries at around 2.4 GtCO₂ yr⁻¹ (Wood et al. 2020a). In both cases, a decrease in carbon intensity of trade just about offset increased trade volumes (Wood et al. 2020a).

2.4 Economic Drivers and Their Trends by Regions and Sectors

This section provides a summary of the main economic drivers of GHG emissions (mostly territorial) by regions and sectors, including those that are more indirect drivers related to economic activity, such as inequality and rapid urbanisation. Trade as a driver of global GHG emissions is described in the Chapter 2 Supplementary Material. Socio-demographic drivers are described in Section 2.6. The Kaya decomposition presented in this section is based on the International Energy Agency (IEA) and Emissions Database for Global Atmospheric Research (EDGAR) v6 databases and tracks global, regional, and sectoral GHG emissions from 1990 to 2019 (Crippa et al. 2021; IEA 2021c; Lamb et al. 2021b; Minx et al. 2021). It shows main contributors to GHG emissions as independent factors, although these factors also interact with each other.

2.4.1 Economic Drivers at Global and Regional Levels

Economic growth (measured as GDP) and its main components – GDP per capita and population growth – remained the strongest drivers of GHG emissions in the last decade, following a long-term trend (*robust evidence, high agreement*) (Liddle 2015; Malik et al. 2016; Sanchez and Stern 2016; Chang et al. 2019; Dong et al. 2019; Liobikiene and Butkus 2019; Liu et al. 2019a; Mardani et al. 2019; Pan et al. 2019; Dong et al. 2020; Parker and Bhatti 2020; Xia et al. 2021). Globally, GDP per capita remained by far the strongest upward driver, increasing almost in tandem with energy consumption and CO₂ emissions up until 2015, after which some modest decoupling occurred (Deutch 2017; Wood et al. 2018) (Section 2.3.3). The main counteracting, yet insufficient, factor that led to emissions reductions was decreased energy use per unit of GDP in almost all regions (–2.0% yr⁻¹ between 2010 and 2019 globally) (see also Lamb et al. 2021b) (Figure 2.16) (*robust evidence, high agreement*). These reductions in energy intensity are a result of technological innovation, structural changes, regulation, fiscal support, and direct investment, as well as increased economic efficiency in underlying sectors (Yao et al. 2015; Sanchez and Stern 2016; Chang et al. 2019; Dong et al. 2019a; Mohammed et al. 2019; Stern 2019; Azhgaliyeva et al. 2020; Goldemberg 2020; Gao et al. 2021; Liddle and Huntington 2021; Liu et al. 2019b; Xia et al. 2021).

The decades-long trend that efficiency gains were outpaced by an increase in worldwide GDP (or income) per capita continued unabated in the last 10 years (*robust evidence, high agreement*) (Wiedmann et al. 2020; Xia et al. 2021). In addition, the emissions-reducing effects of energy efficiency improvements are diminished by the energy rebound effect, which has been found in several studies to largely offset any energy savings (*robust evidence, high agreement*) (Rausch and Schwerin 2018; Colmenares et al. 2020; Stern 2020; Brockway et al. 2021; Bruns et al. 2021). The rebound effect is discussed extensively in Section 9.9.2.

A significant decarbonisation of the energy system was only noticeable in North America, Europe and Eurasia. Globally, the amount of CO₂ per unit of energy used has practically remained unchanged over the last three decades (Tavakoli 2018; Chang et al. 2019), although it is expected to decrease more consistently in the future (Xia et al. 2021). Population growth has also remained a strong and persistent upward driver in almost all regions (+1.2% yr⁻¹ globally from 2010 to 2019) (Lamb et al. 2021) (Figure 2.16), although per capita emission levels are very uneven across world regions. Therefore, modest population increases in

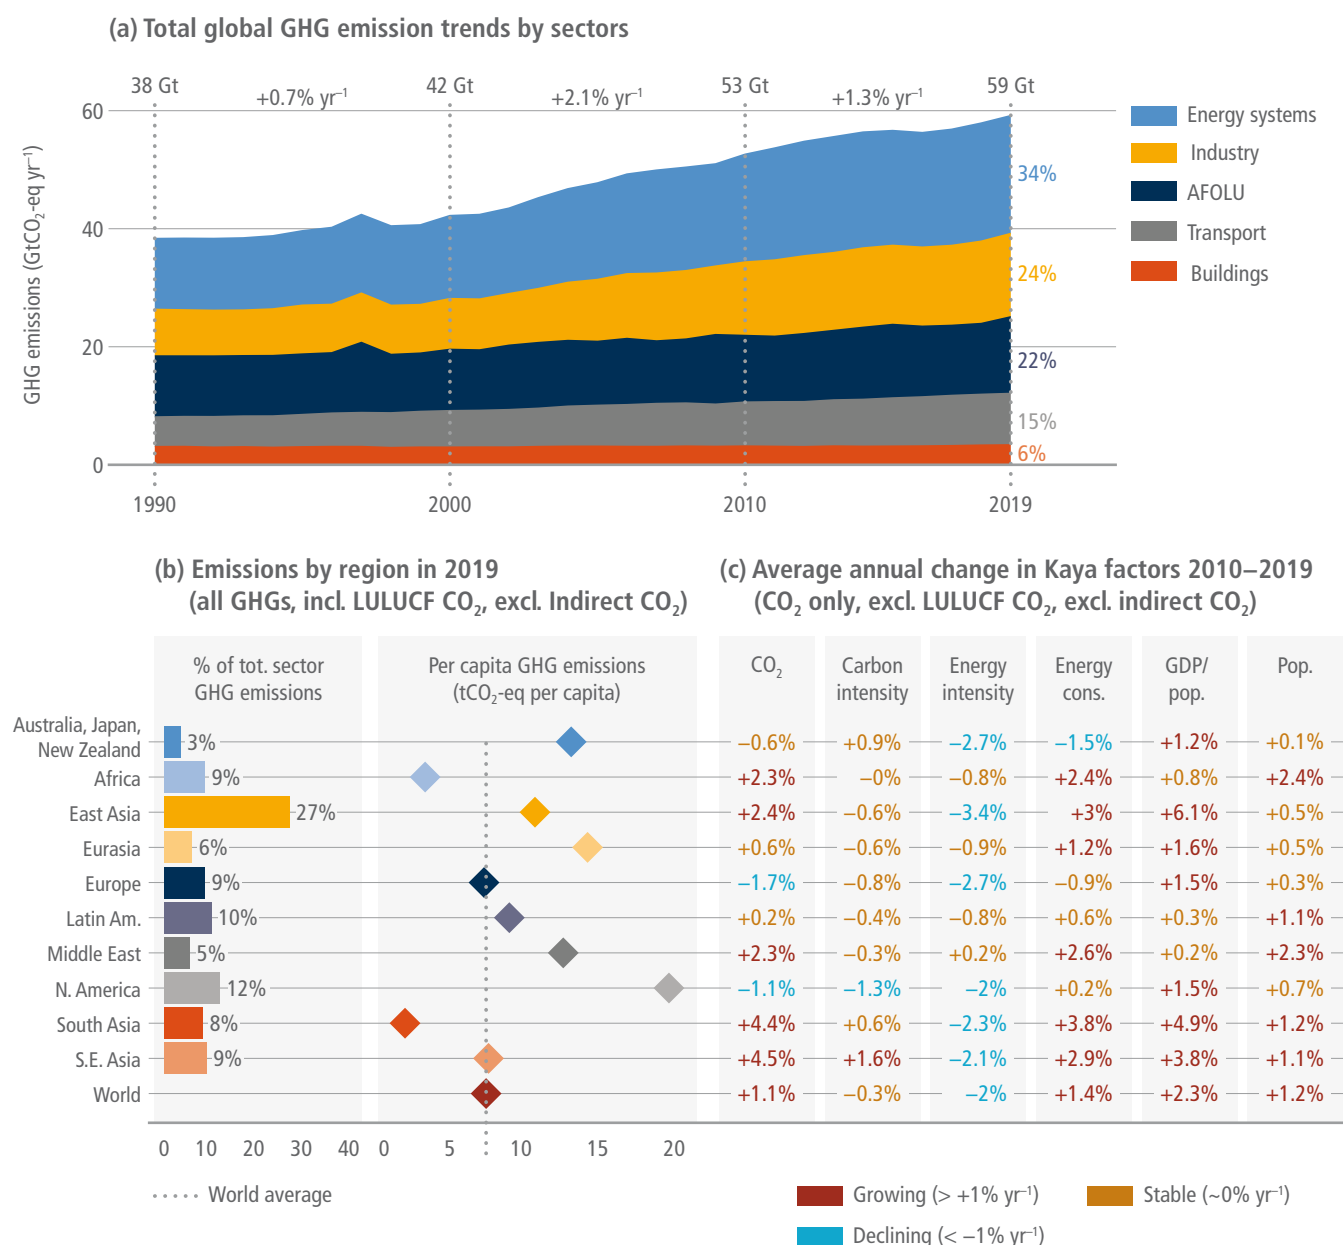

Figure 2.16 | Trends and drivers of global GHG emissions, including: (a) trends of GHG emissions by sectors 1990–2019; (b) share of total and per capita GHG emissions by world region in 2019; and (c) Kaya decomposition of CO₂ emissions drivers. The Kaya decomposition is based on the equation $F = P(G/P)(E/G)(F/E)$, where F is CO₂ emissions, P is population, G/P is GDP per capita, E/G is the energy intensity of GDP and F/E is the carbon intensity of energy. The indicated annual growth rates are averaged across the years 2010–2019 (in panel (c), these are for fossil fuel CO₂ emissions only, in order to ensure compatibility with underlying energy data). Note that the energy consumption by itself (primary energy supply) is not part of the decomposition, but is listed here for comparison with the Kaya factors. Source: data from Crippa et al. (2021), IEA (2021c), Minx et al. (2021).

wealthy countries may have a similar impact on emissions as high population increases in regions with low per capita emission levels.

Developing countries remained major accelerators of global CO₂ emissions growth since 2010, mostly driven by increased consumption and production, in particular in East Asia (*robust evidence, high agreement*) (Jiborn et al. 2020). While energy intensity declined to a similar extent in countries of the Organisation for Economic Co-operation and Development (OECD) and non-OECD countries over the last 30 years, economic growth has been much stronger in non-OECD countries (González-Torres et al. 2021). This led to an average annual growth rate of 2.8% of CO₂ emissions in these countries, whereas they decreased by 0.3% yr⁻¹ in OECD countries (UNEP 2019). The majority of developed economies reduced both production-based and consumption-based CO₂ emissions modestly (Jiborn et al. 2020; Xia et al. 2021). This was due to slower economic growth, increased energy efficiency (less energy per unit of GDP), fuel switching from coal to gas (mostly in North America) (Wang et al. 2020b), and the use of less and cleaner energy from renewables in Europe (Peters et al. 2017; Karstensen et al. 2018; Chang et al. 2019; Wood et al. 2019c).

Economic growth as the main driver of GHG emissions is particularly strong in China and India (*robust evidence, high agreement*) (Liu et al. 2019b; Ortega-Ruiz et al. 2020; Z. Wang et al. 2020b; Yang et al. 2020; Zheng et al. 2020; Xia et al. 2021), although both countries show signs of relative decoupling because of structural changes (Marin and Mazzanti 2019). A change in China's production structure (with relatively less heavy industry and lower-carbon manufacturing) and consumption patterns (i.e., the type of goods and services consumed) has become the main moderating factor of emissions after 2010, while economic growth, consumption levels, and investment remain the dominating factors driving up emissions (Wang and Jiang 2019; Jiborn et al. 2020; Zheng et al. 2020). In India, an expansion of production and trade as well as a higher energy intensity between 2010 and 2014 caused increased emissions (Kanitkar et al. 2015; Wang and Zhou 2020; Z. Wang et al. 2020b).

2.4.2 Sectoral Drivers

GHG emissions continued to rise since 2010 across all sectors and subsectors, most rapidly in electricity production, industry, and transport. Decarbonisation gains from improvements in energy efficiency across different sectors and worldwide have been largely wiped out by increases in demand for goods and services. Prevailing consumption patterns have also tended to aggravate energy use and emissions, with the long-term trend led by developed regions. Decarbonisation trends in some developed regions are limited in size and geographically. Globally, there are enormous unexploited mitigation potentials from adopting best available technologies.

The following subsections discuss main emissions drivers by sector. More detailed analyses of sectoral emissions and mitigation options are presented in Chapters 6–11.

2.4.2.1 Energy Systems

Global energy system emissions growth has slowed down in recent years, but global oil and gas use was still growing (Jackson et al. 2019) and the sector remained the single largest contributor to global GHG emissions in 2019 with 20 GtCO₂-eq (34%) (*high confidence*) (Figure 2.17). Most of the 14 GtCO₂-eq from electricity and heat generation (23% of global GHG emissions in 2019) were due to energy use in industry and in buildings, making these two sectors also prominent targets for mitigation (Davis et al. 2018; Crippa et al. 2019) (see subsections 2.4.2.2 and 2.4.2.3 below).

Growth in CO₂ emissions from energy systems has closely tracked rising GDP per capita globally (Lamb et al. 2021b), affirming the substantial literature describing the mutual relationship between economic growth and demand for energy and electricity (*robust evidence, high agreement*) (Khanna and Rao 2009; Stern, 2011). This relationship has played out strongly in developing regions, particularly in Asia, where a massive scale up of energy supply has accompanied economic growth – with average annual increases of energy demand between 3.8–4.3% in 2010–2019 (Figure 2.17). The key driver for slowing the growth of energy systems CO₂ emissions has been declining energy intensities in almost all regions. Annually, 1.9% less energy per unit of GDP was used globally between 2010 and 2019.

The carbon intensity of power generation varies widely between (and also within) regions (Chapter 6). In North America, a switch from coal to gas for power generation (Peters et al. 2017, 2020; Feng 2019; Mohlin et al. 2019) as well as an overall decline in the share of fossil fuels in electricity production (from 66% in 2010 to 59% in 2018) (Mohlin et al. 2019) has decreased carbon intensity and CO₂ emissions. Since 2007, Europe's carbon intensity improvements have been driven by the steady expansion of renewables in the share of electricity generation (*medium evidence, high agreement*) (Peters et al. 2017, 2020; Le Quéré et al. 2019; Rodrigues et al. 2020). Some studies attribute these effects to climate policies, such as the carbon floor price in the UK, the EU emissions trading scheme, and generous renewable energy subsidies across the continent (Dyrstad et al. 2019; H. Wang et al. 2020). South-East Asian developed countries and Australia, Japan and New Zealand stand out in contrast to other developed regions, with an increase of regional carbon intensity of 1.8 and 1.9% yr⁻¹, respectively (Figure 2.17). Generally, the use of natural gas for electricity production is growing strongly in most countries and gas has contributed to the largest increase in global fossil CO₂ emissions in recent years (Jackson et al. 2019; Peters et al. 2020). Furthermore, gas brings the risk of increased methane (CH₄) emissions from fugitive sources, as well as large cumulative emissions over the lifetime of new gas power plants that may erase early carbon intensity reductions (Shearer et al. 2020).

The growth of emissions from coal power slowed after 2010, and even declined between 2011 and 2019, primarily due to a slowdown of economic growth and fewer coal capacity additions in China (Friedlingstein et al. 2019; Peters et al. 2020). Discussions of a global 'peak coal', however, may be premature, as further growth was observed in 2019 (Friedlingstein et al. 2019; Peters et al. 2020). Large

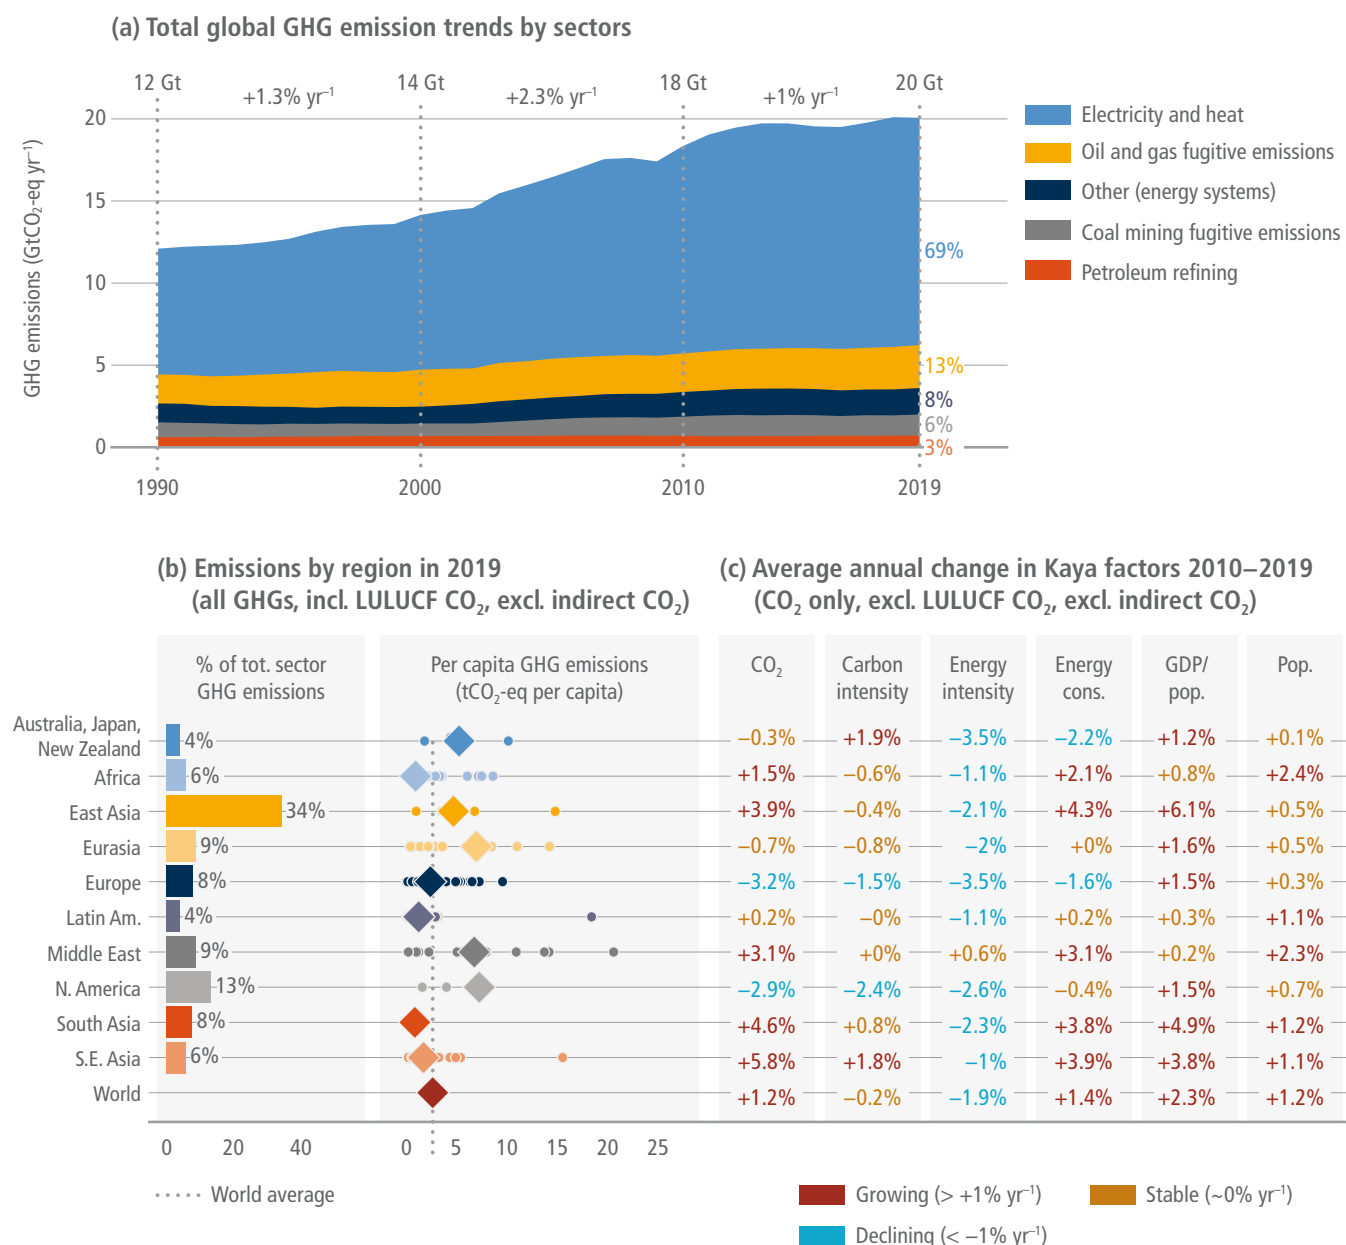

Figure 2.17 | Trends and drivers of global energy sector emissions (see Figure 2.16 caption for details) with energy measured as primary energy supply.

ongoing and planned capacity increases in India, Turkey, Indonesia, Vietnam, South Africa, and other countries has become a driver of thermal coal use after 2014 (UNEP 2017; Edenhofer et al. 2018; Steckel et al. 2019).

2.4.2.2 Industry Sector

When indirect emissions from electricity and heat production are included, industry becomes the single highest emitting sector of GHGs (20.0 GtCO₂-eq in 2019) (*high confidence*). Facilitated by globalisation, East Asia has been the main source and primary driver of global industry emissions growth since 2000 (*robust evidence, high agreement*) (Lamb et al. 2021). However, while East Asia has emitted 45% of the world's industry GHG emissions in 2019, a remarkable decrease of 5.0% yr⁻¹ in energy intensity and 1.6% in

carbon intensity helped to stabilise direct industrial CO₂ emissions in this region (−0.3% yr⁻¹ between 2010 and 2019; Figure 2.18). Direct industry CO₂ emissions have also declined in Latin America, Europe and Australia, Japan and New Zealand, and – to a smaller extent – in North America. In all other regions, they were growing – most rapidly in southern Asia (+4.3% annually for direct CO₂ emissions since 2010) (Figure 2.18).

The main global driver of industry emissions has been a massive rise in the demand for products that are indirectly used in production, such as cement, chemicals, steel, aluminium, wood, paper, plastics, lubricants, fertilisers, and so on. This demand was driven by economic growth, rising affluence, and consumption, as well as a rapid rise in urban populations and associated infrastructure development (*robust evidence, high agreement*) (Krausmann et al. 2018). There is

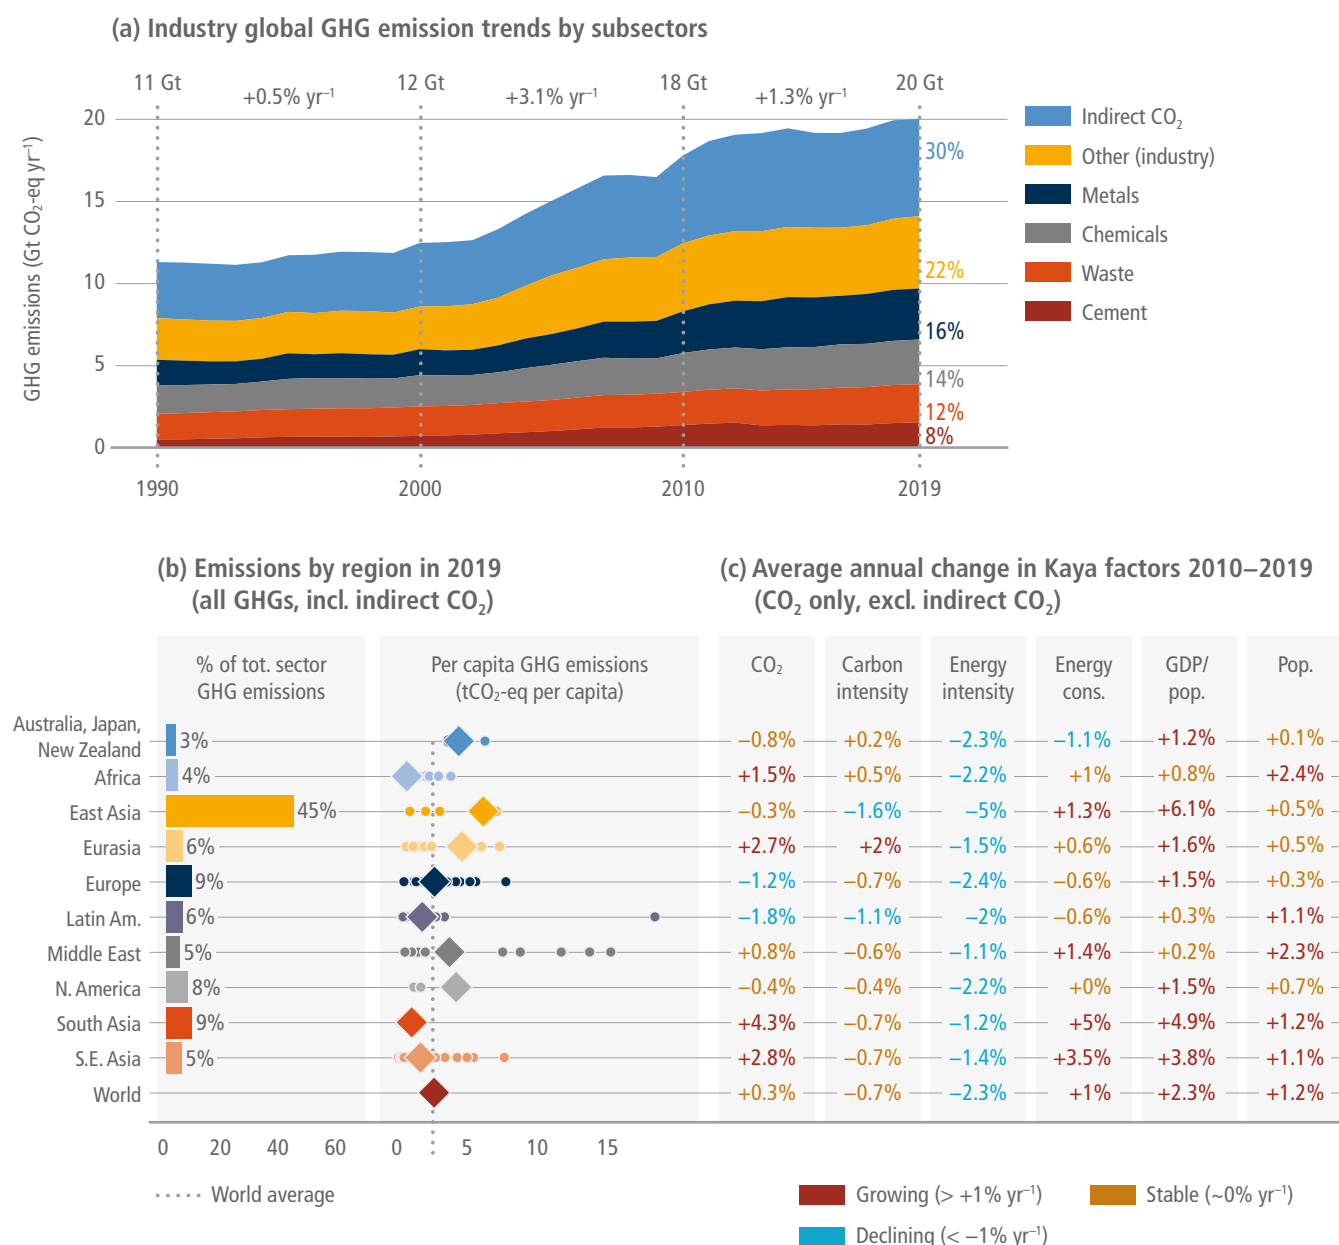

Figure 2.18 | Trends and drivers of global industry sector emissions (see Figure 2.16 caption for details) with energy measured as total final energy consumption.

strong evidence that the growing use of concrete, steel, and other construction materials is particularly tightly coupled to these drivers (Pauliuk et al. 2013; Cao et al. 2017; Krausmann et al. 2017; Plank et al. 2018; Haberl et al. 2020). Per capita stocks of cement and steel show a typical pattern of rapid take-off as countries urbanise and industrialise, before slowing down to low growth at high levels of GDP. Hence, in countries that have recently been industrialising and urbanising – that is Eastern, Southern and South-Eastern Asia – a particularly strong increase of emissions from these subsectors can be observed. Selected wealthy countries seem to stabilise at high per capita levels of stocks, although it is unclear if these stabilisations persist and if they result in significant absolute reductions of material use (Wiedenhofer et al. 2015; Cao et al. 2017; Krausmann et al. 2018). Opportunities for prolonging lifetimes and improving end of

life recycling in order to achieve absolute reductions in extraction activities are as yet unexploited (Krausmann et al. 2017; Zink and Geyer, 2017).

On the production side, improvements in the efficiency of material extraction, processing, and manufacturing have reduced industrial energy use per unit of output (J. Wang et al. 2019). These measures, alongside improved material substitution, lightweight designs, extended product and servicing lifetimes, improved service efficiency, and increased reuse and recycling will enable substantial emissions reductions in the future (Hertwich et al. 2019). In absence of these improvements in energy intensity, the growth of population and GDP per capita would have driven the industrial CO₂ emissions to rise by more than 100% by 2017 compared with 1990, instead

of 56% (Lamb et al. 2021b). Nonetheless, many studies point to deep regional differences in efficiency levels and large globally unexploited potentials to improve industrial energy efficiency by adopting best available technologies and practices for metal, cement, and chemical production (Gutowski et al. 2013; Schulze et al. 2016; Hernandez et al. 2018; Talaei et al. 2018).

2.4.2.3 Buildings Sector

Global direct and indirect GHG emissions from the buildings sector reached 9.7 GtCO₂-eq in 2019, or 16% of global emissions). Most of these emissions (66%, or 6.4 GtCO₂-eq) were upstream emissions from power generation and commercial heat (Figure 2.19). The remaining 33% (3.3 GtCO₂-eq) of emissions were directly produced

in buildings, for instance by gas and coal boilers, and cooking and lighting devices that burn kerosene, biomass, and other fuels (Lamb et al. 2021). Residential buildings accounted for the majority of this sector's emissions (64%, 6.3 GtCO₂-eq, including both direct and indirect emissions), followed by non-residential buildings (35%, 3.5 GtCO₂-eq) (*high confidence*).

Global buildings sector GHG emissions increased by 0.7% yr⁻¹ between 2010 and 2019 (Figure 2.19), growing the most in absolute terms in East and South Asia, whereas they declined the most in Europe, mostly due to the expansion of renewables in the energy sector and increased energy efficiency (Lamb et al. 2021). North America has the highest per capita GHG emissions from buildings and the second highest absolute level after East Asia (Figure 2.19).

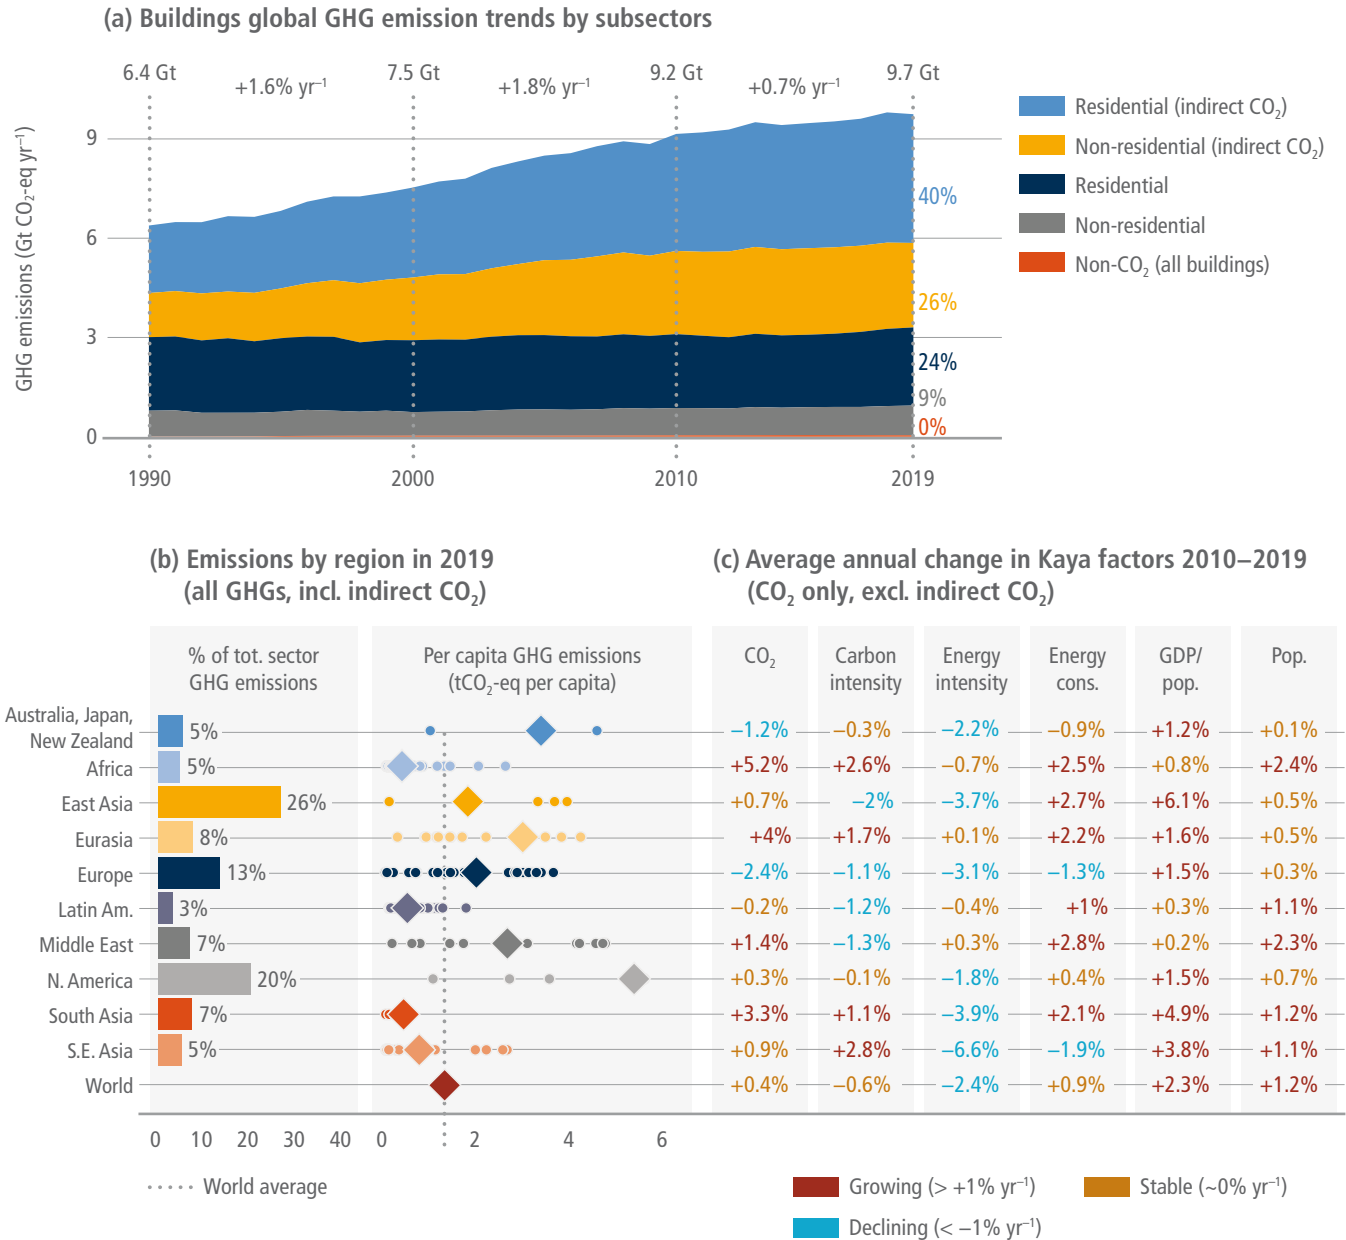

Figure 2.19 | Trends and drivers of global buildings sector emissions (see Figure 2.16 caption for details) with energy measured as total final energy consumption.

Rising wealth has been associated with more floor space being required to service growing demand in the retail, office, and hotel sectors (*medium evidence, high agreement*) (Daiglou et al. 2012; Deetman et al. 2020). In addition, demographic and social factors have driven a cross-national trend of increasing floor space per capita. As populations age and decrease in fertility, and as individuals seek greater privacy and autonomy, households declined in size, at least before the COVID-19 pandemic (Ellsworth-Krebs 2020). These factors led to increased floor space per capita, even as populations stabilise. This in turn is a key driver for building sector emissions, because building characteristics such as size and type, rather than occupant behaviour, tend to explain the majority of energy use within dwellings (Guerra Santin et al. 2009; Ürge-Vorsatz et al. 2015; Huebner and Shipworth 2017) (Chapter 9).

Energy activity levels further drive regional differences. In Eurasia, Europe and North America, thermal demands for space heating dominate building energy use, at 66%, 62% and 48% of residential energy demand, respectively (IEA 2020a). In contrast, cooking has a much higher share of building energy use in regions of the Global South, including China (Cao et al. 2016). And, despite temperatures being on average warmer in the Global South, electricity use for cooling is a more prominent factor in the Global North (Waite et al. 2017). This situation is changing, however, as rapid income growth and demographic changes in the Global South enable households to heat and cool their homes (Ürge-Vorsatz et al. 2015, 2020).

Steady improvements in building energy intensities across regions can be attributed to baseline improvements in building fabrics, appliance efficiencies, energy prices, and fuel shifts. Many countries have adopted a mix of relevant policies, such as energy labelling, building energy codes, and mandatory energy performance requirements (Nie and Kemp 2014; Nejat et al. 2015; Economidou et al. 2020). Efforts towards building refurbishments and retrofits have also been pursued in several nations, especially for historical buildings in Europe, but evidence suggests that the recent retrofit rates have not made a significant dent on emissions (Corrado and Ballarini 2016). The Chinese central government launched various policies, including command and control, economic incentives, and technology measures, but a big gap remains between the total rate of building green retrofit in the nation and the future retrofit potential (G. Liu et al. 2020a, 2020b). Still, one major global factor driving down energy intensities has been the global transition from inefficient coal and biomass use in buildings for heating and cooking, towards natural gas and electricity, in part led by concerted policy action in Asian countries (Ürge-Vorsatz et al. 2015; Kerimray et al. 2017; Thoday et al. 2018). As developing countries construct new buildings, there is sizable potential to reduce and use less carbon-intensive building materials and adopt building designs and standards that lower lifecycle buildings energy use and allow for passive comfort. Chapter 9 describes the mitigation options of the buildings sector.

2.4.2.4 Transport Sector

With a steady, average annual growth of +1.8% yr⁻¹ between 2010 and 2019, global transport GHG emissions reached 8.9 GtCO₂-eq in 2019 and accounted for 15% of all direct and indirect

emissions (Figure 2.20). Road transport passenger and freight emissions represented by far the largest component and source of this growth (6.1 GtCO₂-eq, 69% of all transport emissions in 2019) (*high confidence*). National plus international shipping and aviation emissions together accounted for 2.0 GtCO₂-eq or 22% of the sector's total in 2019. North America, Europe and Eastern Asia stand out as the main regional contributors to global transport emissions and together account for 50% of the sector's total.

The proportion of total final energy used in transport (28%) and its fast expansion over time weighs heavily on climate mitigation efforts, as 92% of transport energy comes from oil-based fuels (IEA 2020b). These trends situate transport as one of the most challenging sectors for climate change mitigation – no country has so far been able to realise significant emissions reductions in the sector. North America's absolute and per capita transport emissions are the highest amongst world regions, but those of South, South-East and East Asia are growing the fastest (*high confidence*) (between +4.6% and +5.2% yr⁻¹ for CO₂ between 2010 and 2019) (Figure 2.20).

More so than any other sector, transport energy use has tracked GDP per capita growth (Figure 2.20), (Lamb et al. 2021). With the exception of road gasoline demand in OECD countries, the demand for all road fuels generally increases at least as fast as the rate at which GDP per capita increases (Liddle and Huntington 2020). Developments since 1990 continue a historical trend of increasing travel distances and a shift from low- to high-speed transport modes that goes along with GDP growth (Schäfer et al. 2009; Gota et al. 2019). Modest improvements in energy efficiency have been realised between 2010 and 2019, averaging -1.5% yr⁻¹ in energy intensity globally, while carbon intensities of the transport sector have remained stable in all world regions (Figure 2.20). Overall, global increases in passenger and freight travel activity levels have outpaced energy efficiency and fuel economy improvements, continuing a long-term trend for the transport sector (*medium evidence, high agreement*) (Gucwa and Schäfer 2013; Grübler 2015; McKinnon 2016).

Despite some policy achievements, energy use in the global transport system remains to the present deeply rooted in fossil fuels (*robust evidence, high agreement*) (Figueroa et al. 2014; IEA 2019). In part this is due to the increasing adoption of larger, heavier combustion-based vehicles in some regions, which have tended to far outpace electric and hybrid vehicle sales (Chapter 10). Yet, stringent material efficiency and lightweight design of passenger vehicles alone would have the potential to cut cumulative global GHG emissions until 2060 by 16–39 GtCO₂-eq (Pauliuk et al. 2021).

While global passenger activity has expanded in all world regions, great disparities exist between low- and high-income regions, and within countries between urban and rural areas (ITF 2019). While private car use is dominant in OECD countries (EC 2019), the growth of passenger-km (the product of number of travellers and distance travelled) has considerably slowed there, down to an increase of just 1% yr⁻¹ between 2000 and 2017 (SLoCaT 2018) (Chapter 10). Meanwhile, emerging economies in the Global South are becoming more car-dependent, with rapidly growing motorisation, on-demand private transport services, urban sprawl, and the emergence of local

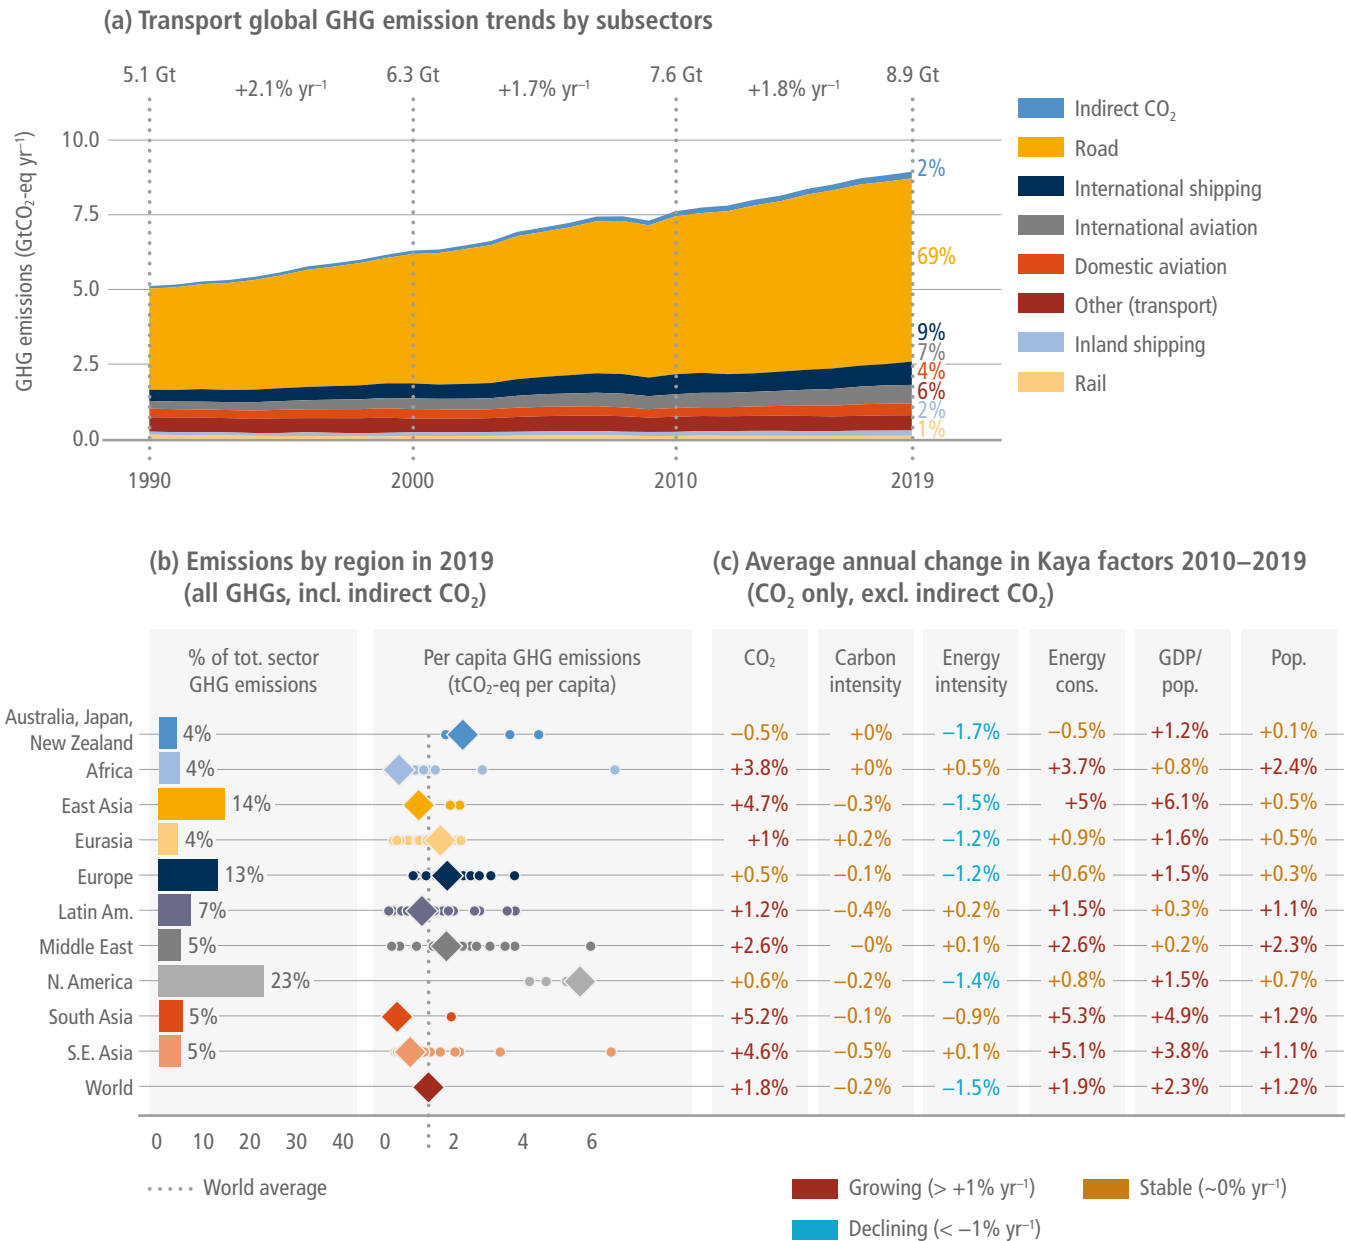

Figure 2.20 | Trends and drivers of global transport sector emissions (see Figure 2.16 caption for details) with energy measured as total final energy consumption.

automotive production, while public transport struggles to provide adequate services (Dargay et al. 2007; Hansen and Nielsen 2017; Pojani and Stead 2017).

Freight travel activity grew across the globe by 68% in the last two decades, driven by global GDP increases, together with the proliferation of online commerce and rapid (i.e., same-day and next-day) delivery (SLoCaT 2018). Growth has been particularly rapid in heavy-duty road freight transport.

While accounting for a small share of total GHG emissions, domestic and international aviation have been growing faster than road transport emissions, with average annual growth rates of +3.3% and +3.4%, respectively, between 2010 and 2019 (Crippa et al. 2021;

Minx et al. 2021;). Energy efficiency improvements in aviation were considerably larger than in road transport, but were outpaced by even larger increases in activity levels (SLoCaT 2018; Lee et al. 2021) (Chapter 10).

2.4.2.5 AFOLU Sector

GHG emissions from agriculture, forestry and other land use (AFOLU) reached 13 GtCO₂-eq globally in 2019 (*medium confidence*) (Figure 2.21). AFOLU trends, particularly those for CO₂-LULUCF, are subject to a high degree of uncertainty (Section 2.2.1). Overall, the AFOLU sector accounts for 22% of total global GHG emissions, and in several regions – Africa, Latin America, and South-East Asia – it is the single largest emitting sector, which is also significantly

affected itself by climate change (AR6 WGI Chapters 8, 11, and 12; and AR6 WGII Chapter 5). Latin America has the highest absolute and per capita AFOLU GHG emissions of any world region (Figure 2.21). CO₂ emissions from land-use change and CH₄ emissions from enteric fermentation together account for 74% of sector-wide GHGs. Note that CO₂-LULUCF estimates included in this chapter are not necessarily comparable with country GHG inventories, due to different approaches to estimating anthropogenic CO₂ sinks (Grassi et al. 2018) (Chapter 7).

Unlike all other sectors, AFOLU emissions are typically higher in developing compared to developed regions (*medium confidence*). In Africa, Latin America, and South-East Asia, CO₂ emissions associated with land-use change and management predominate, dwarfing other AFOLU and non-AFOLU sources and making AFOLU the single largest sector with more than 50% of emissions in these regions (Lamb et al. 2021b). Land-use and land-management emissions are associated with the expansion of agriculture into carbon-dense tropical forest areas (Vancutsem et al. 2021), where large quantities of CO₂ emissions result from the removal and burning of biomass and draining of carbon rich soils (Pearson et al. 2017;

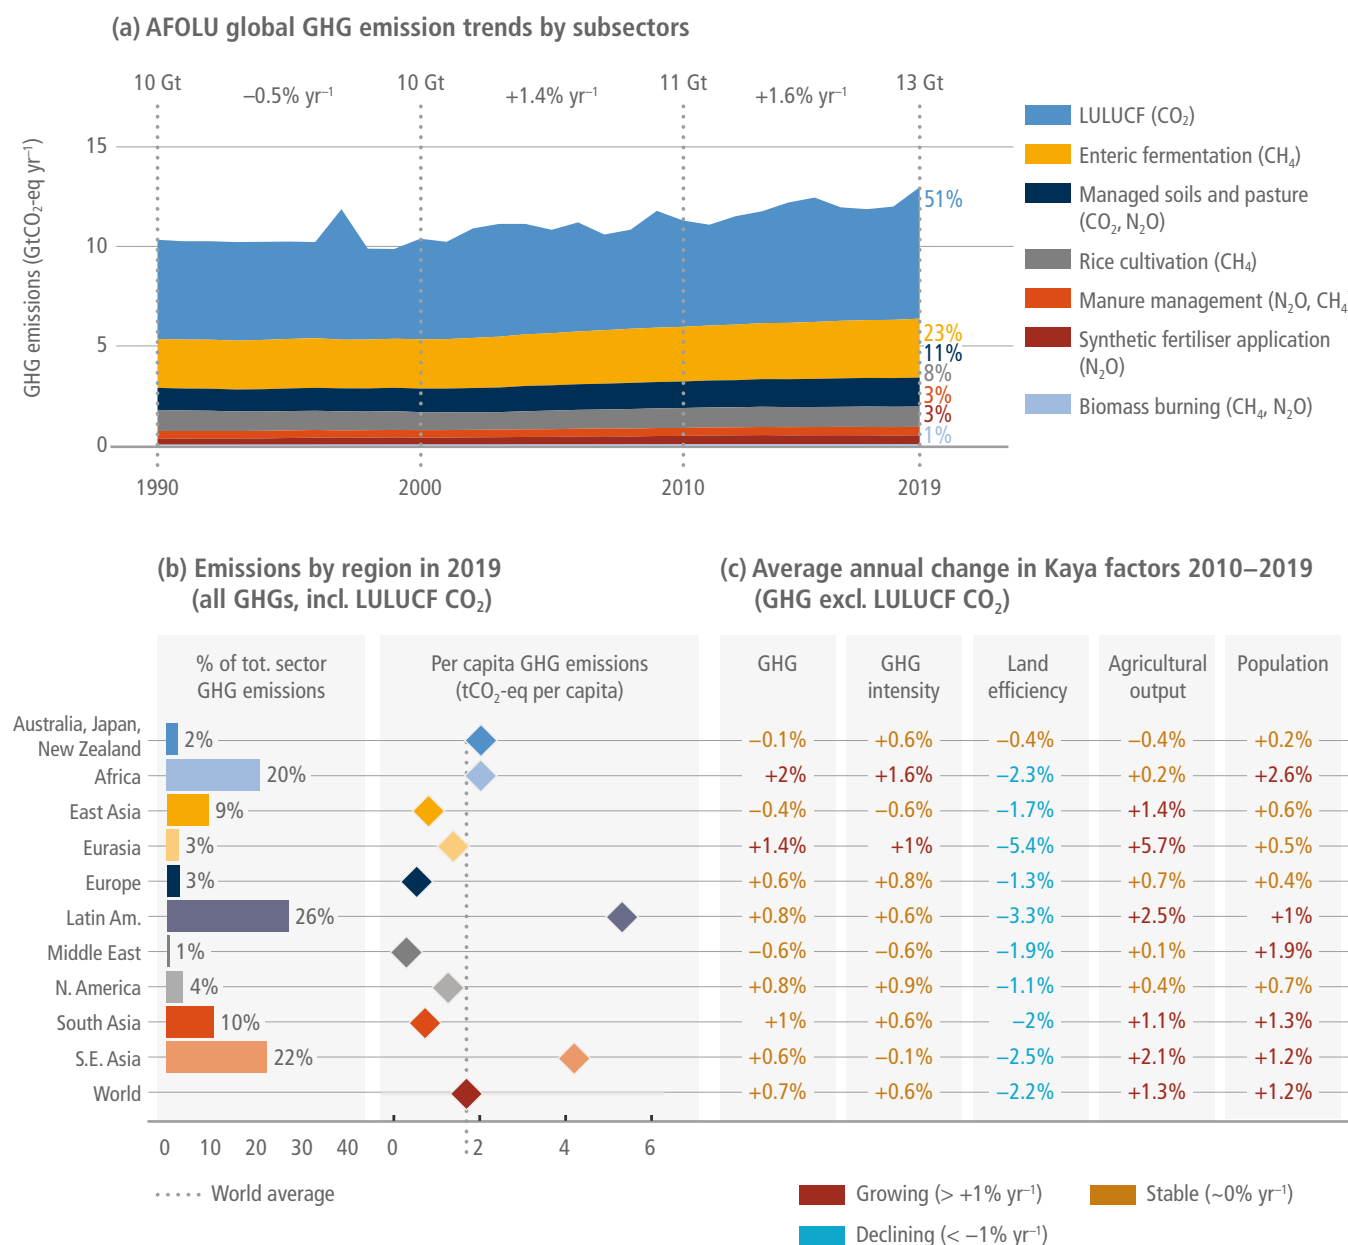

Figure 2.21 | Trends and drivers of global AFOLU sector emissions: (a) trends of GHG emissions by subsectors 1990–2019; (b) share of total sector and per capita GHG emissions by world region in 2019; and (c) Kaya decomposition of GHG emissions drivers. Based on the equation $H = P(A/P)(L/A)(H/L)$, where P is population, A/P is agricultural output per capita, L/A is the land required per unit of agricultural output (land efficiency), and H/L is GHG emissions per unit of land (GHG intensity) (Hong et al. 2021). GHG emissions H comprise agricultural CH₄ and N₂O emissions from EDGAR v6.0. The indicated annual growth rates are averaged across the years 2010–2019 – LULUCF CO₂ emissions are excluded in panel (c). (Note: due to different datasets, the population breakdown for AFOLU emissions is slightly different than that in the other sector figures above).

IPCC 2018; Hong et al. 2021). Ruminant livestock rearing takes place on vast tracts of pasture land worldwide, contributing to large quantities of CH₄ emissions from enteric fermentation in Latin America (0.8 GtCO₂-eq in 2018), Southern Asia (0.6 GtCO₂-eq), and Africa (0.5 GtCO₂-eq), while also playing a sizable role in the total AFOLU emissions of most other regions (Lamb et al. 2021b).

In all regions, the amount of land required per unit of agricultural output has decreased significantly from 2010 to 2019, with a global average of $-2.2\% \text{ yr}^{-1}$ (land efficiency metric in Figure 2.21). This reflects agricultural intensification and technological progress. However, in most regions this was mirrored by an increase in output per capita, meaning that absolute GHG emissions in most regions increased over the last decade. A significant increase in total AFOLU emissions occurred in Africa, driven by both increased GHG emissions per unit of land and increased populations (Figure 2.21).

The AFOLU sector and its emissions impacts are closely tied to global supply chains, with countries in Latin America and South-East Asia using large portions of their land for agricultural and forestry products exported to other countries (Chapter 7). The strong increases in production per capita and associated GHG emissions seen in these regions are at least partly attributable to growing exports and not national food system or dietary changes. At the same time, efforts to promote environmental sustainability in regions such as the EU and the USA (but also fast-growing emerging economies such as China) can take place at the cost of increasing land displacement elsewhere to meet their own demand (Meyfroidt et al. 2010; Yu et al. 2013; Creutzig et al. 2019).

Global diets are a key driver of production per capita, and thus land pressure and AFOLU emissions (Chapter 7). As per capita incomes rise and populations urbanise, traditional, low-calorie diets that emphasise starchy foods, legumes, and vegetables transition towards energy-intensive products such as refined sugars, fats, oils, and meat (Pradhan et al. 2013; Tilman and Clark 2014). At a certain point in national development, affluence and associated diets thus override population growth as the main driver of AFOLU emissions (Kastner et al. 2012). Very high calorie diets have high total GHG emissions per capita (Heller and Keoleian 2015) and are common in the developed world (Pradhan et al. 2013). Over the last few decades, a 'westernisation' of diets has also been occurring in developing countries (Pradhan et al. 2013). Low- and middle-income countries such as India, Brazil, Egypt, Mexico, and South Africa have experienced a rapid dietary shift towards western-style diets (De Carvalho et al. 2013; Pradhan et al. 2013; Popkin 2015). Another driver of higher food requirements per capita is food waste, which has increased more or less continuously since the 1960s in all regions but Europe (Porter and Reay 2016).

2.4.3 Poverty and Inequality

Increasing economic inequality globally has given rise to concern that unequal societies may be more likely to pollute and degrade their environments (Masud et al. 2018; Chancel 2020; Hailemariam et al. 2020; Millward-Hopkins and Oswald 2021). The nature of this

relationship has important implications for the design of income redistribution policies aiming to reduce inequalities (Section 2.6 presents evidence on how affluence and high consumption relate to emissions). Income inequality and carbon intensity of consumption differs across countries and individuals (Baležentis et al. 2020) (Section 2.3.3). Reduced income inequality between nations can reduce emissions intensity of global income growth, if energy intensity reductions from income growth in some nations offset increases in energy and emissions from higher growth in other nations (Rao and Min 2018). Increasing income inequality between individuals can translate into larger energy and emissions inequality if higher incomes are spent on more energy-intensive consumption and affluent lifestyles (Oswald et al. 2020; Wiedmann et al. 2020) (Section 2.6).

Literature shows that more equitable income distributions can improve environmental quality, but the nature of this relationship can vary by level of development (*low evidence, medium agreement*) (Knight et al. 2017; Chen et al. 2020; Hailemariam et al. 2020; Huang and Duan 2020; Liobikienė and Rimkuvienė 2020; Rojas-Vallejos and Lastuka 2020; Uddin et al. 2020). Differences in the energy and carbon intensities of consumption and the composition of consumption baskets across populations and nations matter for emissions. (Jorgenson et al. 2016; Grunewald et al. 2017). There is evidence to suggest that more equal societies place a higher value on environmental public goods (Baumgärtner et al. 2017; Drupp et al. 2018). Additional research shows that reducing top income inequality in OECD countries can reduce carbon emissions and improve environmental quality (Hailemariam et al. 2020) and that the effect of wealth inequality, measured as the wealth share of the top decile, on per capita emissions in high-income countries, is positive (Knight et al. 2017). Evidence from 40 sub-Saharan African countries suggests that a rise in income inequality contributed to increasing CO₂ emissions between 2010 and 2016, controlling for other drivers such as economic growth, population size, and inflation (Baloch et al. 2020).

The key development objective of eradicating extreme poverty (Chakravarty and Tavoni 2013; Hubacek et al. 2017a; Malerba 2020) and providing universal access to modern energy services (Pachauri et al. 2013, 2018; Pachauri 2014; Singh et al. 2017) only marginally affects GHG emissions (*medium evidence, high agreement*). Shifts from biomass to more efficient energy sources and collective provisioning systems for safe water, health, and education are associated with reduced energy demand (Baltruszewicz et al. 2021). Efforts to alleviate multi-dimensional poverty by providing minimum decent living standards universally, however, may require more energy and resources. Recent estimates of the additional energy needed are still within bounds of projections of energy demand under climate stabilisation scenarios (Hubacek et al. 2017a, 2017b; Rao et al. 2019; Pascale et al. 2020; Kikstra et al. 2021). Bottom-up estimates suggest that achieving decent living standards requires 13–40 GJ per capita annually, much less than the current world average energy consumption of 80 GJ per capita in 2020 (Millward-Hopkins et al. 2020) (*medium evidence, high agreement*). Aggregate top-down estimates suggest that achieving a high Human Development Index (HDI) score above 0.8 requires energy consumption between

30–100 GJ per capita yr⁻¹ (Lamb and Rao 2015). There is some evidence, however, of a decoupling between energy consumption and HDI over time (Akizu-Gardoki et al. 2018). The emissions consequences of poverty alleviation and decent living also depend on whether improvements in well-being occur via energy- and carbon-intensive industrialisation or low-carbon development (Semieniuk and Yakovenko 2020; Fu et al. 2021; Huang and Tian 2021).

2.4.4 Rapid and Large-scale Urbanisation as a Driver of GHG Emissions

Economic growth and urbanisation go hand in hand and are both influencing GHG emissions. However, the exact role of urban development in driving emissions is multi-faceted and heterogeneous, depending on development status and other regional factors (*medium evidence, high agreement*) (Jorgenson et al. 2014; Lamb et al. 2014; Liddle and Lung 2014; Creutzig et al. 2015; Pincetl 2017; Azizalrahman and Hasyimi 2019; Muñoz et al. 2020). This calls for a differentiated assessment. This section assesses the process of rapid urban growth in developing countries and how emissions change over time when cities' urban populations and infrastructure expand at fast speed and at a massive scale (Seto et al. 2017; Elmqvist et al. 2021). To distinguish, Section 2.6 includes the carbon footprint of urban lifestyles and the difference in emissions profiles between already urbanised and less urbanised areas. Chapter 8 deals with urban strategies for climate change mitigation.

Urban development is most significant and rapid in developing and transition countries, accompanied by a substantial migration of rural populations to urban areas (Apergis and Li 2016; Azizalrahman and Hasyimi 2019; Z. Wang et al. 2019) and associated impacts on land use (Richardson et al. 2015). If the trend of developing countries following infrastructure stock patterns in industrialised nations continues until 2050, this could cause approximately 350 GtCO₂ from the production of materials (Müller et al. 2013). This would be equivalent to 70% of the 500 GtCO₂ estimated remaining carbon budget from the beginning of 2020 to limit global warming to 1.5°C with a likelihood of 50% (IPCC 2021b).

In many developing countries across the world, the process of urban expansion leads to higher per capita consumption-based GHG emissions (*medium evidence, high agreement*) (Jorgenson et al. 2014; Yao et al. 2015; Zhang et al. 2016; Wood et al. 2018a; Muñoz et al. 2020). The high disparity between rural and urban personal carbon footprints in these countries (Wiedenhofer et al. 2017) (Section 2.6) means that migration to urban areas increases overall emissions as levels of income and expenditure rise, leading to further economic growth and infrastructure development in urban areas (Müller et al. 2013; Li et al. 2015; Wang and Yang 2016; Zhang et al. 2016; Wiedenhofer et al. 2017; Cetin and Bakirtas 2019; Fan et al. 2019; Li and Zhou 2019; Xia et al. 2019; Sarkodie et al. 2020).

For total production-based emissions in general, urbanisation is thought to have a smaller effect than changes in population, GDP per capita, and energy and emissions intensities, which are all more influential (Lin et al. 2017). Another driver of urban emissions is rising

ambient air temperature caused by urban land expansion, which will likely drive a substantive increase in air conditioning use and cold storage for food (Huang et al. 2019). Specific emission drivers, however, depend on city- and place-specific circumstances such as income, household size, density, or local climate (Baiocchi et al. 2015; H. Wang et al. 2019). Geographical factors, urban form, and transport/fuel costs are dependent on each other, and, together with economic activity, have been found to explain 37% of urban direct energy use and 88% of urban transport energy use in a global sample of 274 cities (Creutzig et al. 2015).

2.5 Technological Change is Key to Reducing Emissions

Technological change for climate change mitigation involves improvement in and adoption of technologies, primarily those associated with energy production and use. Technological change has had a mitigating effect on emissions over the long term and is central to efforts to achieving climate goals (*high confidence*). Progress since AR5 shows that multiple low-carbon technologies are improving and falling in cost (*high confidence*); technology adoption is reaching substantial shares, and small-scale technologies are particularly promising on both (*medium confidence*). Faster adoption and continued technological progress can play a crucial role in accelerating the energy transition. However, the historical pace of technological change is still insufficient to catalyse a complete and timely transition to a low-carbon energy system: technological change needs to accelerate (*high confidence*). This section assesses the role of technological change in driving emissions reductions and the factors that drive technological change, with an emphasis on the speed of transitions. Incentives and support for technological change affect technology outcomes (Sivaram et al. 2018; Wilson et al. 2020a). Work since AR5 has focused on evaluating the effectiveness of policies: those that accelerate technological change by enhancing knowledge (technology push) and those that increase market opportunities for successful technologies (demand pull) (Nemet 2013); as well as the importance of tailoring support to country contexts (Barido et al. 2020; Rosenbloom et al. 2020), including the limits of carbon-pricing policies to date (Lilliestam et al. 2020). Section 2.8 and Chapter 13 describe how these policies affect emissions; Chapter 14 and Cross-Chapter Box 12 in Chapter 16 discuss transition dynamics; and Chapter 16 provides a more detailed assessment of the evolution and mitigation impacts of technology development, innovation, and transfer.

2.5.1 Technological Change Has Reduced Emissions

Technological change that facilitates efficient energy utilisation from production to its final conversion into end-use services is a critical driver of carbon emissions reductions (*high confidence*). Technological change can facilitate stringent mitigation, but it can also reduce these effects by changing consumer behaviour, such as through rebound effects (Section 2.6 and Chapter 16). AR6 includes an entire chapter on innovation, technology development, and transfer (Chapter 16). A focus gained in this section is the extent to which aligned,

credible, and durable policies can accelerate technological change factors to put emissions reductions on a trajectory compatible with reaching United Nations Framework Convention on Climate Change (UNFCCC) goals.

Technological change has facilitated the provision of more diverse and efficient energy services (heating, cooling, lighting, and mobility) while generating fewer emissions per unit of service. As seen in Section 2.4, in Kaya identity terms (Lima et al. 2016) (see 'Kaya identity' in Glossary): population and economic growth are factors that have increased emissions, while technological change has reduced emissions (Peters et al. 2017). These Kaya statistics show that, while technological change can facilitate the transition to a low-carbon economy, it needs to proceed at a much faster pace than historical trends (Peters et al. 2017).

Multiple challenges exist in accelerating the past rate of technological change. First, an array of physical assets in the energy system are long-lived and thus involve substantial committed carbon (Section 2.7) (Knapp 1999; Cui et al. 2019). A process of 'exnovation', accelerating the phase-out of incumbent technology through intentional policy (such as by pricing carbon), provides a means to address long lifetimes (Davidson 2019; Rosenbloom and Rinscheid 2020). Second, countries may not have the capacity to absorb the flows of ideas and research results from international knowledge spillovers due to weak infrastructure, limited research capacity, lack of credit facilities (Chapter 15, Section 15.5), and other barriers to technology transfer (Adenle et al. 2015). In a developing country context, processes of innovation and diffusion need to include competence-building systems (Lema et al. 2015; Perrot and Sanni 2018; Stender et al. 2020). Third, public policy is central to stimulating technological change to reduce emissions; policy depends on creating credible expectations of future market opportunities (Alkemade and Suurs 2012), but the historical evidence shows that, despite recent progress, policies related to energy and climate over the long term have been inconsistent (Taylor 2012; Nemet et al. 2013; Koch et al. 2016). Bolstering the credibility and durability of policies related to low-carbon technology are crucial to accelerating technological change and inducing the private sector investment required (Helm et al. 2003; Habermacher et al. 2020).

2.5.2 A Low-carbon Energy Transition Needs to Occur Faster Than Previous Transitions

An illuminating debate on the possibility of faster transitions has emerged since AR5 – with diverging assumptions about future technological change at the core of the discourse (Bazilian et al. 2020; Lu and Nemet 2020). Table 2.5 summarises these arguments.

2.5.2.1 Energy Transitions Can Occur Faster Than in the Past

Recent studies have identified examples supporting fast energy transitions (Sovacool 2016; Bond et al. 2019; Reed et al. 2019). One describes five rapid national-scale transitions in end-use technologies, including lighting in Sweden, cook-stoves in China, liquefied petroleum gas stoves in Indonesia, ethanol vehicles in Brazil, and air conditioning in the USA (Sovacool 2016). Adoption of electric vehicles in Norway and in cities in China have also been rapid (Rietmann and Lieven 2019; Li et al. 2020; Fridstrøm 2021). Examples in energy supply, include electrification in Kuwait, natural gas in the Netherlands, nuclear electricity in France and Sweden, combined heat and power in Denmark, renewable energy in Uruguay, and coal retirements in Ontario, Canada (Qvist and Brook 2015). Reasons that these exemplars could be applied more broadly in the future include: growing urgency on climate change, shifting motivation from price response to proactive resource scarcity, and an increase in the likelihood of technological breakthroughs (*medium confidence*) (Sovacool 2016; Bazilian et al. 2020). The emergence of smaller unit scale, granular technologies (described below) also creates the potential for faster system change (Trancik 2006; Grubler et al. 2018; Wilson et al. 2020a). Energy service prices and government actions that affect demand are critical to the speed and extent of energy transitions (Kramer and Haigh 2009). Reasons scholars consider for expecting a fast transition include: intentional policy and alignment with goals; globalisation which diversifies sources and integrates supply chains; collective action via the Paris Agreement; as well as bottom-up grassroots movements and private sector initiatives (Kern and Rogge 2016). Political support for change can also speed transitions (Burke and Stephens 2017; Stokes and Breetz 2018), as can the credibility of transition-related targets (Li and Pye 2018; Rogge and Dutschke 2018).

Table 2.5 | Summary of reasons to expect a fast energy transition/slow transition.

	Fast transition	Slow transition
Evidentiary basis	Technology and country cases over 50 years	Historical global system over 200 years
Systems	Complementary technologies enable integration	Difficult integration with existing infrastructure
Economics	Falling costs of nascent technology	Mature incumbent technologies Upfront costs and capital constraints
Technology	Digitalisation and global supply chains More abundant innovation Granular technology	Long lifetimes of capital stock Difficult to decarbonise sectors
Actors	Proactive efforts for transition Bottom-up public concern Mobilised low-carbon interest groups	Risk-averse adopters Attributes do not appeal to consumers Rent-seeking by powerful incumbents
Governance	Leaders catalyse faster change	Collective action problems

The important role of leader countries is often missed when looking only at global aggregates (Meckling and Hughes 2018); leaders accumulate important knowledge, provide scaled market, and set positive examples for followers (*medium confidence*) (Schwerhoff 2016; Buchholz et al. 2019). In recent years, the conception of where leadership, climate-relevant innovation, and technology transfer originate has shifted to considering more meaningfully direct South-South and South-North forms of technology transfer, flows of capital, drivers for market access, origins of innovation, and other forms of cooperation (Urban 2018; Köhler et al. 2019). Recent evidence shows that South-South trade is enabling clean technology transfer (Gosens 2020). Leaders can initiate a process of ‘catalytic cooperation’ in which they overcome collective action problems and stimulate rapid change (Hale 2018). Similarly, ‘sensitive intervention points’ – targeted support of social movements, technologies, or policies themselves – can lead to rapid and self-sustaining change (Farmer et al. 2019), such as support for photovoltaics in Germany in the 2000s and student climate activism in Europe in 2019. The focus on leadership, catalysts, and intervention points reflects a systemic view of transitions that emphasises interactions and interdependence (Geels 2018; Meckling and Hughes 2018). Technological change has been at the core of transitions, but is best understood as part of a system in which social aspects are crucial (*medium confidence*) (Cherp et al. 2018; Köhler et al. 2019; Overland and Sovacool 2020).

2.5.2.2 Reasons Why Transitions Will Occur at Historical Rates of Change

Recent work has also reasserted previous claims that the speed of a low-carbon transition will follow historical patterns (*low confidence*). Broad transitions involve technological complexity, time-consuming technological development, risk-averse adopters, high upfront costs, and low immediate individual adoption benefits, attributes that are not all present in the examples of rapid change described above (Grubler et al. 2016). Additional factors that slow transitions include: the need for the transition to occur globally, thus requiring nations with unequal economic resources and development circumstances to engage in near-universal participation; slow progress in recent decades; intermittence of renewables, and the time involved in building supporting infrastructure (Snil 2016); difficulty in decarbonising transportation and industry (Rissman et al. 2020); and material resource constraints (Davidsson et al. 2014).

2.5.3 Improvements in Technologies Enable Faster Adoption

Since AR5, multiple low-carbon technologies have shown dramatic improvement, particularly solar photovoltaic (PV), wind, and batteries (*high confidence*). The observed pace of these changes and the likelihood of their continuation support the arguments in the previous section that future energy transitions are likely to occur more quickly than in the past (*medium confidence*).

2.5.3.1 Technological Change Has Produced Dramatic Cost Reductions

A wide array of technologies shows long-term improvements in performance, efficiency, and cost. Among the most notable are solar PV, wind power, and batteries (*high confidence*) (Chapters 6 and 16). The dynamics for PVs are the most impressive, having fallen in cost by a factor of 10,000 from the first commercial application on a satellite in 1958 (Maycock and Wakefield 1975) to power purchase agreements signed in 2019 (IRENA 2020). Wind has been on a nearly as steep trajectory (Wiser and Bolinger 2019) as are lithium-ion battery packs for electric vehicles (Nykqvist and Nilsson 2015; Service 2019). The future potential for PV and batteries seems especially promising given that neither industry has yet begun to adopt alternative materials with attractive properties as the cost reductions and performance improvements associated with the current generation of each technology continue (*medium confidence*) (Kwade et al. 2018). A key challenge is improving access to finance, especially in developing country contexts, where the costs of financing are of crucial importance (Creutzig et al. 2017; Schmidt 2019).

2.5.3.2 Technological Change has Accelerated Since AR5

Figure 2.22 shows changes in the costs of four dynamic energy technologies. One can see rapid changes since AR5, cost data for which ended in 2010. Solar PV is by far the most dynamic technology, and its cost since AR5 has continued on its steep decline at about the same rate of change as before AR5, but now costs are well within the range of fossil fuels (*high confidence*) (Chapter 6). Very few concentrating solar power (CSP) plants had been built between the 1980s and 2012. Since AR5, 4GW have been built and costs have fallen by half. Onshore wind has continued its pace of cost reductions such that it is well within the range of fossil fuels. Offshore wind has changed the most since AR5. Whereas costs were increasing before AR5, they have decreased by 50% since. None of these technologies shows indications of reaching a limit in their cost reductions. Crucial to their impact will be extending these gains in the electricity and transportation sectors to the industrial sector (Davis et al. 2018).

2.5.3.3 Granular Technologies Improve Faster

The array of evidence of technology learning that has accumulated both before and since AR5 (Thomassen et al. 2020) has prompted investigations about the factors that enable rapid technology learning. From the wide variety of factors considered, unit size has generated the strongest and most robust results. Smaller unit sizes, sometimes referred to as ‘granularity’, tend to be associated with faster learning rates (*medium confidence*) (Sweerts et al. 2020; Wilson et al. 2020). Examples include solar PV, batteries, heat pumps, and to some extent wind power. The explanatory mechanisms for these observations are manifold and well established: more iterations are available with which to make improvements (Trancik 2006); mass production can be more powerful than economies of scale (Dahlgren et al. 2013); project management is simpler and less risky (Wilson et al. 2020); the ease of early retirement can enable risk-taking for innovative designs (Sweerts et al. 2020); and they tend to be less complicated (Malhotra and Schmidt 2020; Wilson

Figure 2.22 | Unit cost reductions and use in some rapidly changing mitigation technologies. The **top panel** shows global costs per unit of energy (USD per MWh) for some rapidly changing mitigation technologies. Solid blue lines indicate average unit cost in each year. Light blue shaded areas show the range between the 5th and 95th percentiles in each year. Grey shading indicates the range of unit costs for new fossil fuel (coal and gas) power in 2020 (corresponding to USD55–148 per MWh). In 2020, the levelised costs of energy (LCOE) of the four renewable energy technologies could compete with fossil fuels in many places. For batteries, costs shown are for 1 kWh of battery storage capacity; for the others, costs are LCOE, which includes installation, capital, operations, and maintenance costs per MWh of electricity produced. The literature uses LCOE because it allows consistent comparisons of cost trends across a diverse set of energy technologies to be made. However, it does not include the costs of grid integration or climate impacts. Further, LCOE does not take into account other environmental and social externalities that may modify the overall (monetary and non-monetary) costs of technologies and alter their deployment. The **bottom panel** shows cumulative global adoption for each technology, in GW of installed capacity for renewable energy and in millions of vehicles for battery-electric vehicles. A vertical dashed line is placed in 2010 to indicate the change since AR5. Shares of electricity produced and share of passenger vehicle fleet are indicated in text for 2020 based on provisional data, i.e., percentage of total electricity production (for PV, onshore wind, offshore wind, CSP) and of total stock of passenger vehicles (for EVs). The electricity production share reflects different capacity factors; for example, for the same amount of installed capacity, wind produces about twice as much electricity as solar PV. [2.5, 6.4] Renewable energy and battery technologies were selected as illustrative examples because they have recently shown rapid changes in costs and adoption, and because consistent data are available. Other mitigation options assessed in the report are not included as they do not meet these criteria.

et al. 2020). Small technologies often involve iterative production processes with many opportunities for learning by doing, and have much of the most advanced technology in the production equipment than in the product itself. In contrast, large unit scale technologies – such as full-scale nuclear power, carbon capture and storage (CCS), low-carbon steel making, and negative emissions technologies such as bioenergy with carbon capture and storage (BECCS) – are often primarily built on site and include thousands to millions of parts, such that complexity and system integration issues are paramount (Nemet 2019). Despite the accumulating evidence of the benefits of granularity, these studies are careful to acknowledge the role of other factors in explaining learning. In a study of 41 energy technologies (Figure 2.23), unit size explained 22% of the variation in learning rates (Sweerts et al. 2020) and a study of 31 low-carbon technologies showed that unit size explained 33% (Wilson et al. 2020). Attributing that amount of variation to a single factor is rare in studies of technological change. The large residual has motivated studies, which find that small-scale technologies provide

opportunities for rapid change, but they do not make rapid change inevitable; a supportive context, including supportive policy and complementary technologies, can stimulate more favourable technology outcomes (*high confidence*).

There is also evidence that small technologies not only learn but become adopted faster than large technologies (*medium confidence*) (Wilson et al. 2020b). Some of the mechanisms related to the adoption rate difference are associated with cost reductions; for example, smaller, less lumpy investments involve lower risk for adopters (Dahlgren et al. 2013; Wilson et al. 2020b). The shorter lifetimes of small technologies allow users to take advantage of new performance improvements (Knapp 1999) and access a large set of small adopters (Finger et al. 2019). Other mechanisms for faster adoption are distinctly related to markets: modular technologies can address a wide variety of niche markets (Geels 2018) with different willingness to pay (Nemet 2019) and strategically find protected niches while technology is maturing (Coles et al. 2018).

Figure 2.23 | Learning rates for 41 energy demand, supply, and storage technologies. Source: Sweerts et al. (2020).

2.5.4 Rapid Adoption Accelerates Energy Transitions

The transition to a more sustainable energy system depends not just on improvement in technologies, but also on their widespread adoption. Work since AR5 has also substantiated the bidirectional causal link between technology improvement and adoption. Cost reductions facilitate adoption, which generates opportunities for further cost reductions through a process of learning by doing (*medium confidence*). The rate of adoption is thus closely related to the speed at which an energy transition is possible.

Results of integrated assessment models (IAMs) show that scale-up needs are massive for 2°C scenarios. Using logistic growth rates of energy shares as in previous work (Wilson 2012; Cherp et al. 2021), most of these technologies include annual adoption growth rates of 20% in the 2020s and 2030s, and are in line with recent adoption of wind and solar. However, it is important to realise that IAMs include faster adoption rates for some mitigation technologies than for others (Peters et al. 2017). Growth rates in IAMs for large-scale CCS – biomass, coal, and gas – are between 15–30% (25th and 75th percentiles) (Figure 2.24). So few plants have been built that there is little historical data to analyse expected growth; with only two full-scale CCS power plants built and a 7% growth rate, if including industrial CCS. In contrast, IAMs indicate that they expect much lower rates of growth in future years for the technologies that have been growing fastest in recent years (wind and solar), without strong evidence for why this should occur.

The overall pattern shows that IAMs expect growth in small-scale renewables to fall to less than half of their recent pace, and large-scale CCS to more than double from the limited deployment assessed (*high confidence*). The emerging work since AR5 showing the rapid adoption and faster learning in small-scale technologies should prompt a keener focus on what technologies the world can depend on to scale up quickly (Grubb et al. 2021). The scenario results make it quite clear that climate stabilisation depends on rapid adoption of low-carbon technologies throughout the 2020–2040 period.

Figure 2.24 | Growth of key technologies (2020–2040) in Paris-consistent mitigation scenarios compared to historical growth. Comparisons of historical growth (grey bars) to growth in 2020–2040 mitigation scenarios (dots). Values on the vertical axis are logistic annual growth rates for share of each technology in electricity supply. Horizontal arrangement of dots within technology categories indicates the count of scenarios at each growth rate. Source: data on scenarios from Chapter 3; historical data from BP (2021).

2.6 Behavioural Choices and Lifestyles

2.6.1 Introduction

This section synthesises how behavioural choices, lifestyles, and consumption preferences affect energy use and emissions. Household consumption is the largest component of a country's gross domestic product (GDP) and the main contributor to greenhouse gas (GHG) emissions through direct energy consumption for heating and cooling or private transportation, and indirectly through carbon emitted during production of final consumption items. There is great variation in individual, group and household behaviour and consumption patterns within and between countries and over time. A number of factors affect people's consumption patterns and associated carbon emissions, such as: socio-demographics; socio-economic status; infrastructure and access to public services; the regulatory framework; availability, affordability and accessibility of more or less sustainable choices on markets; and individual values and preferences (Dietz et al. 2009).

Carbon footprints vary between and within countries and show an uneven distribution because of differences in development levels, economic structure, economic cycle, available public infrastructure, climate and residential lifestyles (Bruckner et al. 2021). Similar emission characteristics can also be found within a country – see, for China: Feng et al. (2013); for the USA: Pizer et al. (2010); Feng et al. (2013); Mieke et al. (2016); Hubacek et al. (2017b); Wang et al. (2018); for Brazil: Sanches-Pereira et al. (2016); and for Latin American countries: Zhong et al. (2020).

In western countries, the largest contribution to the household carbon footprint is from transportation, housing, and consumption of food (Druckman and Jackson 2015). The joint contribution of these three items varies in different countries, depending on consumption patterns, and account for 58.5%, on average, in EU25 countries (Tukker and Jansen 2006). However, different countries, and regions within countries, may have different emission patterns due to differences in income, lifestyle, geography, infrastructure, political and economic situation. For example, the main contributors to the average US household is private transport (19.6%), followed by electricity (14.8%) and meat (5.2%) (Jones and Kammen 2011), while UK households have 24.6% emissions on energy and housing, 13.7% emissions on food, and 12.2% emissions on consumables (Gough et al. 2011). A study of 49 Japanese cities found that energy (31%), food (27%), and accommodation (15%) were the largest sources of household emissions (Long et al. 2017). An investigation of Japan's household emissions found that energy, food, and utility are the three main emissions sources, but their shares are dependent on age (Shigetomi et al. 2014). See Section 12.4 (Chapter 12) and Box 5.4 (Chapter 5) for a more in-depth discussion on food systems and dietary shifts towards lower emission food.

In terms of rapidly growing economies, China is the most extensively researched country. China's household emissions were primarily derived from electricity and coal consumption, as well as residents' consumption of emission-intensive products, such as housing (33.4%), food (23.6%), private transportation and communication (14.8%) (Wang et al. 2018). Space heating was the largest contributor among various daily energy uses in northern cities (Yang and Liu 2017). In comparison, Indonesian rural households have a larger emission

Figure 2.25 | Carbon footprints per capita income and expenditure category for 109 countries ranked by per capita income (consumption-based emissions).

Figure 2.25 (continued): Carbon footprints per capita income and expenditure category for 109 countries ranked by per capita income (consumption-based emissions). Notes: countries and income categories are dependent on data availability. Light blue dots represent income quintiles (lowest, low, middle, higher, and highest) of EU countries and the USA. Yellow dots are for the developing country group provided by the World Bank for four expenditure categories: lowest, low, middle and higher (Hubacek et al. 2017b). Dark blue diamonds represent average per capita carbon footprints. Countries are ranked from the lowest per capita income (bottom) to the highest income (top) within each country group. Countries are grouped using the IPCC's six high-level classification categories. Footprint values for higher income groups in the World Bank data are less reliable.

share on food and a much smaller share on services and recreation than urban households (Irfany and Klasen 2017). Urban Indonesian households have a much larger share of transport-related emissions (Irfany and Klasen 2017). Analysis from the Philippines shows that, on average, households in urban areas emit twice as much as rural ones because of much lower direct energy use in homes and for transport in rural areas (Serino 2017). In other emerging economies, such as India, Brazil, Turkey and South Africa, a high share of transport-related carbon emissions among urban middle- and high-income households is evident (Huang and Tian 2021).

2.6.2 Factors Affecting Household Consumption Patterns and Behavioural Choices

Households' carbon emissions are closely linked to activities and consumption patterns of individuals and as a group in households. Individual and group behaviour, in turn, is shaped by economic, technological, and psychological factors, social contexts (such as family ties, friends and peer pressure) and cultural contexts (social identity, status, and norms) as well as the natural environment (number of hot and cold days) and physical infrastructure, or geography (Jorgenson et al. 2019). For example, a city with an excellent bicycle infrastructure will make it safer and easier for citizens to become highly mobile by using their bikes; a city that has less density and is dominated by automobile infrastructure induces more people to travel by car (Chapters 8 and 10). As a consequence, many climate relevant consumption acts are not consciously decided on or deliberately made part of a lifestyle, but are strongly influenced by the factors listed above. Chapter 5 provides a more in-depth discussion on behavioural drivers and examples of behavioural interventions and policies that can be used to reduce emissions.

Demographic characteristics such as age, sex, and education constitute an important set of determinants influencing emissions patterns. People of different genders have different consumption patterns. For example, men tend to consume more food (especially meat) than women, leading to higher food-related emissions. Also, men spend more money on vehicles and driving (Wang et al. 2018). Similar evidence has been found in Germany, Greece, Norway, and Sweden, where men's energy use is 8%, 39%, 6%, and 22% higher than women's, respectively (Räty and Carlsson-Kanyama 2010).

Income. Due to the differences that shape individuals' consumption patterns, there are enormous differences in the associated carbon footprints – with income being one of the most important predictors. Globally, households with income in the top 10% – income higher than USD23.03 purchasing power parity (PPP) per capita per day – are responsible for 34–45% of GHG emissions, while those in the bottom 50% – income less than USD2.97 PPP per capita per day –

are responsible for only 13–15% of emissions, depending on the study (Chancel and Piketty 2015; Hubacek et al. 2017b) (Figure 2.25). The average carbon footprint of the high household incomes is more than an order of magnitudes larger than that of the lowest expenditure group (Feng et al. 2021). For example, Zhang et al. (2016) analysed the impact of household consumption across different income households on CO₂ emissions in China and concluded that the impact on CO₂ emissions generated by urban households' consumption is 1.8 times as much as that of rural ones. High-income households have higher emissions related to transport and entertainment – such as recreational expenditure, travel, and eating out – than low-income households. Low-income households tend to have a larger share on necessities such as fuel for heating and cooking (Kerkhof et al. 2009). Figure 2.25 shows the carbon footprint per capita ranked by per capita income.

Age. The effect of population ageing on emissions is contested in the literature. Ageing when accompanied by shrinking household size and more energy-intensive consumption and activity patterns results in increased emissions. However, an ageing labour force can also dampen economic growth and result in less energy-intensive activity such as driving, which decreases emissions (Liddle and Lung 2010; Liddle 2011). Ageing of the population characterises the demographic transition in both developed and developing countries. The implications of ageing for emissions depend on labour force participation of the elderly and differences in the consumption and investment patterns of different age groups (O'Neill et al. 2012). Analysis using panel macro data from OECD countries suggests that shifts in age and cohort composition have contributed to rising GHG emissions since the 1960s (Menz and Welsch 2012; Nassen 2014). Household-level data over time for the USA provides evidence that residential energy consumption increases over the lifetime of household members, largely due to accompanying changes in household size (Estiri and Zagheni 2019). Similar insights emerge from Japan, where analysis shows that those in their 70s or older, a group that is growing in size in Japan, have higher emissions than other age groups (Shigetomi et al. 2014, 2018, 2019). Recent analysis from China suggests that the shift to smaller and ageing households is resulting in higher carbon emissions because of the accompanying time-use and consumption shifts (Yu et al. 2018; Li and Zhou 2019). An increase in the dependency ratio – that is, the proportion of children aged under 15 and people over 65 relative to the working-age population – in other analyses, has been shown to lead to reduced CO₂ emissions in China (Wei et al. 2018; Li and Zhou 2019). Implications of the nature of this relationship are important to policy discussions of working hours and retirement age that are likely to have an influence on emissions. For example, children and youth tend to emit more education-related emissions than adults (Han et al. 2015). Older people tend to have higher emissions related to heating and cooling being more sensitive to temperature (Meier and Rehdanz 2010).

Household size. Per capita emissions tend to decrease with family size, as living together becomes more energy efficient (Qu et al. 2013). The household size in most countries is decreasing (Liu et al. 2011), but the degree differs across countries – for example, there is a higher decrease rate in China than in Canada and the UK (Maraseni et al. 2015). The evidence shows that shifts to smaller households are associated with larger per-capita footprints (Liddle and Lung 2014; Underwood and Zahran 2015; Ivanova et al. 2017; Wiedenhofer et al. 2018), at least in developed countries (Meangbua et al. 2019).

Urban living. The carbon footprint of individuals and households is also significantly influenced by urban-rural differences (Ivanova et al. 2018; Wiedenhofer et al. 2018). In some cases, the difference can be explained by the effect of locational and spatial configuration characteristics, such as levels of compactness/density, centrality, proximity and ease of access to services. In all these parameters, urban areas score higher compared with rural or peri-urban (outlying and suburban) areas, thus influencing household emissions in different ways. Urban households tend to have higher emissions than rural households (O'Neill et al. 2010; Liu et al. 2011), but with a different energy and consumption structures. For example, rural households have more diverse energy inputs, such as biomass, biogas, solar, wind, small hydro and geothermal in addition to coal (Maraseni et al. 2016).

In terms of indirect emissions, urban households have more service-related emissions – such as from education and entertainment – than rural households, while rural households tend to have higher emissions related to food consumption or transportation (Büchs and Schnepf 2013; Maraseni et al. 2016) but this is strongly dependent on the specific situation of the respective country, as in poorer regions, rural transport might be mainly based on public transport with lower carbon emissions per capita. Centrality and location also play a role on the level of urban household emissions. Studies on US households found that residents in the urban core have 20% lower household emissions than residents in suburbs, which show a large range of household emissions (from –50% to +60%) (Kahn 2000; Jones and Kammen 2014). Higher population density tends to be associated with lower per capita emissions (Liddle and Lung 2014; Liu et al. 2017).

Location choices are a significant contributor to household emissions. Suburbanites tend to own larger, spacious homes with larger heating and cooling requirements. Commuting distance and access to public transportation, recreation areas, city centres, public services, and shops are other important neighbourhood-specific determinants of carbon emissions (Baiocchi et al. 2010) (see more on this in Chapters 8 and 10).

Time use. A study on the emissions implications of time use (Wiedenhofer et al. 2018) found that the most carbon-intensive activities are personal care, eating and drinking and commuting. Indirect emissions are also high for repairs and gardening. In contrast, home-based activities, such as sleep and resting, cleaning and socialising at home, have low carbon intensities per hour of time use. The same study also found that households in cities and areas with higher incomes tend to substitute personal activities for contracted services, thus shifting away from households to

the service sector (Wiedenhofer et al. 2018). Improvements in the efficiency of time or resource use are diminished by rebound effects that have been shown to reduce emissions savings by 20–40% on average (Gillingham et al. 2015), while other authors argue that, potentially, the size of the rebound effect could be larger (Saunders 2015) (see more coverage of the rebound effect in Chapters 9 and 16). Lifestyle shifts brought about by using information technologies and socio-technological changes are inducing alterations in people's daily activities and time-use patterns.

The reduction of working hours is increasingly discussed as an approach to improve well-being and reduce emissions (Fitzgerald et al. 2015, 2018; Melo et al. 2018; Wiedenhofer et al. 2018; Smetschka et al. 2019). For instance, analysis of differences in working hours across the USA for the period 2007–2013 shows that there is a strong positive relationship between carbon emissions and working hours. This relationship holds, even after controlling for other differences in political, demographic and economic drivers of emissions (Fitzgerald et al. 2018). In other analyses, this relationship is seen to hold in both developed and developing countries (Fitzgerald et al. 2015). One recent study, however, finds evidence of nonlinear relationships between working time and environmental pressure in EU15 countries between 1970 and 2010, in cases where non-work time is spent instead in carbon-intensive leisure activities (Shao and Shen 2017).

Social norms. Evidence from experiments in the US shows that social norms cannot only help in reducing a household's absolute level of electricity use but also shift the time of use to periods when more renewable electricity is in the system (Horne and Kennedy, 2017). Analysis from Sweden shows that adoption of sustainable innovations like solar panels is influenced by perceived behaviour and expectations of others (Palm, 2017). Similar conclusions emerge from analysis in the Netherlands on the adoption of electric vehicles and smart energy systems (Noppers et al. 2019).

Broader contextual factors and cultural trends towards consumerism, individualisation and defining self-worth through conspicuous consumption can drive emissions up (Chancel and Piketty, 2015). However, cohort and generational shifts can drive emissions down. For instance, evidence, from millennials in the OECD shows that fewer younger people have driving licenses compared to older generations (Kuhnimhof et al. 2012). Similar findings are evident from analysis for the US, where changing attitudes, decreased employment and rising virtual mobility explain decreased travel by Millennials (McDonald, 2015). Analysis for France shows that baby boomers are higher emitters than other generations (Chancel, 2014). A change in social norms is taking place with the spread of the sharing economy by which consumers share or borrow goods from other consumers. Sharing opportunities are more advanced within the mobility sector (Greenblatt and Shaheen, 2015). Successful car and bike sharing have rapidly expanded in countries such as China, Indonesia, Mexico, Brazil and Turkey. Technology and data advances are currently barriers to spreading of sharing in low- and lower middle-income cities but the potential offered by these technologies to allow poor countries to leapfrog to more integrated, efficient, multimodal transport systems is important (Yanocha et al. 2020). Despite this potential it is unclear how much shared mobility contributes to transport

decarbonisation or to make it worse as it takes away riders from public transit (ITF, 2019). The evidence so far shows that the potential positive impacts of shared mobility with pooled rides in lowering travel costs, abating congestion, and reduced GHG emissions have not materialised to date (Merlin, 2019) (Chapter 5).

Education and environmental knowledge. A positive relationship was found between general and carbon-specific knowledge and the attitude towards carbon-specific behaviours in US consumers (Polonsky et al. 2012). One example, pertaining to students, found that the gain of environmental knowledge resulted in more environmentally favourable attitude among these high school students (Bradley et al. 1999). A comparison across states in the USA, for example, shows that environmental awareness can be a mitigating factor of territorial GHG emissions (Dietz et al. 2015). A 1% increase in ‘environmentalism’ – defined as the ‘environmental voting record of the state’s Congressional delegation’ (Dietz et al. 2015) – leads to a 0.45% decrease in emissions.

Environmental knowledge is not always directly translating into decreased ecological footprint (Csutora 2012). While pro-environmental action is lagging behind, research shows that this is not caused by people undervaluing the environment, but rather by people structurally underestimating how much others care (Bouman and Steg 2019). Other evidence shows that there are multiple causal pathways through which a more educated population can effect emissions, some of which may be positive and others negative (Lutz et al. 2019). A more educated population is more productive and can drive higher economic growth and therefore emissions (Lenzen and Cummins 2013). Moreover, education that is designed to specifically inform decision makers of the impacts of their decisions and provide behavioural nudges can be a way to reduce emissions (Duarte et al. 2016).

Status competition. As part of a larger consumer society and consumer culture, based on consumer-oriented lifestyles, products frequently provide a source for identity and fulfilment (Stearns 2001; Baudrillard 2017; Jorgenson et al. 2019). People pursue cultural constructs such as status, comfort, convenience, hygiene, nutrition, and necessity. Consumption is, by and large, not an end in itself but a means to achieve some other end, and those ends are diverse and not necessarily connected to one another (Wilk 2010). This shows that consumption patterns cannot be sufficiently understood without also considering the context – for example, the cultural and social contexts leading to status competition and status-related consumption (Veblen 2009; Ehrhardt-Martinez, K. et al. 2015; Wilk 2017). Status seeking can work to reduce emissions when ‘green products’ such as an electric car or photovoltaics on the roof become a sign for high-status (Griskevicius et al. 2010). It also can work to increase emissions through visible and high-carbon intensive consumption items, such as larger homes, fuel-inefficient sport utility vehicles (SUVs), and long-distance vacations (Schor 1998), driven by a notion of having ‘to keep up with the Joneses’ (Hamilton 2011). This can lead to formation of new habits and needs, where products and services become normalised and are quickly perceived as needed, reinforced through social networks and advertisement, making it psychologically easy to convert a luxury item to a perceived necessity (Assadour 2012). For example, the share of adults who

consider a microwave a necessity was about one-third in 1996 but had increased to more than two-thirds in 2006, but retreated in importance during the recession years 2008–2009 (Morin and Taylor 2009). Similar ups and downs have been observed for television sets, air conditioning, dishwashers or clothes dryers. (Druckman and Jackson 2009). Basic needs and luxury items are subject to change over one’s lifetime and in relation to others (Horowitz 1988). This shows that the boundaries of the public’s luxury-versus-necessity perceptions are malleable (Morin and Taylor 2009).

Inequality. Global inequality within and between countries has shifted over the last decade’s expanding consumption and consumer culture (Castilhos and Fonseca 2016; Alvaredo et al. 2018; Short and Martínez 2020). The rise of income of middle-class in countries, mostly in Asia – for example, China, India, Indonesia and Vietnam – and the stagnating incomes of the middle classes in developed economies reduced between countries’ income differences; meanwhile, the population under extreme poverty (a threshold of USD1.9 per person per day) is now concentrated in Sub-Saharan Africa and South Asia (Milanović 2016). A major gap between top and bottom incomes occurred in parallel within countries. Since 1980, the top 1% richest individuals in the world captured twice as much growth as the bottom 50% individuals (Friedman and Savage 2017; Alvaredo et al. 2018). The influence of these dual inequality trends on lifestyles, new consumption patterns and carbon emissions at regional, local and global scale are large and have led to the fastest growth of global carbon emissions, in particular, for fast emerging economies (Sections 2.2. and 2.3). Emissions remain highly concentrated, with the top 10% per capita emitters contributing to between 35–45% of global emissions, while the bottom 50% emitters contribute to 13–15% of global emissions (Hubacek et al. 2017a). Furthermore, the top 1% of income earners by some estimates could have an average carbon footprint 175 times that of an average person in the bottom 10% (Otto et al. 2020). The top 10% high emitters live in all continents, and one-third of them live in emerging countries (Chancel and Piketty 2015; Hubacek et al. 2017a; Semieniuk and Yakovenko 2020). Mitigation pathways need to consider how to minimise the impacts of inequality on climate change and the different mechanisms and effects coming into play between the inequality of income and emissions (Baek and Gweisah 2013; Berthe and Elie 2015; Hao et al. 2016; Grunewald et al. 2017) (Section 2.4.3).

Inequality trends catalyse impact at a demand level, mobilising rapid lifestyles changes, symbolic consumption and ideals of material improvements and upward mobility (Castilhos et al. 2017) and emulation of high-carbon emissions intensive lifestyle of the wealthy (Gough 2017). Decoupling energy use and emissions from income growth and the decarbonisation of energy services have not counteracted these trends (Section 2.4.1). Alternative options to deal with carbon inequality, such as sharing global carbon emissions among high emitters (Chakravarty et al. 2009; Chakravarty and Tavoni 2013) or addressing the discourse of income distribution and the carbon intensity of high emitters lifestyles (Hubacek et al., 2017b; Gössling 2019; Otto et al. 2019) are met with caution that such alternatives may necessitate hard-to-implement institutional changes (Semieniuk and Yakovenko 2020). Growing inequality within countries may make recomposition of emission intensive consumption

more difficult and, it may also exacerbate redistribution and social cohesion dilemmas (Gough 2017; Römpke et al. 2019). Climate mitigation action has different motivational departures in unequal context. An emerging global 'middle class' strengthens consumption at the margin as evidence by first-time purchases of white goods with likely impacts on energy demand (Wolfram et al. 2012), and with a warming climate, the increased use of air conditioning (Davis and Gertler 2015). Inequality may affect the willingness of rich and poor to pay for environmental goods or accept policies to protect the environment (Baumgärtner et al. 2017). Unequal departure for action is strongly manifested in cities of all sizes in developing countries with low-income urban residents hardest hit in lock-in situations such as lack of access to transportation and jobs (Altshuler 2013; Mattioli 2017), lack of green spaces (Joassart-Marcelli et al. 2011), poor access to waste collection (King and Gutberlet 2013) and to energy and clean water provision. The exacerbation of these conditions constrains the feasibility for achieving emissions reductions through lifestyle or behavioural changes alone (Baiocchi et al. 2010; Oxfam 2015). High inequality limits mitigation efforts and conversely, advancing mitigation should not contribute to deepen existing inequalities (Rao and Min 2018; Saheb et al. 2019). It is critically important to account for varying demands and affordability across heterogeneous household groups in access to quality energy, education, health, decent jobs and services, while recomposing consumption and balancing societal trade-offs via policies to boost the inclusion of low-income and energy-poor population groups (Pachauri et al. 2013). Further, there is a need to reduce inequalities and improve the capabilities people have to live the lives they value (Sen 1999; Gough et al. 2011; Gough, 2017; Aranoff et al. 2019).

2.7 Emissions Associated With Existing and Planned Long-lived Infrastructure

2.7.1 Introduction: Clarification of Concepts

Carbon lock-in can be understood as inertia in a system that limits the rate of transformation by a path-dependent process (Seto et al. 2016). For example, long lifetimes of infrastructures such as power plants, roads, buildings or industrial plants may influence the rate of transformation substantially and lock societies into carbon-intensive lifestyles and practices for many decades (Unruh 2000, 2002; Unruh and Carrillo-Hermosilla 2006; Grubler 2012; Seto et al. 2016; Sovacool 2016). Infrastructure stock evolution depends on technological and economic factors, but also on institutional and behavioural ones that are often mutually reinforcing. That is, physical infrastructure such as the built environment of urban areas can shape people's behaviour and practices, which in turn change the demand for such infrastructure and lock-in energy demand patterns (Banister et al. 1997; Makido et al. 2012; Creutzig et al. 2016; Seto et al. 2016; Shove and Trentmann 2018).

There is a broad literature on carbon lock-in related to infrastructure that has analysed different geographical scales and sectors, with a strong focus on the power sector (Fisch-Romito et al. 2020). Available quantifications differ in the time frames of analysis that can be classified as backward-looking, static for a given year, or forward-

looking using scenarios (Fisch-Romito et al. 2020). Quantifications also differ in the indicators used to describe carbon lock-in. Literature has assessed how delays in climate policy affect the evolution of fossil-fuel infrastructure stock in the short term (Bertram et al. 2015; Kefford et al. 2018; McGlade et al. 2018), overall mitigation costs (Riahi et al. 2015; Luderer et al. 2016), or the transition risks from premature retirements or underutilisation of existing assets (Iyer et al. 2015; Johnson et al. 2015; Lane et al. 2016; Luderer et al. 2016; Farfan and Breyer 2017; van Soest et al. 2017; Kefford et al. 2018; Cui et al. 2019; Fofrich et al. 2020; Malik et al. 2020; H. Wang et al. 2020; Pradhan et al. 2021). Only a few authors have relied on indicators related to institutional factors such as technology scale or employment (Erickson et al. 2015; Spencer et al. 2018). Complementary literature has explored how the sheer size of the world's fossil fuel reserves (and resources) and owners' financial interests could contribute to supply-side dynamics that sustain the use of fossil fuels (Jewell et al. 2013; Jakob and Hilaire 2015; McGlade and Ekins 2015; Bauer et al. 2016; Heede and Oreskes 2016; Welsby et al. 2021).

One way of quantifying potential carbon lock-in is to estimate the future CO₂ emissions from existing and planned infrastructure (Davis et al. 2010; Davis and Socolow 2014) based on historic patterns of use and decommissioning. Such estimates focus on CO₂ emissions from operating infrastructure and do not comprise any upstream or downstream emissions across the lifecycle, which are provided elsewhere in the literature (Müller et al. 2013; Creutzig et al. 2016; Krausmann et al. 2020; Fisch-Romito 2021). Estimates tend to focus on energy, while other areas, such as the agricultural sector are usually not covered. Another strand of literature quantifies lock-in by estimating fossil-fuel related CO₂ emissions that are hard to avoid in future scenarios using integrated assessment models (IAMs) (Kriegler et al. 2018b; Luderer et al. 2018). The remainder of this chapter will assess potential carbon lock-in through those two related strands of literature.

2.7.2 Estimates of Future CO₂ Emissions From Long-lived Infrastructures

Table 2.6 summarises studies that apply an accounting approach based on plant-level data to quantify future CO₂ emissions from long-lived fossil fuel infrastructure (Davis et al. 2010; Davis and Socolow 2014; Rozenberg et al. 2015; Edenhofer et al. 2018; Pfeiffer et al. 2018; Cui et al. 2019; Smith et al. 2019; Tong et al. 2019; Pradhan et al. 2021). Differences between studies arise in the scope of the infrastructure covered (including resolution), the inclusion of new infrastructure proposals, the exact estimation methodology applied as well as their assessments of uncertainties. Other studies provide analysis with a sectoral focus (Bullock et al. 2020; Vogl et al. 2021) or with a regional focus on the power sector (Shearer et al. 2017, 2020; González-Mahecha et al. 2019; Grubert 2020; Tao et al. 2020).

Assuming variations in historic patterns of use and decommissioning, comprehensive estimates of cumulative future CO₂ emissions from *current* fossil fuel infrastructures are 720 (550–910) GtCO₂ (Smith et al. 2019) and 660 (460–890) (*high confidence*) (Tong et al. 2019) (Table 2.6 and Figure 2.26). This is about the same size as the

Table 2.6 | Comparing cumulative future CO₂ emissions estimates from existing and proposed long-lived infrastructures by sector. Future CO₂ emissions estimates are reported from the 'year of dataset'. Note that, in some cases, the totals may not correspond to the sum of underlying sectors due to rounding (based on Tong et al. 2019). Initial estimates of future CO₂ emissions from fossil fuel infrastructures by Davis et al. (2010) are considerably lower than more recent estimates by Smith et al. (2019) and Tong et al. (2019) due to substantial growth in fossil energy infrastructure, as represented by more recent data. Estimates presented here are rounded to two significant digits.

overall cumulative net CO₂ emissions until reaching net zero CO₂ of 510 (330–710) Gt in pathways that limit warming to 1.5°C with no or limited overshoot (Chapter 3). About 50% of cumulative future CO₂ emissions from *current* fossil fuel infrastructures come from the power sector and 70% of these (or about 40% of the total) are from coal plants only. Like global annual CO₂ emissions (Friedlingstein et al. 2020; Peters et al. 2020), future CO₂ emissions from fossil fuel infrastructures have increased over time – that is, future CO₂ emissions from fossil fuel infrastructure additions in a given year still outgrow ‘savings’ from infrastructure retirements (Davis and Socolow 2014; Tong et al. 2019). This could add further inertia to the system as it may require more and faster retirement of fossil-fuel based infrastructures later, and lead to higher costs for meeting climate goals (e.g., Bertram et al. 2015; Johnson et al. 2015).

Estimates of total cumulative future CO₂ commitments from *proposed infrastructure* focus only on the power sector due to data availability (Table 2.6 and Figure 2.26). Infrastructure proposals can be at various stages of development involving very different probabilities of implementation. About one-third of the currently proposed projects are more probable as they are already under construction (Cui et al. 2019). Pfeiffer et al. (2018) and Tong et al. (2019) assess the cumulated CO₂ emissions from proposed infrastructure in the entire power sector at 270 GtCO₂ and 190 GtCO₂ respectively. Estimates of CO₂ emissions implications for new coal power infrastructure plans are more frequent (Edenhofer et al. 2018; Pfeiffer et al. 2018; Cui et al. 2019; Tong et al. 2019) ranging between 100 and 210 GtCO₂. Differences across estimates of future CO₂ emissions from proposed power infrastructure mostly reflect substantial cancellations of coal infrastructure proposals in 2017 and 2018 (Tong et al. 2019).

The global estimate of future CO₂ emissions from *current and planned* fossil-fuel infrastructures is 850 (600–1100) GtCO₂ (Tong et al. 2019). This already exceeds total cumulative net CO₂ emissions in pathways that limit warming to 1.5°C with no or limited overshoot (see above). It is about the same size as the total cumulative net CO₂ emissions of 890 (640–1160) GtCO₂ from pathways that limit warming to 2°C (<67%) (Chapter 3). Hence, cumulative net CO₂ emissions to limit warming to 2°C (<67%) or lower could already be exhausted by current and planned fossil fuel infrastructure (*high confidence*) even though this estimate only covers a fraction of all infrastructure developments over the 21st century as present in mitigation pathways, does not cover all sectors (e.g., AFOLU) and does not include currently infrastructure development plans in transport, buildings, and industry due to a lack of data.

Hence, the Paris climate goals could move out of reach unless there are dedicated efforts for early decommissioning, and reduced utilisation of existing fossil fuel infrastructures, cancellation of plans for new fossil fuel infrastructures, or compensation efforts by removing some of the CO₂ emissions from the atmosphere (Cui et al. 2019; Smith et al. 2019; Tong et al. 2019; Pradhan et al. 2021). For example, Fofrich et al. (2020) suggest in a multi-model study that coal and gas power infrastructure would need to be retired 30 (19–34) and 24 (21–26) years earlier than the historical averages of 39 and 36 years when following 1.5°C pathways and 23 (11–33) and 19 (11–16) years earlier when following 2°C pathways. Cui et al. (2019) arrive at more conservative estimates for coal power plants, but only consider the existing and currently proposed capacity. Premature retirement of power plants pledged by members of the Powering Past Coal Alliance would cut emissions by 1.6 GtCO₂, which is 150 times less than future CO₂ emissions from existing coal power plants (Jewell et al. 2019).

Figure 2.26 | Future CO₂ emissions from existing and currently planned fossil fuel infrastructure in the context of Paris carbon budgets in GtCO₂ based on historic patterns of infrastructure lifetimes and capacity utilisation. Future CO₂ emissions estimates of existing infrastructure for the electricity sector as well as all other sectors (industry, transport, buildings, other fossil fuel infrastructures) and of proposed infrastructures for coal power as well as gas and oil power. Grey bars on the right depict the range (5th–95th percentile) in overall cumulative net CO₂ emissions until reaching net zero CO₂ in pathways that limit warming to 1.5°C with no or limited overshoot (1.5°C scenarios), and in pathways that limit warming to 2°C (<67%) (2°C scenarios). Source: based on Edenhofer et al. (2018) and Tong et al. (2019).

Few quantifications of carbon lock-in from urban infrastructure, in particular urban form, have been attempted, in part because they also relate to behaviours that are closely tied to routines and norms that co-evolve with 'hard infrastructures' and technologies, as well as 'soft infrastructure' such as social networks and markets (Seto et al. 2016). There are some notable exceptions providing early attempts (Guivarch and Hallegatte 2011; Driscoll 2014; Seto et al. 2014; Lucon et al. 2014; Erickson and Tempest 2015; Creutzig et al. 2016). Creutzig et al. (2016) attempt a synthesis of this literature and estimate the total cumulative future CO₂ emissions from existing urban infrastructure at 210 Gt, and from new infrastructures at 495 Gt for the period 2010–2030.

2.7.3 Synthesis – Comparison with Estimates of Residual Fossil Fuel CO₂ Emissions

A complementary strand of literature uses IAMs to assess the cumulative gross amount of unabated CO₂ emissions from fossil fuels across decarbonisation pathways that are not removed from the system, even under strong (short- and long-term) climate policy ambitions. Lower bound estimates for such a minimum amount of unabated residual CO₂ emissions across the 21st century that is not removed from the system, even under very ambitious climate policy assumptions, may be around 600–700 GtCO₂ (Kriegler et al. 2018b). This range increases to 650–1800 GtCO₂ (Table 2.7) as soon as a broader set of policy assumptions are considered, including delayed action in scenarios that limit warming to 1.5°C and 2°C respectively (Luderer et al. 2018).

Notably, the lower end of residual fossil fuel emissions in IAM scenarios (Luderer et al. 2018) is remarkably similar to global estimates from the accounting studies of the previous section, as shown in Table 2.6. Yet, there are important conceptual and interpretative differences that are also reflected in the very different distribution of reported future CO₂ emissions attached to current and future fossil fuel infrastructures (Table 2.7). Accounting studies start from granular, plant-based data for existing fossil fuel infrastructure and make statements about their future CO₂ emissions, assuming variations of historic patterns of use and decommissioning. Expansions to the future are limited to proposals for new infrastructures that we know of today. Scenario studies quantifying residual fossil fuel emissions start from aggregate infrastructure descriptions, but dynamically update those through new investment decisions in each time step across the 21st century based on the development of energy and energy service demands, as well as technology availability, guided by defined climate policy goals (or their absence).

In accounting studies, estimates of future CO₂ emissions from current fossil fuel infrastructures are dominated by the power sector with its large fossil fuel capacities. In contrast, scenario studies highlight residual emissions from non-electric energy – particularly in the transport and industry sectors. Fossil-fuel infrastructure in the power sector can be much more easily retired than in those sectors, where there are fewer and more costly alternatives. IAMs therefore account for continued investments into fossil-based energy technologies in areas with limited decarbonisation potential, such as some areas of

Table 2.7 | Residual (gross) fossil fuel emissions (GtCO₂) in climate change mitigation scenarios strengthening mitigation action after 2020 ('early strengthening'), compared to scenarios that keep Nationally Determined Contribution (NDC) ambition level until 2030 and only strengthen thereafter.

Cumulative gross CO₂ emissions from fossil fuel and industry until reaching net zero CO₂ emissions are given in terms of the mean as well as minimum and maximum (in parentheses) across seven participating models: AIM/CGE, GCAM, IMAGE, MESSAGES, POLES, REMIND, WITCH. Scenario design prescribes a harmonised, global carbon price in line with long-term carbon budget. Delay scenarios follow the same price trajectory, but 10 years later. Carbon dioxide removal requirements represent ex-post calculations that subtract gross fossil fuel emissions from the carbon budget associated with the respective long-term warming limit. We take the carbon budget for limiting warming to 1.5°C with a 50% probability and to 2°C with a 67% probability (Canadell et al. 2021). Hence, carbon dioxide removal (CDR) requirements reflect a minimum amount of CDR for a given mitigation trajectory. Results are reported at two significant digits. Sources: Luderer et al. (2018); Tong et al. (2019).

Future CO ₂ emissions from existing and planned fossil fuel infrastructure (accounting studies)				Residual fossil fuel emissions – cumulative gross CO ₂ emissions from fossil fuel and industry until reaching net zero CO ₂ emissions (in GtCO ₂)					
		Tong et al. (2019)				Early strengthening from (2020)		Delayed strengthening from 2030	
		GtCO ₂	Year			Well below 2°C	Below 1.5°C in 2100	Well below 2°C	Below 1.5°C in 2100
Existing and proposed	Electricity	550 (380–730)	2018	Existing AND future instalments	Electricity	180 (140–310)	130 (90–160)	250 (220–340)	200 (190–230)
	Non-electric supply				Non-electric supply	100 (42–130)	59 (27–83)	120 (55–150)	75 (40–100)
Existing	Industry	160 (110–220)	2017		Industry	260 (160–330)	140 (86–180)	290 (200–370)	200 (130–250)
	Transportation	64 (53–75)	2017		Transportation	310 (190–370)	170 (110–220)	310 (250–400)	200 (140–260)
	Buildings	74 (52–110)	2018		Buildings	110 (75–110)	58 (35–77)	120 (80–150)	73 (51–93)
	All sectors and proposed electricity	850 (600–1100)			All sectors (2021 – net zero CO ₂)	960 (730–1100)	570 (400–640)	1100 (900–1200)	770 (590–860)
					All sectors (2021–2100)	1300 (970–1500)	850 (650–1100)	1400 (1200–1600)	1000 (860–1300)
					<i>Implied minimum requirement for carbon dioxide removal until 2100</i>	150 (0–350)	350 (150–600)	250 (50–450)	500 (360–800)

transportation (in particular aviation, shipping and road-based freight) or some industrial processes (such as cement production or feedstocks for chemicals). This explains the key discrepancies observable in Table 2.7. Therefore, our overall assessment of these available lines of evidence strongly emphasises the importance of decommissioning, reduced utilisation of existing power sector infrastructure, as well as continued cancellation of new power sector infrastructures in order to limit warming to well below 2°C (*high confidence*) (Kriegler et al. 2018b; Luderer et al. 2018; Chen et al. 2019; Cui et al. 2019; Fofrich et al. 2020). This is important as the power sector is comparatively easy to decarbonise (IPCC 2014a; Krey et al. 2014; Davis et al. 2018; Méjean et al. 2019) and it is crucial to make space for residual emissions from non-electric energy end uses that are more difficult to mitigate (*high confidence*). Any further delay in climate policy substantially increases carbon lock-in and mitigation challenges as well as a dependence on carbon dioxide removal technologies for meeting the Paris climate goals (Kriegler et al. 2018b; Luderer et al. 2018).

2.8 Climate and Non-Climate Policies and Measures and their Impacts on Emissions

2.8.1 Introduction

The key to achieving climate change mitigation targets includes crafting environmentally effective, economically efficient and socially equitable policies. For the purposes of this section, policies are defined broadly as actions to guide decisions to reach explicit goals and, accordingly, climate (mitigation) policies are the ones whose primary objective is to reduce GHG emissions. They include a range of domains from economic and institutional to research and development (R&D) and social policies, and are implemented by various instruments (e.g., market-based and regulatory in the economic domain) and measures (e.g., legal provisions and governance arrangements in the institutional domain) (Chapter 13, and see ‘mitigation policies’ in Glossary). Yet GHG emissions are also affected by policies enacted in various social, economic and environmental areas to pursue primarily non-climatic objectives. This section presents succinct assessments of the outcomes and effectiveness of a few selected policy instruments applied in the last two decades that target climate protection (Sections 2.8.2 and 2.8.3) and GHG emissions impacts of selected other policies primarily aimed at improvements in environmental quality and natural resource management (Section 2.8.4).¹²

It is rather difficult, though not impossible, to discern the genuine impacts of climate and non-climate policies on GHG emissions. Most current and past policies target only a small part of global emissions in a limited geographical area and/or from a small number of economic sectors. However, in addition to the targeted

region or sector, policies and measures tend to affect GHG emissions in other parts of the world. Emissions leakage is the key channel by which such phenomena and complex interactions occur.¹³ Uncertainties in impacts, synergies, and trade-offs between policies and measures also complicate the evaluation of emissions impacts. These make it challenging to identify the impacts of any specific policy or measure on emissions of any specific region or sector. Rigorous statistical analyses are necessary for building strong empirical evidence, but the experience with climate-related policy experiments to date is limited.

2.8.2 Comprehensive Multinational Assessments

Comprehensive multinational evaluations with wider regional and sectoral coverage enable the assessment of emissions impacts without distortions from emissions leakage. Among the wide range of climate policy instruments, pricing carbon – such as a carbon tax or an emissions trading system – has been one of the most widely used and effective options to reduce GHG emissions (*robust evidence, high agreement*). In a comparison of 142 countries with and without carbon pricing, countries with a carbon price show annual CO₂ emission growth rates of 2 percentage points lower than countries without such policies (Best et al. 2020). A more comprehensive evaluation of carbon prices shows that countries with a lower carbon pricing gap (a higher carbon price) tend to be more carbon-efficient, that is, they have a lower carbon intensity of GDP (OECD 2018).¹⁴ An empirical analysis of the effects of environmental regulation and innovation on the carbon emissions of OECD countries during the period 1999–2014 indicates that a 1% increase in environmentally friendly patents reduced carbon emissions by 0.017%, and a 1% increase in environmental tax revenue per capita reduced carbon emissions by 0.03% (Hashmi and Alam 2019).

Domestic and international climate legislation have also contributed to the reduction of GHG emissions. An empirical analysis of legislative activity in 133 countries over the period 1999–2016 based on panel data indicates that each new law reduced annual CO₂ emissions per unit of GDP by 0.78% nationally in the first three years, and by 1.79% beyond three years. Additionally, climate laws as of 2016 were associated with an annual reduction in global CO₂ emissions of 5.9 GtCO₂ and 38 GtCO₂ cumulatively since 1999 (Eskander and Fankhauser 2020). It is notable that 36 countries that accepted legally binding targets under the Kyoto Protocol all complied (Shishlov et al. 2016). It is impossible to disentangle precisely the contribution of individual mitigation policies, but it is clear that the participating countries, especially those in the OECD, did make substantial policy efforts with material impact (Grubb 2016). An ex-post evaluation shows a significant impact of the Protocol on emissions reductions (Maamoun 2019).

¹² This section only reviews the emission impacts of selected policy instruments. Other important aspects such as equity and cost-effectiveness are assessed in Chapter 13, presenting comprehensive evaluations of policies and measures.

¹³ Refer to Chapter 13 on policies and institutions for a detailed discussion of emissions leakages and complex interactions from policy mixes.

¹⁴ The OECD (2018) measures carbon prices using the *effective carbon rate* (ECR), which is the sum of three components: specific taxes on fossil fuels; carbon taxes; and prices of tradable emissions permits. The *carbon pricing gap* measures the difference between actual ECRs and benchmark rates. The carbon pricing gap indicates the extent to which polluters do not pay for the damage from carbon emissions.

Renewable energy policies, such as Renewable Portfolio Standards and Feed-in-Tariff, have played an essential role in the massive expansion of renewable energy capacities, another key driver of GHG emissions reductions (*robust evidence, high agreement*). Drivers of decreasing CO₂ emissions seen in a group of 18 developed economies that decarbonised over the period 2005–2015 are the displacement of fossil fuels by renewable energy and decreases in energy use (Le Quéré et al. 2019). Renewable energy policies both at the EU and member states level have played an essential role in abating GHG emissions (ICF International 2016).

2.8.3 National, Sectoral, and Cross-sectoral Policies

2.8.3.1 National and Regional Carbon Pricing

Carbon prices – such as carbon taxes and GHG emissions trading schemes (ETSs) – are among the most widely used climate policy instruments across the globe, together with technology support instruments (IRENA 2018). As of May 2020, there were 61 carbon pricing schemes in place or scheduled for implementation, consisting of 31 ETSs and 30 carbon tax regimes, covering 12 GtCO₂-eq or about 22% of annual global GHG emissions (World Bank 2020). The performance of carbon pricing in practice varies by countries and sectors, and depends on the policy environment (*robust evidence, high agreement*).

The European Union Emissions Trading Scheme (EU ETS), the longest-standing regional climate policy instrument to date, has reduced emissions, though the estimates of the amount vary by study, by country, and by sector; ranging from 3–28% (McGuinness and Ellerman 2008; Ellerman et al. 2010; Abrell et al. 2011; Anderson and Di Maria 2011; Egenhofer et al. 2011; Petrick and Wagner 2014; Arlinghaus 2015; Martin et al. 2016). The EU ETS avoided emitting about 1.2 GtCO₂ between 2008 and 2016 (3.8%), almost half of what EU governments promised to reduce under their Kyoto Protocol commitments (Bayer and Aklin 2020).

China's emission trading pilots have resulted in a decline in carbon intensity in the pilot provinces by adjusting the industrial structure (Zhou et al. 2019). The Regional Greenhouse Gas Initiative (RGGI) in the USA has induced leakage in emissions through increases in electricity generation in surrounding non-RGGI areas, but it has led to the reduction of emissions by way of changes in the fuel mix from coal to gas (Fell and Maniloff 2018). Actual emissions declined in six of the 10 ETSs for which data is available, although other factors, such as the 2009 recession, have had significant impacts on those emissions as well (Haites et al. 2018).

The evidence of environmental effectiveness of carbon taxes in Western European countries is varied depending on country and study (*robust evidence, high agreement*). A significant impact is found in Finland but insignificant impacts are found in Denmark and the Netherlands, and there are mixed results for Sweden (Lin and Li 2011; Brännlund et al. 2014). Only six of the 17 taxes, where data are available, have reduced actual emissions subject to the tax. Tax rates tend to be too low in many cases and the scale and frequency of the

rate changes has not been sufficient to stimulate further emissions reductions (Haites et al. 2018).

2.8.3.2 Selected Sectoral Climate Policy Instruments

Many governments have implemented sector-specific policies, in addition to nationwide measures, to reduce GHG emissions (*high confidence*). Examples of sectoral climate policies include carbon taxes on transportation fuels, low-carbon fuel standards, and regulation of coal power generation.

The implementation of a carbon tax and value-added tax on gasoline and diesel in Sweden resulted in significant reductions of CO₂ emissions in the transportation sector (Shmelev and Speck 2018; Andersson 2019). An assessment of a variety of carbon tax schemes across various sectors in the EU shows a negative relationship between CO₂ emissions and a CO₂ tax (Hájek et al. 2019). In British Columbia (Canada), the carbon tax resulted in a decrease in demand for gasoline and a reduction in total GHG emissions (not exclusive to the transportation sector) estimated to be between 5–15% (Murray and Rivers 2015; Rivers and Schaufele 2015). The Low Carbon Fuel Standard in California has contributed to reducing carbon emissions in the transportation sector by approximately 9.85–13.28% during 1997–2014 (Huseynov and Palma 2018).

The power sector typically accounts for a large portion of countries' CO₂ emissions. Market-based regulation and government subsidies in China contributed to improving operational efficiency and reducing emissions (Zhao et al. 2015). In addition, the implementation of ultra-low emission standards has also resulted in a significant reduction in emissions from China's power plants (Tang et al. 2019). Mandatory climate and energy policies, including the California Global Warming Solutions Act, reduced CO₂ emissions by 2.7–25% of the average state-level annual emissions from the power sector over the period 1990–2014 in the USA. Mandatory GHG registry/reporting, electric decoupling and a public benefit fund have been effective in further decreasing power sector emissions in the USA (Martin and Saikawa 2017). In the UK electricity sector, a carbon price floor, combined with electricity market reform (competitive auctions for both firm capacity and renewable energy), displaced coal, whose share fell from 46% in 1995 to 7% in 2017, halving CO₂ emissions, while renewables grew from under 4% in 2008 to 22% by 2017 (Grubb and Newbery 2018). See Chapter 13 for more information.

An alternative approach to a carbon tax is an indirect emissions tax on fuels such as an excise tax, or on vehicles, based on the expected CO₂ intensity of new passenger vehicles. Vehicle purchase taxes can result in a reduction in GHG emissions through reducing the CO₂ emissions intensity of vehicles, while also discouraging new vehicle purchases (Aydin and Esen 2018). For example, a vehicle tax policy in Norway resulted in a reduction of average CO₂ intensity per kilometre of 7.5 gCO₂ km⁻¹ (Ciccone 2018; Steinsland et al. 2018). Despite such evidence, studies of carbon pricing find that additional policies are often needed to stimulate sufficient emissions reductions in transportation (*medium confidence*) (Tvinnereim and Mehling 2018).

Electric vehicles (EVs) powered by clean electricity can reduce GHG emissions, and such policies are important for spurring adoption of such vehicles (Kumar and Alok 2020; Thiel et al. 2020). The extent to which EV deployment can decrease emissions by replacing internal combustion engine-based vehicles depends on the generation mix of the electric grid (Abdul-Manan 2015; Nichols et al. 2015; Canals Casals et al. 2016; Hofmann et al. 2016; Choi et al. 2018; Teixeira and Sodré 2018) although, even with current grids, EVs reduce emissions in almost all cases (Knobloch et al. 2020). Policy incentives for EV adoption can be an effective mechanism to increase EV sales (Langbroek et al. 2016) and may include discounts, purchase subsidies, regulations, and government leadership (*medium confidence*) (Bakker and Jacob Trip 2013; Silvia and Krause 2016; Teixeira and Sodré 2018; Qiu et al. 2019; Santos and Davies 2020). The presence of charging infrastructure and publicly available charging increases the adoption rate of EVs (Vergis and Chen 2015; Javid et al. 2019). A comparison of EV adoption rates across 30 countries shows a positive correlation between charging stations and EV market share (Sierczula et al. 2014). A rollout of 80,000 DC fast chargers across the USA is estimated to have resulted in a 4% reduction in emissions compared to a baseline of no additional fast chargers (Levinson and West 2018). More recently, bans on internal combustion engine vehicles have provided a much more direct approach to stimulating the adoption of EVs and its supporting infrastructure; however, the efficacy of such measures depends on enforcement (Plötz et al. 2019).

Public transit can reduce vehicle travel and lower GHG emissions by reducing the number of trips taken by private vehicles and the length of those trips (*medium confidence*). Changes to the operation of public transportation systems (such as density of bus stops, distance from stops to households, duration and frequency of trip times, and lowering ridership costs) can result in a mode shift from private car trips to public transit trips (Cats et al. 2017; Choi 2018; Carroll et al. 2019). These changes in the public transit system operation and network optimisation have been shown to have reduced GHG emissions in cases such as San Francisco, where the cost optimisation of the transit network was estimated to decrease emissions by a factor of three (Cheng et al. 2018) and Barcelona, where the optimisation of the urban bus system was estimated to reduce GHG emissions by 50% (Griswold et al. 2017). For every 1% increase in investment in transit services and transit-oriented design, there is an estimated 0.16% reduction in private vehicle kilometres travelled per capita (McIntosh et al. 2014).

Bike- and car-sharing programmes can reduce GHG emissions (*medium confidence*). Albeit a study of eight cities in the USA with larger bike share systems and higher ridership found that their potential to reduce total emissions is limited to <0.1% of total GHG emissions from the transportation sectors of these cities (Kou et al. 2020). The emissions reductions effects of car-sharing programmes depends on the specifics of programmes: the mode shift from public transit to car-sharing services can outweigh the decreases in GHG emissions associated with a reduced number of cars on the road (Jung and Koo 2018), whereas car-sharing programmes with EV fleets may reduce GHG emissions (Luna et al. 2020).

2.8.4 Emission Impacts of Other Related Policies

Policies other than those intended directly to mitigate GHGs can also influence these emissions. Policies to protect the stratospheric ozone layer is a case in point. Implementing the Montreal Protocol and its amendments, emissions of controlled ozone-depleting substances (ODSs) (those covered by the protocol) declined to a very low level of about 1.4 GtCO₂-eq yr⁻¹ by 2010, avoiding GHG emissions of an estimated 13.3–16.7 GtCO₂-eq yr⁻¹ (9.7–12.5 GtCO₂-eq yr⁻¹ when accounting for the ozone depletion and hydrofluorocarbons (HFCs) offsets) (Velders et al. 2007). Yet fluorinated gases (F-gases), the substances introduced to substitute ODSs are also potent GHGs. See Section 2.2 for emissions data, and Chapter 13 on current policies to mitigate HFCs and other F-gases. GHG implications of two other categories of non-climate policies are briefly assessed in this section.

2.8.4.1 Co-impacts of Air Quality, Sector-specific and Energy Policies on Climate Mitigation

Co-impacts of local or regional air pollution abatement policies for climate mitigation are widely studied in the literature. Cross-border externalities of air pollution have also made these a focus of several international agreements (Mitchell et al. 2020). Evaluating the effectiveness of such treaties and policies is difficult because deriving causal inferences and accurate attribution requires accounting for several confounding factors, and direct and indirect spillovers (Isaksen 2020). Nevertheless, several studies assess the effectiveness of such treaties and regulations (De Foy et al. 2016; Li et al. 2017a, 2017b; Morgenstern 2018; Mardones and Cornejo 2020). However, there is little ex-post empirical analysis and a greater focus on ex-ante studies in the literature.

At a local scale, air pollutants are often co-emitted with GHGs in combustion processes. Many air quality policies and regulations focus on local pollution from specific sources that can potentially either substitute or complement global GHG emissions in production and generation processes. Also, policies that reduce certain air pollutants, such as sulphur dioxide (SO₂), have a positive radiative forcing effect (Navarro et al. 2016). The evidence on individual air pollution control regulation and policies for GHG emissions is therefore mixed (*medium evidence, medium agreement*). Evidence from the USA suggests that increased stringency of local pollution regulation had no statistically detectable co-benefits or costs on GHG emissions (Brunel and Johnson 2019). Evidence from China suggests that the effectiveness of policies addressing local point sources differed from those of non-point sources and the co-benefits for climate are mixed, though policies addressing large industrial point sources have been easier to implement and have had significant impact (Huang and Wang 2016; Xu et al. 2016; van der A et al. 2017; Dang and Liao 2019; Fang et al. 2019; Yu et al. 2019). Legislation to reduce emissions of air pollutants in Europe have significantly improved air quality and health but have had an unintended warming effect on the climate (Turnock et al. 2016).

Often, the realisation of potential co-benefits depends on the type of pollutant addressed by the specific policy, and whether complementarities between local pollution and global GHG emissions are considered in policy design (*medium evidence, high agreement*) (Rafaj et al. 2014; Li et al. 2017a). Effective environmental regulations that also deliver co-benefits for climate mitigation require integrated policies (Schmale et al. 2014; Haines et al. 2017). Uncoordinated policies can have unintended consequences and even increase emissions (Holland et al. 2015). Many studies suggest that policies that target both local and global environmental benefits simultaneously may be more effective (*medium evidence, medium agreement*) (Klemun et al. 2020). Furthermore, air pollution policies aimed at inducing structural changes – for example, closure of polluting coal power plants or reducing motorised miles travelled – are more likely to have potential positive spillover effects for climate mitigation, as compared to policies incentivising end-of-pipe controls (Wang 2021).

Other policies that typically have potential co-benefits for climate mitigation include those specific to certain sectors and are discussed in Chapters 5–11. Examples of such policies include those that encourage active travel modes, which have been found to have ancillary benefits for local air quality, human health, and GHG emissions (Fujii et al. 2018). Policies to reduce energy use through greater efficiency have also been found to have benefits for air quality and the climate (*robust evidence, medium agreement*) (Tzeiranaki et al. 2019; Bertoldi and Mosconi 2020). Important air quality and climate co-benefits of renewable or nuclear energy policies have also been found (*medium evidence, medium agreement*) (Lee et al. 2017; Apergis et al. 2018; Sovacool and Monyei 2021).

Policies specific to other sectors, such as encouraging green building design, can also reduce GHG emissions (Eisenstein et al. 2017). Evidence from several countries also shows that replacing polluting solid biomass cooking with cleaner gas-burning or electric alternatives have strong co-benefits for health, air quality, and climate change (*robust evidence, high agreement*) (Anenberg et al. 2017; Singh et al. 2017; Tao et al. 2018).

2.8.4.2 Climate Impacts of Agricultural, Forestry, Land Use, and AFOLU-related Policies

Policies on agriculture, forestry, and other land use (AFOLU), and AFOLU sector-related policies have had a long history in many developing and developed countries. Co-impacts of these policies on the climate have been only marginally studied, although their impacts might be quite important because the AFOLU sector is responsible for 22% of total GHG emissions (*robust evidence, high agreement*). The results of afforestation policies around the world and the contribution to CCS are also important.

Private and governmental policies can have a major impact on the climate. Experience indicates that ‘climate proofing’ a policy is likely to require some stimulus, resources, and expertise from agencies or organisations from outside the country. Stimulus and support for adaptation and mitigation can come from the UN system and from international development institutions (FAO 2009). These findings are also valid for small/organic farmers vis-à-vis large-scale

agro-industry. For example, small/medium and environmentally concerned farmers in Europe are often asking for more policies and regulations, and see it as necessary from a climate perspective, and also to maintain competitiveness relative to large agro-industrial complexes. Therefore, the need for governmental support for small producers in regulations encompasses all AFOLU sectors.

Forestry case: zero deforestation

Forest is generally defined as land spanning more than 0.5 hectares with trees higher than 5 metres and a canopy cover of more than 10%, or trees able to reach these thresholds in situ (FAO 1998). Zero-deforestation (i.e., both gross and net zero deforestation) initiatives generate results at multiple levels (Meijer 2014). Efforts to achieve zero-deforestation (and consequently emissions) are announced by non-governmental organisations (NGOs), companies, governments, and other stakeholder groups. NGOs engage through their campaigning, but also propose tools and approaches for companies (Leijten et al. 2020). The extent to which companies can actually monitor actions conducive to zero-deforestation pledges depends on their position in the supply chain. Beyond the business practices of participating companies, achieving long-term positive societal impacts requires upscaling from supply chains towards landscapes, with engagement of all stakeholders, and in particular small producers. The various success indicators for zero deforestation mirror the multiple levels at which such initiatives develop: progress towards certification, improved traceability, and legality are apparent output measures, whereas direct-area monitoring and site selection approaches target the business practices themselves.

Such efforts have led to the development of the High Carbon Stock (HCS) approach that combines carbon stock values with the protection of HCS areas (including peatlands and riparian zones) and areas important for the livelihoods of local communities (Rosoman et al. 2017). Long-term positive impacts, however, will need to be assessed with hindsight and focus on national and global statistics. Successful initiatives targeting zero deforestation at jurisdictional level would also need to improve the enforcement of forest laws and regulations (Eli 2015; Meyer and Miller 2015).

Large-scale agribusiness, banks, and consumer goods companies dominate supply chain-focused zero-deforestation initiatives, but only the producers, including local communities and smallholders, can change the production circumstances (TFD 2014). Producers shoulder much of the burden for meeting environmental requirements of pledges. And local communities and small producers are vulnerable to being cut out when supply chains reorient. The zero-deforestation pledges do not always devise programmes for introducing new sourcing strategies, and governments may have an important contribution to make, particularly in safeguarding the interests of small producers.

Other than in Brazil and Indonesia, beyond individual supply chains, there is still little evidence on positive results of zero-deforestation commitments, as information available for companies to judge their progress is scarce. Moreover, many zero-deforestation pledges set targets to be achieved by 2020 or 2030, and, consequently,

many companies have not yet reported publicly on their progress. Similarly, only a few governments have yet shown progress in reducing deforestation, but the New York Declaration on Forests, the Sustainable Development Goals (SDGs) and the Paris Agreement were adopted relatively recently. The effectiveness of private-sector zero-deforestation pledges depends on the extent to which they can be supported by governmental action and foster a cooperative environment with the engagement of all stakeholders. Where the pledges are coordinated with regulation, multi-stakeholder dialogues, and technical and financial support, a true paradigm shift becomes possible. Many governments are still building the capacity to improve overall forest governance, but implementing ambitious international targets is likely to depend on technical and major financial support that has not yet been mobilised.

2.9 Knowledge Gaps

- Global GHG emissions estimates are published less frequently and with greater reporting lags than, for example, CO₂ from fossil fuel and industry. Data quality and reporting frequency remains an issue, particularly in developing countries where the statistical infrastructure is not well developed. Efforts to compile a global GHG emissions inventory by country, sector, and across time, that is annually updated based on the best-available inventory information, similar to ongoing activities for carbon dioxide (CO₂), methane (CH₄) or nitrous oxide (N₂O), could fill this gap. Uncertainties and their methodological treatment in GHG emissions estimates are still not comprehensively understood.
- There is a more fundamental data gap for F-gas emissions, where data quality in global inventories is poor due to considerable gaps in the underlying activity data – particularly in developing countries. Comprehensive tracking of fluorinated gases (F-gas) emissions would also imply the inclusion of other gases not covered under the Paris Agreement, such as chlorofluorocarbons, hydrochlorofluorocarbons and others.
- Currently, despite advances in terms of data availability, sectoral and spatial resolution, the results in consumption-based emission estimates are dependent on the database used, the level of sectoral aggregation and country resolution. More fine-grained data at spatial resolution as well as the product level would support exploring the mitigation options at the sub-national level, companies and households.
- Consumption-based emission accounts suffer from lack of quantification of uncertainties at the subnational level and especially in data-scarce environments, such as for developing countries. A better understanding of drivers that caused decoupling of emissions at the national and especially sub-national level are important to explore.
- Understanding how socio-economic drivers modulate emission mitigation is crucial. Technological improvements (e.g., improved energy or land-use intensity of the economy) have shown a persistent pattern over the last few decades, but gains have been outpaced by increases in affluence (GDP per capita) and population growth, leading to continued emissions growth. Therefore the key gap in knowledge is how these drivers of emissions can be mitigated by demand management, alternative economic models, population control and rapid technological transition to different extents and in different settings. More research on decoupling and sustainability transformations would help to answer these questions. Key knowledge gaps also remain in the role of trade – in particular, how supporting low-carbon technologies in developing and exporting countries can counteract the upward-driving effect of trade, and how to achieve decoupling without outsourcing emissions to others and often to less developed regions.
- Understanding of how inequality affects emissions is in a nascent stage. Less is known about the causal mechanisms by which different dimensions of inequality – such as income, socio-economic, spatial, socio-cultural-gender and ethnicity – affect emissions. In particular, limited knowledge exists on the linkages between dimensions of inequality other than income or wealth and emissions arising from different service demands. Research gaps are apparent on how inequalities in living standards relate to emissions and how changes in inequalities between genders, social groups, and other marginalised communities impact emissions trends.
- Digitalisation of the economy is often quoted as providing new mitigation opportunities, but knowledge and evidences are yet limited – such as understanding of the role of smart apps and the potential and influence of disruptive technologies at the demand and supply side on GHG emissions.
- Despite growing evidence of technological progress across a variety of mitigation areas and the availability of increasingly precise datasets, knowledge gaps remain on technological change and innovation and evidence on speed of transitions to clarify what would make them fast or slow. Innovation is an inherently uncertain process and there will always be imperfect ex ante knowledge on technological outcomes and their effects on mitigation. The extent to which a low-carbon transition can proceed faster than historical examples is crucial to aid future mitigation. That depends on a better understanding of the speed of building, updating and replacing infrastructure. Additionally, how and whether financing for low-carbon technology investment in low- and middle-income countries can be delivered at low-cost and sustained over time are important questions. The emerging findings that small-scale technologies learn faster and are adopted more quickly need to be tested against a broader set of cases, and in particular against the large dispersion in data.
- Future CO₂ emissions from existing and planned infrastructure is not well understood and quantified outside the power sector. Further integration of bottom-up accounting and scenario approaches from integrated assessment seems promising. Comprehensive assessments of hard-to-abate residual fossil fuel emissions and their relationship to CO₂ removal activities are lacking, but will be important for informing net-zero emissions strategies.
- Empirical evidence of emission impacts from climate policies, including carbon pricing, is not sufficient for unambiguous attribution assessment, mainly due to the limited experience with climate-related policy experiments to date. More attention to the methodology for comprehensive evaluation of climate policies and measures, such as effective carbon rates is apparent. Key knowledge gaps also exist on ex-post evaluations of climate and non-climate policies and measures for their impact on emissions, particularly at the global scale, considering national circumstances and priorities.

Frequently Asked Questions (FAQs)

FAQ 2.1 | Are emissions still increasing or are they falling?

Global greenhouse gas (GHG) emissions continued to rise and reached 59 ± 6.6 GtCO₂-eq in 2019, although the rate of growth has fallen compared to the previous decade. However, emissions were higher than at any point in human history before. Emissions were around 12% and 54% higher than in 2010 and 1990, respectively. Average annual GHG emissions for 2009–2019 were higher compared to the periods 2000–2009 and 1990–1999, respectively. GHG emissions growth slowed since 2010: while average annual GHG emissions growth was 2.1% for 2000–2010, it was only 1.3% for 2010–2019. In order to stop the temperature increase, however, net emissions must be zero.

FAQ 2.2 | Are there countries that have reduced emissions and grown economically at the same time?

About 24 countries have reduced territorial CO₂ and GHG emissions for more than 10 years. Uncertainties in emission levels and changes over time prevent a precise assessment in some country cases. In the short observation period of 2010–2015, 43 out of 166 countries have achieved absolute decoupling of consumption-based CO₂ emissions from economic growth, which means that these countries experienced GDP growth while their emissions have stabilised or declined. A group of developed countries, such as some EU countries and the USA, and some developing countries, such as Cuba, have successfully achieved an absolute decoupling of consumption-based CO₂ emissions and GDP growth. Decoupling has been achieved at various levels of per capita income and per capita emissions. Overall, the absolute reduction in annual emissions achieved by some countries has been outweighed by growth in emissions elsewhere in the world.

FAQ 2.3 | How much time do we have to act to keep global warming below 1.5 degrees?

If global CO₂ emissions continue at current rates, the remaining carbon budget for keeping warming to 1.5°C will likely be exhausted before 2030. Between 1850 and 2019, total cumulative CO₂ emissions from the fossil fuel industry (FFI) and agriculture, forestry, and other land use (AFOLU) were 2400 (± 240 GtCO₂). Of these, about 410 ± 30 GtCO₂ were added since 2010. This is about the same size as the remaining carbon budget for keeping global warming to 1.5°C and between one-third and one-half of the 1150 ± 220 (1350, 1700) GtCO₂ for limiting global warming below 2°C with a 67% (50%, 33%) probability, respectively (Canadell et al. 2021). At current (2019) rates of emissions, it would only take 8 (2–15) and 25 (18–35) years to emit the equivalent amount of CO₂ for a 67th percentile 1.5°C and 2°C remaining carbon budget, respectively. This highlights the dependence of 1.5°C pathways on the availability of substantial CO₂ removal capacities, as discussed in Chapters 3, 4, and 12, but also Section 2.7 of this chapter.

2.SM.1 Historic Greenhouse Gas Emissions 1990–2019: Dataset Description

This section provides a brief description of the dataset on historic greenhouse gas (GHG) emissions compiled for AR6 WGIII (the contribution of Working Group III to the IPCC Sixth Assessment Report) on climate change mitigation. The dataset is publicly available (<https://zenodo.org/record/5566761>) and has undergone additional peer review (Minx et al. 2021). Sections 2.SM.1 and 2.SM.2 included in this Supplementary Material are taken (in most parts) directly from Minx et al. (2021). It is included here solely to provide full transparency over the data used in this report and enable easy access to all information.

2.SM.1.1 Overview

The historic emissions dataset used in Chapter 2 provides a comprehensive, synthetic set of estimates for global GHG emissions disaggregated by 27 economic sectors and 228 countries and territories. Its focus is on anthropogenic GHG emissions: natural sources and sinks are not included. Five groups of gases are distinguished: (i) CO₂ emissions from fossil fuel combustion and industry (CO₂-FFI); (ii) CO₂ emissions from land use, land-use change and forestry (CO₂-LULUCF); (iii) methane emissions (CH₄); (iv) nitrous oxide emissions (N₂O); (v) fluorinated gases (F-gases) comprising hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆) as well as nitrogen trifluoride (NF₃). Other F-gases that are internationally regulated as ozone-depleting substances under the Montreal Protocol such as chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) are not included. GHG emissions data are analysed both in native units (except F-gases) as well as in CO₂-equivalents (CO₂-eq) as commonly done in wide parts of the climate change mitigation community using global warming potential with a 100-year time horizon (GWP100) from AR6 (Forster et al. 2021). The impact of using alternative metric choices in tracking aggregated GHG emissions is discussed in Section 2.SM.3 of this Supplementary Material.

The dataset is compiled from four sources: (i) the full EDGARv6.0 release for CO₂-FFI as well as non-CO₂ GHGs covering the time period 1970–2018 (Crippa et al. 2021); (ii) EDGARv6.0 fast-track data for CO₂-FFI providing preliminary estimates for 2019 and 2020 (Crippa et al. 2021); (iii) CO₂-LULUCF as the average of three bookkeeping models, consistent with the approach of the global carbon project (Friedlingstein et al. 2020); and (iv) 2019 non-CO₂ emissions based on Olivier and Peters (2018). The resulting synthetic dataset as presented here has undergone additional peer review (Minx et al. 2021).

As shown in Table 2.SM.1, sectoral detail is organised along five major economic sectors harmonised with the sector chapters used in this report: energy supply (Chapter 6); building (Chapter 9); transport (Chapter 10); Industry (Chapter 11); and Agriculture, Forestry and Other Land Use (AFOLU) (Chapter 7). A further classification for assigning our 228 countries and territories to regions is used, combining the standard Annex I/non-Annex I distinction with geographical location, as documented in Annex II of this

report. The dataset including the sector and region classification, and GWP100 by gas can be found at <https://zenodo.org/record/5566761>.

While there is a growing number of global emissions inventories, only a few of them provide a wide coverage of gases, sectors, activities, and countries or regions that are sufficiently up to date to comprehensively track progress and thereby aid discussions in science and policy. Table 2.SM.2 provides an overview of global emission inventories. Many inventories focus on individual gases and subsets of activities. Few provide sectoral detail and, particularly for non-CO₂ GHG emissions, there is often a considerable time-lag in reporting. GHG emissions reporting under the United Nations Framework Convention on Climate Change (UNFCCC) provides reliable, comprehensive and up-to-date statistics for Annex I countries across all major GHGs. Non-Annex I countries – except least-developed countries and small island states for which this is not mandatory – provide GHG emissions inventory information through biennial update reports (BURs), but with much less stringent reporting requirements in terms of sector, gas and time coverage (Gütschow et al. 2016; Deng et al. 2021). As a result, many still lack a well-developed statistical infrastructure to provide detailed and timely reports (Janssens-Maenhout et al. 2019).

Table 2.SM.1 | Overview of the two-level sector aggregation with reference to assigned source/sink categories conforming to the IPCC reporting guidelines (IPCC 2006, 2019) as well as relevant GHGs.

Sector	Sub-sector	IPCC (2006)	Gases

Note that EDGARv6.0 distinguishes biogenic CO₂ and CH₄ sources with a 'bio' label, with all other sectors 'fossil' by default, even if that source is not related to fossil fuel activities. The fossil/bio label is hence not descriptive in nature. Two HCFC gases (denoted with *) are included in the dataset, despite being neither PFCs nor HFCs (and hence regulated under Montreal). This is to preserve consistency with current and previous versions of EDGAR, which include these gases. Their total warming effect is low (about 10 MtCO₂-eq in 2019) and the major HCFC sources are not included. Source: Minx et al. (2021).

2.SM.1.2 The Emissions Database for Global Atmospheric Research (EDGAR)

EDGAR emission estimates included in Chapter 2 emissions dataset are derived from the full version 6 release (Crippa et al. 2021). This includes CO₂ and non-CO₂ GHG emission estimates from 1970 to 2018 computed from stable international statistics, and fast-track estimates of fossil CO₂ emissions up to the year 2020. The following general EDGAR methodological description is largely taken from Janssens-Maenhout et al. (2019). EDGAR bottom-up emission inventory estimates are calculated from international activity data and emission factors following the 2006 IPCC Guidelines for National Greenhouse Gas Inventories (IPCC 2006) – updated according to the latest scientific knowledge. Emissions (*EMs*) from a given sector *i* in a country *C* accumulated during a year *t* for a chemical compound *x* are calculated with the country-specific activity data (*AD*), quantifying the activity in sector *i*, with the mix of *j* technologies (*TECH*) and with the mix of *k* (end-of-pipe) abatement measures (*EOP*) installed with the share *k* for each technology *j*, the emission rate with an uncontrolled emission factor (*EF*) for each sector *i* and technology *j* and relative reduction (*RED*) by abatement measure *k*, as summarised in the following formula:

Equation 2.SM.1

$$EM_i(C, t, x) = \sum_{j,k} [AD_i(C, t) \cdot TECH_{i,j}(C, t) \cdot EOP_{i,j,k}(C, t) \cdot EF_{i,j}(C, t, x) \cdot (1 - RED_{i,j,k}(C, t, x))]$$

The activity data are sector dependent and vary from fuel combustion in energy units of a particular fuel type, to the amount of products manufactured, or to the number of animals or the area or yield of cultivated crops. The technology mixes, (uncontrolled) emission factors and end-of-pipe measures are determined at different levels: country-specific, regional, country group (e.g., Annex I/non-Annex I), or global. Technology-specific emission factors are used to enable an IPCC Tier-2 approach (see Box 2.SM.1), taking into account the different management and technology processes or infrastructures (e.g., different distribution networks) under specific ‘technologies’, and modelling explicitly abatements/ emission reductions – for example, the CH₄ recovery from coal mine gas at country level under the ‘end-of-pipe measures’. As with national inventories, emissions are accounted over a period of one calendar year in the country

or territory in which they took place (i.e., a territorial accounting principle) (IPCC 2006, 2019). A more complete description of the data sources and methodology for EDGARv6 is provided in Crippa et al. (2021).

To compute emissions up to the most recent years, a fast-track methodology is applied, as described in Oreggioni et al. (2021). The underlying principle is to extrapolate trends based on observed activity patterns in representative sectors. For CO₂-FFI emissions, the fast track estimates were based on the latest BP coal, oil and natural gas consumption data (BP 2021). Emission updates for cement, lime, ammonia and ferroalloys production beyond 2018 are based on stable statistics. In particular these include US Geological Survey statistics, urea production and consumption statistics from the International Fertilizer Association, gas flaring statistics from the Global Gas Flaring Reduction Partnership, steel production statistics from the World Steel Association, and cement clinker production statistics from UNFCCC data. Fast-track extensions for non-CO₂ GHG emissions are based on Olivier and Peters (2018). For CH₄ and N₂O these are based on agricultural statistics from the UN’s Food and Agricultural Organization (FAO) (CH₄ and N₂O), fuel production and transmission statistics from the International Energy Agency (IEA) and BP (CH₄) as well as data from national GHG inventory reports on coal production (CH₄ recovery) and the production of chemicals (N₂O abatement) submitted by Annex-I countries to the UNFCCC following a common reporting format (CRF) (e.g., UNFCCC 2021). For F-gases the fast-track extension was based on the most recent national emission inventories, submitted under the UNFCCC (up to 2018). Given the absence of international statistics, for all remaining countries and years, a simple extrapolation was used, with fast-track data by Olivier and Peters (2020). Here the procedure was to calculate the country- and sector-specific emissions growth between 2018 and 2019 in Olivier and Peters (2020), then multiply each growth rate with the 2018 values in the Chapter 2 emissions data.

2.SM.1.3 Accounting for CO₂ Emissions Land Use, Land-use Change and Forestry (CO₂-LULUCF)

All fluxes of CO₂-LULUCF are considered. This includes CO₂ fluxes from the clearing of forests and other natural vegetation (by anthropogenic fire and/or clear-cut), afforestation, harvest activities, land-use related forest degradation, shifting cultivation (cycles of

Box 2.SM.1 | Methodological Standards for Compiling Greenhouse Gas Inventories According to IPCC Guidelines

The 2006 Guidelines for National Greenhouse Gas Inventories and their 2019 refinements by the Intergovernmental Panel on Climate Change (IPCC) provide methodological guidance for compiling greenhouse gas (GHG) emissions inventories at different levels of sophistication (IPCC 2006, 2019). The levels of methodological complexity for estimating GHG emissions and removals are organised according to different *tiers*. *Tier 1* is the most basic method. It applies a simple default methodology as well as default emission factors and other parameters defined in the IPCC Guidelines. *Tier 2* methods replace those default values by country-specific data and can use more detailed calculations and activity data. *Tier 3* refers to methods that may apply country-specific equations for calculating emissions along with more details regarding activity data, technologies and practices, providing the most granular approach to estimation. *Tier 2* and *Tier 3* are also referred to as *higher tier methods* and are generally considered to be more accurate than a *Tier 1* method, especially when it comes to reporting changes in emissions over time (IPCC 2006).

forest clearing for agriculture, then abandonment), and regrowth of forests and other natural vegetation following wood harvest or abandonment of agriculture, and emissions from peat burning and drainage. Some of these activities lead to emissions of CO₂ to the atmosphere, while others lead to CO₂ sinks. CO₂-LULUCF therefore is the net sum of emissions and removals from all human-induced land-use changes and land management. Note that CO₂-LULUCF is referred to as (net) land-use change emissions, E_{LUC} , in the context of the global carbon budget (Friedlingstein et al. 2020). Agriculture per se, apart from conversions between different agricultural types, does not lead to substantial CO₂ emissions as compared to land-use changes such as clearing or regrowth of natural vegetation. Therefore, CO₂ fluxes in the AFOLU sector refer almost exclusively to forestry and other land use (changes), while the agricultural part of the sector is mainly characterised by CH₄ and N₂O fluxes.

Since in reality anthropogenic CO₂-LULUCF emissions co-occur with natural CO₂ fluxes in the terrestrial biosphere, models have to be used to distinguish anthropogenic and natural fluxes (Friedlingstein et al. 2020). CO₂-LULUCF as reported here is calculated via a bookkeeping approach, as originally proposed by Houghton et al. (2003), tracking carbon stored in vegetation and soils before and after land-use change. Response curves are derived from the literature and observations to describe the temporal evolution of the decay and regrowth of vegetation and soil carbon pools for different ecosystems and land-use transitions, including product pools of different lifetimes. These dynamics distinguish bookkeeping models from the common approach of estimating ‘committed emissions’ (assigning all present and future emissions to the time of the land-use change event), which is frequently derived from remotely-sensed land-use area or biomass observations (Ramankutty et al. 2007). Most bookkeeping models also represent the long-term degradation of primary forest as the reduction of standing vegetation and soil carbon stocks in secondary forests, and include forest management practices such as wood harvesting. Since the effects of environmental changes are excluded by the bookkeeping approach, bookkeeping CO₂-LULUCF emissions estimates isolate the effects of anthropogenic (land-use-related) drivers.

The definition of CO₂-LULUCF emissions by global carbon cycle models, as used here and in Canadell et al. (2021), differs from IPCC definitions (IPCC 2006) applied in national greenhouse gas inventories (NGHGI) for reporting under the climate convention (Grassi et al. 2018) and, similarly, from FAO estimates of carbon fluxes on forest land (Tubiello et al. 2021). This means that NGHGI data include natural terrestrial fluxes caused by changes in environmental conditions, such as the effects of rising atmospheric CO₂ (CO₂-fertilisation), climate change, and nitrogen deposition – sometimes called ‘indirect effects’ as opposed to the direct anthropogenic effects of land-use change and management (Houghton et al. 2012) (Section 2.2.2.1 and Chapter 7) – through adoption of the IPCC so-called land-use proxy approach when they occur on areas that countries declare as managed. Since environmental changes turned the terrestrial biosphere into a massive sink, removing about one-third of annual anthropogenic emissions in the last decade (Friedlingstein et al. 2020), it is unsurprising that global emission estimates are smaller based on NGHGI than for global models’ definitions (Figure 2.SM.1).

About 3.2 GtCO₂ yr⁻¹ (for the period 2005–2014) was found to be explicable by these conceptual differences in anthropogenic forest sink estimation related to the representation of environmental change impacts and the areas considered as managed (Grassi et al. 2018).

These two conceptually different approaches have different aims: the global models’ approach separates natural from anthropogenic drivers – that is, the effects of changes in environmental conditions from effects of land-use change and land management. By contrast, the NGHGI approach separates fluxes based on areas, with all those occurring on managed land being declared anthropogenic. Given that observational data of carbon stocks or fluxes cannot distinguish the co-occurring effects of environmental changes and land-use activities, an area-based approach that does not require this distinction can more consistently be implemented across countries. These conceptual differences between global models and NGHGI approaches have been acknowledged (Petrescu et al. 2020a; Canadell et al. 2021) and approaches have been developed to map the two definitions to each other (Grassi et al. 2018, 2021). For non-CO₂ GHGs, drivers and areas coincide, such that FAOSTAT data for CH₄ and N₂O is complementary to bookkeeping CO₂-LULUCF emissions.

Following the approach taken by the global carbon budget (Friedlingstein et al. 2020), the approach taken here is to use the average of estimates from three bookkeeping models: Bookkeeping of land-use emissions (BLUE) (Hansis et al. 2015), H&N (Houghton and Nassikas, 2017), and an earth system compact model (OSCAR) (Gasser et al. 2020). Key differences across these estimates, including land-use forcing, are summarised in Table 2.SM.4. Since bookkeeping models do not include emissions from organic soils, emissions from peat fires and peat drainage are added from external datasets: Peat burning is based on the Global Fire Emissions Database (GFEDv4) (van der Werf et al. 2017) and introduces large interannual variability to the CO₂-LULUCF emissions due to synergies of land-use and climate variability, particularly in Southeast Asia, strongly noticeable during El Niño events such as in 1997. Peat drainage is based on estimates by Hooijer et al. (2010) for Indonesia and Malaysia in H&N, and added to BLUE and OSCAR from the global FAO data on organic soils emissions from croplands and grasslands (Conchedda and Tubiello 2020).

2.SM.2 Uncertainties in GHG Emissions Estimates

Estimates of historic GHG emissions – CO₂, CH₄, N₂O and F-gases (HFCs, PFCs, SF₆, NF₃) – are uncertain to different degrees. Assessing and reporting uncertainties is crucial in order to understand whether available estimates are sufficiently accurate to answer – for example, whether GHG emissions are still rising, or if a country has achieved an emissions-reduction goal (Marland 2008). These uncertainties can be of a scientific nature, such as when a process is not sufficiently understood. They also arise from incomplete or unknown parameter information (activity data, emission factors, and so on), as well as estimation uncertainties from imperfect modelling techniques. There are at least three major ways to examine uncertainties in emission estimates (Marland et al. 2009): (i) by comparing estimates made

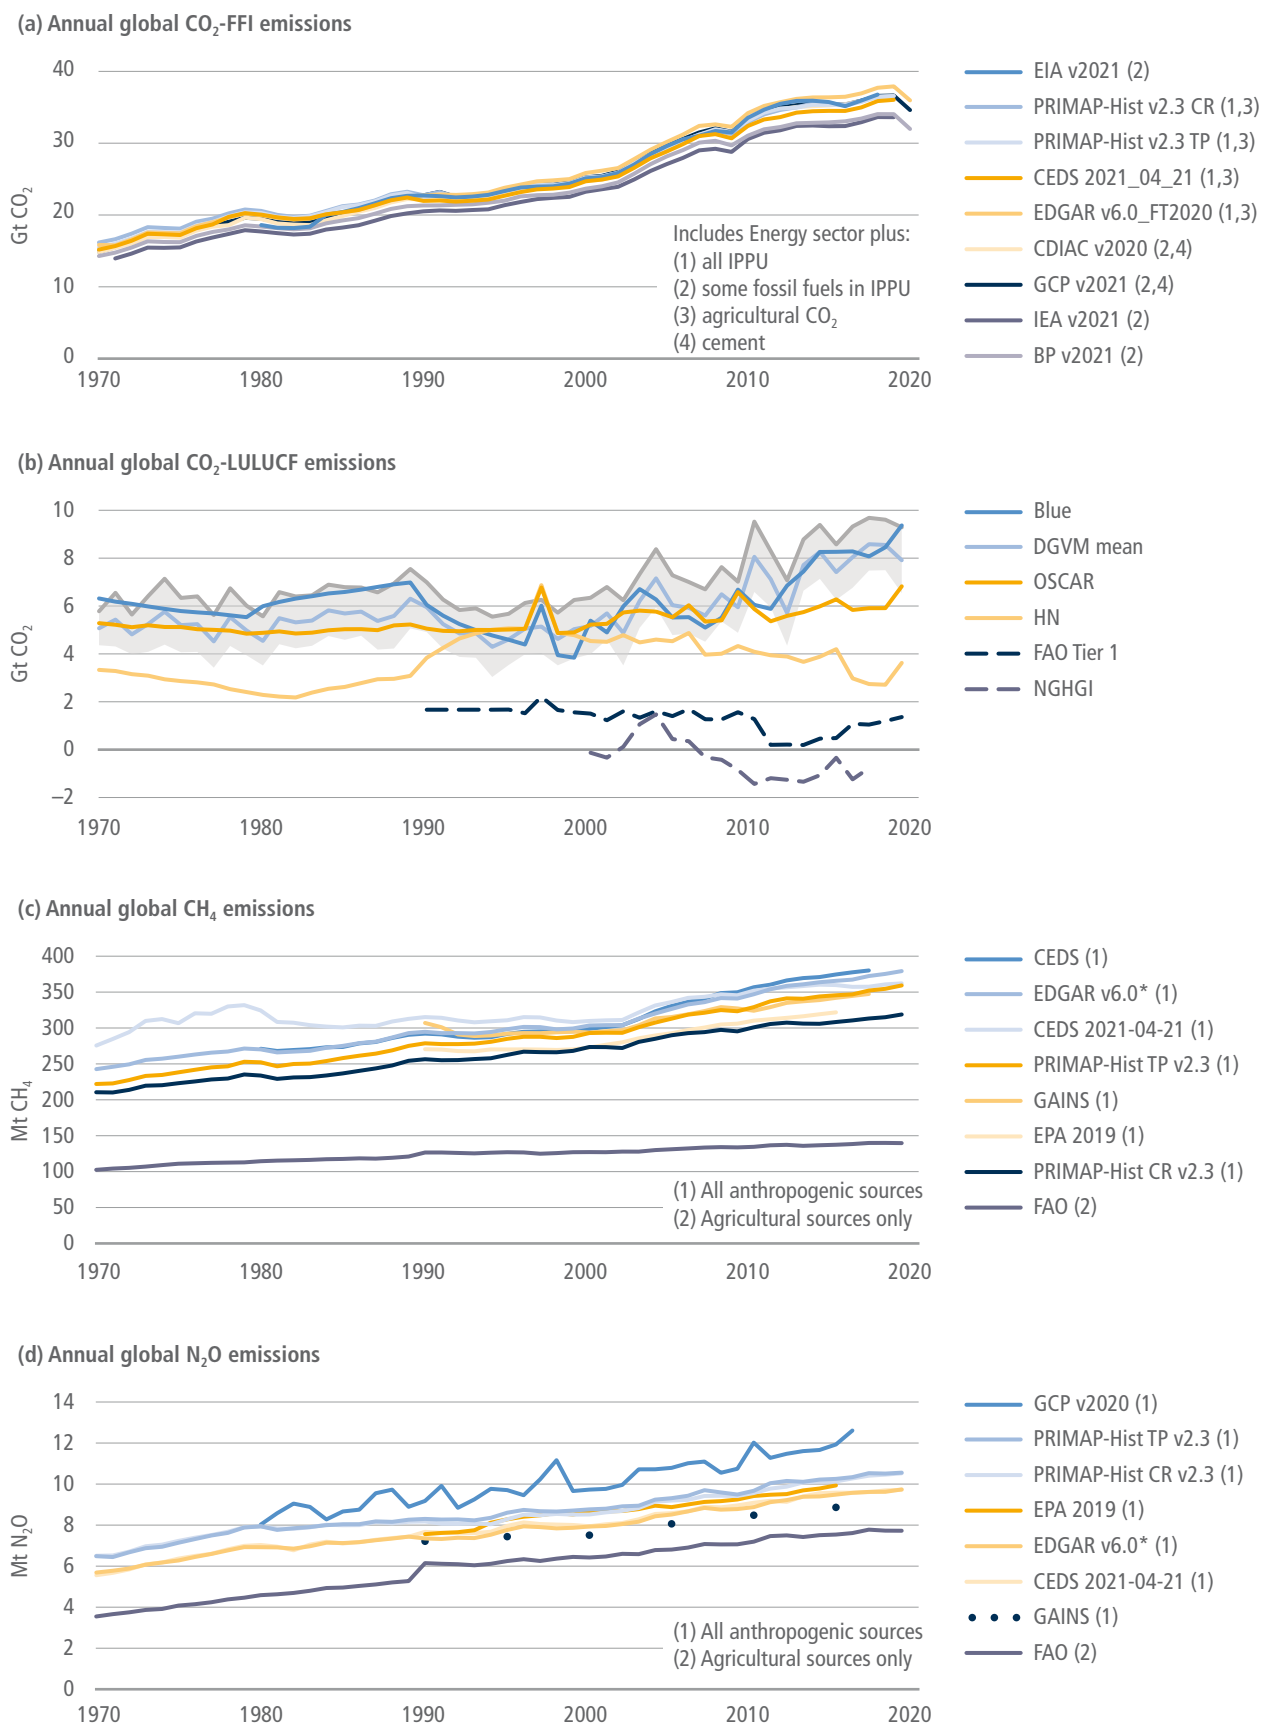

Figure 2.SM.1 | Estimates of global anthropogenic greenhouse gas emissions from different data sources 1970–2019.

Figure 2.SM.1 (continued): Estimates of global anthropogenic greenhouse gas emissions from different data sources 1970–2019. **Top-left panel:** CO₂-FFI emissions from: EDGAR – Emissions Database for Global Atmospheric Research (this dataset) (Crippa et al. 2021); GCP – Global Carbon Project (Friedlingstein et al. 2020; Andrew and Peters 2021); CEDS – Community Emissions Data System (Hoesly et al. 2018; O'Rourke et al. 2021); CDIAC Global, Regional, and National Fossil-Fuel CO₂ Emissions (Gilfillan et al. 2020); PRIMAP-hist – Potsdam Real-time Integrated Model for probabilistic Assessment of emissions Paths (Gütschow et al. 2016, 2021b); EIA – Energy Information Administration International Energy Statistics (EIA 2019); BP – BP Statistical Review of World Energy (BP 2021); IEA – International Energy Agency (IEA 2021b); (a); IPPU refers to emissions from industrial processes and product use. **Top-right panel:** Net anthropogenic CO₂-LULUCF emissions from: BLUE – Bookkeeping of land-use emissions (Hansis et al. 2015; Friedlingstein et al. 2020); DGVM-mean – Multi-model mean of CO₂-LULUCF emissions from dynamic global vegetation models (Friedlingstein et al. 2020); OSCAR – an earth system compact model (Friedlingstein et al. 2020; Gasser et al. 2020); H&N – Houghton and Nassikas Bookkeeping Model (Houghton and Nassikas 2017; Friedlingstein et al. 2020); for comparison, the net CO₂ flux from FAOSTAT (FAO Tier 1) is plotted, which comprises net emissions and removals on forest land and from net forest conversion (FAOSTAT 2021; Tubiello et al. 2021), emissions from drained organic soils under cropland/grassland (Conchedda and Tubiello 2020), and fires in organic soils (Conchedda and Tubiello 2020; Prosperi et al. 2020), as well as a net CO₂ flux estimate from National Greenhouse Gas Inventories (NGHGI) based on country reports to the UNFCCC, which include land-use change, and fluxes in managed lands (Grassi et al. 2021). **Bottom-left panel:** Anthropogenic CH₄ emissions from: EDGAR (above); CEDS (above); PRIMAP-hist (above); GAINS – The Greenhouse gas – Air pollution Interactions and Synergies Model (Höglund-Isaksson et al. 2020); EPA-2019: Greenhouse gas emission inventory (US-EPA 2019); FAO –FAOSTAT inventory emissions (Tubiello et al. 2013; Tubiello 2018; FAOSTAT 2021); **Bottom-right panel:** Anthropogenic N₂O emissions from: GCP – global nitrous oxide budget (Tian et al. 2020); CEDS (above); EDGAR (above); PRIMAP-hist (above); GAINS (Winiwarter et al. 2018); EPA-2019 (above); FAO (above). Differences in emissions across different versions of the EDGAR dataset are shown in the Supplementary Material (Figure 2.SM.2). Source: Minx et al. (2021).

by independent methods and observations (e.g., comparing top-down vs bottom-up estimates; modelling against remote sensing data) (Li et al. 2020; Saunio et al. 2020; Petrescu et al. 2020a, 2021); (ii) by comparing estimates from multiple sources and understanding sources of variation (Macknick, 2011; Andres et al. 2012; Andrew 2020; Ciais et al. 2021); (iii) by evaluating multiple estimates from a single source (Hoesly and Smith 2018) including approaches such as uncertainty ranges estimated through statistical sampling across parameter values applied, for example, at the country or sectoral level (Monni et al. 2007; Andres et al. 2014; Solazzo et al. 2021), or to spatially distributed emissions (Tian et al. 2019).

Uncertainty estimates can be rather different depending on the method chosen. For example, the range of estimates from multiple sources is bounded by their interdependency; they can be lower than true structural plus parameter uncertainty estimates or than estimates made by independent methods. In particular, it is important to account for potential bias in estimates, which can result from using common methodological or parameter assumptions across estimates, or from missing sources, which can result in a systemic bias in emission estimates (see N₂O discussion below). Independent top-down observational constraints are, therefore, particularly useful to bound total emission estimates (Petrescu et al. 2021).

Solazzo et al. (2021) evaluated the uncertainty of EDGAR's source categories and totals for the main GHGs (CO₂-FFI, CH₄, N₂O). This study is based on the propagation of the uncertainty associated with input parameters (activity data and emission factors) as estimated by expert judgement (Tier-1) and compiled by the IPCC (2019, 2006). A key methodological challenge is determining how well uncertain parameters are correlated between sectors, countries, and regions. The more highly correlated parameters (e.g., emission factors) are across scales, the higher the resulting overall uncertainty estimate. Solazzo et al. (2021) assume full covariance between the same source categories where similar assumptions are being used, and independence otherwise. For example, they assume full covariance where the same emission factor is used between countries or sectors, while assuming independence where country-specific emission factors are used. This strikes a balance between extreme assumptions (full independence or full covariance in all cases) that are likely unrealistic, but still leans towards higher uncertainty estimates. When aggregating emission sources, assuming full covariance

increases the resulting uncertainty estimate. Uncertainties calculated with this methodology tend to be higher than the range of values from ensemble of dependent inventories (Saunio et al. 2016, 2020). The uncertainty of emission estimates derived from ensembles of gridded results from bio-physical models (Tian et al. 2018) adds an additional dimension of spatial variability, and is therefore not directly comparable with aggregate country or regional uncertainty, estimated with the methods discussed above.

This section provides an assessment of uncertainties in GHG emissions data at the global level. The uncertainties reported here combine statistical analysis, comparisons of global emissions inventories and expert judgement of the likelihood of results lying outside a defined confidence interval, rooted in an understanding gained from the relevant literature. At times, we also use a qualitative assessment of confidence levels to characterise the annual estimates from each term, based on the type, amount, quality, and consistency of the evidence as defined by the IPCC (IPCC 2014).

Such a comprehensive uncertainty assessment covering all major groups of GHGs and considering multiple lines of evidence has been missing in the literature. The absence has provided a serious challenge for a transparent, scientific reporting of GHG emissions in climate change assessments such as those by IPCC's Working Group III or the UN Emissions Gap Report, which have only more recently started to deal with the issue (Blanco et al. 2014; UNEP 2020). Most of the available studies in the peer-reviewed literature using multiple lines of evidence for their assessment have focused on individual gases as in the Global Carbon Budget (Friedlingstein et al. 2020), the Global Methane Budget (Saunio et al. 2020) or the Global Nitrous Oxide Budget (Tian et al. 2020) or covered multiple gases, but mainly considered individual lines of evidence (Janssens-Maenhout et al. 2019; Solazzo et al. 2021).

We adopt a 90% confidence interval (5th–95th percentile) to report the uncertainties in our GHG emissions estimates – that is, there is a 90% likelihood that the true value will be within the provided range if the errors have a Gaussian distribution, and no bias is assumed. This is in line with previous reporting in IPCC AR5 (Blanco et al. 2014; Ciais et al. 2014). Note that national emissions inventories submitted to the UNFCCC are requested to report uncertainty using a 95% or 2 σ confidence interval. The use of this broader uncertainty

Figure 2.SM.2 | Comparison of estimates from different versions of the EDGAR database for CO₂ from fossil fuel combustion and industry. EDGAR v6.0 FT2020 refers to the Chapter 2 emissions dataset, as documented in this supplementary material and in Minx et al. (2021).

interval implies, however, a relatively high degree of knowledge about the uncertainty structure of the associated data, particularly regarding the distribution of uncertainty in the tails of the probability distributions. Such a high degree of knowledge is not present across all regions, emission sectors, and species considered here. Note that, in some cases below, we convert 1σ uncertainty results from the literature to a 90% confidence interval by implicitly assuming a normal distribution. While we do this as a necessary assumption to obtain a consistent estimate across all GHGs, we note that this itself is an assumption that may not be valid. We have made use of the best available information in the literature, but note that much more work on uncertainty quantification remains to be done. Using IPCC uncertainty language, we cannot assign *high confidence* to the robustness of most existing uncertainty estimates.

2.SM.2.1 CO₂ Emissions from Fossil Fuels and Industrial Processes (CO₂-FFI)

Several studies have compared estimates of annual CO₂-FFI emissions from different global inventories (Macknick 2011; Andres et al. 2012; Gütschow et al. 2016; Janssens-Maenhout et al. 2019; Andrew, 2020; Petrescu et al. 2020b). However, estimates are not fully independent as they all ultimately rely on many of the same data sources. For example, all global inventories use one of four global energy datasets to estimate CO₂ emissions from energy use, and these energy datasets themselves all rely on the same national energy statistics, with few exceptions (Andrew 2020). Some divergence between these estimates (Figure 2.SM.2) are related to differences in the estimation methodology, conversion factors, emission coefficients, assumptions about combustion efficiency, and calculation errors (Marland et al. 2009; Andrew 2020). Key differences for nine global datasets are highlighted in Table 2.SM.3 (see also Table 2.SM.2 for further information on the inventories).

Another important source of divergence between datasets is differences in their respective system boundaries (Macknick 2011; Andres et al. 2012; Andrew 2020). Hence, differences across CO₂-FFI emissions estimates do not reflect full uncertainty due to source data dependencies. At the same time, the observed range across estimates from different databases exaggerates uncertainty, to the extent that they largely originate in system boundary differences (Macknick 2011; Andrew 2020).

Across global inventories, mean global annual CO₂-FFI emissions track at 34 ± 2 GtCO₂ in 2014, reflecting a variability of about $\pm 5.4\%$ (Figure 2.SM.1). However, this variability is almost halved when system boundaries are harmonised (Andrew 2020). EDGAR CO₂-FFI emissions, as used there, track at the top of the range as shown in Figure 2.SM.1. This is partly due to the comprehensive system boundaries of EDGAR, but also due to the assumption of 100% oxidation of combusted fuels as per IPCC default assumptions. Once system boundaries are harmonised, EDGAR continues to track at the upper end of the range, but no longer at the top. EDGAR CO₂-FFI estimates are further well-aligned with emission inventories submitted by Annex I countries to the UNFCCC – even though some variation can occur for individual countries (Andrew 2020; Minx et al. 2021). Differences in FFI-CO₂ emissions across different versions of the EDGAR dataset are shown in Figure 2.SM.2.

Uncertainties in CO₂-FFI emissions arise from the combination of uncertainty in activity data and uncertainties in emission factors including assumptions for combustion completeness and non-combustion uses. CO₂-FFI emissions estimates are largely derived from energy consumption activity data, where data uncertainties are comparatively small due to well-established statistical monitoring systems, although there are larger uncertainties in some countries and time periods (Macknick 2011; Andres et al. 2012; Ballantyne et al. 2015; Janssens-Maenhout et al. 2019; Andrew, 2020). Most

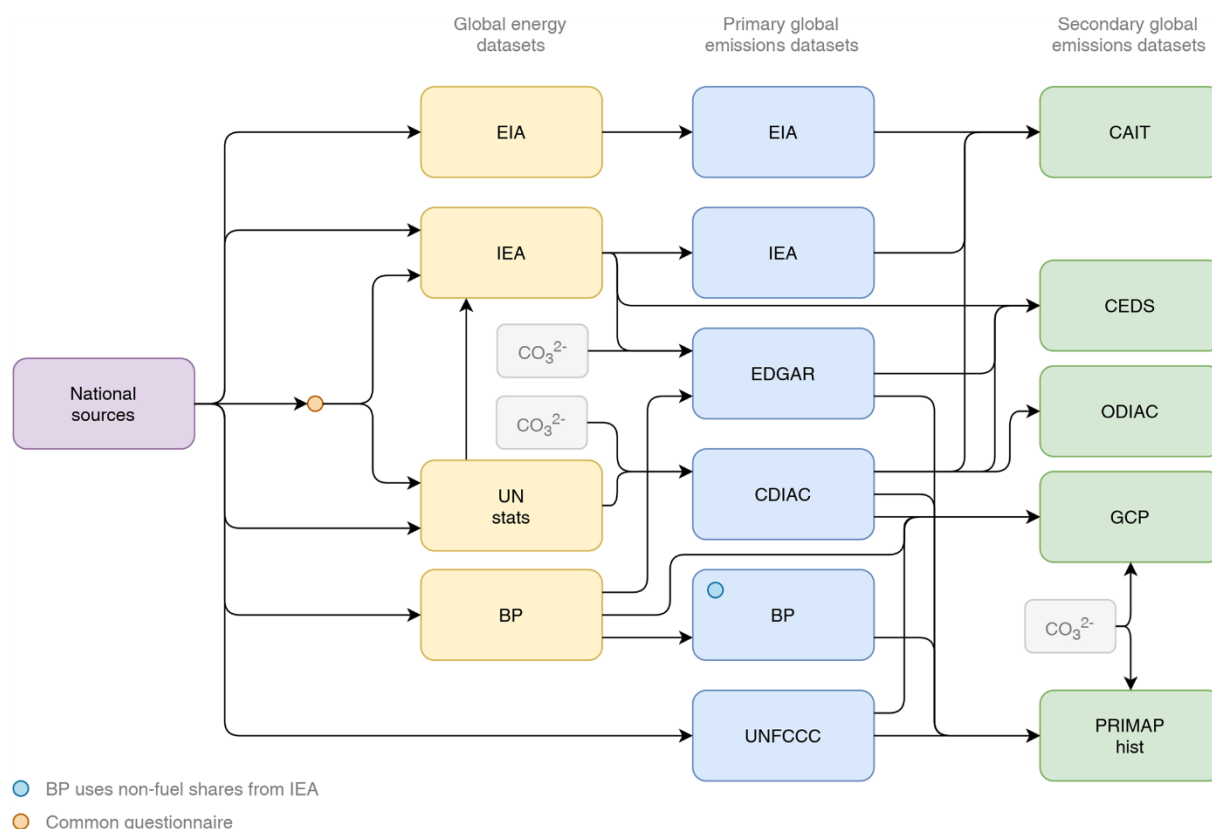

Figure 2.SM.3 | Dependencies of selected global energy and CO₂ emissions datasets. Here a 'primary' emissions dataset is one that calculated emissions directly from energy data, rather than collating emissions estimates from other sources. In addition to energy data sources, some emissions datasets include emissions from carbonates, which rely on other data sources. Some national data are first collated by regional organisations. 'UN stats' is the United Nations Statistics Office (not UNFCCC). Source: Andrew (2020).

of the underlying uncertainties are systematic and related to underlying biases in the energy statistics and accounting methods used (Friedlingstein et al. 2020). Uncertainties are lower for fuels with relatively uniform properties such as natural gas, oil or gasoline, and higher for fuels with more diverse properties, such as coal (IPCC 2006; Blanco et al. 2014). Uncertainties in CO₂ emissions estimates from industrial processes – that is, non-combustive oxidation of fossil fuels and decomposition of carbonates – are higher than for fossil fuel combustion. At the same time, products such as cement also take up carbon over their life cycle, which are often not fully considered in carbon balances (Xi et al. 2016; Sanjuán et al. 2020; Guo et al. 2021). However, recent versions of the global carbon budget include specific estimates for the cement carbonation sink and estimate average annual CO₂ uptake at 0.70 GtCO₂ for 2010–2019 (Friedlingstein et al. 2020).

Uncertainties for energy consumption data (and, therefore, CO₂-FFI emissions) are generally higher for the first year of their publication when less data is available to constrain estimates. In the BP energy statistics, 70% of data points are adjusted by an average of 1.3% of a country's total fossil fuel use in the subsequent year, with further more modest revisions later on (Hoesly and Smith 2018). Uncertainties are also higher for developing countries, where

statistical reporting systems do not have the same level of maturity as in many industrialised countries (Gregg et al. 2008; Marland, 2008; Andres et al. 2012; Guan et al. 2012; Korsbakken et al. 2016; Janssens-Maenhout et al. 2019; Friedlingstein et al. 2019, 2020; Andrew, 2020). However, these customary country groupings do not always predict the extent to which a country's energy data has undergone historical revisions (Hoesly and Smith 2018). Uncertainties in CO₂-FFI emissions before the 1970s are higher than for more recent estimates. Over the last two to three decades uncertainties have increased again because of increased fuel production and consumption in some developing countries with less rigorous statistics and more uncertain fuel properties (Marland et al. 2009; Ballantyne et al. 2015; Friedlingstein et al. 2020).

The global carbon project (Le Quéré et al. 2018; Friedlingstein et al. 2019, 2020) assesses uncertainties in global anthropogenic CO₂-FFI emissions estimates within one standard deviation (1σ) as ±5% (±10% at 2σ). This is broadly consistent with the ±8.4% uncertainty estimate for CDIAC (Andres et al. 2014) as well as the ±7 to ±9% uncertainty estimate for EDGARv4.3.2 and v5 (Janssens-Maenhout et al. 2019; Solazzo et al. 2021) at 2σ. It remains at the higher end of the ±5% to ±10% range provided by Ballantyne et al. (2015). Consistent with the above uncertainty assessments, we present

Table 2.SM.3 | System boundaries and other key features of global FFI-CO₂ emissions datasets. Comparison of some important general characteristics of nine emissions datasets, with green indicating a characteristic that might be considered a strength. Columns four to six refer to CO₂ emission estimates for industrial processes and product use. Since all datasets are under development, these details are subject to change. Based on Andrew (2020). uncertainties for global anthropogenic CO₂ emissions at $\pm 8\%$ for a 90% confidence interval in line with IPCC AR5 (Blanco et al. 2014).

2.SM.2.2 Anthropogenic CO₂ Emissions from Land use, Land-use Change and Forestry (CO₂-LULUCF)

CO₂-LULUCF emissions are drawn from three global bookkeeping models. For 1990–2019, average net CO₂-LULUCF emissions are estimated at 6.1, 4.3, and 5.6 GtCO₂ yr⁻¹ for Bookkeeping of land-use emissions (BLUE), Houghton and Nassikas Bookkeeping Model (H&N), and an earth system compact model (OSCAR) (Friedlingstein et al. 2020). Gross emissions 1990–2019 for BLUE, H&N, OSCAR are 17, 9.6 and 19 GtCO₂ yr⁻¹, while gross removals are 11, 5.3, 13 GtCO₂ yr⁻¹, respectively. For 1990–2019 maximum average differences are 9.1 and 7.8 GtCO₂ yr⁻¹ for gross emissions and removals, respectively (Friedlingstein et al. 2020). Note that 2016–2019 is extrapolated in H&N and 2019 in OSCAR based on the anomalies of the net flux for the gross fluxes. Differences in the models underlying this observed variability are reported in Table 2.SM.4. In the longer term, a consistent general upward trend since 1850 across models is reversed during the second part of the 20th century. Since the 1980s, however, differing trends across models are related to, among other things, different land-use forcings (Gasser et al. 2020). Further differences between BLUE and H&N can be traced in particular to: (i) differences in carbon densities between natural and managed vegetation, or between primary and secondary vegetation; (ii) a higher allocation of cleared and harvested material to fast turnover pools in BLUE compared to H&N; and (iii) to the inclusion sub-grid scale transitions (Bastos et al. 2021).

Uncertainties in CO₂-LULUCF emissions can be more comprehensively assessed through comparisons across a suite of dynamic global vegetation models (DGVM) (Friedlingstein et al. 2020). DGVM models are not included in the CO₂-LULUCF mean estimate provided here, because the typical DGVM setup includes the loss of additional sink capacity. The loss of additional sink capacity arises because DGVMs isolate LULUCF emissions from natural fluxes caused by historical environmental changes by subtracting a counterfactual simulation without land-use change from one with land-use change (Pongratz et al. 2014). In particular, forests have increased their carbon density over time due to CO₂ and other environmental effects beneficial for plant growth. The ‘additional sink capacity’ forests would have created at the unaltered pre-industrial extent is ‘lost’ through land-use change and included in the DGVM estimates of CO₂-LULUCF, but excluded in bookkeeping estimates that disregard changes in carbon densities in response to environmental changes. The loss of additional sink capacity makes up about 40% of the DGVM estimate in recent years (Obermeier et al. 2021).

Nonetheless, a CO₂-LULUCF estimate from the DGVM multi-model mean remains consistent with the average estimate from the bookkeeping models, as shown in Figure 2.SM.1. Variation across DGVMs is large with a standard deviation at around 1.8 GtCO₂ yr⁻¹, but is still smaller than the average difference between bookkeeping models at 2.6 GtCO₂ yr⁻¹ as well as the current estimate of H&N (Houghton and Nassikas 2017) and its previous model versions (Houghton et al. 2012). DGVMs differ in methodology, input data and how comprehensively they represent land-use-related processes. In particular land management, such as crop harvesting, tillage, or grazing (all implicitly included in observation-based carbon densities of bookkeeping models) can alter CO₂ flux estimates substantially, but are included to varying extents in DGVMs, thus increasing model

Table 2.SM.4 | Key differences between global bookkeeping estimates for CO₂-LULUCF emissions.

Literature: ^a Hansis et al. (2015); ^b Houghton and Nassikas (2017); ^c Gasser et al. (2020); ^d Hurtt et al. (2020); ^e Chini et al. (2021); ^f FAO (2015); ^g based on rangeland-pasture distinction of the HYDE dataset (Goldewijk et al. 2017) and forest cover map of Hurtt et al. (2020); see Friedlingstein et al. (2020) for details; ^h Conchedda and Tubiello, (2020); ⁱ Hooijer et al. (2010).

spread (Arneth et al. 2017). For all types of models, land-use forcing is a major determinant of emissions and removals, and its high uncertainty impacts CO₂-LULUCF estimates (Bastos et al. 2021). The reconstruction of land-use change of the historical past, which has to cover decades to centuries of legacy LULUCF fluxes, is based on sparse data or proxies (Goldewijk et al. 2017; Hurtt et al. 2020), while satellite-based products suffer from complications in distinguishing natural from anthropogenic drivers (Hansen et al. 2013; Li et al. 2018) or accounting for small-scale disturbances and degradation (Matricardi et al. 2020). Lastly, regional carbon budgets can be substantially over- or under-estimated when the carbon embodied in trade products is not accounted for (Ciais et al. 2021).

Friedlingstein et al. (2020) is taken as the reference point for our uncertainty assessment. The Global Carbon Budget provides a best-value judgement for the $\pm 1\sigma$ absolute uncertainty range of CO₂-LULUCF emissions at $\pm 2.6 \text{ GtCO}_2 \text{ yr}^{-1}$, constant over the last decades. This constant, absolute uncertainty estimate corresponds roughly to a relative uncertainty of about $\pm 50\%$ over 1970–2019, which is much higher than for most fossil-fuel related emissions, but reflects the large model spread and large differences between the current estimate of H&N and its previous model versions (Houghton et al. 2012). This corresponds to a relative uncertainty of about $\pm 80\%$ for a 90% confidence interval (5th–95th percentile). However, here we opt for a slightly lower relative uncertainty estimate of about $\pm 70\%$ for a 90% confidence interval, given that the mean of the CO₂-LULUCF estimates has been increasing over the last few decades. This provides absolute uncertainty estimates that are consistent in magnitude with the constant value in Friedlingstein et al. (2020) over time – slightly lower for earlier years and slightly higher for the most recent years. Compared to AR5 this is larger than the $\pm 50\%$ uncertainty estimate applied in the assessment, but still in line with the upper end of the broader relative uncertainty range considered of $\pm 50\%$ to $\pm 75\%$ (Blanco et al. 2014). Finally note that much larger uncertainties in CO₂-LULUCF emissions have been identified across the literature, but were traced back to different definitions used

in various modelling frameworks (Pongratz et al. 2014) as well as inventory data (Grassi et al. 2018).

Uncertainties can be much higher at a national level than at global level, since regional biases tend to cancel out. Land-use forcing has been identified as major driver of differences at regional and global level (Gasser et al. 2020; Hartung et al. 2021; Rosan et al. 2021), as have assumptions on carbon densities and the allocation of cleared or harvested material to slash or product pools of various lifetimes, for which accurate global data over long time periods is missing (Bastos et al. 2021). Although the bookkeeping models are conceptually similar, the bookkeeping estimates include country-specific information to different extents: for example, fire suppression (for the USA) is included in H&N (Houghton and Nassikas 2017), but not the other estimates. H&N includes peat drainage emissions only for Southeast Asia, while the FAO emissions estimates for organic soil drainage added to BLUE and OSCAR cover all countries (Friedlingstein et al. 2020). The effect of smoothing the FAO cropland and pasture information, which can be very variable in some countries, with a five-year running mean in H&N, while the annual data is used for the recent decades in History database of the Global Environment (HYDE) underlying BLUE and OSCAR, must also be expected to contribute to the spread in estimates on a country level. Overall, great care has to be taken when comparing estimates of individual countries across models so as not to over-interpret differences.

Finally, note that attempts to constrain the estimates of CO₂-LULUCF emissions from bookkeeping models and DGVMs by observed biomass densities have been undertaken, but were successful only in some non-tropical regions (Li et al. 2017). While providing valuable independent and observation-driven information, remote-sensing derived estimates of carbon stock changes have limited applicability for model evaluation for the total CO₂-LULUCF flux, since they usually only quantify vegetation biomass changes and exclude legacy emissions from the pre-satellite era. Further, with the exception of the (pan-tropical) estimates by Baccini et al. (2012) they either track committed instead of actual emissions (Tyukavina et al. 2015),

combine a static carbon density map with forest cover changes, or include the natural land sink (e.g., Baccini et al. 2017) to infer fluxes directly from the carbon stock time series. None of these approaches therefore fully distinguishes natural from anthropogenic disturbances for actual emissions as the CO₂-LULUCF emissions estimate provided here do, based on bookkeeping models and DGVMs, such that a direct evaluation is hampered.

2.SM.2.3 Anthropogenic CH₄ Emissions

About 60% of total global methane emissions come from anthropogenic sources – that is, they are caused by direct human activities since pre-industrial times/pre-agricultural times (Saunois et al. 2020). Some studies suggest larger anthropogenic fossil emissions than currently estimated (e.g., Hmiel et al. 2020). Anthropogenic methane emissions cover a range of different sectors: livestock (enteric fermentation and manure management, rice cultivation, fossil fuel production, distribution and use, waste handling (solid and water waste) as well as biomass and biofuel burning. About 90% of biomass burning events are thought to be triggered by human action (Andreae 1991); as biomass burning contributes less than 5% to anthropogenic methane emissions, the misallocations of natural fires is likely lower than the overall uncertainty. Methane emissions can be derived either using bottom-up estimates that rely on anthropogenic inventories such as EDGAR (Janssens-Maenhout et al. 2019), land surface models that infer part of natural emissions (Wania et al. 2013) or flux observation-based estimates for some specific sources such as geological sources (Etiope et al. 2019). Alternatively, top-down approaches can be used, such as atmospheric transport models that assimilate methane atmospheric observations to estimate past methane emissions (Houweling et al. 2017). These techniques are applied to infer emissions for a specific facility, sector, region or other aggregation, based on in-situ or satellite-based observations. Satellite observations have greatly improved the coverage of available data to

better constrain top-down approaches. Local or regional studies have proved important as independent estimate of inventories while being spared of the chemical sink uncertainty (Maasakkers et al. 2021). Some top-down systems aim to optimise certain emission sectors based on differences in their spatial and temporal distributions (Bergamaschi et al. 2013), while others only solve for net emissions at the surface. Then the partitioning of top-down posterior (output) fluxes between specific source sectors is carried out with various degrees of uncertainty, depending of the methods and the degree of refinement of sectors, but often rely on ratios from the prior knowledge of fluxes. Comprehensive assessments of methane sources and sinks have been provided by Saunois et al. (2016, 2020) and Kirschke et al. (2013).

EDGAR (Crippa et al. 2019, 2021; Janssens-Maenhout et al. 2019) is one of multiple global methane bottom-up inventories available. Other inventories – namely GAINS (Höglund-Isaksson 2012; Höglund-Isaksson et al. 2020), US-EPA (EPA 2011, 2021), CEDS (Hoesly et al. 2018; McDuffie et al. 2020; O'Rourke et al. 2020), PRIMAP-hist (Gütschow et al. 2016, 2021b) as well as FAOSTAT-CH₄ (Tubiello 2013, 2018, 2019; Federici et al. 2015) – can differ in terms of their country and sector coverage as well as detail. EDGAR, CEDS, US-EPA and GAINS cover all major source sectors (fossil fuels, agriculture and waste, biofuel) – except large-scale biomass burning – but this can be added from different databases such as FINN (Wiedinmyer et al. 2011), GFAS (Kaiser et al. 2012), GFED (Giglio et al. 2013) or QFED (Darmenov and da Silva 2013). Much like CO₂-FFI, these inventories of anthropogenic emissions are not completely independent as they either follow the same IPCC methodology to derive emissions, rely on similar data sources (e.g., FAOSTAT activity data for agriculture, reported fossil fuel production), or draw on reported country inventory data (Petrescu et al. 2020a). However, they may differ in the assumptions and data used for the calculation, and in the choice of IPCC Tier levels for the methodology (Box 2.SM.1). For example, while the US-EPA inventory uses the reported emissions by the countries

Figure 2.SM.4 | Comparison of estimates from different versions of the EDGAR database for anthropogenic CH₄ emissions.

to UNFCCC, other inventories produce their own estimates using a consistent approach for all countries, and country-specific activity data, emission factor and technological abatement when available. FAOSTAT and EDGAR mostly apply a Tier 1 approach to estimate CH₄ emissions while GAINS uses a Tier 2 approach (Box 2.SM.1). CEDS is based on pre-existing emission estimates from FAOSTAT and EDGAR, which are then scaled to match country-specific inventories, largely those reported to UNFCCC.

Global anthropogenic CH₄ emission estimates are compared in Figure 2.SM.4. EDGARv5.0 has revised total global CH₄ emissions by about 10 MtCH₄ yr⁻¹ compared to the previous version due to a higher estimate for the waste sector (Figure 2.SM.1). Subsequent revisions of the estimation methodology in EDGARv6 in alignment with the IPCC guidelines refinement (IPCC 2019) lead to very substantial differences in total CH₄ emissions that are up to 50 MtCH₄ yr⁻¹ lower before the 1990s compared to previous versions, but differences are smaller ranging from 1–13 MtCH₄ yr⁻¹ since the 2000s (Figure 2.SM.1). The cause of these differences is a new procedure to separately

estimate the venting component for gas and oil in the venting and flaring sector (1B2a/b2). Differences across different versions of the EDGAR dataset are shown in Figure 2.SM.4. US-EPA show the lowest estimates, probably due to missing estimates from a significant number of countries not reporting to UNFCCC (US-EPA 2020 includes estimates from only 195 countries) and incomplete sectoral coverage. EDGARv6 estimates of anthropogenic CH₄ emissions, as used here, are in the upper range of the different inventories across most anthropogenic sources. However, none of these inventories cover CH₄ emissions from forest and grassland burning, which amount to about 10–12 Mt yr⁻¹ globally.

Saunio et al. (2020) provide estimates of CH₄ sources and sinks based on bottom-up and top-down approaches associated with an uncertainty range based on the minimum and maximum values of available studies (because for many individual source and sink estimates the number of studies is often relatively small). Thus, they do not consider the uncertainty of the individual estimates. As shown in Table 2.SM.5, uncertainties in total global CH₄ emissions across

Table 2.SM.5 | Uncertainties estimated for CH₄ sources at the global scale: based on ensembles of bottom-up (BU) and top-down (TD) estimates, national reports and specific uncertainty assessments of EDGAR. (2021).

^{*} Mainly due to difficulties in attributing emissions to small specific emission sector.

all anthropogenic and natural sources are comparatively small at $\pm 6\%$ – a range larger than errors in transport models only (Locatelli et al. 2015). However, this uncertainty on total emissions is probably underestimated as the uncertainty in the chemical sink was not fully considered in the top-down estimates in Saunio et al. (2020). About 90% of the chemical sink of methane is due to the oxidation by the hydroxyl radical (OH). Uncertainty on the global burden of OH is about $\pm 5\%$, much lower than uncertainties derived from detailed analysis using EDGAR data by Janssens-Maenhout (2019) and Solazzo et al. (2021), reaching around $\pm 45\%$ at 2σ . Saunio et al. (2020) reported uncertainty of 10–15%, which translates to an uncertainty of about $\pm 10\%$ to $\pm 30\%$ depending on the category, with larger uncertainty in the fossil fuel sectors than in the agriculture and waste sector (Saunio et al. 2020). However, these uncertainties are also underestimated as they do not consider the uncertainty in each individual estimate, which includes potential uncertainties in activity data, emission factors, and equations used to estimate emissions.

Uncertainties in EDGAR CH₄ emissions using a Tier 1 approach are estimated at -33% to $+46\%$ at 2σ , but there is great variability across individual sectors ranging from $\pm 30\%$ (agriculture) to more than $\pm 100\%$ (fuel combustion), with high uncertainties in oil and gas sector ($\pm 93\%$) and coal fugitive emissions ($\pm 65\%$) (Solazzo et al. 2021). As an example of developed country with well-established emissions reporting, US methane emissions also report large uncertainties depending on the sector (NASEM 2018); although the activity data uncertainty may be lower than those for less-developed countries. For example, global inventories, such as EDGAR, estimate uncertainties in national anthropogenic emissions of about $\pm 32\%$ for the 24 member countries of OECD, and up to $\pm 57\%$ for other countries, which have more uncertain activity data (Janssens-Maenhout et al. 2019).

The 2020 UN emissions gap report (UNEP 2020) gives an uncertainty range for global anthropogenic CH₄ emissions with one standard

deviation of $\pm 30\%$ (i.e., $\pm 60\%$ for 2σ). On the other hand, IPCC AR5 provides a comparatively low estimate at $\pm 20\%$ for a 90% confidence interval. Overall, we apply a best value judgement of $\pm 30\%$ for global anthropogenic CH₄ emissions for a 90% confidence interval. This is justified by the larger uncertainties reported in studies on the EDGAR dataset (Janssens-Maenhout et al. 2019; Solazzo et al. 2021) as well as for FAO activity statistics by Tubiello et al. (2015).

2.SM.2.4 Anthropogenic N₂O Emissions

Anthropogenic nitrous oxide (N₂O) emissions occur in a number of sectors, namely agriculture, fossil fuel and industry, biomass burning, and waste. The emissions from the agriculture sector have four components: (i) direct and indirect emissions from soil and water bodies (inland, coastal, and oceanic waters); (ii) manure left on pasture; (iii) manure management; and (iv) aquaculture. Besides these main sectors, a final 'other' category represents the sum of the effects of climate, elevated atmospheric CO₂, and land cover change. This is a new sector that was developed as part of the global N₂O budget (Tian et al. 2020) – a recent assessment to quantify all sources and sinks of N₂O emissions updating previous work (Mosier et al. 1998; Kroeze et al. 1999; Mosier and Kroeze, 2000; Syakila and Kroeze, 2011). Estimates from the global N₂O budget are referred to as GCP-N₂O since the assessment was facilitated by the Global Carbon Project (GCP). Overall, anthropogenic sources contributed just over 40% to total global N₂O emissions (Tian et al. 2020).

There are a variety of approaches for estimating N₂O emissions. These include inventories (Tubiello et al. 2013; Tian et al. 2018; Janssens-Maenhout et al. 2019), statistical extrapolations of flux measurements (Wang et al. 2020a), and process-based land and ocean modelling (Tian et al. 2019; Yang et al. 2020). There are at least five relevant global N₂O emissions inventories available: EDGAR (Crippa et al. 2019, 2021; Janssens-Maenhout et al. 2019), GAINS

Figure 2.SM.5 | Comparison of estimates from different versions of the EDGAR database for anthropogenic N₂O emissions.

Table 2.SM.6 | Comparison of four global N₂O inventories: EDGAR (Crippa et al. 2019; Janssens-Maenhout et al. 2019); GCP (Tian et al. 2020); GAINS (Winiwarter et al. 2018; Höglund-Isaksson et al. 2020); FAOSTAT (Tubiello et al. 2013; Tubiello 2018). Source: Minx et al. (2021).

Name	Time coverage	Geographical coverage	Activity split	IPCC Emissions factors	Reported emissions in 2015 (in MtN ₂ O)					
					Agriculture	Fossil fuel and industry	Biomass burning	Waste and waste sector	Other	Total
EDGAR	1970–2018	Global, 226 countries	4 main sectors, 24 sub-sectors	Yes	6.2	2.3	0.05	0.4	–	8.9
GCP	1980–2016	Global, 10 regions	5 main sectors, 14 sub-sectors	No	8.4	1.6	1.1	0.6	0.3	11.9
GAINS	1990–2015 (every 5 years)	Global, 172 regions	3 main sectors, 16 sub-sectors	No	6.8	1.3	–	0.7	–	8.8
FAOSTAT	1961–2019	Global, 231 countries	2 main sectors, 9 sub-sectors	Yes	8.3	–	0.9	–	–	9.2

(Winiwarter et al. 2018), FAOSTAT-N₂O (Tubiello et al. 2013; Tubiello 2018), CEDS (Hoesly et al. 2018; McDuffie et al. 2020; O'Rourke et al. 2020), PRIMAP-hist (Gütschow et al. 2016, 2021b), and GFED (van der Werf et al. 2017). While EDGAR and GAINS cover all sectors except biomass burning, FAOSTAT-N₂O is focused on agriculture and biomass burning and GFED on biomass burning only. As shown in Figure 2.SM.1, EDGAR, GAINS, CEDS and FAOSTAT emissions are consistent in magnitude and trend. Recent revisions in estimating indirect N₂O emissions in EDGARv6 led to an average increase of 1.5% yr⁻¹ in total N₂O emissions estimates between 1999 and 2018 compared to the two previous versions (differences before 1999 were negligible at less than 1% yr⁻¹). Differences across versions of the EDGAR dataset are shown in Figure 2.SM.5. The main discrepancies across different global inventories are in agriculture, where emissions estimates from the global N₂O budget and FAOSTAT are, on average, 1.5 MtN₂O yr⁻¹ higher than those from GAINS and EDGAR during 1990–2016. This is due to higher estimates of direct emissions from fertilised soils and manure left on pasture. GCP-N₂O provides the largest estimate (Figure 2.SM.1), because it synthesised from the other three inventories and further informed by additional bottom-up modelling estimates – and is more comprehensive in scope due to the new sector discussed above. EDGAR estimates of anthropogenic N₂O emissions as used in this dataset should therefore be considered as lower bound estimates (see also Table 2.SM.6).

Anthropogenic N₂O emissions estimates are subject to considerable uncertainty – larger than those from FFI-CO₂ or CH₄ emissions. N₂O inventories suffer from high uncertainty on input data, including fertiliser use, livestock manure availability, storage and applications (Galloway et al. 2010; Steinfeld et al. 2010) as well as nutrient, crops and soils management (Ciais et al. 2014; Shcherbak et al. 2014). Emission factors are also uncertain (Crutzen et al. 2008; Hu et al. 2012; IPCC 2019; Yuan et al. 2019) and several sources are not yet well understood (e.g., peatland degradation, permafrost) (Elberling et al. 2010; Wagner-Riddle et al. 2017; Winiwarter et al. 2018). Model-based estimates face uncertainties associated with the specific model configuration as well as parametrisation (Buitenhuis et al. 2018; Tian et al. 2018, 2019). Total uncertainty is also large, because N₂O emissions are dominated by emissions from soils, where the level of process understanding is rapidly changing.

For EDGAR, uncertainties in N₂O emissions are estimated based on default values (IPCC 2006) at ±42% for 24 OECD90 countries and at ±93% for other countries for a 95% confidence interval (Janssens-Maenhout et al. 2019). However, Solazzo et al. (2021) arrive at substantially larger values allowing for correlation of uncertainties between sectors, countries and regions. At a sector level, uncertainties are larger for agriculture (263%) than for energy (113%), waste (181%), industrial processes and product use (14%) and other (112%). In the recent Emissions Gap Report (UNEP 2020) relative uncertainties for global anthropogenic N₂O emissions are estimated at ±50% for a 68% (1σ) confidence interval. This is larger than the ±60% uncertainties reported in IPCC AR5 for a 90% confidence interval (Blanco et al. 2014), but is comparable with the ranges for anthropogenic emissions in the global N₂O budget (Tian et al. 2020). Overall, we assess the relative uncertainty for global anthropogenic N₂O emissions at ±60% for a 90% confidence interval.

2.SM.2.5 Fluorinated Gases

Fluorinated gases comprise over a dozen different species that are primarily used as refrigerants, solvents and aerosols. Here we compare global emissions of F-gases estimated in EDGAR to top-down estimates from the 2018 World Meteorological Organization's (WMO) Scientific Assessment of Ozone Depletion (Engel and Rigby 2018; Montzka and Velders 2018). The top-down estimates were based on measurements by the Advanced Global Atmospheric Gases Experiment (AGAGE) (Prinn et al. 2018) and National Oceanic and Atmospheric Administration (NOAA) (Montzka et al. 2015), assimilated into a global box model – using the method described in Rigby et al. (2014) and Engel and Rigby, et al. (2018). Uncertainties in the top-down estimates are due to measurement and transport model uncertainty. As F-gas emissions are almost entirely anthropogenic in nature, top-down estimates of anthropogenic fluxes are much better known than CO₂, CH₄, N₂O, where large natural fluxes contribute to the observed trends. For substances with relatively short lifetimes (~50 years or less), uncertainties are typically dominated by uncertainties in the atmospheric lifetimes. Comparisons between the EDGAR and WMO 2018 estimates were available for HFCs 125, 134a, 143a, 152a, 227ea, 23, 236fa, 245fa, 32, 365mfc and 43-10-mee, PFCs CF₄, C₂F₆, C₃F₈ and c-C₄F₈, SF₆ and

NF₃ (EDGARv6 only). For the higher molecular weight PFCs (C₄F₁₀, C₅F₁₂, C₆F₁₄, C₇F₁₆), top-down estimates were not available in WMO (2018). Top-down estimates have previously been published for these compounds (Ivy et al. 2012), however, this comparison is not included here due to their very low emissions. For a small number of species,

global top-down estimates are available for some years, based on an atmospheric model independent to that used in WMO (2018), although most of these inversions use similar measurement datasets: Fortems-Cheiney et al. (2015) for HFC-134a; Lunt et al. (2015) for

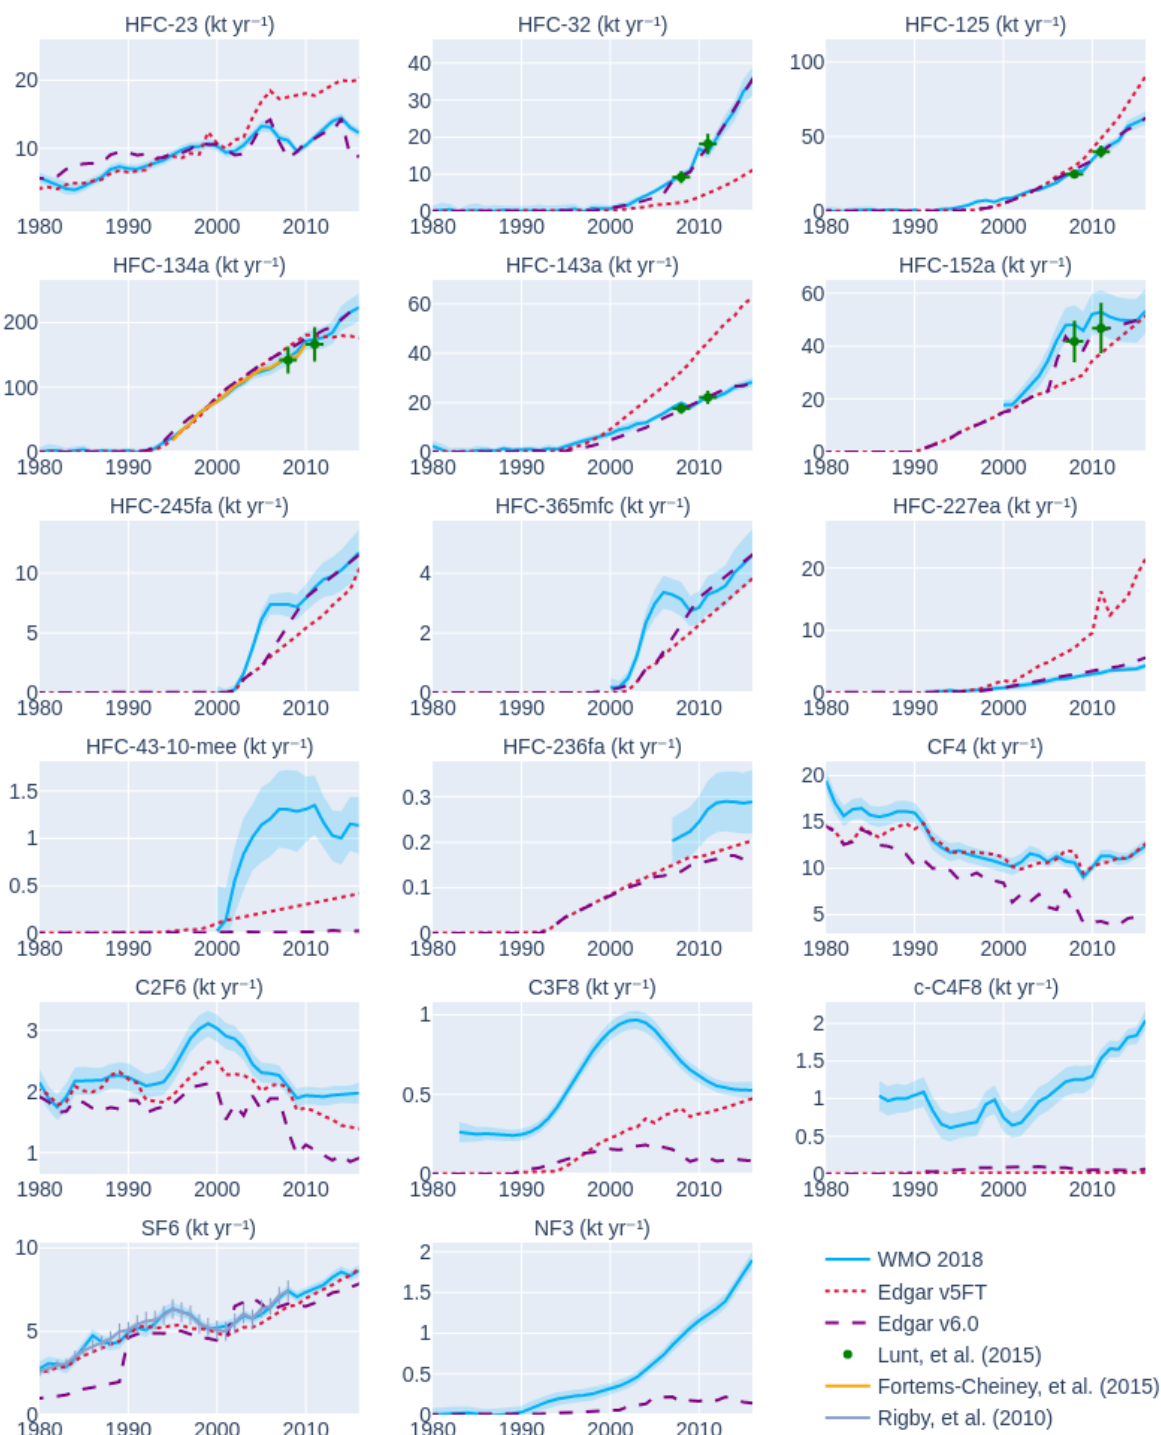

Figure 2.SM.6 | Comparison of top-down and bottom-up estimates for individual species of fluorinated gases in Olivier and Peters (2020) (EDGARv5FT) and EDGARv6 for 1980–2016. C₄F₁₀, C₅F₁₂, C₆F₁₄ and C₇F₁₆ are excluded. Top-down estimates from WMO 2018 (Engel and Rigby 2018; Montzka and Velders 2018) are shown as blue lines with blue shading indicating 1σ uncertainties. Bottom-up estimates from EDGARv5 and v6 (the emissions data used in Chapter 2) are shown in red dotted lines and purple dashed lines, respectively. Top-down estimates for some species are shown from Rigby et al. (2010), Fortems-Cheiney et al. (2015) and Lunt et al. (2015). Source: Minx et al. (2021).

HFC-134a; and –125, –152a, –143a and –32 and Rigby et al. (2010) for SF₆.

The comparison of global top-down and bottom-up emissions for EDGARv6 and Olivier and Peters (2020) (EDGARv5FT) F-gas species (excluding heavy PFCs) is shown in Figure 2.SM.6 for the years 1980–2016 (or a subset thereof, depending on the availability of the top-down estimates). Where available, the various top-down estimates agree with each other within uncertainties. The magnitude of the difference between the WMO (2018) and EDGAR estimates varies markedly between species, years and versions of EDGAR; for several HFCs, the top-down and bottom-up estimates often agree within uncertainties for EDGARv6 (but much less often in v5), whereas for c-C₄F₈, the top-down estimate is more than 100 times the EDGAR estimates. Some similarities and differences have been previously noted for earlier versions of EDGAR (Mühle et al. 2010, 2019; Rigby et al. 2010; Lunt et al. 2015). For SF₆, the relatively close agreement between EDGARv4.0 and a top-down estimate has been discussed in Rigby, et al. (2010). They estimated uncertainties in EDGARv4.0 of ±10% to ±15%, depending on the year, and top-down values were consistent within these uncertainties. However, the agreement is now poorer during the 1980s in EDGARv6. For some PFCs (e.g., CF₄, C₂F₆), it was previously noted that some assumptions within EDGARv4.0 had been validated against atmospheric observations, hence EDGAR might be considered a hybrid of top-down and bottom-up

methodologies for these species (Mühle et al. 2010). However, it is unclear for which other species similar validation has taken place, or how these assumptions vary between versions of EDGAR.

When species are aggregated into F-gas total emissions, weighted by their current 100-year GWPs based on IPCC AR6 (Forster et al. 2021), we note that, in the left panel of Figure 2.SM.7, the Olivier and Peters (2020) (EDGARv5FT) estimates are around 10% lower than the WMO 2018 values in the 1980s. Subsequently, EDGARv5FT estimates grow more rapidly than the top-down values and are almost 30% higher than WMO 2018 by the 2010s. EDGARv6 emissions are around 10% lower than the WMO 2018 values throughout. Given that detailed uncertainty estimates are not available for all EDGAR F-gas species, we base our uncertainty estimate solely on this comparison with the top-down values (Figure 2.SM.7, left panel), and therefore suggest a conservative uncertainty in aggregated F-gas emissions of ±30% for a 90% confidence interval. For individual species, the magnitude of this discrepancy can be orders of magnitude larger.

The F-gases in EDGAR exclude species such as chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs), which are groups of substances regulated under the Montreal Protocol. Historically, total CO₂-eq F-gas emissions have been dominated by the CFCs (Engel and Rigby 2018). In particular, during the 1980s, peak annual emissions due to CFCs reached 9.1 ± 0.4 GtCO₂-eq yr⁻¹ (Figure 2.SM.7), comparable

Figure 2.SM.7 | Comparison between top-down estimates and bottom-up EDGAR inventory data on GHG emissions for 1980–2016. Left panel: Total GWP100-weighted emissions based on IPCC AR6 (Forster et al. 2021) of F-gases in Olivier and Peters (2020) (EDGARv5FT) (red dashed line, excluding C₄F₁₀, C₅F₁₂, C₆F₁₄ and C₇F₁₆) and EDGARv6 (purple dashed line) (Crippa et al. 2021) compared to top-down estimates based on AGAGE and NOAA data from WMO (2018) (blue lines; Engel and Rigby (2018); Montzka and Velders (2018)). Right panel: Top-down aggregated emissions for the three most abundant CFCs (–11, –12 and –113) and HCFCs (–22, –141b, –142b) not covered in bottom-up emissions inventories are shown in green and orange. For top-down estimates the shaded areas between two respective lines represent 1σ uncertainties. Source: Minx et al. (2021).

to that of CH₄, and substantially larger than the 2019 emissions of the gases included in EDGARv5FT and v6 (1.4 GtCO₂-eq). Subsequently, following the controls of the Montreal Protocol, emissions of CFCs declined substantially, while those of HCFCs and HFCs rose, such that CO₂-eq emissions of the HFCs, HCFCs and CFCs were approximately equal by 2016, with a smaller contribution from PFCs, SF₆, NF₃ and some more minor F-gases. Therefore, the GWP-weighted F-gas emissions in EDGAR, which are dominated by the HFCs, represent less than half of the overall CO₂-eq F-gas emissions in 2016.

2.SM.2.6 Aggregated GHG Emissions

Based on the assessment of relevant uncertainties above, constant, relative uncertainty estimates for GHGs are applied at a 90% confidence interval that range from relatively low for CO₂ FFI ($\pm 8\%$), to intermediate values for CH₄ and F-gases ($\pm 30\%$), to higher values for N₂O ($\pm 60\%$) and CO₂ from LULUCF ($\pm 70\%$). To aggregate these and estimate uncertainties for total GHGs in terms of CO₂-eq emissions, the square root of the squared sums of absolute uncertainties for individual (groups of) gases are taken, using 100-year global warming potentials (GWP100) with values from IPCC AR6 (Forster et al. 2021, Section 7.6 and Supplementary Material 7.SM.6) to weight emissions of non-CO₂ gases but excluding uncertainties in the metric itself. An estimate of this 'metric uncertainty' is provided in the next section. Overall, this uncertainty assessment is broadly in line with IPCC AR5 (Blanco et al. 2014), but provides important adjustments in the evaluation of uncertainties of individual gases (CH₄, F-gases, CO₂-LULUCF) as well as the approach in reporting total uncertainties across GHGs.

2.SM.2.7 Uncertainties of GHG Emission Metrics Used to Report Aggregated Emissions

GHG emission metrics are necessary if emissions of non-CO₂ gases and CO₂ are to be aggregated into CO₂-eq emissions (Section 2.3). GWP100 is the most common metric and has been adopted for emissions reporting under the transparency framework for the Paris Agreement (UNFCCC 2019), but many alternative metrics exist in the scientific literature. The most appropriate choice of metric depends on the climate policy objective and the specific use of the metric to support that objective (i.e., why do we want to aggregate or compare emissions of different gases? What specific actions do we wish to inform?).

Different metric choices and time horizons can result in very different weightings of the emissions of short-lived climate forcers (SLCFs), such as CH₄. For example, 1t CH₄ represents as much as 81 tCO₂-eq if a global warming potential (GWP) is used with a time horizon of 20 years, or as little as 5.4t CO₂-eq if the global temperature change potential (GTP) is used with a time horizon of 100 years (Forster et al. 2021a). More recent metric developments that compare emissions in new ways – e.g., the additional warming from sustained changes in SLCF emissions compared to pulse emissions of CO₂ – increase the range of metric values further and can even result in negative

metric values for SLCFs, if their emissions are falling rapidly (Allen et al. 2018; Cain et al. 2019; Collins et al. 2019; Lynch et al. 2020).

The contribution of SLCF emissions to total GHG emissions expressed in CO₂-eq thus depends critically on the choice of GHG metric and its time horizon. However, even for a given choice, the metric value for each gas is also subject to uncertainties. For example, the GWP100 for biogenic CH₄ has changed from 21 based on the IPCC Second Assessment Report (SAR) in 1995 to 28 or 34 based on IPCC AR5 (excluding or including climate-carbon cycle feedbacks), and to 27 based on IPCC AR6. These changes and remaining uncertainties arise from parametric uncertainties, differences in methodological choices, and changes in metric values over time due to changing background conditions.

Parametric uncertainties arise from uncertainties in climate sensitivity, radiative efficacy and atmospheric lifetimes of CO₂ and non-CO₂ gases, etc. The WGI contribution to AR6 assessed the parametric uncertainty of GWP for CH₄ as $\pm 32\%$ and $\pm 40\%$ for time horizons of 20 and 100 years, $\pm 43\%$ and $\pm 47\%$ for N₂O, and ± 26 –31 and ± 33 –38% for various F-gases (Forster et al. 2021). The uncertainty of GTP100 for CH₄ was estimated at $\pm 83\%$, which is larger than the uncertainty in a forcing-based metric due to uncertainties in climate responses to forcing (e.g., transient climate sensitivity).

Methodological choices introduce a different type of uncertainty, namely which indirect effects are included in the calculation of metric values and the strength of those feedbacks. For CH₄, indirect forcing caused by photochemical decay products (mainly tropospheric ozone and stratospheric water vapour) contributes almost 40% of the total forcing from CH₄ emissions. More than half of the changes in GWP100 values for CH₄ in successive IPCC assessments from 1995 to 2013 are due to re-evaluations of these indirect forcings. In addition, warming due to the emission of non-CO₂ gases extends the lifetime of CO₂ already in the atmosphere through climate-carbon cycle feedbacks (Friedlingstein et al. 2013). Including these feedbacks results in higher metric values for all non-CO₂ gases, but the magnitude of this effect is uncertain – for example, AR5 found the GWP100 value for CH₄ without climate-carbon cycle feedbacks to be 28, whereas including this feedback would raise the value to between 31 and 34 (Myhre et al. 2013; Gasser et al. 2016; Sterner and Johansson 2017). The AR6 includes climate-carbon cycle feedbacks (Forster et al. 2021). These parametric uncertainties associated with different feedbacks are incorporated into the above uncertainty estimates by WGI.

A third uncertainty arises from changes in metric values over time. Metric values depend on the radiative efficacy of CO₂ and non-CO₂ emissions, which in turn depend on the changing atmospheric background concentrations of those gases. Rising temperature can further affect the lifetime of some gases and hence their contribution to forcing over time for different emission scenarios (Reisinger et al. 2011). Successive IPCC assessments take changing starting-year background conditions into account, which explains part of the changes in GWP100 metric values in different reports. Applying a single metric value to a multi-decadal historical time series of emissions is therefore only an approximation of the correct metric value for any given emissions year – as, for example, the correct

GWP100 value for CH₄ emitted in the year 1970 will be different to the GWP100 value for an emission in the year 2018. However, the literature does not offer a complete set of GWP100 metric values for past concentrations and climate conditions covered in our time series.

Overall, we estimate the uncertainty in GWP100 metric values, if applied to an extended historical emission time series, as $\pm 50\%$ for CH₄ and other SLCFs, and $\pm 40\%$ for non-CO₂ gases with longer atmospheric lifetimes (specifically, those with lifetimes longer than 20 years). If uncertainties in GHG metrics are considered and assumed to be independent for each gas (which may lead to an underestimate), the overall uncertainty of total GHG emissions in 2019 increases from $\pm 11\%$ to $\pm 13\%$. However, these GWP-related uncertainties are not included in the global, regional or sectoral emissions estimates in the remainder of the assessment.

The WGIII assessment uses GWP100 metric values from the WGI contribution to AR6 (Forster et al. 2021) as a default metric when presenting aggregated emissions and removals of different GHGs (Cross-Chapter Box 2, Supplementary Material Section 2.SM.3, and Annex II.8).

2.SM.3 GHG Emission Metrics

2.SM.3.1 Definition and Scope

GHG emission metrics are used to compare climate effects of different GHGs and to aggregate emissions and removals of different GHGs, such as for national inventory reporting and development of mitigation policies. GHG emission metrics provide simplified information about the effects that emissions of different gases GHGs have on global temperature or other aspects of climate, usually expressed relative to the effect of emitting CO₂.

The common glossary for the IPCC Sixth Assessment Report (AR6) defines GHG emission metrics as follows:

A simplified relationship used to quantify the effect of emitting a unit mass of a given greenhouse gas (GHG) on a specified key measure of climate change. A relative GHG emission metric expresses the effect from one gas relative to the effect of emitting a unit mass of a reference GHG on the same measure of climate change. There are multiple emission metrics, and the most appropriate metric depends on the application. GHG emission metrics may differ with respect to: (i) the key measure of climate change they consider; (ii) whether they consider climate outcomes for a specified point in time or integrated over a specified time horizon; (iii) the time horizon over which the metric is applied; (iv) whether they apply to a single emission pulse, emissions sustained over a period of time, or a combination of both; and (v) whether they consider the climate effect from an emission compared to the absence of that emission or compared to a reference emissions level or climate state.

Notes: most relative GHG emission metrics (such as the global warming potential (GWP), global temperature change potential

(GTP), global damage potential, and GWP*), use carbon dioxide (CO₂) as the reference gas. Emissions of non-CO₂ gases, when expressed using such metrics, are often referred to as 'carbon dioxide equivalent' emissions. A metric that establishes equivalence regarding one key measure of the climate system response to emissions does not imply equivalence regarding other key measures. The choice of a metric, including its time horizon, should reflect the policy objectives for which the metric is applied.

Emission metrics also exist for aerosols, but these are not commonly used in climate policy. This assessment focuses on GHG emission metrics only.

Parties to the Paris Agreement decided in the Paris Agreement Rulebook to report aggregated emissions based on the global warming potential with a time horizon of 100 years (GWP100) from AR5, or to use GWP100 values from a subsequent IPCC report as agreed upon by the CMA (UNFCCC 2019, 18/CMA.1), and to account for their second and subsequent Nationally Determined Contributions in accordance with this approach (UNFCCC 2019, 4/CMA.1). However, parties can report supplemental information about aggregate emissions and removals using other GHG emission metrics (e.g., global temperature change potential) expressed in CO₂-eq and assessed by the IPCC.

Apart from international reporting and accounting, countries or sectors might consider other GHG emission metrics to help achieve specific domestic policy objectives. A clear assessment of metrics can help decision-makers determine the consistency between policy goals and metrics and avoid potentially inadvertent consequences of alternative metric choices.

This Supplementary Material provides additional explanations, references and figures to the assessment of GHG emission metrics from a mitigation perspective in Cross-Chapter Box 2 on GHG emission metrics in Chapter 2. Both the Cross-Chapter Box and this Supplementary Material build on the physical science assessment of GHG emission metrics by WGI (Forster et al. 2021, Section 7.6).

2.SM.3.2 Key Characteristics of Pulse Emission Metrics GWP and GTP

The global warming potential (GWP) and the global temperature change potential (GTP) were the main metrics assessed in AR5 (Myhre et al. 2013; IPCC 2014; Kolstad et al. 2014). GWP with a time horizon of 100 years (GWP100) is the predominant metric used in literature assessed by WGIII.

These metrics compare the effect on climate of emitting a unit mass of a non-CO₂ gas over a chosen time horizon with the effect of emitting the same unit mass of CO₂. GWP compares CO₂ and non-CO₂ emissions based on the radiative forcing they would cause integrated over the entire time horizon, whereas GTP compares emissions based on the global mean surface temperature change they would cause only at the end point of the chosen time horizon.

Table 2.SM.7 | Illustrative metric values for CH₄ under a range of metrics and time horizons. GWP and GTP compare pulse emissions of non-CO₂ gases with a pulse emission of CO₂. Combined global temperature change potential (CGTP) compares a sustained step-change in non-CO₂ emissions with a pulse emission of CO₂. Values are based on Forster et al. (2021).

	GWP20	GWP100	GWP500	GTP20	GTP30	GTP50	GTP100	CGTP50 (years)	CGTP100 (years)
CH ₄ (fossil)	82.5	29.8	10	54.4	30.6	13.2	7.5	2823	3531
CH ₄ (biogenic)	80.8	27.0	7.3	51.7	27.9	10.3	4.7	2701	3254

The WGI contribution to AR6 includes updated values for these metrics based on updated scientific understanding of the response of the climate system to emissions of different gases, including changing background concentrations (Forster et al. 2021). It also assesses new metrics published since AR5. Metric values in AR6 include climate-carbon cycle feedbacks by default; this provides an important update and clarification from AR5 which reported metric values both with and without such feedbacks (Table 2.SM.7).

By far the most commonly used, static time horizon for GWP, including in reporting under the UNFCCC and the Paris Agreement, is 100 years, but other time horizons (e.g., GWP20, GWP500) have also been applied (recent examples include Tanaka et al. 2019, 2021; and Skytt et al. 2020).

For GTP, both static and dynamic time horizons are used in the literature. A static GTP evaluates warming due to an emissions pulse at the end point of the stated time horizon (Shine et al. 2005). For example, the static GTP100 would evaluate emissions occurring in 2020 based on the warming they would cause in the year 2120, whereas emissions occurring in 2030 would be evaluated based on the warming they would cause in the year 2130. By contrast, the dynamic GTP (Shine et al. 2007) evaluates each emission based on its contribution to warming in a specified future target year. Depending on application, this can be the year in which global average temperature is expected to peak within a mitigation scenario, or any other time-bound temperature-related climate target. Policy-relevant time horizons and resulting metric values for the dynamic GTP therefore depend on the chosen temperature goal and implied target year.

The time horizon of a dynamic GTP shrinks for successive emissions as the target year is approached, which increases the weight given to emissions of short-lived climate forcers (SLCFs) such as CH₄ over time. For example, for a climate policy goal of limiting warming to 1.5°C with no or limited overshoot (scenario Category C1 in Chapter 3), global average surface temperature would peak by around 2055. To compare the importance of abating non-CO₂ and CO₂ emissions in any given year relative to that policy goal, emissions occurring in the year 2020 would be evaluated using GTP35, whereas emissions in 2030 would be evaluated using GTP25, and so on (see Table 2.SM.7 for illustrative values).

A key limitation of pulse emission metrics such as GWP and GTP, noted in AR5 and emphasised in more recent literature (Allen et al. 2018; Cain et al. 2019; Collins et al. 2019; Allen et al. 2021; see Forster et al. 2021 for the WGI assessment), is that metric values depend strongly on the selected time horizon, given that warming from a CH₄ emission pulse declines over time, whereas warming from a pulse of

CO₂ is nearly constant over centuries. Universal use of a single metric and time horizon can thus result in mismatches between policy goals and actual climate outcomes. Moreover, 'CO₂ equivalence' of pulse emissions based on GWP or GTP does not imply equivalent climate outcomes from cumulative emissions, nor at all times even from a single emissions pulse.

This is illustrated in Figure 2.SM.8, which shows that the warming from CH₄ emissions sustained at a constant rate is greater than the warming from an 'equivalent' (based on GWP100) amount of sustained CO₂ emissions for the first 100 years, but the rate of warming from sustained CH₄ emissions declines over time and the total warming becomes less than that from sustained CO₂ emissions beyond the first century. The different cumulative behaviour of CO₂ and SLCF emissions is particularly relevant in mitigation scenarios: each tonne of additional CO₂ emissions causes further warming until emissions reach net zero (Canadell et al. 2021). By contrast, declining SLCF emissions can result in a declining SLCF contribution to global temperature since the warming from past emissions does not persist and declines over time. This behaviour is well known and can be readily replicated with simple climate models (Figure 2.SM.8) but cumulative SLCF emissions based on GWP100 do not capture this decline (Lynch et al. 2020).

A more detailed discussion of recently developed step-change metrics GWP* (Allen et al. 2018; Cain et al. 2019; Smith et al. 2021) and combined global temperature change potential (CGTP) (Collins et al. 2019) and their ability to reproduce temperature changes resulting from sustained changes in SLCF emissions is provided in Forster et al. (2021). These metrics indicate greater climate benefits from rapid and sustained CH₄ reductions compared to CO₂ over the next few decades than if such reductions are weighted by GWP100, while conversely, sustained methane increases have greater adverse climate impacts (Collins et al. 2019; Lynch et al. 2020; Brazzola et al. 2021). However, as indicated in Figure 2.SM.8, the warming from CH₄ (or conversely, the benefits of CH₄ reduction) do not continue to accumulate at the initial rate.

2.SM.3.3 Relationship of GWP and GTP to Cost-benefit and Cost-effectiveness Frameworks

The GWP with a static time horizon approximates the global damage potential – that is, the notion that the emission of a non-CO₂ forcer at any point in time should be weighted by the marginal economic damages from this emission, relative to the marginal damages from emitting a unit mass of CO₂ (Reilly and Richards 1993; Kandlikar 1996; Kolstad et al. 2014).

Figure 2.SM.8 | Temperature responses over time to emission pulses and sustained and declining emissions of CO₂ and CH₄. **Left:** Single emissions pulse of 1 tCH₄ and 27 tCO₂. **Middle panels:** Sustained annual emission (top) of 1 tCH₄ and 27 tCO₂, and temperature response (bottom). **Right:** Emissions linearly declining from 1 tCH₄ and 27 tCO₂ in year zero, to zero emissions of both gases in year 100 (top), and temperature outcome (bottom). The amount of 27 tCO₂ is chosen for illustrative purposes as it represents the 'CO₂-equivalent' emission of 1t CH₄ based on GWP100. Temperature responses are based on response functions from Forster et al. (2021).

The GWP time horizon can be linked to the social discount rate used in the global damage potential to calculate the net present value of economic damages over time from each emission. Recent studies (Sarofim and Giordano 2018; Mallapragada and Mignone 2019) confirm earlier work (Fuglestedt et al. 2003; Boucher 2012) that, for methane, GWP100 is consistent with a discount rate of about 3%, with the specific value depending on the gas and other assumptions such as non-linearity of damages with warming. Detailed sensitivity analysis by Sarofim and Giordano (2018) gives an interquartile range of 2.7–4.1% for the implied discount rate for GWP100 in the case of CH₄, depending on a range of assumptions about climate scenarios, shape of damage functions, climate feedbacks and global economic growth. GWP20 would imply much higher discount rates of 11.1–14.6%, given the stronger weighting of near-term effects on climate. Use of a single discount rate based on pure time preference and future growth in wealth and its effects (known as the simple Ramsey rule) can be problematic (Drupp et al. 2018) but no studies so far have evaluated metrics with varying discount rates over time. In addition, the relationship between GWP time horizon and discount rate is not universal as it depends on the lifetime of the SLCF (Fuglestedt et al. 2003).

Shindell et al. (2017) evaluated the social cost of methane emissions directly based on time-varying changes in climate and inferred economic damages, and found a wide range of possible values. This reflects the range of judgements in determining social costs of pollutants including non-climate effects. However, their results are broadly consistent with a GWP100-based weighting of CH₄ relative to CO₂ when similar discount rates and consistent assumptions about climate-related damages and the temperature dependence of damage functions are chosen for both gases.

These studies indicate that, even though the GWP100 was not designed to meet any economic objectives and was not designed as a damage potential, the discount rate implied in GWP100 for CH₄ is broadly similar to social discount rates of 3–5% that are used in integrated assessment models (Chapter 3) and investments with multi-decadal lifetimes (Giglio et al. 2015; HM Treasury 2018).

In principle, GHG emission metrics focused on cost-effectiveness are better matched to the Paris Agreement's temperature goal than cost-benefit metrics, and are also supported by the UNFCCC principle that mitigation policies and measures should be cost-effective (Johansson, 2011; Tol et al. 2012; Tanaka et al. 2020). In cost-effectiveness metrics, values for SLCF emissions necessarily change over time since the closer SLCF emissions occur to the target year, the greater their contribution to climate change in that year (Aaheim and Mideksa 2017). The dynamic GTP (Shine et al. 2007) reflects such a cost-effectiveness approach by providing information on the marginal contribution of SLCF emissions in any given year to the expected peak warming at a future date (Tol et al. 2012; Mallapragada and Mignone 2017; Tanaka et al. 2020). However, the dynamic GTP does not fully match the optimal weighting of gases in least-cost mitigation pathways (also referred to as the global cost potential; e.g., Michaelis 1992; Manne and Richels 2001) because overall mitigation costs and hence the economically optimal amount and timing of SLCF abatement also depends on the discount rate as well as treatment of uncertainties, not only their contribution to warming in the target year (Johansson 2011; Ekholm 2014; Streffler et al. 2014; Tanaka et al. 2020).

The GTP with any static time horizon (e.g., GTP50 or GTP100) is not clearly matched to either a cost-benefit or a cost-effectiveness framework, as the year for which temperature outcomes are evaluated would shift forward each year and hence would not match the year

when the global temperature limit is reached or the overall damages caused by each emission (Tol et al. 2012; Edwards and Trancik 2014; Streifer et al. 2014; Mallapragada and Mignone 2017). However, use of GTP with a static time horizon may be relevant where it is applied to emissions only in a given year or finite period, and if the time horizon matches a relevant climate policy goal (Fuglestedt et al. 2010; Grewe and Dahlmann 2015; Balcombe et al. 2018).

2.SM.3.4 Global Cost-effectiveness of Physical-based Pulse Emission Metrics

A number of studies since AR5 have evaluated the impact of different pulse GHG emission metrics and time horizons on the global economic costs of limiting global average temperature change to a pre-determined level, including to *likely* below 2°C and to 1.5°C (Ekholm et al. 2013; Deuber et al. 2014; Streifer et al. 2014; Huntingford et al. 2015; Van Den Berg et al. 2015; Harmsen et al. 2016; Tanaka et al. 2020). These studies show consistently, with very few exceptions, that global costs to achieve the same temperature target below 2°C in 2100, or the same peak temperature before 2100, are higher if CH₄ emissions are weighted consistently less than indicated by GWP100 (e.g., if using GTP100 or GWP500). The increase in global mitigation costs ranges from a few percent to more than 30% in most studies, depending not only on the specific metric values used but also on the temperature limit, degree of overshoot, and abatement costs and potentials of different gases assumed in those studies. These studies also indicate, albeit less consistently and less significantly than for GTP100, that global mitigation costs would also increase if CH₄ emissions are valued consistently more highly than in GWP100 (e.g., using GWP20). Collectively, these studies indicate that, even though GWP100 does not represent the most cost-effective metric and time horizon choice possible (Tanaka et al. 2020), it is more cost-effective than any of the other static metrics and time horizons that have been tested in economic models and are used most commonly in the scientific literature.

Studies available for AR5 suggested that using a dynamic GTP or economic optimisation approaches, which defer high-cost CH₄ abatement until closer to the target year, could reduce global abatement costs compared to GWP100 by a few percent (Manne and Richels 2001; Shine et al. 2007; Johansson 2011; Reisinger et al. 2012). More recent studies confirm this theoretical cost saving in principle. However, these studies also demonstrate that the extent to which this cost saving would be realised depends on a range of assumptions, including the stringency of the target, degree of policy foresight, the speed with which CH₄ emissions can be reduced as metric values increase, allowance for any temporary temperature overshoot for end-of-century targets, the shape of marginal abatement cost curves, and the treatment of uncertainty (Ekholm et al. 2013; Streifer et al. 2014; Huntingford et al. 2015; Van Den Berg et al. 2015; Harmsen et al. 2016; Tanaka et al. 2020).

One reason why the literature shows only a limited, if any, reduction in global mitigation costs from using dynamic GTP or economic optimisation compared to GWP100 lies in the broad similarity of the metric values or exchange rates for CH₄ for temperature limits

of *likely* below 2°C and lower. For such temperature limits, peak temperature would be reached between about 2050 and 2080 (Chapter 3). This means that emissions occurring in the year 2030 would be weighted by GTP20 to GTP50, but emissions in the year 2040 by GTP10 to GTP40, and so on. Across such time horizons, the numerical values of the dynamic GTP for CH₄ (as the main short-lived GHG) over the next few decades are broadly comparable on average to GWP100 (Table 2.SM.7). Since a large fraction of the total abatement potential for CH₄ is assumed to be available at relatively low costs (Harmsen et al. 2019) or co-abated with fossil CO₂ (Rogelj et al. 2014), abatement choices based on GWP100 differ little in such pathways from those based on the dynamic GTP or economic optimisation. For modelled mitigation pathways that *likely* limit warming to 2°C or below and with limited overshoot, GWP100 therefore results in overall abatement levels and costs at the global scale that are not very different from those based on dynamic GTP or economic optimisation, even though GWP100 reflects a cost-benefit rather than cost-effectiveness framework. However, differences can be more pronounced for individual sectors.

A common feature of virtually all GHG emission metrics studies to date is that they use a single emission metric (either static GWP or GTP, or dynamic GTP with predictably changing values) to inform abatement choices over the entire 21st century and beyond. This is not well matched to the new scenario logic proposed by Rogelj et al. (2019) for the Paris Agreement, which suggests that separate policy choices exist regarding the timing and magnitude of the temperature peak and the post-peak rate of temperature decline. This new scenario logic has not yet been used to evaluate GHG metrics, but Tanaka et al. (2021) show that global cost reductions could be obtained by using GWP100 as a starting metric and updating the GWP time horizon in discrete steps, depending on when and by how much the temperature goal might be exceeded based on actual emissions. This approach could reduce mitigation costs by a few percent, relative to GWP100 being used throughout the 21st century, in very high overshoot scenarios that reach the long-term temperature goal of 1.5°C or 2°C only in the 22nd century. For such scenarios, the most cost-effective weighting of SLCF emissions is generally less than GWP100 in the next few decades, but two to three times higher than GWP100 once temperature has peaked. These findings strengthen the conclusions by Fuglestedt et al. (2018) and Tanaka and O'Neill (2018) that the choice of GHG metric is particularly important for the rate of temperature decline once net zero GHG emissions have been reached.

2.SM.3.5 Role of GHG Emission Metrics at the Sectoral Level Including Lifecycle Assessment

The AR5 noted that the choice of metric and time horizon could have significant implications for regions or sectors with high fractions of SLCF emissions (Brennan and Zaitchik 2013; Myhre et al. 2013; IPCC 2014; Streifer et al. 2014). The choice of GHG emission metric is therefore linked not only to cost-effectiveness but also to equity. Sectoral and national perspectives on mitigation pathways, including GHG emission metrics to inform such pathways, may therefore differ from a global least-cost perspective (Klinsky and Winkler 2018), but

the literature has not provided a consistent framework for assessing GHG emission metrics based on a wider set of equity principles.

The shifting of costs between emitters due to different metrics has been demonstrated for the case of agriculture in New Zealand, which has a high fraction of enteric methane emissions. Even though global mitigation costs to limit warming to below 2°C would be lower under GWP100 than GTP100, costs to farmers would be greater under GWP100 than GTP100 if climate policy were to price all GHG emissions and place the cost burden on emitters (Dorner and Kerr 2017).

Various studies evaluated the extent to which cost-effective sectoral abatement strategies might change under different climate metrics. In some instances (e.g., for transport and fuel choices), the choice of metric can change abatement preferences and timing (Edwards and Trancik 2014; Edwards et al. 2016; Edwards et al. 2017). Similarly, the magnitude of the climate impact from aviation when expressed in CO₂-equivalents depends strongly on the choice of emission metric and time horizon, as SLCF emissions and contrails enhance warming significantly over days to decades, in addition to the warming from CO₂ that occurs over centuries to millennia (Fuglestedt et al. 2010; Azar and Johansson 2012; Deuber et al. 2013; Lund et al. 2017; Lee et al. 2021). For the energy sector, Tanaka et al. (2019) show that switching from coal to gas (which has lower CO₂ but higher CH₄ emissions) for energy supply offers consistent climate benefits regardless of metric and time horizon unless CH₄ leakage rates are very high and a short-term metric (GWP20) is selected. Lynch and Pierrehumbert (2019) show that the climate impact of cultured meat (which they assume to have higher CO₂ but lower CH₄ emissions than cattle meat and a lower GHG footprint based on GWP100) increases over time, given the cumulative warming from CO₂ emissions. Substituting cattle meat with cultured meat would result in lower warming for at least the next several decades but could eventually result in higher warming than cattle meat, if this substitution is sustained over centuries and if the carbon intensity of energy supply for the manufacture of cultured meat does not decline.

For some sectors, mitigation strategies and the relative merit of specific technologies or practices compared to others (such as intensive vs extensive agricultural production and mitigation options, or choices to reduce air pollutants with a climate forcing effect) have been shown to be relatively robust against the choice of metric (Reisinger and Ledgard 2013; Ledgard and Reisinger 2014; Reisinger et al. 2017; Åström and Johansson 2019). Clark et al. (2020) show that current emissions trends in the global food system alone would be sufficient to exceed a 1.5°C temperature limit and associated global emission targets even if GWP* is used to calculate CO₂-equivalent emissions. This indicates that the importance of limiting food system emissions is not an artefact of using GWP100 as GHG emission metric, though it can change the quantification of CO₂-eq emissions over time. Even if the most effective mitigation option does not depend strongly on the choice of GHG emission metric, the cost to emitters (if emissions were priced based on their CO₂-equivalent values as part of national policies) can depend strongly on the GHG metric (Dorner and Kerr 2017).

The United Nations Environment Programme Society of Environmental Toxicology and Chemistry (UNEP-SETAC) task force on lifecycle assessment (LCA) recommended that at least two, but potentially even three, metrics with divergent weightings for SLCFs (GWP100 and GTP100 and potentially also GWP20) be used to better understand the extent to which GHG metric choices may implicitly or inadvertently affect reported carbon footprints (Cherubini et al. 2016; Levasseur et al. 2016; Jolliet et al. 2018). This matches recommendations by other researchers for the use of multiple metrics (Grewe and Dahmann 2015; Ocko et al. 2017; Balcombe et al. 2018; Cooper et al. 2020; Allen et al. 2021) especially where there is no unambiguous policy goal for a sectoral or entity-level LCA. While there is a strong agreement in the literature that using multiple metrics provides a more nuanced understanding of the climate effects of emissions, there is no strong consensus specific pairs or sets of metrics to use (e.g., GWP20 and GWP100, or GWP100 and GTP100). GWP* has only had limited use in LCA so far, mainly to understand the impact of sustained changes in CH₄ emissions resulting from system changes or lifetime dietary choices, consistent with its focus on the effect of sustained emission changes (Clark et al. 2020; Barnsley et al. 2021).

Some studies use simple climate models or pulse-response functions to understand the climate impacts of emissions of different gases directly rather than relying on emission metrics (Berntsen and Fuglestedt 2008; Reisinger and Clark 2017; Lynch and Pierrehumbert 2019; Mayfield et al. 2019; Cooper et al. 2020; Lee et al. 2021; Reisinger et al. 2021). Treating GHGs with different lifetimes separately supports the targeted treatment of different pollutants and avoids embedding value judgements about the climate outcome of concern, time horizons and reference levels into GHG emission metrics. This does not avoid the need for such value judgements to be made, but can allow them to be made more explicitly.

2.SM.3.6 Difference Between Marginal and Additional Warming and Relationship to Metrics

Cross-Chapter Box 2 in Chapter 2 notes that GWP* can calculate negative CO₂-eq emissions, while GWP or GTP calculate positive CO₂-eq emissions for the same CH₄ emissions path.

Rapidly declining CH₄ emissions can have a negative CO₂-warming-equivalent value based on GWP* because SLCF emissions that decline at a sufficient rate result in declining temperature, relative to the warming at a previous point in time caused by past SLCF emissions from that same source. The rate at which SLCF emissions have to decline to result in a roughly constant contribution to warming depends on the emissions history, changing background concentrations, and lifetime of the gas; for global CH₄ emissions, this has been estimated at about 0.3% per year (Forster et al. 2021).

GWP or GTP always assign a positive CO₂-equivalent value to SLCF emissions because every SLCF emission from any source results in increased future radiative forcing and higher global average temperature than would be the case without this emission, regardless of whether the rate of SLCF emissions is rising or declining

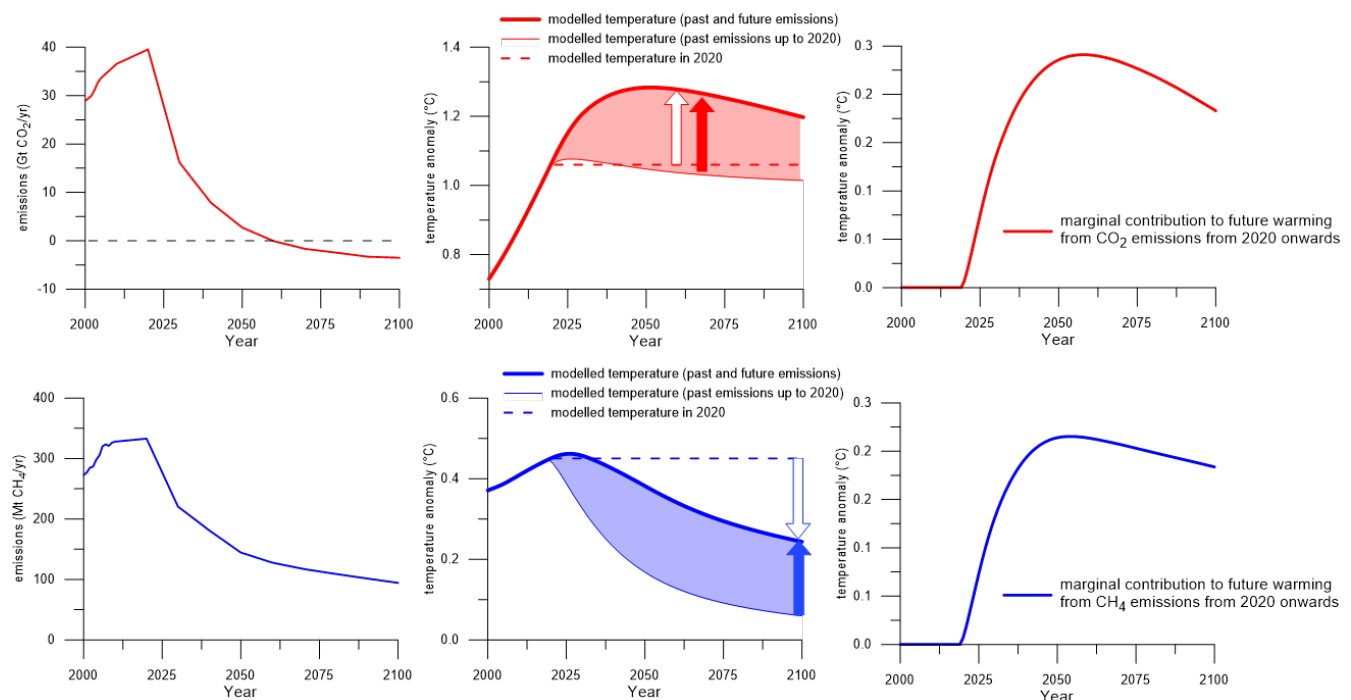

Figure 2.SM.9 | CO₂ (top) and CH₄ (bottom) emissions (left) and simulated temperature response (middle and right), for an Illustrative Mitigation Pathway (IMP-Ren15) that would limit likely warming to below 2°C. The middle panels show the modelled overall warming from the given CO₂ and CH₄ emissions trajectories (thick solid lines), the contribution to past and future warming from past emissions (up to 2020; thin solid lines), and the contribution to warming in the year 2020 from past emissions (dashed lines). The *marginal* warming from future CO₂ and CH₄ emissions (i.e., the difference between warming caused by emissions up to 2020, and warming caused by past and future emissions) are shown as shaded areas and solid arrows. The additional warming (i.e., the temperature change relative to the warming in 2020) is indicated by hollow arrows. The right panels show the marginal warming from CO₂ and CH₄ emissions from 2020 onwards (i.e., the increase in global average surface temperature that would occur with, compared to without, those emissions). Figure adapted from Reisinger et al. (2021); temperature responses are modelled using the pulse-response functions used in the assessment of GHG emission metrics by Forster et al. (2021).

over time. The amount of climate change (integrated radiative forcing, or temperature change at a given point in time) that occurs from these emissions, relative to the absence of these emissions (everything else being equal), has also been referred to as ‘*marginal warming*’ (Reisinger et al. 2021), in alignment with the concepts of *marginal damages* and *marginal costs* that underpin the economics literature on multi-pollutant problems (Michaelis 1992, 1999; Reilly and Richards 1993; Kandlikar 1996; Manne and Richels 2001; Tol et al. 2012).

Figure 2.SM.9 illustrates these different perspectives: in an Illustrative Mitigation Pathway that limits warming to 1.5°C with no or limited overshoot (IMP-Ren15) (Chapter 3 and Annex III), the *marginal* warming from future CH₄ emissions is always positive and can be comparable to the *marginal* warming from future CO₂ emissions. That is, emissions of CH₄ and CO₂ from 2020 onwards (or any other specified reference year) both result in future global temperature being higher than it would be without those future emissions. Marginal warming is relevant for choices about the effort and costs that might be justified (from a damages, cost-benefit or cost-effectiveness perspective) to mitigate future emissions of either gas. The specific policy objective can then help determine what specific metric and time horizon would be optimal to use, provided that metrics are applied in a way that captures this marginal warming from future emissions. Information about marginal warming by definition does not include warming from past emissions that may continue into the future.

Warming relative to a given reference point provides a different perspective: the contribution from CH₄ emissions to global warming declines with declining emissions, whereas the contribution from CO₂ emissions to global warming continues to rise even when its emissions decline, and this contribution keeps rising until CO₂ emissions are reduced to net zero. CO₂ therefore remains and becomes the increasingly dominant driver of anthropogenic warming in virtually all emission scenarios (see also WGI Summary for Policymakers, Figure SPM.4). This information is relevant for policies and perspectives that are concerned with the changing contribution of individual gases and sectors to global warming over multiple decades, including their historical emissions (e.g., Lynch et al. 2021). Figure 2.SM.9 shows that, for CO₂, the marginal and additional warming from future emissions is virtually identical, whereas the marginal and additional warming from future CH₄ emissions point in opposite directions in a mitigation pathway. Marginal metrics such as GWP and GTP, and step/pulse metrics such as GWP* (as applied in the literature so far) can differ substantially in the CO₂ emissions they calculate as ‘equivalent’ to CH₄ emissions, because they focus on different aspects of climate change. The specific policy objective (e.g., a focus on cost-effective abatement, a cost-benefit approach, or a focus on additional warming compared to a reference level) is therefore crucial for choosing and applying a metric that matches a given objective.

2.SM.3.7 Influence of GHG Emission Metrics on the Timing of Reported Net Zero GHG Emissions

Cross-Chapter Box 2 in Chapter 2 notes that different metric choices can alter the reported quantity of CO₂-eq emissions and the time at which net zero GHG emissions are calculated to be reached, or whether net zero GHG emissions are reached at all. This is also an important conclusion from the assessment by WGI (Forster et al. 2021) building on Fuglestad et al. (2018) and Tanaka and O'Neill (2018), and highlighted by Schleussner et al. (2019) in relation to Article 4.1 of the Paris Agreement.

The degree to which reported CO₂-eq emissions would differ under alternative metrics, for the same actual emissions of different gases, is illustrated in Figure 2.SM.10. It shows calculated CO₂-eq emissions for four different IMPs from Chapter 3 (IMP-REN15, IMP-SP, IMP-REN2, and IMP-GS; see Chapter 3 for details on these pathways) for an illustrative range of metrics.

The following metrics and time horizons are used:

- GWP100 (using values from the Second Assessment Report (SAR); Fifth Assessment Report with and without climate-carbon cycle feedbacks (AR5-ccfb, and AR5-nofb); and the Sixth Assessment Report (AR6))
- GTP100 (using AR6 values)
- GWP20 (using AR6 values)
- GWP* (using the formula in Lynch et al. 2020, using AR6 values for GWP100).¹

Overall, differences in the timing of net zero GHG (CO₂-eq) emissions are smaller for different versions of GWP100 than for fundamentally different choices of metric and/or time horizon (GWP20 or GTP100), and differ materially for GWP*.

Using GWP100 values from different IPCC assessment reports has a relatively minor effect on CO₂-eq emissions. It shifts the timing of net zero emissions by up to 10 years for those pathways that reach net zero before 2100. For pathways that reach net zero GHG emissions only very late in the 21st century, this could result in net zero not being reached at all before 2100 under some versions of GWP100. For example, IMP-GS reaches net zero GHG emissions in 2095 for GWP100 (SAR) but remains (just) above zero until after 2100 for GWP100 (AR5-ccfb) and for GWP100 (AR6).

Using GTP100 gives consistently lower weighting to SLCF emissions compared to GWP100. This brings the year of net zero GHG emissions forward by 12–18 years compared to GWP100 (AR6), since the remaining gross SLCF emissions would be aggregated into lower CO₂-eq emissions and hence would be compensated by a lower amount of net negative CO₂ emissions, which is reached earlier.

The difference in timing of net zero GHG emissions under GTP100 compared to GWP100 depends on the magnitude of SLCF (mostly CH₄) emissions at that point, as well as the slope of the emissions pathway when approaching net zero. IMP-SP has the largest reductions in CH₄ emissions and hence the difference between GTP100 and GWP100 is relatively smaller than for other pathways. Conversely, IMP-Ren2 has relatively high residual CH₄ emissions. Therefore, expressing CO₂-equivalent emissions using GTP100 has a bigger impact on total CO₂-eq emissions compared to GWP100.

Using GWP20 gives consistently higher weighting to SLCF emissions compared to GWP100. This shifts the year of net zero emissions back by more than 20 years, as more net negative CO₂ emissions are needed to balance residual SLCF emissions; again the extent to which timing shifts depends on the amount of CH₄ emissions in the different pathways. Under GWP20, only IMP-REN2 reaches net zero in 2100 as it has the largest net-negative CO₂ emissions in 2100 of those four pathways; the three other pathways would remain at greater than net zero GHG emissions in 2100.

Using GWP* as a metric results in a significant change, not only in the timing of net zero emissions, but also the overall shape of the CO₂-eq emissions pathway. In the two pathways consistent with limiting warming to 1.5°C with no or limited overshoot (IMP-Ren15 and IMP-SP), CO₂-equivalent emissions using GWP* drop well below net zero before 2040 but then rebound again. IMP-Ren15 returns to net-positive GHG emissions before returning to net zero by 2100, while IMP-SP has emissions close to net zero for most of the second half of the 21st century.

CO₂-equivalent emissions using GWP* for IMP-GS follow a similar shape but have higher overall levels; net GHG emissions would briefly reach net zero in 2040 before returning to positive levels and dropping to net zero by 2080. For IMP-Ren2, CO₂-equivalent emissions based on GWP* look more similar to the emissions pathway based on other metrics but reach net zero GHG emissions about 20 years earlier than if using GWP100.

The reason for those different shapes of CO₂-equivalent emission trajectories under GWP* is that this metric translates rapid reductions of CH₄ emissions into negative CO₂-equivalent emissions. IMP-Ren2 pathway has less rapid reductions of CH₄ emissions in the near term than the three other pathways. The rapid reduction of methane in these three pathways results in a significantly faster and greater reduction of total CO₂-equivalent emissions under GWP*. As a result, net zero GHG emissions would be reached well before 2050, although (depending on further reductions) only temporarily in some pathways as the reduction of CH₄ emissions does not continue at the same rate.

Note that the different reported CO₂-equivalent emissions do not affect the climate outcome, as the actual emissions of individual gases in these pathways are unchanged. What Figure 2.SM.10 shows

¹ The GWP* formula was applied to the following gases: CH₄, HFC-134a, HFC-32, HFC-43-10-mee, HFC-152a, HFC-365-mfc. The parameters used in the calculation are based on the atmospheric lifetime of CH₄ and are not necessarily matched to other short-lived gases. Results should therefore be seen as indicative only; the existing literature provides parameters only for CH₄. Using further updated parameters from Smith et al. (2021) would not change the overall results substantially.

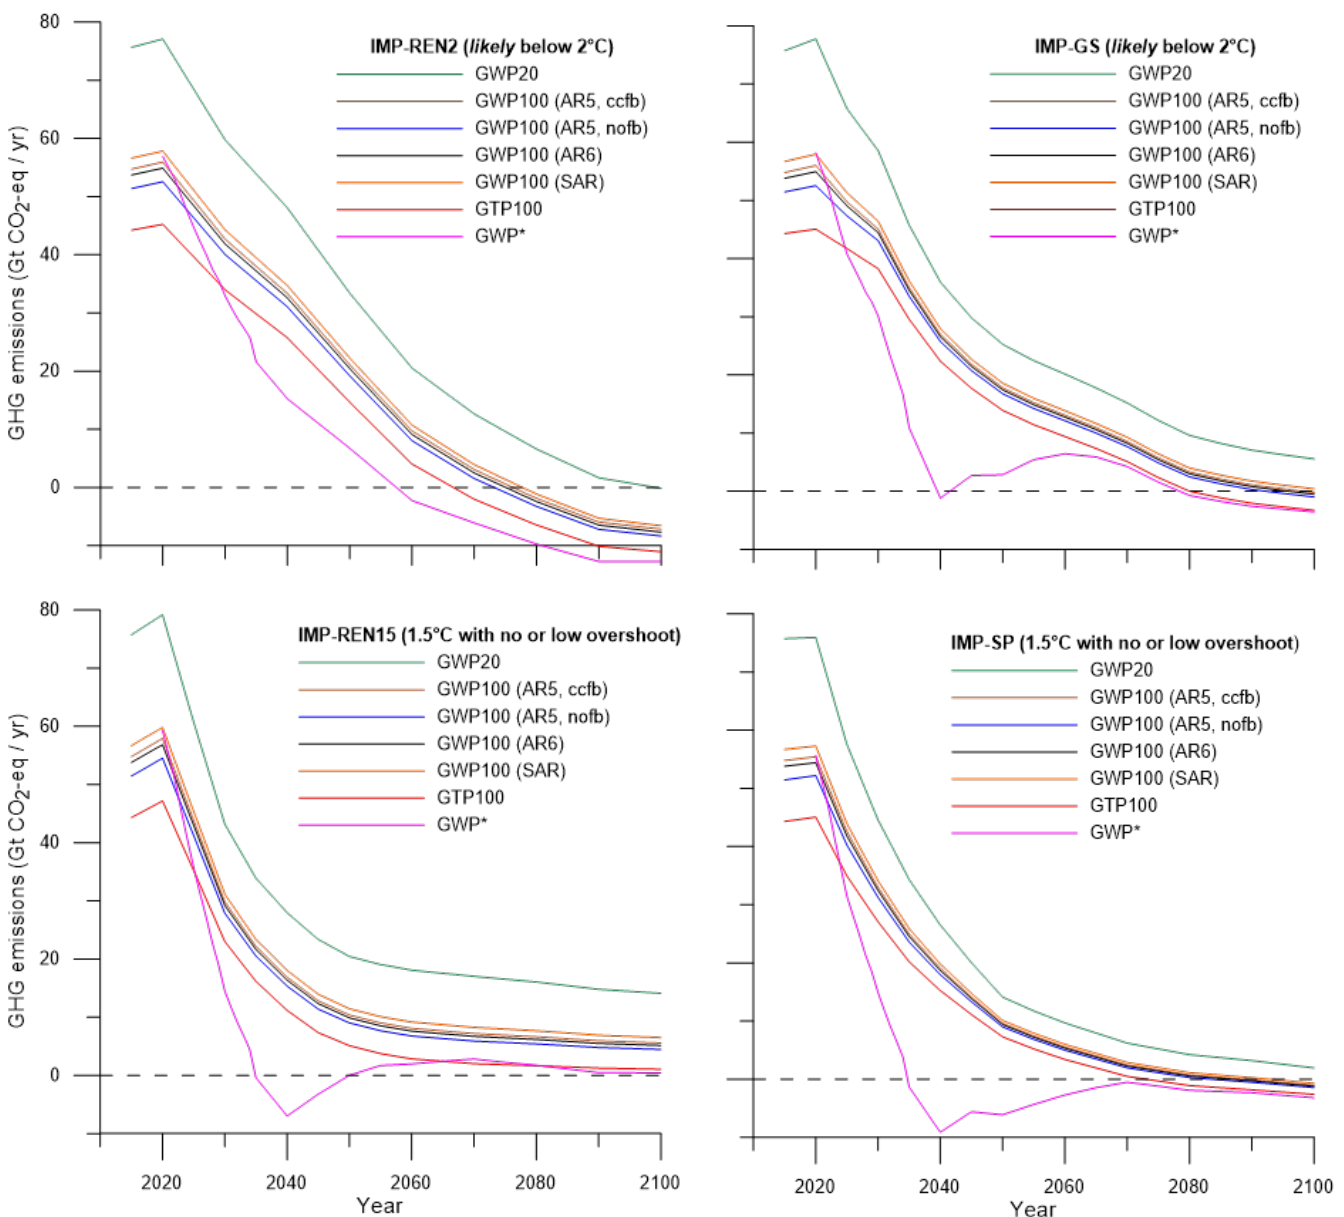

Figure 2.SM.10 | GHG emissions expressed in CO₂-eq, for four illustrative mitigation pathways (IMPs) from Chapter 3, using a range of GHG emission metrics assessed in AR6 (for details, see text). Illustrative Mitigation Pathways (IMPs) explore different ways of achieving long-term temperature goals. The four IMPs shown here are: higher Renewable Energy (IMP-Ren2 and IMP-Ren15); Gradual Strengthening of current policies (IMP-GS); and a Shifting Pathway (IMP-SP). Each of these pathways can be implemented with different levels of ambition. The IMP-Ren2 and IMP-GS (top panels) are consistent with limiting warming *likely* below 2°C, while IMP-Ren15 and IMP-SP (bottom panels) are consistent with limiting warming to 1.5°C with no or limited overshoot. (Box 3.1, 3.2.5, Annex III).

is only how the global aggregated emissions and removals would be reported for each pathway under different metrics.

The significant differences in the timing of net zero GHG emissions imply, however, that alternative emissions pathways that reach the same net zero GHG emissions target, but do so based on different GHG metrics, would necessarily result in different climate outcomes and would imply different levels of ambition to reach such an emissions target.

This is because depending on the GHG emission metric, a given amount of residual SLCF emissions in mitigation pathways would require different amounts of carbon dioxide removal (CDR) to achieve

net zero GHG emissions. Emission metrics that give less weight to ongoing SLCF emissions imply a lesser rate of CO₂ removal and hence greater overall warming and/or lesser reduction in warming over time after net zero GHG emissions have been reached. Conversely, a given amount of CDR would permit different rates of SLCF emissions to achieve net zero GHG emissions under different metrics. This would result in different amounts of warming contributed by SLCF emissions in addition to the warming from CO₂.

For a given net zero target in a given year, using different metrics to monitor and verify achievement of that target therefore results in different levels of peak warming and different contributions of individual gases to this warming, and different rates of temperature

change if net zero GHG emissions are sustained after the peak (Fuglestvedt et al. 2018; Tanaka and O'Neill 2018; Schleussner et al. 2019). This is before taking into account how the use of different GHG emission metrics might shape abatement choices leading up to an emission target.

2.SM.4 Trade as a Driver of Global GHG Emissions

This section assesses how trade openness and liberalisation may have changed the *global level* of GHG emissions, and complements Sections 2.3 and 2.4 in Chapter 2. It does not describe whether trade *has shifted* emissions between countries (transfer of embodied emissions) or has changed the level of emissions in individual countries (this is described in Chapter 2, Section 2.3). The effect of international emissions trading schemes, mechanisms, and policies are described in Chapter 2, Sections 2.8 and 14.5, respectively.

The question of whether international trade drives increases or decreases in global GHG emissions is difficult to answer since it not only depends on the emissions intensity of traded products, but also on the synergistic influence of trade on economic growth, income, consumption patterns, and the diffusion of low-carbon technologies or practices. All of these in turn are drivers of GHG emissions and the counterfactual question to answer is: What would happen without trade? (Jakob and Marschinski 2013). Trade also affects emissions through enhancing innovation and exchanging technologies between trading partners. These complex interactions are currently not fully understood (*limited evidence, low agreement*) (Cherniwchan et al. 2017). Consumption-based accounting alone (Chapter 2, Section 2.3) is therefore not suited to assess whether or not trade is driving global GHG emissions (Jakob and Marschinski 2013; Kander et al. 2015; Jiborn et al. 2018).

Only very few studies over the AR6 target time frame of 2010–2019 investigated the impacts of trade. Studies investigating global CO₂ emissions changes between 1995 and 2007/2008 found that the contribution of trade was moderately positive, whereas increases in overall and per capita consumption levels contributed much more strongly to the increase and improved technology had a significant decreasing effect (Arto and Dietzenbacher 2014; Hoekstra et al. 2016). A recent study modelled that international trade in 2015 increased global GDP by 10% and global total GHG emissions by 2% compared to a scenario where there was no trade (Wu et al. 2021).

Lin et al. (2019) investigated different scenarios on trade restrictions and found that a scenario with significant trade barriers based on additional 25% of tariffs would reduce global CO₂ emissions by 6.3% and GDP by 9.0%. On the other hand, the free trade scenario would increase global export volume by 5.4% and global CO₂ emissions by 1.2% for the base year of 2014 because of enhanced global production, especially in developing regions with high emissions intensities (Lin et al. 2019). It seems, however, that increased global GHG emissions only occur when the free trade agreements are between developed and developing countries (Nemati et al. 2019)

because emissions reductions in the former group are counteracted by higher increases in the latter group of countries (Yao et al. 2019).

In contrast, one study suggests that international trade avoided 15 GtCO₂ emissions globally between 1995 and 2009, when compared to a hypothetical situation without trade (López et al. 2018). Zhu and Jiang (2019) found that the recent slowdown in globalisation from 2012 to 2016 did not lower but instead increased global CO₂ emissions by 202 Mt. This is because the consumption of domestic intermediate and final products increased in many countries, in particular in China and India, leading to increased domestic and therefore global CO₂ emissions (Mi et al. 2017; Guan et al. 2018; Khochiani and Nademi 2019; Liu et al. 2019; Wang and Jiang 2019; Zheng et al. 2019; Wang et al. 2020c). Partly, this is due to the fact that non-OECD countries have a higher emissions intensity than OECD economies at the aggregate level (Zhu and Jiang 2019; González-Torres et al. 2021). Scenario modelling of the USA-China trade war in 2018–2019 showed an increase in global CO₂ emissions, despite a decrease in global economic output (Lu et al. 2020). This was because the modelled change in trade patterns as a consequence of the trade war meant that increased emissions from land-use changes and higher production in some countries far exceeded the reductions through structural effects in other countries (Lu et al. 2020).

In summary, there is *low agreement* and *limited evidence* on how international trade influences global GHG emissions. Since the pricing of energy resources and GHG emissions is inconsistent across countries, the overall outcome of trade on global emissions is coincidental rather than by design. If shifts in production are accompanied by large-scale transfers of and investment in low-carbon technologies in carbon-intensive countries, the effects of trade on emissions can be mitigated (Jiang and Green 2017; Gozgor et al. 2020). While such investments and knowledge transfers are more likely to come from net importing nations leading in low-carbon technology, net exporters can help by targeting carbon-intensive export industries with additional mitigation measures (Ren et al. 2014; Liu et al. 2015b; Ji et al. 2017). Section 13.7 of this report deals with international interactions of national mitigation policies.

2.SM.5 Supporting Figures

Figure 2.SM.11 | Global GHG emissions trends 1990–2019 by individual (groups of) gases and in aggregate: GHGs (black); CO₂-FFI (light green); CO₂-LULUCF (dark green); CH₄ (blue); N₂O (orange); fluorinated gases (pink). Aggregate GHG emissions trends by groups of gases reported in GtCO₂-eq converted based on global warming potential with a 100-year time horizon (GWP100) from IPCC AR5 (Myhre et al. 2013). Coloured shadings show the associated uncertainties at a 90% confidence interval without considering uncertainties in GDP and population data (see below). First column shows emissions trends in absolute levels (GtCO₂-eq). Second column shows per capita emissions trends (tCO₂-eq per capita) using UN population data for normalisation (World Bank 2021). Third column shows emissions trends per unit of GDP (kgCO₂-eq per USD) using GDP data in constant USD2010 from the World Bank for normalisation (World Bank 2021). Data: Minx et al. (2021).

Figure 2.SM.12 | Global GHG emissions trends 1990–2019: CH₄ (blue); N₂O (orange). Aggregate GHG emissions trends by groups of gases reported in original mass units. Coloured shadings show the associated uncertainties at a 90% confidence interval without considering uncertainties in GDP and population data (see below). First column shows emissions trends in absolute levels (MtCO₂-eq). Second column shows per capita emissions trends (kg per capita) using UN population data for normalisation (World Bank 2021). Third column shows emissions trends per unit of GDP (g per USD) using GDP data in constant USD2010 from the World Bank for normalisation (World Bank 2021). Data: Minx et al. (2021).

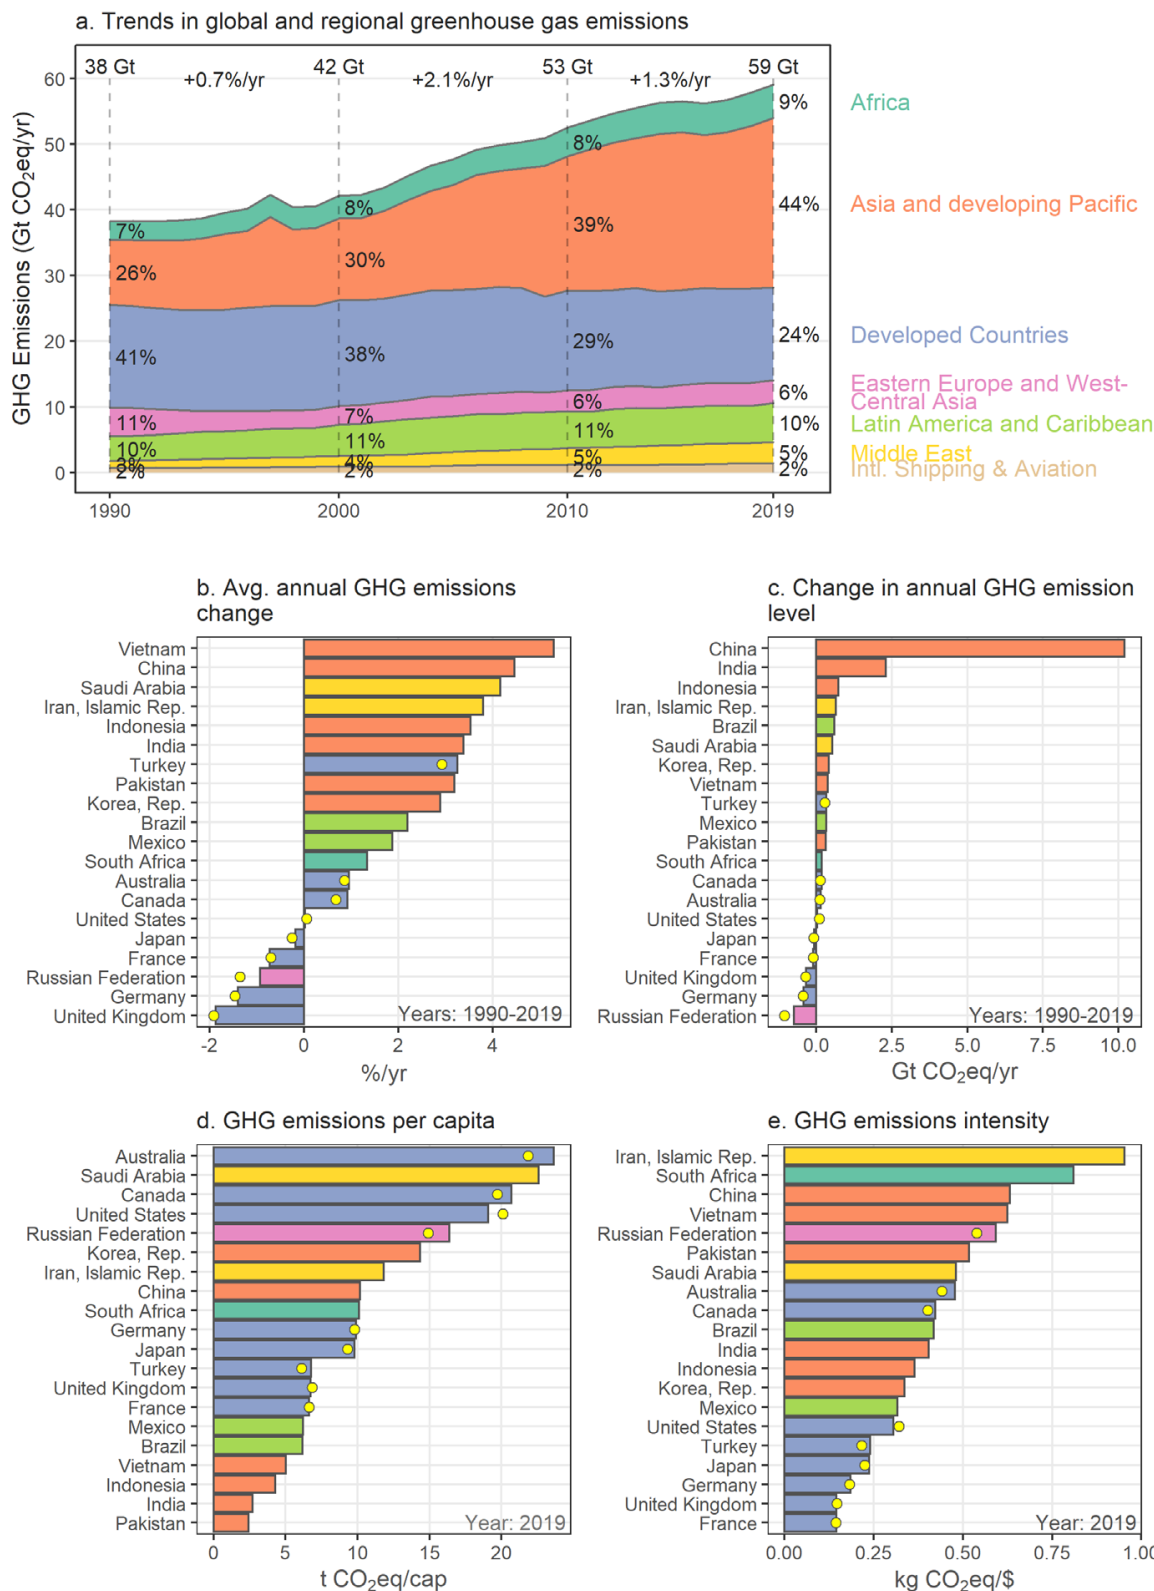

Figure 2.SM.13 | Change in regional GHGs from multiple perspectives and their underlying drivers. Panel (a): Regional GHG emissions trends (in GtCO₂-eq yr⁻¹) for 1990–2019. GHG emissions from international aviation and shipping are not assigned to individual countries and shown separately. Panels (b) and (c): Changes in GHG emissions for the 20 largest emitters (as of 2019) for 1990–2019 in relative (% annual change) and absolute terms (GtCO₂-eq). Panels (d) and (e): GHG emissions per capita and per unit of GDP in 2019 for the 20 largest emitters (as of 2019). GDP estimated using constant international purchasing power parity (USD2017). Emissions are converted into CO₂-equivalents based on global warming potential with a 100-year time horizon (GWP100) from IPCC's AR6 (Forster et al. 2021). The yellow dots represent the emissions data from UNFCCC-CRFs (2021) that were accessed through Gütschow et al. (2021a). Net LULUCF CO₂ emissions are included in panel (a), based on the average of three bookkeeping models (Chapter 2, Section 2.2), but are excluded in panels (b) to (e) due to a lack of country resolution.

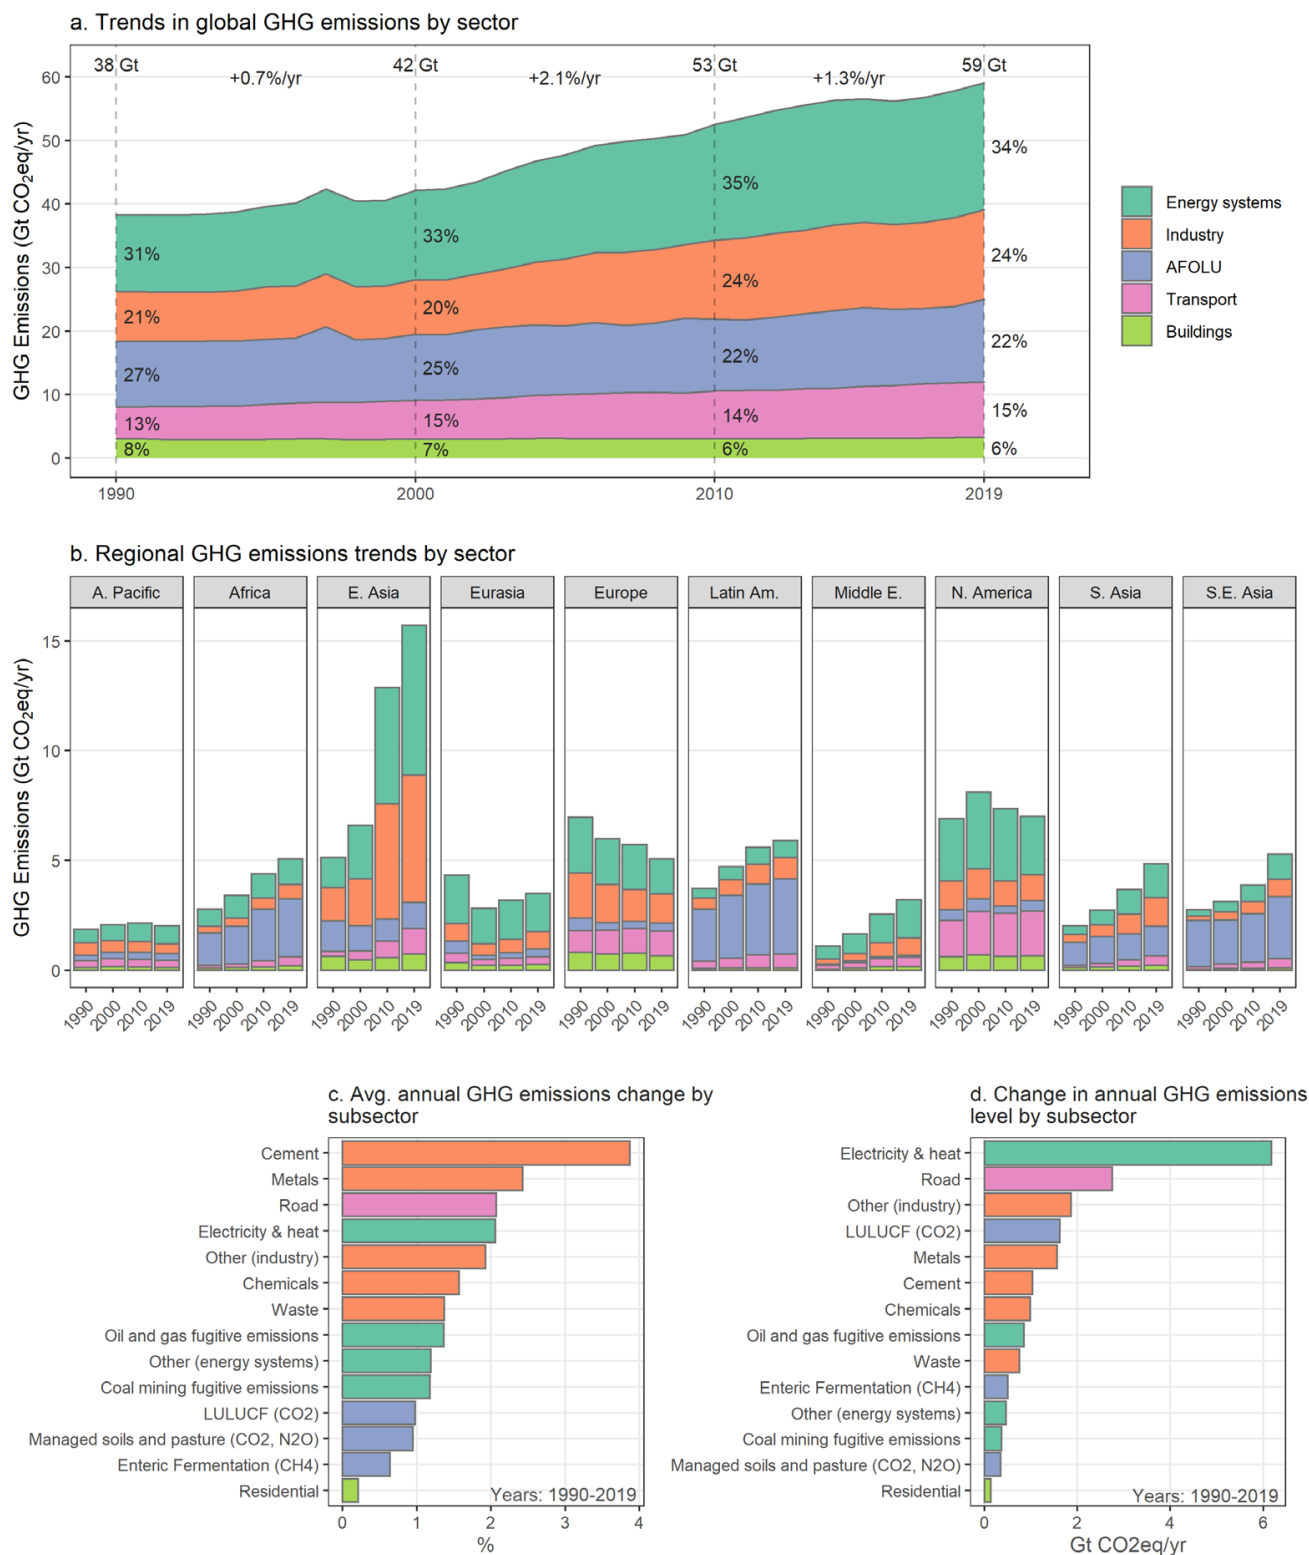

Figure 2.SM.14 | Total annual anthropogenic GHG emissions by major economic sector and their underlying trends by region. Panel (a): Trends in total annual anthropogenic GHG emissions (in GtCO₂-eq yr⁻¹) by major economic sector. **Panel (b):** Trends in total annual anthropogenic GHG emissions (in GtCO₂-eq yr⁻¹) by major economic sector and region. **Panels (c) and (d):** Largest sub-sectoral changes in GHG emissions for the reporting period 1990–2019 in relative (% annual change) and absolute terms (GtCO₂-eq). Emissions are converted into CO₂-equivalents based on global warming potential with a 100-year time horizon (GWP100) from IPCC's AR6. Based on Lamb et al. (2021); Data: Crippa et al. (2021); Minx et al. (2021).

Executive Summary

Chapter 3 assesses the emissions pathways literature in order to identify their key characteristics (both in commonalities and differences) and to understand how societal choices may steer the system into a particular direction (*high confidence*). More than 2000 quantitative emissions pathways were submitted to the IPCC's Sixth Assessment Report AR6 scenarios database, out of which 1202 scenarios included sufficient information for assessing the associated warming consistent with WGI. Five illustrative Mitigation Pathways (IMPs) were selected, each emphasising a different scenario element as its defining feature: heavy reliance on renewables (IMP-Ren), strong emphasis on energy demand reductions (IMP-LD), extensive use of carbon dioxide removal (CDR) in the energy and the industry sectors to achieve net negative emissions (IMP-Neg), mitigation in the context of broader sustainable development (IMP-SP), and the implications of a less rapid and gradual strengthening of near-term mitigation actions (IMP-GS). {3.2, 3.3}

Pathways consistent with the implementation and extrapolation of countries' implemented policies until the end of 2020 see greenhouse gas (GHG) emissions reaching 54–61 GtCO₂-eq yr⁻¹ by 2030 and to 47–67 GtCO₂-eq yr⁻¹ by 2050, leading to a median global warming of 2.2°C to 3.5°C by 2100 (*medium confidence*). These pathways consider policies at the time that they were developed. The Shared Socio-economic Pathways (SSPs) permit a more systematic assessment of future GHG emissions and their uncertainties than was possible in AR5. The main emissions drivers include growth in population, reaching 8.5–9.7 billion by 2050, and an increase in global GDP of 2.7–4.1% per year between 2015 and 2050. Final energy demand in the absence of any new climate policies is projected to grow to around 480–750 EJ yr⁻¹ in 2050 (compared to around 390 EJ in 2015) (*medium confidence*). The highest emissions scenarios in the literature result in global warming of >5°C by 2100, based on assumptions of rapid economic growth and pervasive climate policy failures (*high confidence*). {3.3}

Many pathways in the literature show how to limit global warming compared to pre-industrial times to 2°C (>67%) with no overshoot or to limit warming to 1.5°C (>50%) with no or limited overshoot. The likelihood of limiting warming to 1.5°C with no or limited overshoot has dropped in AR6 compared to the *Special Report on Global Warming of 1.5°C* (SR1.5) because global GHG emissions have risen since the time SR1.5 was published, leading to higher near-term emissions (2030) and higher cumulative CO₂ emissions until the time of net zero (*medium confidence*). Only a small number of published pathways limit global warming to 1.5°C without overshoot over the course of the 21st century. {3.3, Annex III.II.3}

Cost-effective mitigation pathways assuming immediate action¹ to limit warming to 2°C (>67%) are associated with net global GHG emissions of 30–49 GtCO₂-eq yr⁻¹ by 2030 and 14–26 GtCO₂-eq yr⁻¹ by 2050 (*medium confidence*). This corresponds to reductions, relative to 2019 levels, of 13–45% by 2030 and 52–76% by 2050. Pathways that limit global warming to below 1.5°C with no or limited overshoot require a further acceleration in the pace of the transformation, with net GHG emissions typically around 21–36 GtCO₂-eq yr⁻¹ by 2030 and 1–15 GtCO₂-eq yr⁻¹ by 2050; thus, reductions of 34–60% by 2030 and 73–98% by 2050 relative to 2019 levels. {3.3}

Pathways following Nationally Determined Contributions (NDCs) announced prior to COP26² until 2030 reach annual emissions of 47–57 GtCO₂-eq by 2030, thereby making it impossible to limit warming to 1.5°C with no or limited overshoot and strongly increasing the challenge to limit warming to 2°C (>67%) (*high confidence*). A high overshoot of 1.5°C increases the risks from climate impacts and increases the dependence on large-scale carbon dioxide removal from the atmosphere. A future consistent with NDCs announced prior to COP26 implies higher fossil fuel deployment and lower reliance on low-carbon alternatives until 2030, compared to mitigation pathways with immediate action to limit warming to 2°C (>67%) or lower. To limit warming to 2°C (>67%) after following the NDCs to 2030, the pace of global GHG emission reductions would need to accelerate rapidly from 2030 onward: to an average of 1.4–2.0 GtCO₂-eq yr⁻¹ between 2030 and 2050, which is around two-thirds of the global CO₂ emission reductions in 2020 due to the COVID-19 pandemic, and around 70% faster than in immediate action pathways that limit warming to 2°C (>67%). Accelerating emission reductions after following an NDC pathway to 2030 would be particularly challenging because of the continued buildup of fossil fuel infrastructure that would be expected to take place between now and 2030. {3.5, 4.2}

Pathways accelerating actions compared to NDCs announced prior to COP26 that reduce annual GHG emissions to 48 (38–52) GtCO₂-eq by 2030, or 2–9 GtCO₂-eq below projected emissions from fully implementing NDCs announced prior to COP26, reduce the mitigation challenge for limiting warming to 2°C (>67%) after 2030 (*medium confidence*). The accelerated action pathways are characterised by a global, but regionally differentiated, roll out of regulatory and pricing policies. Compared to NDCs, they see less fossil fuels and more low-carbon fuels until 2030, and narrow, but do not close the gap to pathways assuming immediate global action using all available least-cost abatement options. All delayed or accelerated action pathways that limit warming to 2°C (>67%) converge to a global mitigation regime at some point after 2030 by putting a significant value on reducing carbon and other GHG emissions in all sectors and regions. {3.5}

¹ Immediate action in modelled global pathways refers to the adoption between 2020 and at latest before 2025 of climate policies intended to limit global warming to a given level. Modelled pathways that limit warming to 2°C (>67%) based on immediate action are summarised in category C3a in Table SPM.2. All assessed modelled global pathways that limit warming to 1.5°C (>50%) with no or limited overshoot assume immediate action as defined here (Category C1 in Table SPM.2).

² NDCs announced prior to COP26 refer to the most recent nationally determined contributions submitted to the UNFCCC up to the literature cut-off date of this report, 11 October 2021, and revised NDCs announced by China, Japan and the Republic of Korea prior to October 2021 but only submitted thereafter.

Mitigation pathways limiting warming to 1.5°C (>50%) with no or limited overshoot reach 50% reductions of CO₂ in the 2030s, relative to 2019, then reduce emissions further to reach net zero CO₂ emissions in the 2050s. Pathways limiting warming to 2°C (>67%) reach 50% reductions in the 2040s and net zero CO₂ by 2070s (*medium confidence*). {3.3, Cross-Chapter Box 3 in this chapter}

Peak warming in mitigation pathways is determined by the cumulative net CO₂ emissions until the time of net zero CO₂ and the warming contribution of other GHGs and climate forcers at that time (*high confidence*). Cumulative net CO₂ emissions from 2020 to the time of net zero CO₂ are 510 (330–710) GtCO₂ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot and 890 (640–1160) GtCO₂ in pathways limiting warming to 2°C (>67%). These estimates are consistent with the assessment of remaining carbon budgets by WGI after adjusting for differences in peak warming levels. {3.3, Box 3.4}

Rapid reductions in non-CO₂ GHGs, particularly methane, would lower the level of peak warming (*high confidence*). Residual non-CO₂ emissions at the time of reaching net zero CO₂ range between 5 and 11 GtCO₂-eq yr⁻¹ in pathways limiting warming to 2°C (>67%) or lower. Methane (CH₄) is reduced by around 19% (4–46%) in 2030 and 45% (29–64%) in 2050, relative to 2019. Methane emission reductions in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot are substantially higher by 2030, 34% (21–57%), but only moderately so by 2050, 51% (35–70%). Methane emissions reductions are thus attainable at relatively lower GHG prices but are at the same time limited in scope in most 1.5°C–2°C pathways. Deeper methane emissions reductions by 2050 could further constrain the peak warming. N₂O emissions are reduced too, but similar to CH₄, emission reductions saturate for more stringent climate goals. In the mitigation pathways, the emissions of cooling aerosols are reduced due to reduced use of fossil fuels. The overall impact on non-CO₂-related warming combines these factors. {3.3}

Net zero GHG emissions imply net negative CO₂ emissions at a level compensating residual non-CO₂ emissions. Only 30% of the pathways limiting warming to 2°C (>67%) or lower reach net zero GHG emissions in the 21st century (*high confidence*). In those pathways reaching net zero GHGs, it is achieved around 10 to 40 years later than for net zero CO₂ (*medium confidence*). The reported quantity of residual non-CO₂ emissions depends on accounting: the choice of GHG metric. Reaching and sustaining global net zero GHG emissions, measured in terms of GWP-100, results in a gradual decline of temperature (*high confidence*). {Cross-Chapter Box 2 in Chapter 2, 3.3, Cross-Chapter Box 3 in this chapter}

Pathways limiting warming to 2°C (>67%) or lower exhibit substantial reductions in emissions from all sectors (*high confidence*). Projected CO₂ emissions reductions between 2019 and 2050 in 1.5°C (>50%) pathways with no or limited overshoot are around 77% (31–96%) for energy demand, 115% (90–167%) for energy supply, and 148% (94–387%) for agriculture, forestry and other land use (AFOLU). In pathways limiting warming to 2°C

(>67%), projected CO₂ emissions are reduced between 2019 and 2050 by around 49% for energy demand, 97% for energy supply, and 136% for AFOLU (*medium confidence*). {3.4}

Delaying or sacrificing emissions reductions in one sector or region involves compensating reductions in other sectors or regions if warming is to be limited (*high confidence*). Mitigation pathways show differences in the timing of decarbonisation and when net zero CO₂ emissions are achieved across sectors and regions. At the time of global net zero CO₂ emissions, emissions in some sectors and regions are positive while others are negative; the ordering depends on the mitigation options available, the cost of those options, and the policies implemented. In cost-effective mitigation pathways, the energy-supply sector typically reaches net zero CO₂ before the economy as a whole, while the demand sectors reach net zero CO₂ later, if ever (*high confidence*). {3.4}

Pathways limiting warming to 2°C (>67%) or lower involve substantial reductions in fossil fuel consumption and a near elimination of the use of coal without carbon capture and storage (CCS) (*high confidence*). These pathways show an increase in low-carbon energy, with 88% (69–97%) of primary energy coming from these sources by 2100. {3.4}

Stringent emissions reductions at the level required for 2°C (>67%) or lower are achieved through increased direct electrification of buildings, transport, and industry, resulting in increased electricity generation in all pathways (*high confidence*). Nearly all electricity in pathways limiting warming to 2°C (>67%) or lower is from low- or no-carbon technologies, with different shares of nuclear, biomass, non-biomass renewables, and fossil CCS across pathways. {3.4}

The measures required to limit warming to 2°C (>67%) or lower can result in large-scale transformation of the land surface (*high confidence*). Pathways limiting warming to 2°C (>67%) or lower are projected to reach net zero CO₂ emissions in the AFOLU sector between the 2020s and 2070, with an increase of forest cover of about 322 million ha (–67 to 890 million ha) in 2050 in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot. Cropland area to supply biomass for bioenergy (including bioenergy with carbon capture and storage – BECCS) is around 199 (56–482) million ha in 2050 in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot. The use of bioenergy can lead to either increased or reduced emissions, depending on the scale of deployment, conversion technology, fuel displaced, and how/where the biomass is produced (*high confidence*). {3.4}

Anthropogenic land CO₂ emissions and removals in Integrated Assessment Model (IAM) pathways cannot be directly compared with those reported in national GHG inventories (*high confidence*). Methodologies enabling a more like-for-like comparison between models' and countries' approaches would support more accurate assessment of the collective progress achieved under the Paris Agreement. {3.4, 7.2.2.5}

Pathways that limit warming to 2°C (>67%) or lower involve some amount of CDR to compensate for residual GHG emissions remaining after substantial direct emissions reductions in all sectors and regions (*high confidence*). CDR deployment in pathways serves multiple purposes: accelerating the pace of emissions reductions, offsetting residual emissions, and creating the option for net negative CO₂ emissions in case temperature reductions need to be achieved in the long term (*high confidence*). CDR options in the pathways are mostly limited to BECCS, afforestation and direct air carbon capture and storage (DACCS). CDR through some measures in AFOLU can be maintained for decades but not in the very long term because these sinks will ultimately saturate (*high confidence*). {3.4}

Mitigation pathways show reductions in energy demand relative to reference scenarios, through a diverse set of demand-side interventions (*high confidence*). Bottom-up and non-IAM studies show significant potential for demand-side mitigation. A stronger emphasis on demand-side mitigation implies less dependence on CDR and, consequently, reduced pressure on land and biodiversity. {3.4, 3.7}

Limiting warming requires shifting energy investments away from fossil fuels and towards low-carbon technologies (*high confidence*). The bulk of investments are needed in medium- and low-income regions. Investment needs in the electricity sector are on average 2.3 trillion USD₂₀₁₅ yr⁻¹ over 2023 to 2052 for pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and 1.7 trillion USD₂₀₁₅ yr⁻¹ for pathways that limit warming to 2°C (>67%). {3.6.1}

Pathways limiting warming to 2°C (>67%) require more rapid near-term transformations and are associated with higher upfront transition costs, but meanwhile bring long-term gains for the economy as well as earlier benefits in avoided climate change impacts (*high confidence*). This conclusion is independent of the discount rate applied, though the modelled cost-optimal balance of mitigation action over time does depend on the discount rate. Lower discount rates favour earlier mitigation, reducing reliance on CDR and temperature overshoot. {3.6.1, 3.8}

Mitigation pathways that limit warming to 2°C (>67%) entail losses in global GDP with respect to reference scenarios of between 1.3% and 2.7% in 2050; and in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, losses are between 2.6% and 4.2%. Yet, these estimates do not account for the economic benefits of avoided climate change impacts (*medium confidence*). In mitigation pathways that limit warming to 2°C (>67%), marginal abatement costs of carbon are about 90 (60–120) USD₂₀₁₅ tCO₂ in 2030 and about 210 (140–340) USD₂₀₁₅ tCO₂ in 2050; in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, they are about 220 (170–290) USD₂₀₁₅ tCO₂ in 2030 and about 630 (430–990) USD₂₀₁₅ tCO₂ in 2050.³ {3.6.1}

The global benefits of pathways limiting warming to 2°C (>67%) outweigh global mitigation costs over the 21st century, if aggregated economic impacts of climate change are at the moderate to high end of the assessed range, and a weight consistent with economic theory is given to economic impacts over the long term. This holds true even without accounting for benefits in other sustainable development dimensions or non-market damages from climate change (*medium confidence*). The aggregate global economic repercussions of mitigation pathways include the macroeconomic impacts of investments in low-carbon solutions and structural changes away from emitting activities, co-benefits and adverse side effects of mitigation, (avoided) climate change impacts, and (reduced) adaptation costs. Existing quantifications of global aggregate economic impacts show a strong dependence on socio-economic development conditions, as these shape exposure and vulnerability and adaptation opportunities and responses. (Avoided) impacts for poorer households and poorer countries represent a smaller share in aggregate economic quantifications expressed in GDP or monetary terms, whereas their well-being and welfare effects are comparatively larger. When aggregate economic benefits from avoided climate change impacts are accounted for, mitigation is a welfare-enhancing strategy (*high confidence*). {3.6.2}

The economic benefits on human health from air quality improvement arising from mitigation action can be of the same order of magnitude as mitigation costs, and potentially even larger (*medium confidence*). {3.6.3}

Differences between aggregate employment in mitigation pathways compared to reference scenarios are relatively small, although there may be substantial reallocations across sectors, with job creation in some sectors and job losses in others (*medium confidence*). The net employment effect (and its sign) depends on scenario assumptions, modelling framework, and modelled policy design. Mitigation has implications for employment through multiple channels, each of which impacts geographies, sectors and skill categories differently (*medium confidence*). {3.6.4}

The economic repercussions of mitigation vary widely across regions and households, depending on policy design and level of international cooperation (*high confidence*). Delayed global cooperation increases policy costs across regions, especially in those that are relatively carbon intensive at present (*high confidence*). Pathways with uniform carbon values show higher mitigation costs in more carbon-intensive regions, in fossil fuel exporting regions and in poorer regions (*high confidence*). Aggregate quantifications expressed in GDP or monetary terms undervalue the economic effects on households in poorer countries; the actual effects on welfare and well-being are comparatively larger (*high confidence*). Mitigation at the speed and scale required to limit warming to 2°C (>67%) or lower implies deep economic and structural changes, thereby raising multiple types of distributional concerns across regions, income classes and sectors (*high confidence*). {3.6.1, 3.6.4}

³ Numbers in parenthesis represent the interquartile range of the scenario samples.

The timing of mitigation actions and their effectiveness will have significant consequences for broader sustainable development outcomes in the longer term (*high confidence*). Ambitious mitigation can be considered a precondition for achieving the Sustainable Development Goals (SDGs), especially for vulnerable populations and ecosystems with little capacity to adapt to climate impacts. Dimensions with anticipated co-benefits include health, especially regarding air pollution, clean energy access and water availability. Dimensions with potential trade-offs include food, employment, water stress, and biodiversity, which come under pressure from large-scale CDR deployment, energy affordability/access, and mineral-resource extraction (*high confidence*). {3.7}

Many of the potential trade-offs of mitigation measures for other sustainable development outcomes depend on policy design and can thus be compensated or avoided with additional policies and investments or through policies that integrate mitigation with other SDGs (*high confidence*). Targeted SDG policies and investments, for example in the areas of healthy nutrition, sustainable consumption and production, and international collaboration, can support climate change mitigation policies and resolve or alleviate trade-offs. Trade-offs can be addressed by complementary policies and investments, as well as through the design of cross-sectoral policies integrating mitigation with the Sustainable Development Goals of health, nutrition, sustainable consumption and production, equity and biodiversity. {3.7}

Decent living standards, which encompass many SDG dimensions, are achievable at lower energy use than previously thought (*high confidence*). Mitigation strategies that focus on lower demands for energy and land-based resources exhibit reduced trade-offs and negative consequences for sustainable development relative to pathways involving either high emissions and climate impacts or those with high consumption and emissions that are ultimately compensated by large quantities of BECCS. {3.7}

Different mitigation pathways are associated with different feasibility challenges, though appropriate enabling conditions can reduce these challenges (*high confidence*). Feasibility challenges are transient and concentrated in the next two to three decades (*high confidence*). They are multidimensional, context-dependent and malleable to policy, technological and societal trends. {3.8}

Mitigation pathways are associated with significant institutional and economic feasibility challenges rather than technological and geophysical feasibility challenges (*medium confidence*). The rapid pace of technological development and deployment in mitigation pathways is not incompatible with historical records. Institutional capacity is rather a key limiting factor for a successful transition. Emerging economies appear to have the highest feasibility challenges in the short to medium term. {3.8}

Pathways relying on a broad portfolio of mitigation strategies are more robust and resilient (*high confidence*). Portfolios of technological solutions reduce the feasibility risks associated with the low-carbon transition. {3.8}

3.1 Introduction

3.1.1 Assessment of Mitigation Pathways and Their Compatibility With Long-term Goals

Chapter 3 takes a long-term perspective on climate change mitigation pathways. Its focus is on the implications of long-term targets for the required short- and medium-term system changes and associated greenhouse gas (GHG) emissions. This focus dictates a more global view and on issues related to path-dependency and up-scaling of mitigation options necessary to achieve different emissions trajectories, including particularly deep mitigation pathways that require rapid and fundamental changes.

Stabilising global average-temperature change requires reducing CO₂ emissions to net zero. Thus, a central cross-cutting topic within the chapter is the timing of reaching net zero CO₂ emissions and how a 'balance between anthropogenic emissions by sources and removals by sinks' could be achieved across time and space. This includes particularly the increasing body of literature since the *IPCC Special Report on Global Warming of 1.5°C (SR1.5)* which focuses on net zero CO₂ emissions pathways that avoid temperature overshoot and hence do not rely on net negative CO₂ emissions. The chapter conducts a systematic assessment of the associated economic costs as well as the benefits of mitigation for other societal objectives, such as the Sustainable Development Goals (SDGs). In addition, the chapter builds on SR1.5 and introduces a new conceptual framing for the assessment of possible social, economic, technical, political, and geophysical 'feasibility' concerns of alternative pathways, including the enabling conditions that would need to fall into place so that stringent climate goals become attainable.

The structure of the chapter is as follows: Section 3.2 introduces different types of mitigation pathways as well as the available modelling. Section 3.3 explores different emissions trajectories given socio-economic uncertainties and consistent with different long-term climate outcomes. A central element in this section is the systematic categorisation of the scenario space according to key characteristics of the mitigation pathways (including e.g., global average-temperature change, socio-economic development, technology assumptions, etc.). In addition, the section introduces selected Illustrative Mitigation Pathways (IMPs) that are used across the whole report. Section 3.4 conducts a sectoral analysis of the mitigation pathways, assessing the pace and direction of systems changes across sectors. Among others, this section aims at the integration of the sectoral information across AR6 WGIII chapters through a comparative assessment of the sectoral dynamics in economy-wide systems models compared to the insights from bottom-up sectoral models (from Chapters 6 to 11). Section 3.5 focuses on the required timing of mitigation actions, and the implication of near-term choices for the attainability of a range of long-term climate goals. After having explored the underlying systems transitions and the required timing of the mitigation actions, Section 3.6 assesses the economic implications, mitigation costs and benefits; and Section 3.7 assesses related co-benefits, synergies, and possible trade-offs for sustainable development and other societal (non-climate) objectives. Section 3.8 assumes a central role in the chapter and introduces a multidimensional feasibility metric

that permits the evaluation of mitigation pathways across a range of feasibility concerns. Finally, methods of the assessment and knowledge gaps are discussed in Section 3.9, followed by Frequently Asked Questions (FAQs).

3.1.2 Linkages to Other Chapters in the Report

Chapter 3 is linked to many other chapters in the report. The most important connections exist with Chapter 4 on mitigation and development pathways in the near to mid-term; with the sectoral chapters (Chapters 6–11); with the chapters dealing with cross-cutting issues (Chapters 12 and 17, e.g., feasibility); and finally also with AR6 WGI and WGII.

Within the overall framing of the AR6 report, Chapter 3 and Chapter 4 provide important complementary views of the required systems transitions across different temporal and spatial scales. While Chapter 3 focuses on the questions concerning the implications of the long-term objectives for the medium-to-near-term transformations, Chapter 4 comes from the other direction, and focuses on current near-term trends and policies (such as the Nationally Determined Contributions – NDCs) and their consequences with regards to GHG emissions. The latter chapter naturally focuses much more on the regional and national dimensions, and the heterogeneity of current and planned policies. Bringing together the information from these two chapters enables the assessment of whether current and planned actions are consistent with the required systems changes for the long-term objectives of the Paris Agreement.

Important other linkages comprise the collaboration with the 'sectoral' Chapters 6 to 11 to provide an integrated cross-sectoral perspective. This information (including information also from the sectoral chapters) is taken up ultimately also by Chapter 5 on demand/services and Chapter 12 for a further assessment of sectoral potential and costs.

Linkages to other chapters exist also on the topic of feasibility, which are informed by the policy, the sectoral and the demand chapters, the technology and finance chapters, as well as Chapter 4 on national circumstances.

Close collaboration with WGI permitted the use of AR6-calibrated emulators, which assure full consistency across the different working groups. Linkages to WGII concern the assessment of macroeconomic benefits of avoided impacts that are put into the context of mitigation costs as well as co-benefits and trade-offs for sustainable development.

3.1.3 Complementary Use of Large Scenario Ensembles and a Limited Set of Illustrative Mitigation Pathways (IMPs)

The assessment of mitigation pathways explores a wide scenario space from the literature within which seven Illustrative Pathways (IPs) are explored. The overall process is indicated in Figure 3.5a.

For a comprehensive assessment, a large ensemble of scenarios is collected and made available through an interactive AR6 Scenarios Database⁴. The collected information is shared across the chapters of AR6 and includes more than 3000 different pathways from a diverse set of studies. After an initial screening and quality control, scenarios were further vetted to assess if they sufficiently represented historical trends (Annex III.II.3.1). Subsequently, the climate consequences of each scenario were assessed using the climate emulator (leading to further classification). The assessment in Chapter 3 is, however, not limited to the scenarios from the database, and wherever necessary other literature sources are also assessed in order to bring together multiple lines of evidence.

In parallel, based on the overall AR6 assessment, seven illustrative pathways (IP) were defined representing critical mitigation strategies discussed in the assessment. The seven pathways are composed of two sets: (i) one set of five Illustrative Mitigation Pathways (IMPs) and (ii) one set of two reference pathways illustrative for high emissions. The IMPs are on the one hand representative of the scenario space but also help to communicate archetypes of distinctly different systems transformations and related policy choices. Subsequently, seven scenarios were selected from the full database that fitted these storylines of each IP best. For these scenarios more strict vetting criteria were applied. The selection was done by first applying specific filters based on the storyline followed by a final selection (Box 3.1 and Figure 3.5a).

3.2 Which Mitigation Pathways are Compatible With Long-term Goals?

3.2.1 Scenario and Emission Pathways

Scenario and emission pathways are used to explore possible long-term trajectories, the effectiveness of possible mitigation strategies, and to help understand key uncertainties about the future. A **scenario** is an integrated description of a possible future of the human–environment system (Clarke et al. 2014), and could be a qualitative narrative, quantitative projection, or both. Scenarios

typically capture interactions and processes that change key driving forces such as population, GDP, technology, lifestyles, and policy, and the consequences on energy use, land use, and emissions. Scenarios are not predictions or forecasts. An emission pathway is a modelled trajectory of anthropogenic emissions (Rogelj et al. 2018a) and, therefore, a part of a scenario.

There is no unique or preferred method to develop scenarios, and future pathways can be developed from diverse methods, depending on user needs and research questions (Turnheim et al. 2015; Trutnevyte et al. 2019a; Hirt et al. 2020). The most comprehensive scenarios in the literature are qualitative narratives that are translated into quantitative pathways using models (Clarke et al. 2014; Rogelj et al. 2018a). Schematic or illustrative pathways can also be used to communicate specific features of more complex scenarios (Allen et al. 2018). Simplified models can be used to explain the mechanisms operating in more complex models (e.g., Emmerling et al. 2019). Ultimately, a diversity of scenario and modelling approaches can lead to more robust findings (Schinko et al. 2017; Gambhir et al. 2019).

3.2.1.1 Reference Scenarios

It is common to define a reference scenario (also called a baseline scenario). Depending on the research question, a reference scenario could be defined in different ways (Grant et al. 2020): (i) a hypothetical world with no climate policies or climate impacts (Kriegler et al. 2014b), (ii) assuming current policies or pledged policies are implemented (Roelfsema et al. 2020), or (iii) a mitigation scenario to compare sensitivity with other mitigation scenarios (Kriegler et al. 2014a; Sognaes et al. 2021).

No-climate-policy reference scenarios have often been compared with mitigation scenarios (Clarke et al. 2014). A no-climate-policy scenario assumes that no future climate policies are implemented, beyond what is in the model calibration, effectively implying that the carbon price is zero. No-climate-policy reference scenarios have a broad range depending on socio-economic assumptions and model characteristics, and consequently are important when assessing mitigation costs (Riahi et al. 2017; Rogelj et al. 2018b). As

Box 3.1 | Illustrative Mitigation Pathways (IMPs)

The literature shows a wide range of possible emissions trajectories, depicting developments in the absence of new climate policies or showing pathways consistent with the Paris Agreement. From the literature, a set of five Illustrative Mitigation Pathways (IMPs) was selected to denote implications of choices on socio-economic development and climate policies, and the associated transformations of the main GHG-emitting sectors (Figure 3.5b). The IMPs include a set of transformative pathways that illustrate how choices may lead to distinctly different transformations that may keep temperature increase to below 2°C (>67%) or 1.5°C. These pathways illustrate the implications of a focus on renewable energy such as solar and wind; reduced energy demand; extensive use of CDR in the energy and the industry sectors to achieve net negative emissions and reliance on other supply-side measures; strategies that avoid net negative carbon emissions, and gradual strengthening. In addition, one IMP explores how climate policies consistent with keeping limit warming to 1.5°C (>50%) can be combined with a broader shift towards sustainable development. These IMPs are used in various chapters, exploring for instance their implications for different sectors, regions, and innovation characteristics (Figure 3.5b).

⁴ Available at: <https://doi.org/10.5281/zenodo.5886911>. All figures and tables in this chapter source data from the AR6 Scenarios Database, unless otherwise stated.

countries move forward with climate policies of varying stringency, no-climate-policy baselines are becoming increasingly hypothetical (Hausfather and Peters 2020). Studies clearly show current policies are having an effect, particularly when combined with the declining costs of low-carbon technologies (IEA 2020a; Roelfsema et al. 2020; Sognaes et al. 2021; UNEP 2020), and, consequently, realised trajectories begin to differ from earlier no-climate-policy scenarios (Burgess et al. 2020). High-end emission scenarios, such as RCP8.5 and SSP5-8.5, are becoming less likely with climate policy and technology change (Box 3.3), but high-end concentration and warming levels may still be reached with the inclusion of strong carbon or climate feedbacks (Hausfather and Peters 2020; Pedersen et al. 2020).

3.2.1.2 Mitigation Scenarios

Mitigation scenarios explore different strategies to meet climate goals and are typically derived from reference scenarios by adding climate or other policies. Mitigation pathways are often developed to meet a predefined level of climate change, often referred to as a backcast. There are relatively few IAMs that include an endogenous climate model or emulator due to the added computational complexity, though exceptions do exist. In practice, models implement climate constraints by either iterating carbon-price assumptions (Strefler et al. 2021b) or by adopting an associated carbon budget (Riahi et al. 2021). In both cases, other GHGs are typically controlled by CO₂-equivalent pricing. A large part of the AR5 literature has focused on forcing pathways towards a target at the end of the century (van Vuuren et al. 2007, 2011; Clarke et al. 2009; Blanford et al. 2014; Riahi et al. 2017), featuring a temporary overshoot of the warming and forcing levels (Geden and Lössel 2017). In comparison, many recent studies explore mitigation strategies that limit overshoot (Johansson et al. 2020; Riahi et al. 2021). An increasing number of IAM studies also explore climate pathways that limit adverse side effects with respect to other societal objectives, such as food security (van Vuuren et al. 2019; Riahi et al. 2021) or larger sets of sustainability objectives (Soergel et al. 2021a).

3.2.2 The Utility of Integrated Assessment Models

Integrated Assessment Models (IAMs) are critical for understanding the implications of long-term climate objectives for the required near-term transition. For doing so, an integrated systems perspective including the representation of all sectors and GHGs is necessary. IAMs are used to explore the response of complex systems in a formal and consistent framework. They cover a broad range of modelling frameworks (Keppo et al. 2021). Given the complexity of the systems under investigation, IAMs necessarily make simplifying assumptions and therefore results need to be interpreted in the context of these assumptions. IAMs can range from economic models that consider only carbon dioxide emissions through to detailed process-based representations of the global energy system, covering separate regions and sectors (such as energy, transport, and land use), all GHG emissions and air pollutants, interactions with land and water, and a reduced representation of the climate system. IAMs are generally driven by economics and can have a variety of characteristics such as partial-, general- or non-equilibrium; myopic or perfect foresight; be

based on optimisation or simulation; have exogenous or endogenous technological change amongst many other characteristics. IAMs take as input socio-economic and technical variables and parameters to represent various systems. There is no unique way to integrate this knowledge into a model, and due to their complexity, various simplifications and omissions are made for tractability. IAMs therefore have various advantages and disadvantages which need to be weighed up when interpreting IAM outcomes. Annex III.I contains an overview of the different types of models and their key characteristics.

Most IAMs are necessarily broad as they capture long-term dynamics. IAMs are strong in showing the key characteristics of emission pathways and are most suited to questions related to short- versus long-term trade-offs, key interactions with non-climate objectives, long-term energy and land-use characteristics, and implications of different overarching technological and policy choices (Clarke et al. 2014; Rogelj et al. 2018a). While some IAMs have a high level of regional and sectoral detail, for questions that require higher levels of granularity (e.g., local policy implementation) specific region and sector models may be better suited. Utility of the IAM pathways increases when the quantitative results are contextualized through qualitative narratives or other additional types of knowledge to provide deeper insights (Geels et al. 2016a; Weyant 2017; Gambhir et al. 2019).

IAMs have a long history in addressing environmental problems, particularly in the IPCC assessment process (van Beek et al. 2020). Many policy discussions have been guided by IAM-based quantifications, such as the required emission reduction rates, net zero years, or technology deployment rates required to meet certain climate outcomes. This has led to the discussion about whether IAM scenarios have become performative, meaning that they act upon, transform or bring into being the scenarios they describe (Beck and Mahony 2017, 2018). Transparency of underlying data and methods is critical for scenario users to understand what drives different scenario results (Robertson 2020). A number of community activities have thus focused on the provision of transparent and publicly accessible databases of both input and output data (Riahi et al. 2012; Huppmann et al. 2018; Krey et al. 2019; Daioglou et al. 2020), as well as the provision of open-source code, and increased documentation (Annex III.I.9). Transparency is needed to reveal conditionality of results on specific choices in terms of assumptions (e.g., discount rates) and model architecture. More detailed explanations of underlying model dynamics would be critical to increase the understanding of what drives results (Bistline et al. 2020; Butnar et al. 2020; Robertson 2020).

Mitigation scenarios developed for a long-term climate constraint typically focus on cost-effective mitigation action towards a long-term climate goal. Results from IAM as well as sectoral models depend on model structure (Mercure et al. 2019), economic assumptions (Emmerling et al. 2019), technology assumptions (Pye et al. 2018), climate/emissions target formulation (Johansson et al. 2020), and the extent to which pre-existing market distortions are considered (Guivarch et al. 2011). The vast majority of IAM pathways do not consider climate impacts (Schultes et al. 2021). Equity hinges upon ethical and normative choices. As most IAM pathways follow the

cost-effectiveness approach, they do not make any additional equity assumptions. Notable exceptions include Tavoni et al. (2015), Pan et al. (2017), van den Berg et al. (2020), and Bauer et al. (2020). Regional IAM results therefore need to be assessed with care, considering that emissions reductions are happening where it is most cost-effective, which needs to be separated from who is ultimately paying for the mitigation costs. Cost-effective pathways can provide a useful benchmark, but may not reflect real-world developments (Calvin et al. 2014a; Trutnevyte 2016). Different modelling frameworks may lead to different outcomes (Mercure et al. 2019). Recent studies have shown that other desirable outcomes can evolve with only minor deviations from cost-effective pathways (Bauer et al. 2020; Neumann and Brown 2021). IAM and sectoral models represent social, political, and institutional factors only in a rudimentary way. This assessment is thus relying on new methods for the *ex post* assessment of feasibility concerns (Jewell and Cherp 2020; Brutschin et al. 2021). A literature is emerging that recognises and reflects on the diversity and strengths/weaknesses of model-based scenario analysis (Keppo et al. 2021).

The climate constraint implementation can have a meaningful impact on model results. The literature so far includes many temperature overshoot scenarios with heavy reliance on long-term CDR and net negative CO₂ emissions to bring back temperatures after the peak (Rogelj et al. 2019b; Johansson et al. 2020). New approaches have been developed to avoid temperature overshoot. The new generation of scenarios show that CDR is important beyond its ability to reduce temperature, but is essential also for offsetting residual emissions to reach net zero CO₂ emissions (Rogelj et al. 2019b; Johansson et al. 2020; Riahi et al. 2021; Streffer et al. 2021b).

Many factors influence the deployment of technologies in the IAMs. Since AR5, there has been fervent debate on the large-scale deployment of bioenergy with carbon capture and storage (BECCS) in scenarios (Fuss et al. 2014; Geden 2015; Anderson and Peters 2016; Smith et al. 2016; van Vuuren et al. 2017; Galik 2020; Köberle 2019). Hence, many recent studies explore mitigation pathways with limited BECCS deployment (Grubler et al. 2018; van Vuuren et al. 2019; Riahi et al. 2021; Soergel et al. 2021a). While some have argued that technology diffusion in IAMs occurs too rapidly (Gambhir et al. 2019), others argued that most models prefer large-scale solutions resulting in a relatively slow phase-out of fossil fuels (Carton 2019). While IAMs are particularly strong on supply-side representation, demand-side measures still lag in detail of representation despite progress since AR5 (Grubler et al. 2018; Lovins et al. 2019; van den Berg et al. 2019; O'Neill et al. 2020b; Hickel et al. 2021; Keyßer and Lenzen 2021). The discount rate has a significant impact on the balance between near-term and long-term mitigation. Lower discount rates <4% (than used in IAMs) may lead to more near-term emissions reductions – depending on the stringency of the target (Emmerling et al. 2019; Riahi et al. 2021). Models often use simplified policy assumptions (O'Neill et al. 2020b) which can affect the deployment of technologies (Sognaes et al. 2021). Uncertainty in technologies can lead to more or less short-term mitigation (Grant et al. 2021; Bednar et al. 2021). There is also a recognition to put more emphasis on what drives the results of different IAMs (Gambhir et al. 2019) and suggestions to focus more on what is driving differences in result across IAMs (Nikas et al. 2021). As noted by Weyant (2017, p. 131),

'IAMs can provide very useful information, but this information needs to be carefully interpreted and integrated with other quantitative and qualitative inputs in the decision-making process.'

3.2.3 The Scenario Literature and Scenario Databases

IPCC reports have often used voluntary submissions to a scenario database in its assessments. The database is an ensemble of opportunity, as there is not a well-designed statistical sampling of the hypothetical model or scenario space: the literature is unlikely to cover all possible models and scenarios, and not all scenarios in the literature are submitted to the database. Model intercomparisons are often the core of scenario databases assessed by the IPCC (Cointe et al. 2019; Nikas et al. 2021). Single-model studies may allow more detailed sensitivity analyses or address specific research questions. The scenarios that are organised within the scientific community are more likely to enter the assessment process via the scenario database (Cointe et al. 2019), while scenarios from different communities, in the emerging literature, or not structurally consistent with the database may be overlooked. Scenarios in the grey literature may not be assessed even though they may have greater weight in a policy context.

One notable development since AR5 is the Shared Socio-economic Pathways (SSPs), conceptually outlined in Moss et al. (2010) and subsequently developed to support integrated climate research across the IPCC Working Groups (O'Neill et al. 2014). Initially, a set of SSP narratives were developed, describing worlds with different challenges to mitigation and adaptation (O'Neill et al. 2017a): SSP1 (sustainability), SSP2 (middle of the road), SSP3 (regional rivalry), SSP4 (inequality) and SSP5 (rapid growth). The SSPs have now been quantified in terms of energy, land-use, and emission pathways (Riahi et al. 2017), for both no-climate-policy reference scenarios and mitigation scenarios that follow similar radiative-forcing pathways as the Representative Concentration Pathways (RCPs) assessed in AR5 WGI. Since then the SSPs have been successfully applied in thousands of studies (O'Neill et al. 2020b) including some critiques on the use and application of the SSP framework (Pielke and Ritchie 2021; Rosen 2021). A selection of the quantified SSPs are used prominently in AR6 WGI as they were the basis for most climate modelling since AR5 (O'Neill et al. 2016). Since 2014, when the first set of SSP data was made available, there has been a divergence between scenario and historic trends (Burgess et al. 2020). As a result, the SSPs require updating (O'Neill et al. 2020b). Most of the scenarios in the AR6 database are SSP-based and consider various updates compared to the first release (Riahi et al. 2017).

3.2.4 The AR6 Scenario Database

To facilitate this assessment, a large ensemble of scenarios has been collected and made available through an interactive AR6 WGIII scenario database. The collection of the scenario outputs is coordinated by Chapter 3 and expands upon the IPCC SR1.5 scenario explorer (Huppmann et al. 2018; Rogelj et al. 2018a). A complementary database for national pathways has been established by Chapter 4. Annex III.II.3 contains full details on how the scenario database was compiled.

Number of scenarios from each model family

Figure 3.1 | Scenario counts from each model family defined as all versions under the same model’s name.

Number of scenarios from each project

Figure 3.2 | Scenario counts from each named project.

The AR6 scenario database contains 3131 scenarios (Figure 3.5a). After an initial screening and quality control, scenarios were further vetted to assess if they sufficiently represented historical trends (Annex III.II.3.1). Of the initial 2266 scenarios with global scope, 1686 scenarios passed the vetting process and are assessed in this chapter. The scenarios that did not pass the vetting are still available in the database. The vetted scenarios were from over 50 different model families, or over 100 when considering all versions of the same family (Figure 3.1). The scenarios originated from over 15 different model

intercomparison projects, with around one-fifth originating from individual studies (Figure 3.2). Because of the uneven distribution of scenarios from different models and projects, uncorrected statistics from the database can be misleading.

Each scenario with sufficient data is given a temperature classification using climate model emulators. Three emulators were used in the assessment: FAIR (Smith et al. 2018), CICERO-SCM (Skeie et al. 2021), MAGICC (Meinshausen et al. 2020). Only the

Table 3.1 | Classification of emissions scenarios into warming levels using MAGICC

Category	Description	WGI SSP	WGIII IP/IMP	Scenarios
C1: Limit warming to 1.5°C (>50%) with no or limited overshoot	Reach or exceed 1.5°C during the 21st century with a likelihood of ≤67%, and limit warming to 1.5°C in 2100 with a likelihood >50%. Limited overshoot refers to exceeding 1.5°C by up to about 0.1°C and for up to several decades.	SSP1-1.9	IMP-SP, IMP-LD, IMP-Ren	97
C2: Return warming to 1.5°C (>50%) after a high overshoot	Exceed warming of 1.5°C during the 21st century with a likelihood of >67%, and limit warming to 1.5°C in 2100 with a likelihood of >50%. High overshoot refers to temporarily exceeding 1.5°C global warming by 0.1°C–0.3°C for up to several decades.		IMP-Neg ^a	133
C3: Limit warming to 2°C (>67%)	Limit peak warming to 2°C throughout the 21st century with a likelihood of >67%.	SSP1-2.6	IMP-GS	311
C4: Limit warming to 2°C (>50%)	Limit peak warming to 2°C throughout the 21st century with a likelihood of >50%.			159
C5: Limit warming to 2.5°C (>50%)	Limit peak warming to 2.5°C throughout the 21st century with a likelihood of >50%.			212
C6: Limit warming to 3°C (>50%)	Limit peak warming to 3°C throughout the 21st century with a likelihood of >50%.	SSP2-4.5	ModAct	97
C7: Limit warming to 4°C (>50%)	Limit peak warming to 4°C throughout the 21st century with a likelihood of >50%.	SSP3-7.0	CurPol	164
C8: Exceed warming of 4°C (≥50%)	Exceed warming of 4°C during the 21st century with a likelihood of ≥50%.	SSP5-8.5		29
C1, C2, C3: limit warming to 2°C (>67%) or lower	All scenarios in Categories C1, C2 and C3			541

^a The Illustrative Mitigation Pathway ‘Neg’ has extensive use of carbon dioxide removal (CDR) in the AFOLU, energy and the industry sectors to achieve net negative emissions. Warming peaks around 2060 and declines to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as C3, it strongly exhibits the characteristics of C2 high-overshoot pathways, hence it has been placed in the C2 category. See Box SPM.1 for an introduction of the IPs and IMPs.

Number of scenarios in each climate category

Figure 3.3 | Of the 1686 scenarios that passed vetting, 1202 had sufficient data available to be classified according to temperature, with an uneven distribution across warming levels.

results of MAGICC are shown in this chapter as it adequately covers the range of outcomes. The emulators are calibrated against the behaviour of complex climate models and observation data, consistent with the outcomes of AR6 WGI (Cross-Chapter Box 7.1). The climate assessment is a three-step process of harmonisation, infilling and a probabilistic climate model emulator run (Annex III.II.2.5). Warming projections until the year 2100 were derived for 1574 scenarios, of which 1202 passed vetting, with the remaining scenarios having insufficient information (Figure 3.3 and Table 3.1). For scenarios that limit warming to 2°C or lower, the SR1.5 classification was adopted in AR6, with more disaggregation provided for higher warming levels (Table 3.1).

These choices can be compared with the selection of common global warming levels (GWs) of 1.5°C, 2°C, 3°C and 4°C to classify climate change impacts in the WGII assessment.

In addition to the temperature classification, each scenario is assigned to one of the following policy categories: (P0) diagnostic scenarios – 99 of 1686 vetted scenarios; (P1) scenarios with no globally coordinated policy (500) and (P1a) no climate mitigation efforts – 124, (P1b) current national mitigation efforts – 59, (P1c) Nationally Determined Contributions (NDCs) – 160, or (P1d) other non-standard assumptions – 153; (P2) globally coordinated climate policies with immediate

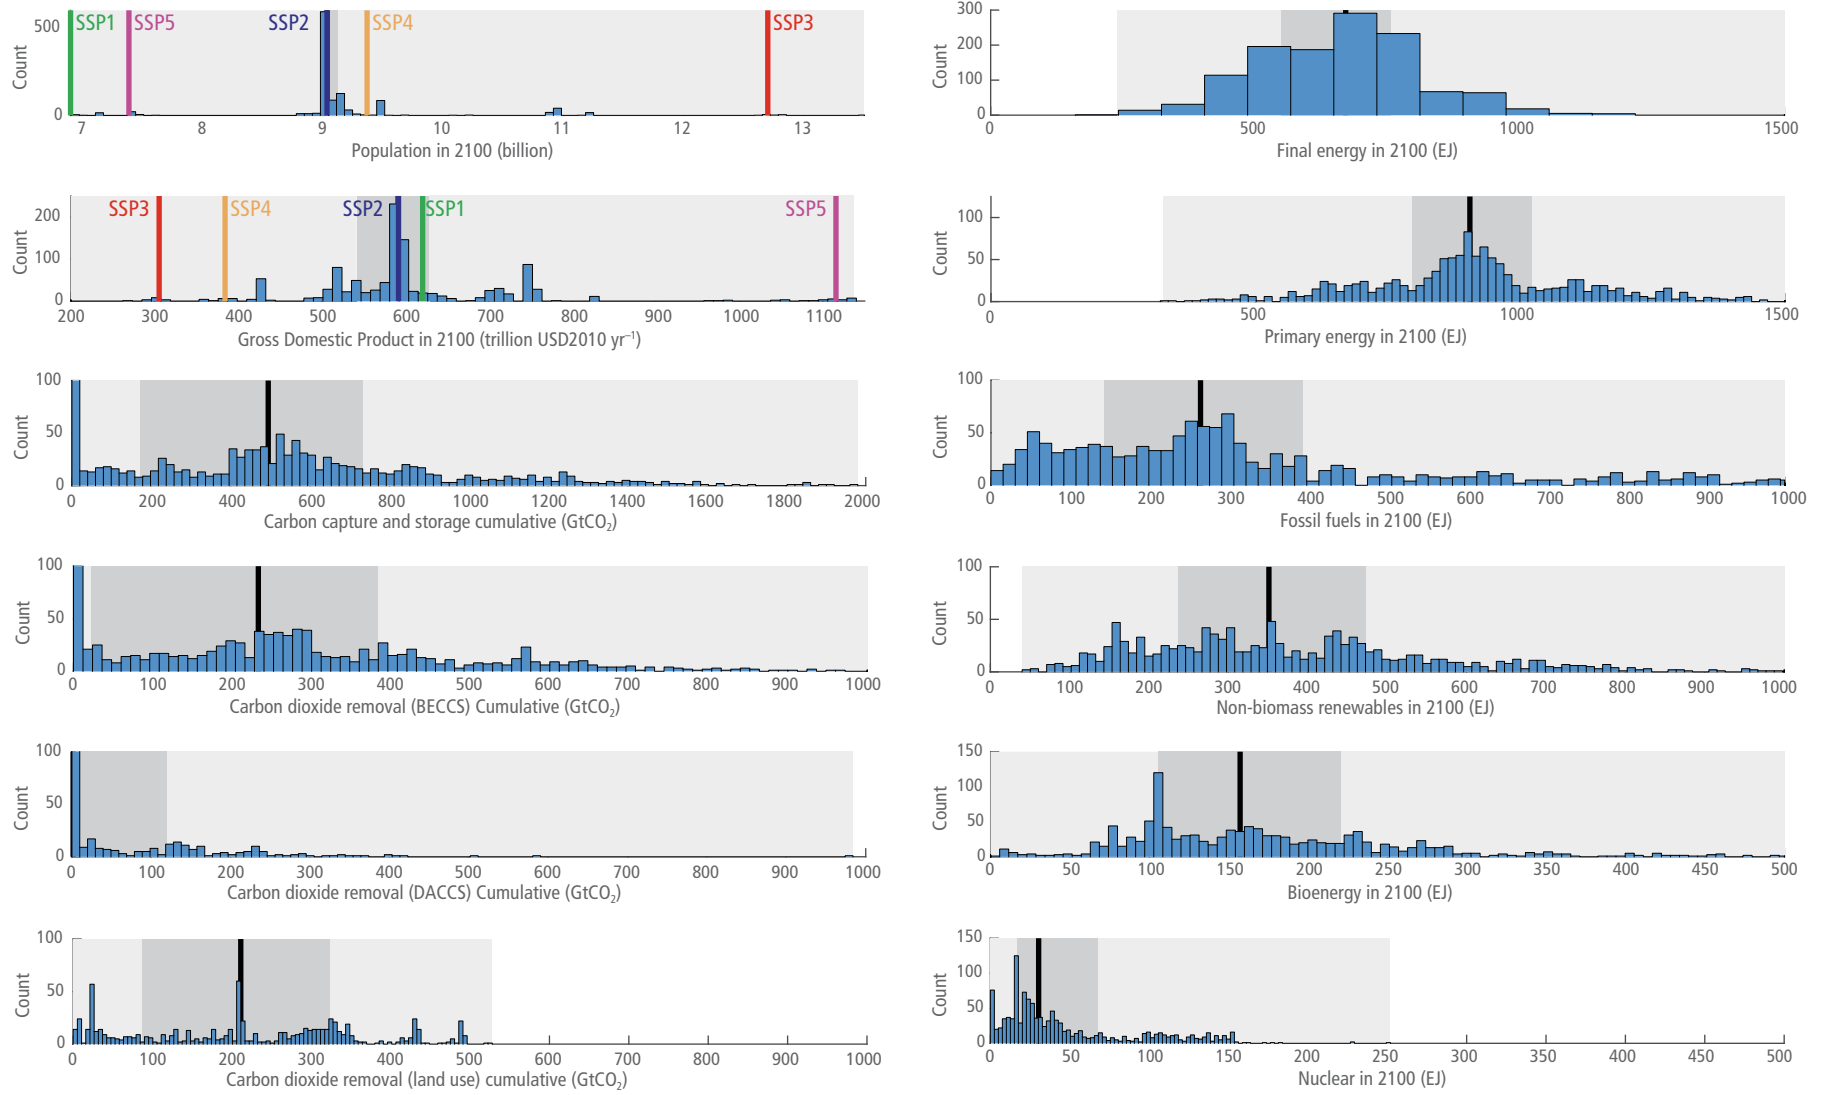

Figure 3.4 | Histograms for key categories in the AR6 scenario database. Only scenarios that passed vetting are shown. For population and GDP, the SSP input data are also shown. The grey shading represents the 0–100% range (light grey), 25–75% range (dark grey), and the median is a black line. The figures with white areas are outside of the scenario range, but the axis limits are retained to allow comparability with other categories. Each sub-figure potentially has different x- and y-axis limits. Each figure also potentially contains different numbers of scenarios, depending on what was submitted to the database. Source: AR6 scenarios database.

action (634) and (P2a) without any transfer of emission permits – 435, (P2b) with transfers – 70; or (P2c) with additional policy assumptions – 55; (P3) globally coordinated climate policies with delayed (i.e., from 2030 onwards or after 2030) action (451), preceded by (P3a) no mitigation commitment or current national policies – 7, (P3b) NDCs – 426, (P3c) NDCs and additional policies – 18; (P4) cost-benefit analysis (CBA) – 2. The policy categories were identified using text pattern matching on the scenario metadata and calibrated on the best-known scenarios from model intercomparisons, with further validation against the related literature, reported emission and carbon price trajectories, and exchanges with modellers. If the information available is enough to qualify a policy category number but not sufficient for a subcategory, then only the number is retained (e.g., P2 instead of P2a/b/c). A suffix added after P0 further qualifies a diagnostic scenario as one of the other policy categories. To demonstrate the diversity of the scenarios, the vetted scenarios were classified into different categories along the dimensions of population, GDP, energy, and cumulative emissions (Figure 3.4). The number of scenarios in each category provides some insight into the current literature, but this does not indicate a higher probability of that category occurring in reality. For population, the majority of scenarios are consistent with the SSP2 ‘middle of the road’ category, with very few scenarios exploring the outer extremes. GDP has a slightly larger variation, but overall most scenarios are around the SSP2 socio-economic assumptions. The level of CCS and CDR is expected to change depending on the extent of mitigation, but there remains extensive use of both CDR and CCS in scenarios. CDR is dominated by bioenergy with CCS (BECCS) and sequestration on land, with relatively few scenarios using direct air capture with carbon storage (DACCS) and even less with enhanced weathering (EW) and other technologies (not shown). In terms of energy consumption, final energy has a much smaller range than primary energy as conversion losses are not included in final energy. Both mitigation and reference scenarios are shown, so there is a broad spread in different energy carriers represented in the database. Bioenergy has a number of scenarios at around 100 EJ, representing a constraint used in many model intercomparisons.

3.2.5 Illustrative Mitigation Pathways

Successive IPCC Assessment Reports (ARs) have used scenarios to illustrate key characteristics of possible climate (policy) futures. In AR5 four RCPs made the basis of climate modelling in WGI and WGII, with WGIII assessing over 1000 scenarios spanning those RCPs (Clarke et al. 2014). Of the over 400 scenarios assessed in SR1.5, four scenarios were selected to highlight the trade-off between short-term emission reductions and long-term deployment of BECCS (Rogelj et al. 2018a), referred to as ‘Illustrative Pathways’ (IPs). AR6 WGI and WGII rely on the scenarios selected for CMIP6, called ScenarioMIP (O’Neill et al. 2016), to assess warming levels. In addition to the full set of scenarios, AR6 WGIII also uses selected Illustrative Mitigation Pathways (IMPs).

In WGIII, IMPs were selected to denote the implications of different societal choices for the development of future emissions and associated transformations of main GHG-emitting sectors (Figure 3.5a and Box 3.1). The most important function of the IMPs is to illustrate key themes that form a common thread in the report, both with a storyline and a quantitative illustration. The storyline describes the

key characteristics that define an IMP. The quantitative versions of the IMPs provide numerical values that are internally consistent and comparable across chapters of the report. The quantitative IMPs have been selected from the AR6 scenario database. No assessment of the likelihood of each IMP has been made.

The selected scenarios (IPs) are divided into two sets (Figures 3.5 and 3.6): two reference pathways illustrative of high emissions and five Illustrative Mitigation Pathways (IMPs). The narratives are explained in full in Annex III.II.2.4. The two reference pathways explore the consequences of current policies and pledges: Current Policies (*CurPol*) and Moderate Action (*ModAct*). The *CurPol* pathway explores the consequences of continuing along the path of implemented climate policies in 2020 and only a gradual strengthening after that. The scenario illustrates the outcomes of many scenarios in the literature that project the trend from implemented policies until the end of 2020. The *ModAct* pathway explores the impact of implementing the Nationally Determined Contributions (NDCs) as formulated in 2020 and some further strengthening after that. In line with current literature, these two reference pathways lead to an increase in global mean temperature of more than 2°C (Section 3.3).

The Illustrative Mitigation Pathways (IMPs) properly explore different pathways consistent with meeting the long-term temperature goals of the Paris Agreement. They represent five different pathways that emerge from the overall assessment. The IMPs differ in terms of their focus, for example, placing greater emphasis on renewables (*IMP-Ren*), deployment of carbon dioxide removal that results in net negative global GHG emissions (*IMP-Neg*), and efficient resource use and shifts in consumption patterns, leading to low demand for resources, while ensuring a high level of services (*IMP-LD*). Other IMPs illustrate the implications of a less rapid introduction of mitigation measures followed by a subsequent gradual strengthening (*IMP-GS*), and how shifting global pathways towards sustainable development, including by reducing inequality, can lead to mitigation (*IMP-SP*). In the IMP framework, *IMP-GS* is consistent with limiting warming to 2°C (>67%) (C3), *IMP-Neg* shows a strategy that also limits warming to 2°C (>67%) but returns to nearly 1.5°C (>50%) by the end of the century (hence indicated as C2*). The other variants that can limit warming to 1.5°C (>50%) (C1) were selected. In addition to these IMPs, sensitivity cases that explore alternative warming levels (C3) for *IMP-Neg* and *IMP-Ren* are assessed (*IMP-Neg-2.0* and *IMP-Ren-2.0*).

The IMPs are selected to have different mitigation strategies, which can be illustrated looking at the energy system and emission pathways (Figure 3.7 and Figure 3.8). The mitigation strategies show the different options in emission reduction (Figure 3.7). Each panel shows the key characteristics leading to total GHG emissions, consisting of residual (gross) emissions (fossil CO₂ emissions, CO₂ emissions from industrial processes, and non-CO₂ emissions) and removals (net land-use change, bioenergy with carbon capture and storage – BECCS, and direct air carbon capture and storage – DACCS), in addition to avoided emissions through the use of carbon capture and storage on fossil fuels. The *IMP-Neg* and *IMP-GS* scenarios were shown to illustrate scenarios with a significant role of CDR. The energy supply (Figure 3.8) shows the phase-out of fossil fuels in the *IMP-LD*, *IMP-Ren* and *IMP-SP* cases, but a less substantial decrease in the *IMP-Neg* case. The *IMP-GS* case

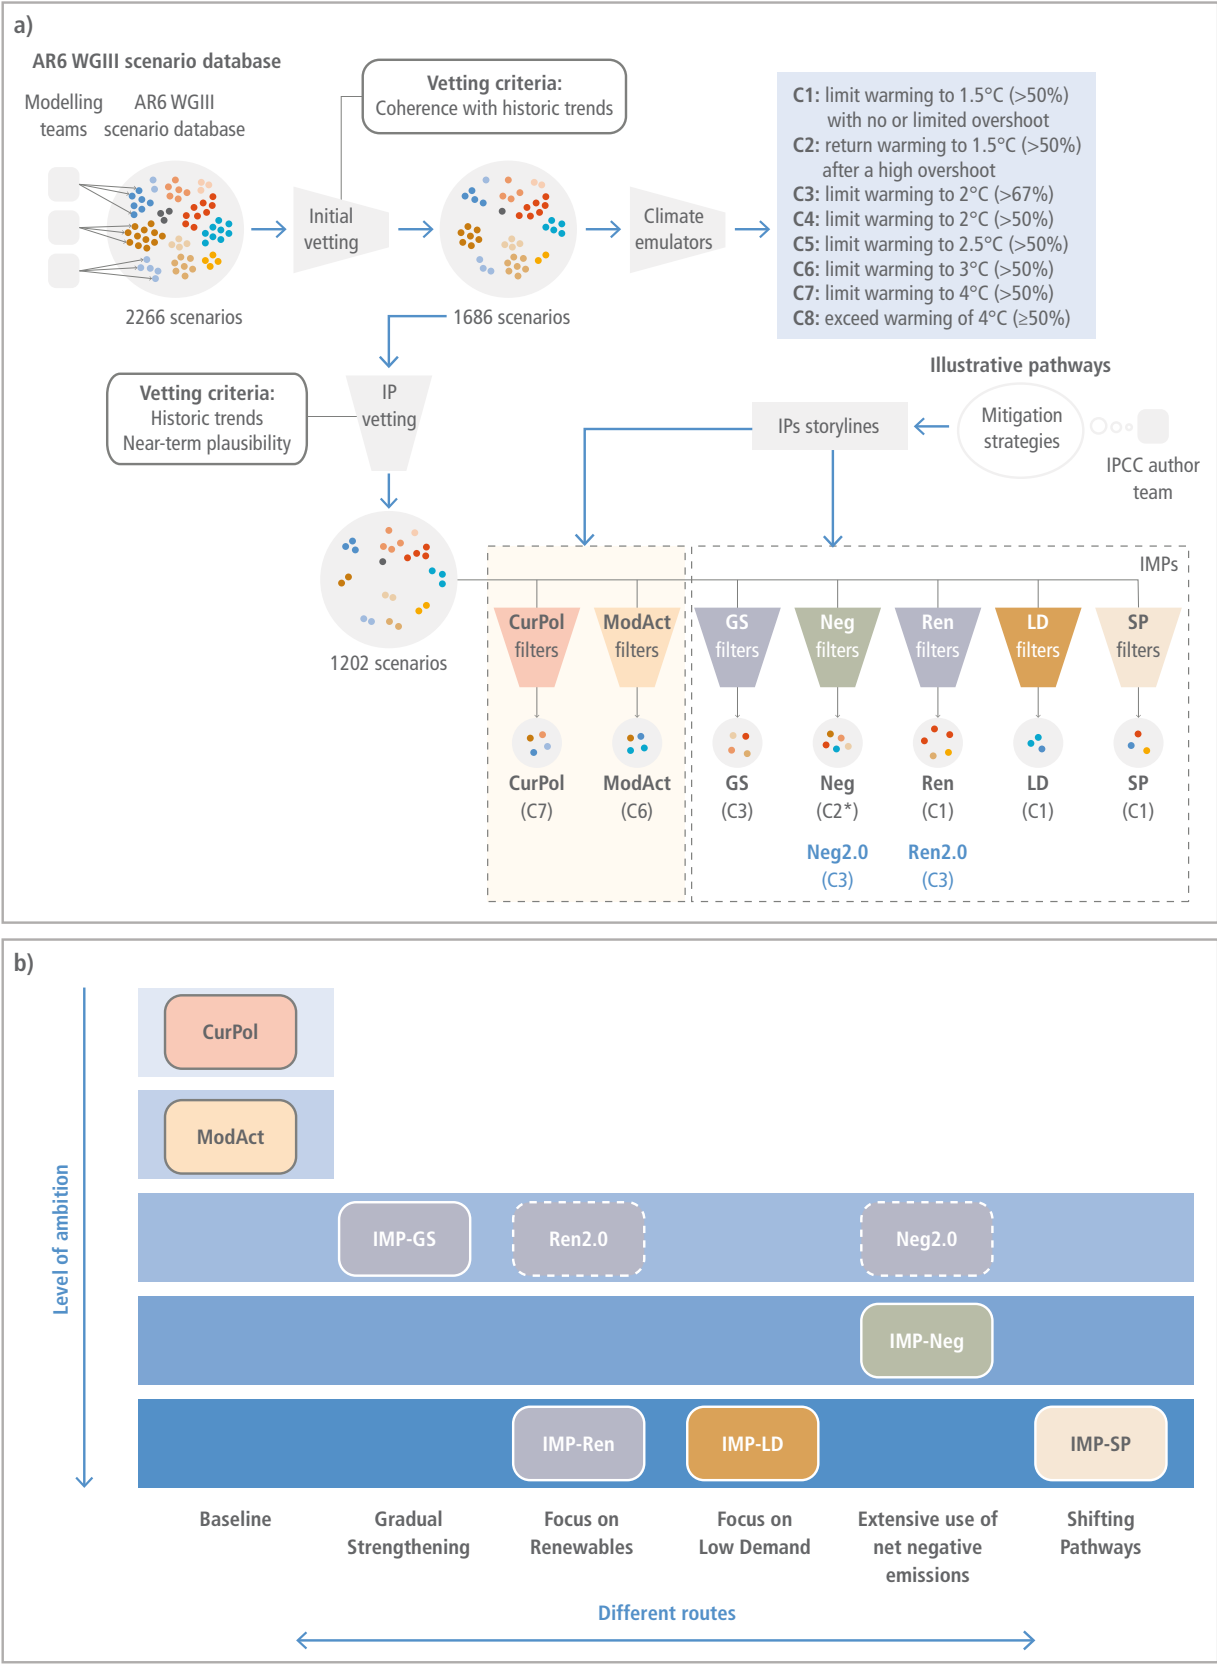

Figure 3.5 | (a) Process for creating the AR6 scenario database and selecting the illustrative (mitigation) pathways. The compiled scenarios in the AR6 scenarios database were vetted for consistency with historical statistics and subsequently a temperature classification was added using climate model emulators. The illustrative (mitigation) pathways were selected from the full set of pathways based on storylines of critical mitigation strategies that emerged from the assessment. **(b)** An overview of the Illustrative Pathways selected for use in IPCC AR6 WGIII, consisting of pathways illustrative of higher emissions, Current Policies (*CurPol*) and Moderate Action (*ModAct*), and Illustrative Mitigation Pathways (IMPs): gradual strengthening of current policies (*IMP-GS*), extensive use of net negative emissions (*IMP-Neg*), renewables (*IMP-Ren*), low demand (*IMP-LD*), and shifting pathways (*IMP-SP*). The *Ren2.0* and *Neg2.0* scenarios are alternative scenarios to the IMPs. These pathways are based on renewables and extensive use of negative emissions, respectively, but leading to temperature levels comparable to the C3 category and have sometimes been used for comparison.

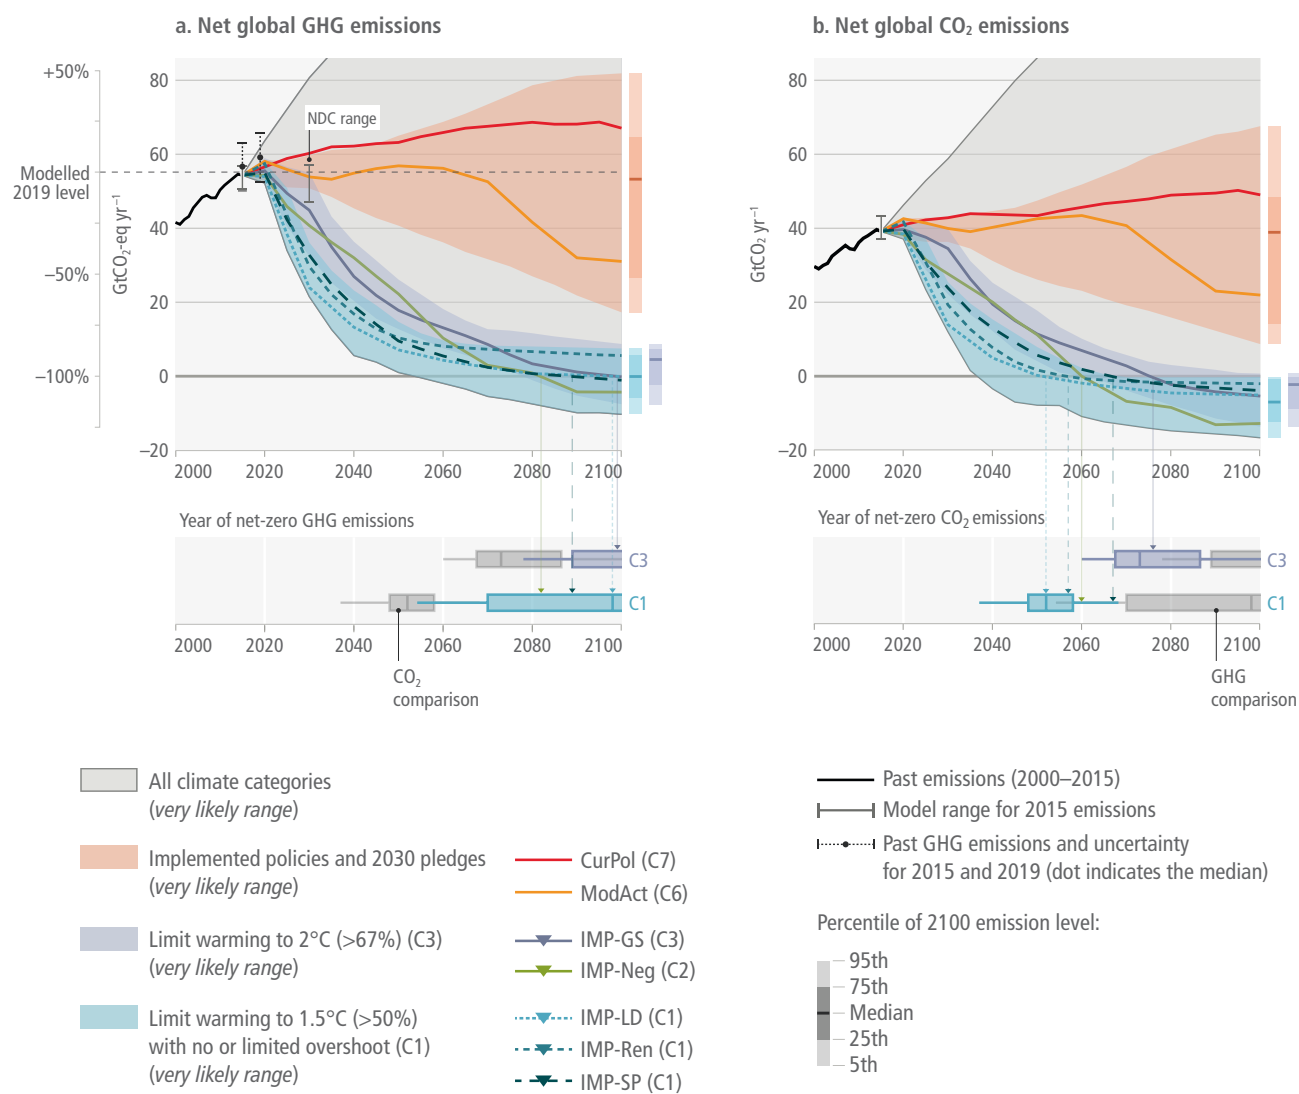

Figure 3.6 | Overview of the net CO₂ emissions and Kyoto greenhouse gas (GHG) emissions for each Illustrative Mitigation Pathway (IMP).

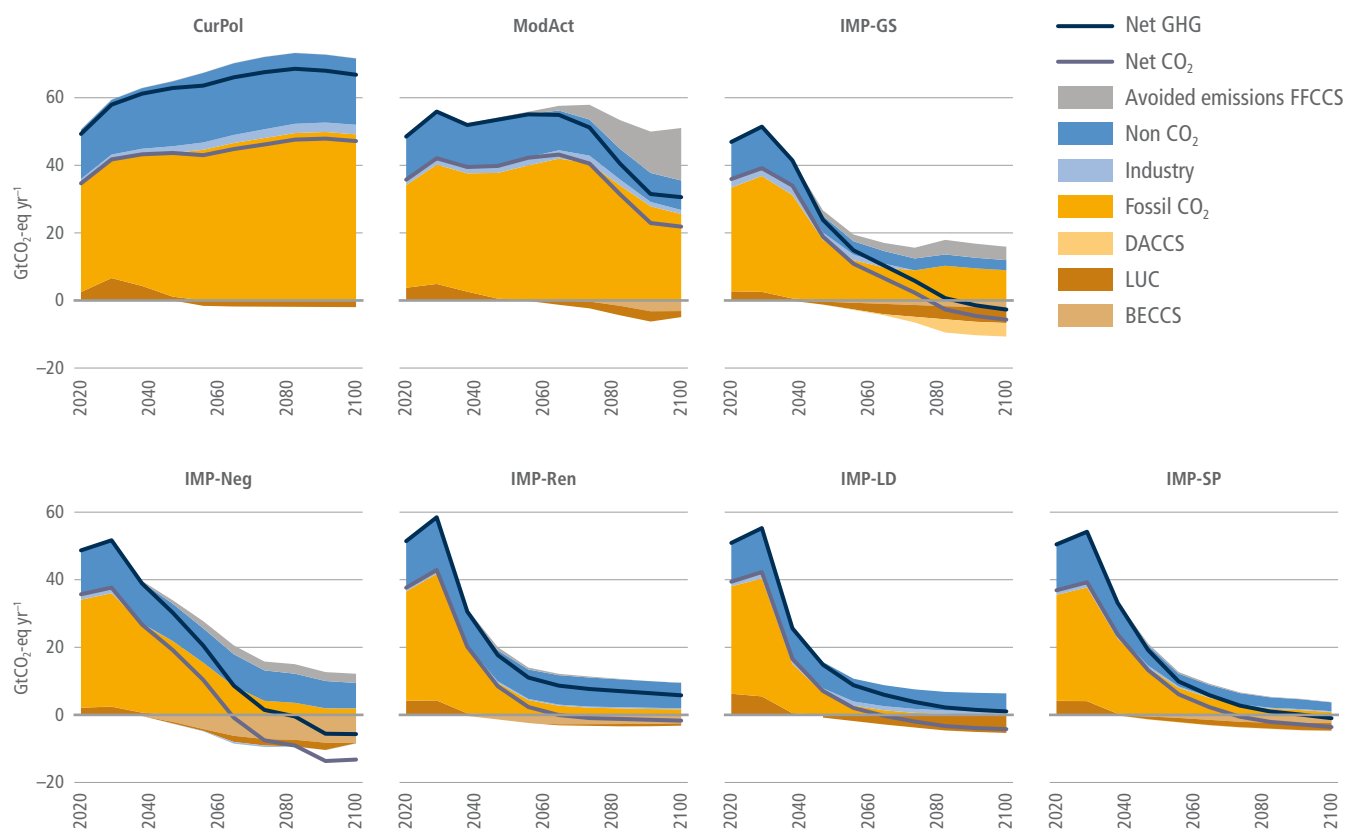

Figure 3.7 | The residual fossil fuel and industry emissions, carbon dioxide removal (CDR) {LUC, DACCS, BECCS}, and non-CO₂ emissions (using AR6 GWP-100) for each of the seven illustrative pathways (IPs). Fossil CCS is also shown, though this does not lead to emissions to the atmosphere (Section 3.2.5).

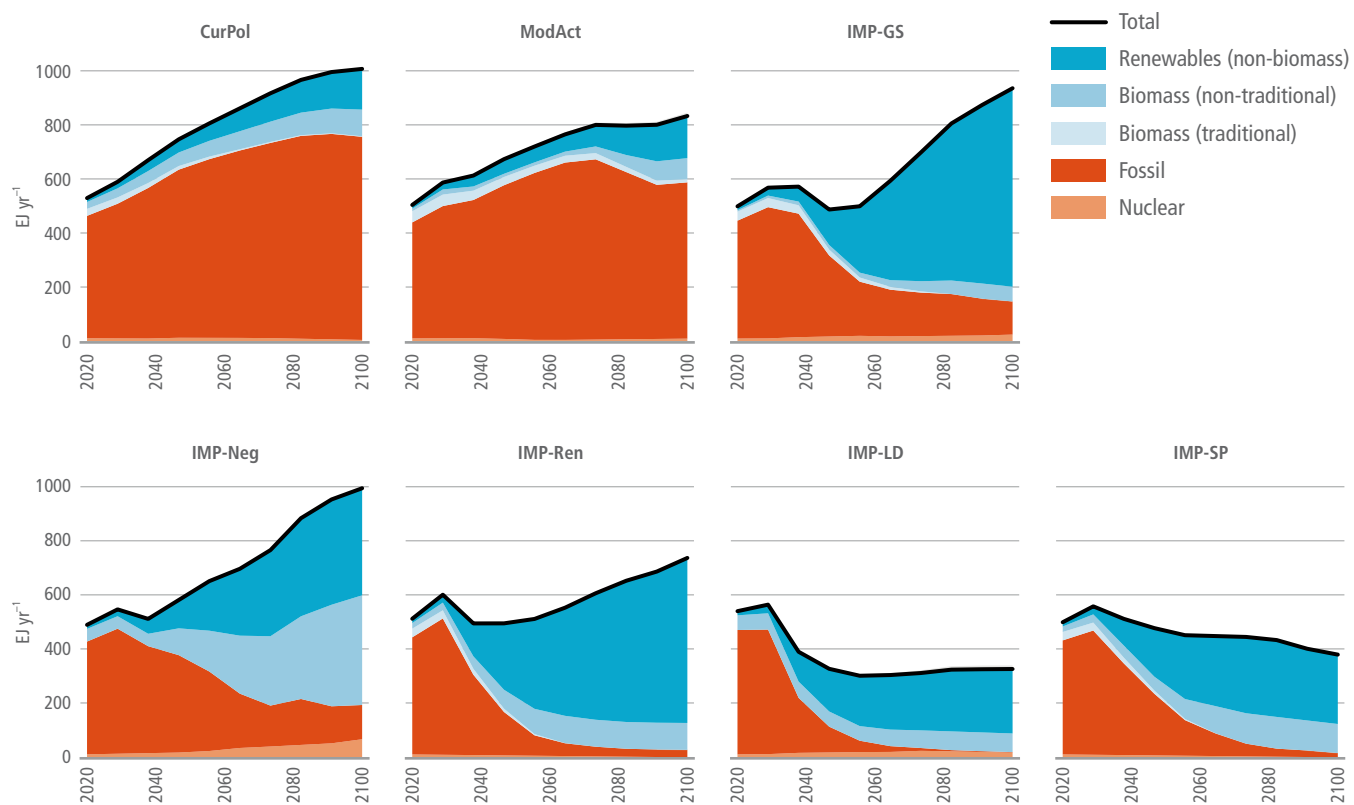

Figure 3.8 | The energy system in each of the illustrative pathways (IPs).

needs to make up its slow start by (i) rapid reductions mid-century and (ii) massive reliance on net negative emissions by the end of the century. The *CurPol* and *ModAct* cases both result in relatively high emissions, showing a slight increase and stabilisation compared to current emissions, respectively.

3.3 Emission Pathways, Including Socio-economic, Carbon Budget and Climate Responses Uncertainties

3.3.1 Socio-economic Drivers of Emissions Scenarios

Greenhouse gas (GHG) emissions mainly originate from the use and transformation of energy, agriculture, land use (change) and industrial activities. The future development of these sources is influenced by trends in socio-economic development, including population, economic activity, technology, politics, lifestyles, and climate policy. Trends for these factors are not independent, and scenarios provide a consistent outlook for these factors together (Section 3.2). Marangoni et al. (2017) show that in projections, assumptions influencing energy intensity (e.g., structural change, lifestyle and efficiency) and economic growth are the most important determinants of future CO₂ emissions from energy combustion. Other critical factors include technology assumptions, preferences, resource assumptions and policy (van Vuuren et al. 2008). As many of the factors are represented differently in specific models, the model itself is also an important factor – providing a reason for the importance of model diversity (Sognnaes et al. 2021). For land use, Stehfest et al. (2019) show that assumptions on population growth are more dominant given that variations in per capita consumption of food are smaller than for energy. Here, we only provide a brief overview of some key drivers. We focus first on so-called reference scenarios (without stringent climate policy) and look at mitigation scenarios in detail later. We use the SSPs to discuss trends in more detail. The SSPs were published in 2017, and by now, some elements will have to be updated (O'Neill et al. 2020b). Still, the ranges represent the full literature relatively well.

Historically, population and GDP have been growing over time. Scenario studies agree that further global population growth is likely up to 2050, leading to a range of possible outcomes of around 8.5–11 billion people (Figure 3.9a). After 2050, projections show a much wider range. If fertility drops below replacement levels, a decline in the global population is possible (as illustrated by SSP1 and SSP5). This typically includes scenarios with rapid development and investment in education. However, median projections mostly show a stabilisation of the world population (e.g., SSP2), while high-end projections show a continued growth (e.g., SSP3). The UN Population Prospects include considerably higher values for both the medium projection and the high end of the range than the SSP scenarios (KC and Lutz 2017; UN 2019). The most recent median UN projection reaches almost 11 billion people in 2100. The key differences are in Africa and China: here, the population projections are strongly influenced by the rate of fertility change (faster drop in SSPs). Underlying these differences, the UN approach is more based on current demographic trends while the SSPs assume a broader range of factors (including education) driving future fertility.

Economic growth is even more uncertain than the population projections (Figure 3.9c). The average growth rate of GDP was about 2.8% per year (constant USD) in the 1990–2019 period (The World Bank 2021). In 2020, the COVID-19 crisis resulted in a considerable drop in GDP (estimated around 4–5%) (IMF 2021). After a recovery period, most economic projections assume growth rates to converge back to previous projections, although at a lower level (IMF 2021; OECD 2021) (see also Box 3.2). In the long term, assumptions on future growth relate to political stability, the role of the progress of the technology frontier and the degree to which countries can catch up (Johansson et al. 2013). The SSP scenarios cover an extensive range, with low per-capita growth in SSP3 and SSP4 (mostly in developing countries) and rapid growth in SSP1 and SSP5. At the same, however, also scenarios outside the range have some plausibility – including the option of economic decline (Kallis et al. 2012) or much faster economic development (Christensen et al. 2018). The OECD long-term projection is at the global level reasonably consistent with SSP2. Equally important economic parameters include income distribution (inequity) and the type of growth (structural change, i.e., services vs manufacturing industries). Some projections (like SSP1) show a considerable convergence of income levels within and across countries, while in other projections, this does not occur (e.g., SSP3). Most scenarios reflect the suggested inverse relationship between the assumed growth rate for income and population growth (Figure 3.9e). SSP1 and SSP5 represent examples of scenarios with relatively low population increase and relatively high-income increase over the century. SSP3 represents an example of the opposite – while SSP2 and SSP4 are placed more in the middle. Nearly all scenarios assessed here do not account for climate impacts on growth (mostly for methodological reasons). As discussed in Section 3.5 these impacts can be considerable. An emerging area of literature emphasises the possibility of stabilisation (or even decline) of income levels in developed countries, arguing that such a trend would be preferred or even needed for environmental reasons (Anderson and Larkin 2013; Hickel and Kallis 2020; Kallis et al. 2020; Hickel et al. 2021; Keyßer and Lenzen 2021) (see also Chapter 5). Such scenarios are not common among IAM outcomes, that are more commonly based on the idea that decarbonisation can be combined with economic growth by a combination of technology, lifestyle and structural economic changes. Still, such scenarios could result in a dramatic reduction of energy and resource consumption.

Scenarios show a range of possible energy projections. In the absence of climate policy, most scenarios project the final energy demand to continue to grow to around 650–800 EJ yr⁻¹ in 2100 (based on the AR6 Scenarios Database, Figure 3.9b). Some projections show a very high energy demand up to 1000 EJ yr⁻¹ (comparable to SSP5). The scenario of the IEA lies within the SSP range but near the SSP1 projection. However, it should be noted that the IEA scenario includes current policies (most reference scenarios do not) and many scenarios published before 2021 did not account for the COVID-19 crisis. Several researchers discuss the possibility of decoupling material and energy demand from economic growth in the literature, mainly in developed countries (Kemp-Benedict 2018) (decoupling here refers to either a much slower increase in demand or even a decrease). In the scenario literature, this is reflected by scenarios with very low demand for final energy based on increased energy efficiency and less energy-intensive lifestyles (e.g., SSP1 and the LED scenario) (Grubler et al. 2018; van Vuuren et al. 2018). While these studies show the feasibility of such

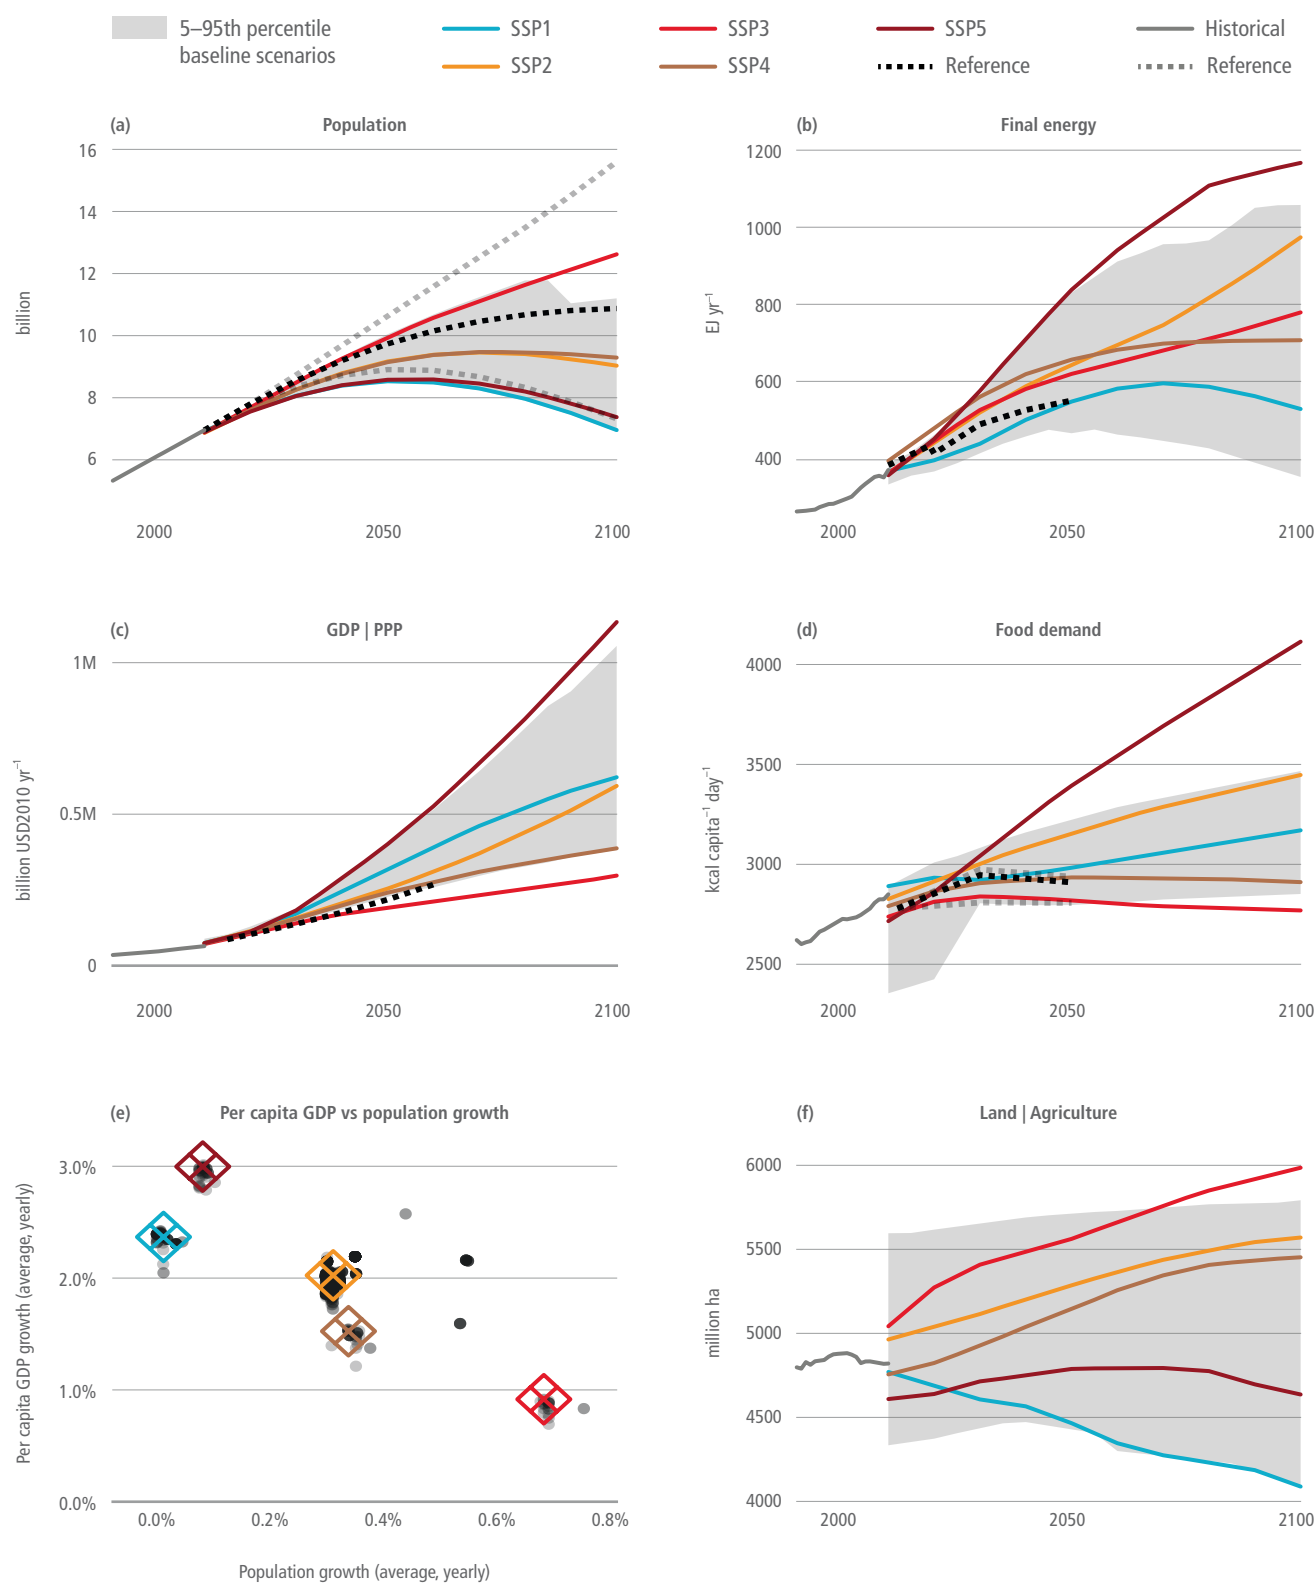

Figure 3.9 | Trends in key scenario characteristics and driving forces as included in the SSP scenarios (showing 5–95th percentiles of the reference scenarios as included in the database in grey shading). Reference (dotted lines) refers to the UN low-, medium- and high-population scenarios (UN 2019), the OECD long-term economic growth scenario (OECD 2021), the scenarios from the IEA's World Energy Outlook (IEA 2019), and the scenarios in the FAO assessment (FAO 2018).

pathways, their energy efficiency improvement rates are considerably above the historic range of around 2% (Gütschow et al. 2018; Jeffery et al. 2018; Vrontisi et al. 2018; Haberl et al. 2020; Roelfsema et al. 2020; Giarola et al. 2021; Höhne et al. 2021; IEA 2021a; Höhne et al. 2021; Sognnaes et al. 2021). These scenarios also show clear differences in food consumption and the amount of land used for agriculture. Food demand in terms of per-capita caloric intake is projected to increase in most scenarios (Figure 3.9d). However, it should be noted that there are large differences in dietary composition across the scenarios (from more meat-intensive in scenarios such as SSP5 to a decrease in meat consumptions in other scenarios such as SSP1). Land-use projections also depend on assumed changes in yield and the population scenarios (Figure 3.9f). Typically, changes in land use are less drastic than some other parameters (in fact, the 5–95th percentile database range is almost stable). Agriculture land is projected to increase in SSP3,

SSP2, and SSP4 – it is more-or-less stable in SSP5 and is projected to decline in SSP1.

3.3.2 Emission Pathways and Temperature Outcomes

3.3.2.1 Overall Mitigation Profiles and Temperature Consequences

Figure 3.10 shows the GHG and CO₂ emission trajectories for different temperature categories as defined in Section 3.2 (the temperature levels are calculated using simple climate models, consistent with the outcomes of the recent WGI assessment, Cross-Chapter Box 7.1). It should be noted that most scenarios currently in the literature do not account for the impact of COVID-19 (Box 3.2).

Figure 3.10 | Total emissions profiles in the scenarios based on climate category for GHGs (AR6 GWP-100) and CO₂. The illustrative mitigation pathways (IMPs) are also indicated.

Box 3.2 | Impact of COVID-19 on Long-term Emissions

The reduction in CO₂ emissions of the COVID-19 pandemic in 2020 was estimated to be about 6% (Section 4.2.2.4 and Table 4.SM.2) lower than 2019 levels (Forster et al. 2020; Friedlingstein et al. 2020; Liu et al. 2020c; BP 2021; Crippa et al. 2021; IEA 2021; Le Quéré et al. 2021). Near-real-time monitoring estimates show a rebound in emissions levels, meaning 2021 emissions levels are expected to be higher than 2020 (Le Quéré et al. 2021). The longer-term effects are uncertain but so far do not indicate a clear structural change for climate policy related to the pandemic. The increase in renewable shares in 2020 could stimulate a further transition, but slow economic growth can also slow down (renewable) energy investments. Also, lifestyle changes during the crisis can still develop in different directions (working from home, but maybe also living further away from work). Without a major intervention, most long-term scenarios project that emissions will start to follow a similar pathway as earlier projections (although at a reduced level) (IEA 2020b; Kikstra et al. 2021a; Rochedo et al. 2021). If emissions reductions are limited to only a short time, the adjustment of pathways will lead to negligible outcomes in the order of 0.01K (Forster et al. 2020; Jones et al. 2021). At the same time, however, the large amount of investments pledged in the recovery packages could provide a unique opportunity to determine the long-term development of infrastructure, energy systems and land use (Andrijevic et al. 2020b; Hepburn et al. 2020; Pianta et al. 2021). Near-term alternative recovery pathways have been shown to have the potential to influence carbon-price pathways, and energy investments and electrification requirements under stringent mitigation targets (Bertram et al. 2021; Kikstra et al. 2021a; Pollitt et al. 2021; Rochedo et al. 2021; Shan et al. 2021). Most studies suggest a noticeable reduction in 2030 emissions. However, much further reductions would be needed to reach the emission levels consistent with mitigation scenarios that limit warming to 2°C (>67%) or lower (see Chapter 4). At the moment, the share of investments in greenhouse gas reduction is relatively small in most recovery packages, and no structural shifts for climate policies are observed linked to the pandemic. Finally, most of the scenarios analysed in this Chapter do not include the 2020 emissions reduction related to the COVID-19 pandemic. The effect of the pandemic on the pathways will likely be very small. The assessment of climate mitigation pathways in this chapter should be interpreted as being almost exclusively based on the assumption of a fast recovery with limited persistent effects on emissions or structural changes.

3

The higher categories (C6 and C7) mostly included scenarios with no or modest climate policy. Because of the progression of climate policy, it is becoming more common that reference scenarios incorporate implemented climate policies. Modelling studies typically implement current or pledged policies up until 2030 (Vrontisi et al. 2018; Roelfsema et al. 2020; Sognnaes et al. 2021) with some studies focusing also on the policy development in the long term (Höhne et al. 2021; IEA 2021a; Jeffery et al. 2018; Gütschow et al. 2018). Based on the assessment in Chapter 4, reference pathways consistent with the implementation and trend from implemented policies until the end of 2020 are associated with increased GHG emissions from 59 (53–65) GtCO₂-eq yr⁻¹ in 2019 to 54–60 GtCO₂-eq yr⁻¹ by 2030 and to 47–67 GtCO₂-eq yr⁻¹ by 2050 (Figure 3.6). Pathways with these near-term emissions characteristics lead to a median global warming of 2.2°C to 3.5°C by 2100 (see also further in this section). These pathways consider policies at the time that they were developed. A recent model comparison that harmonised socio-economic, technological, and policy assumptions (Giarola et al. 2021) found a 2.2°C–2.9°C median temperature rise in 2100 for current and stated policies, with the results sensitive to the model used and the method of implementing policies (Sognnaes et al. 2021). Scenario inference and construction methods using similar policy assumptions lead to a median range of 2.9°C–3.2°C in 2100 for current policies and 2.4°C–2.9°C in 2100 for 2030 pledges (Höhne et al. 2021). The median spread of 1°C across these studies (2.2°C–3.2°C) indicates the deep uncertainties involved with modelling temperature outcomes of 2030 policies through to 2100 (Höhne et al. 2021).

The lower categories include increasingly stringent assumed climate policies. For all scenario categories, except the highest category,

emissions peak in the 21st century. For the lowest categories, the emissions peak is mostly before 2030. In fact, for scenarios in the category that avoids temperature overshoot for the 1.5°C scenario (C1 category), GHG emissions are reduced already to almost zero around the middle of the century. Typically, CO₂ emissions reach net zero about 10 to 40 years before total GHG emissions reach net zero. The main reason is that scenarios reduce non-CO₂ greenhouse gas emissions less than CO₂ due to a limited mitigation potential (Section 3.3.2.2). Figure 3.10 also shows that many scenarios in the literature with a temperature outcome below 2°C show net negative emissions. There are, however, also exceptions in which more immediate emission reductions limits the need for CDR. The IMPs illustrate alternative pathways to reach the C1–C3 temperature levels.

Figure 3.11 shows the possible consequences of the different scenario categories for global mean temperature calculated using a reduced complexity model (RCM) calibrated to the IPCC AR6 WGI assessment (see Annex III.II.2.5 of this report and Cross-Chapter Box 7.1 in AR6 WGI report). For the C5–C7 categories (containing most of the reference and current policy scenarios), the global mean temperature is expected to increase throughout the century (and further increase will happen after 2100 for C6 and C7). While warming would *more likely than not* be in the range from 2.2°C to 3.5°C, warming up to 5°C cannot be excluded. The highest emissions scenarios in the literature combine assumptions about rapid long-term economic growth and pervasive climate policy failures, leading to a reversal of some recent trends (Box 3.3). For the categories C1–C4, a peak in global mean temperature is reached mid-century for most scenarios in the database, followed by a small (C3/C4) or more considerable decline (C1/C2). There is a clear distinction between the scenarios with no or

Box 3.3 | The Likelihood of High-end Emissions Scenarios

At the time the Representative Concentration Pathways (RCPs) were published, they included three scenarios that could represent emission developments in the absence of climate policy: RCP4.5, RCP6 and RCP8.5, described as, respectively, low, medium and high-end scenarios in the absence of strong climate policy (van Vuuren et al. 2011). RCP8.5 was described as representative of the top 5% scenarios in the literature. The SSPs-based set of scenarios covered the RCP forcing levels, adding a new low scenario (at 1.9 W m^{-2}). Hausfather and Peters (2020) pointed out that since 2011, the rapid development of renewable energy technologies and emerging climate policy have made it considerably less likely that emissions could end up as high as RCP8.5. Still, emission trends in developing countries track RCP8.5 Pedersen et al. (2020), and high land-use emissions could imply that emissions would continue to do so in the future, even at the global scale (Schwalm et al. 2020). Other factors resulting in high emissions include higher population or economic growth as included in the SSPs (Section 3.3.1) or rapid development of new energy services. Climate projections of RCP8.5 can also result from strong feedbacks of climate change on (natural) emission sources and high climate sensitivity (AR6 WGI Chapter 7), and therefore their median climate impacts might also materialise while following a lower emission path (e.g., Hausfather and Betts 2020). The discussion also relates to a more fundamental discussion on assigning likelihoods to scenarios, which is extremely difficult given the deep uncertainty and direct relationship with human choice. However, it would help to appreciate certain projections (e.g., Ho et al. 2019). All in all, this means that high-end scenarios have become considerably less likely since AR5 but cannot be ruled out. It is important to realise that RCP8.5 and SSP5-8.5 do not represent a typical 'business-as-usual' projection but are only useful as high-end, high-risk scenarios. Reference emission scenarios (without additional climate policy) typically end up in the C5–C7 categories included in this assessment.

Figure 3.11 | Global mean temperature outcome of the ensemble of scenarios included in the climate categories C1–C8 (based on a reduced complexity model – RCM – calibrated to the WGI assessment, both in terms of future and historic warming). The left panel shows the ranges of scenario uncertainty (shaded area) with the P50 RCM probability (line). The right panel shows the P5 to P95 range of combined RCM climate uncertainty (C1–C8 is explained in Table 3.1) and scenario uncertainty, and the P50 (line).

limited overshoot (typically $<0.1^{\circ}\text{C}$, C1) compared to those with high overshoot (C2): in emissions, the C1 category is characterised by steep early reductions and a relatively small contribution of net negative emissions (like *IMP-LD* and *IMP-Ren*) (Figure 3.10). In addition to the temperature caused by the range of scenarios in each category (main panel), climate uncertainties also contribute to a range of temperature outcomes (including uncertainties regarding the carbon cycle, climate sensitivity, and the rate of change, see AR6 WGI). The bars on the right of Figure 3.11 show the uncertainty range for each

category (combining scenario and climate uncertainty). While the C1 category *more likely than not* limits warming to 1.5°C ($>50\%$) by the end of the century, even with such a scenario, warming above 2°C cannot be excluded (95th percentile). The uncertainty range for the highest emission categories (C7) implies that these scenarios could lead to a warming above 6°C .

3.3.2.2 The Role of Carbon Dioxide and Other Greenhouse Gases

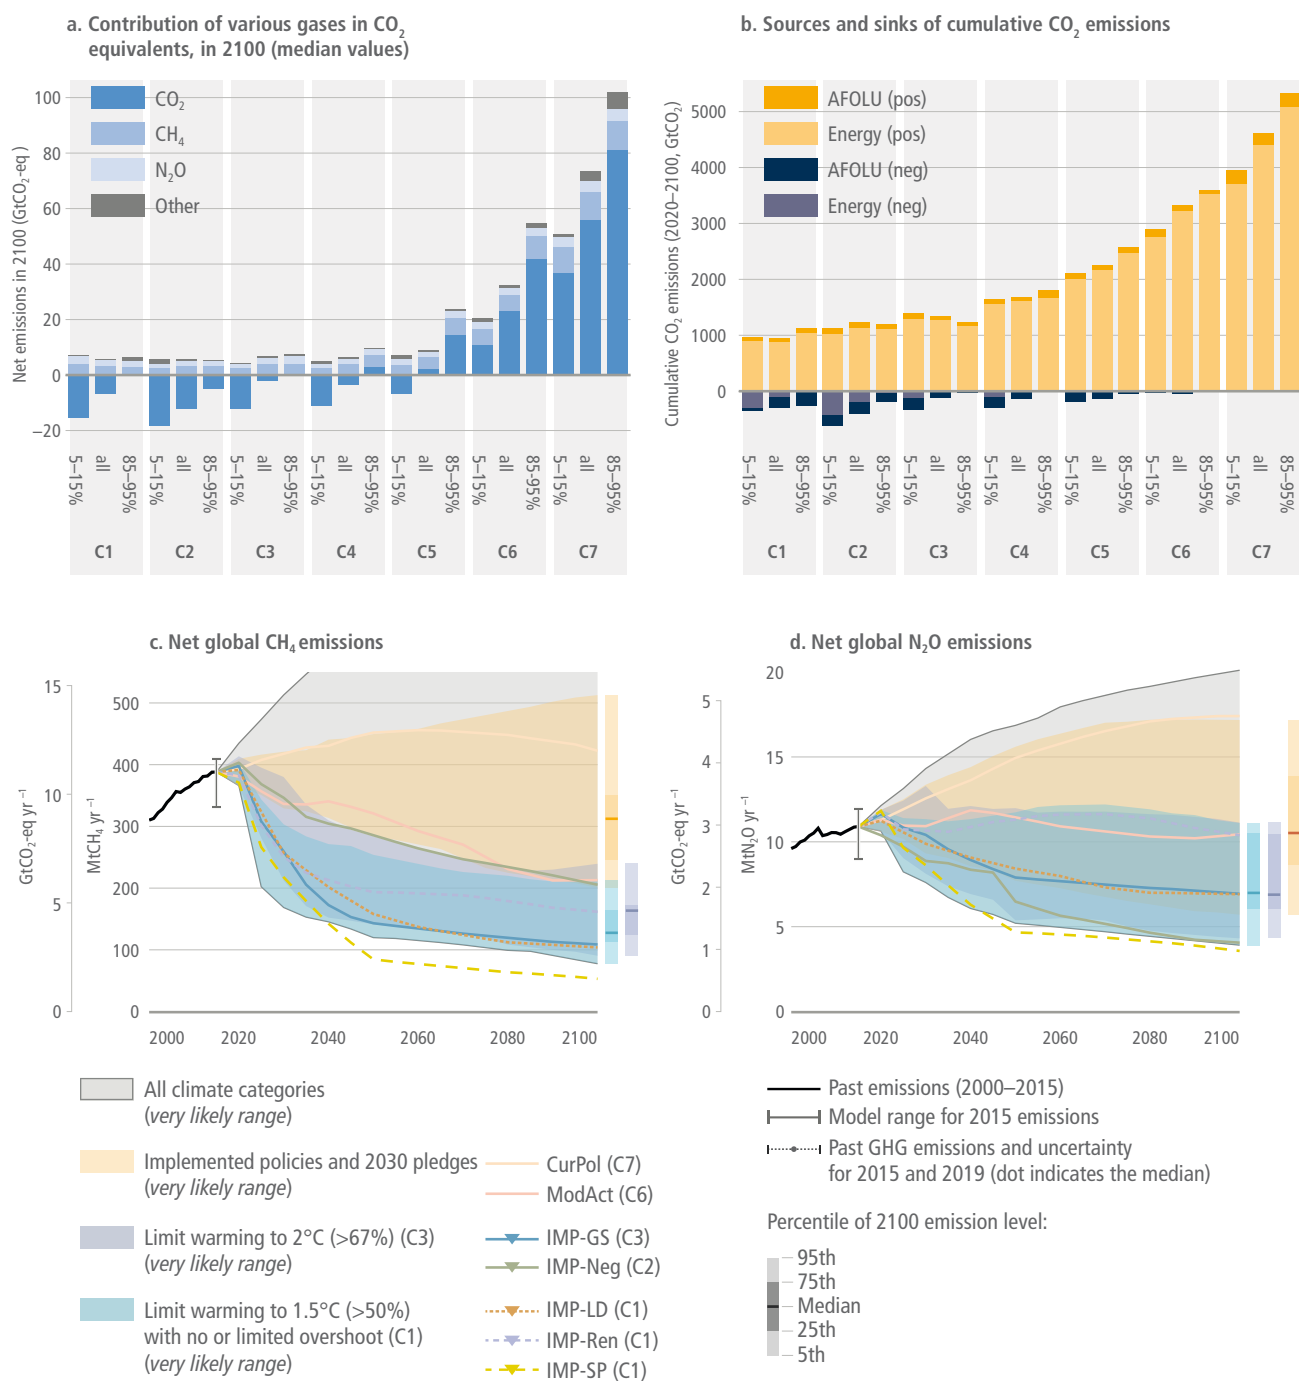

Figure 3.12 | (a) The role of CO₂ and other greenhouse gases. Emission in CO₂-eq in 2100 (using AR6 GWP-100) (other = halogenated gases) and **(b)** cumulative CO₂ emissions in the 2020–2100 period. Panels **(c)** and **(d)** show the development of CH₄ and N₂O emissions over time. Energy emissions include the contribution of BECCS. For both energy and AFOLU sectors, the positive and negative values represent the cumulated annual balances. In both panels, the three bars per scenario category represent the lowest 5–15th percentile, the average value and the highest 5–15th percentile. These illustrate the range of scenarios in each category. The definition of C1–C7 can be found in Table 3.1.

The trajectory of future CO₂ emissions plays a critical role in mitigation, given CO₂ long-term impact and dominance in total greenhouse gas forcing. As shown in Figure 3.12, CO₂ dominates total greenhouse gas emissions in the high-emissions scenarios but is also reduced most, going from scenarios in the highest to lower categories. In C4 and below, most scenarios exhibit net negative CO₂ emissions in the second half of the century compensating for some of the residual emissions of non-CO₂ gases as well as reducing overall warming from an intermediate peak. Still, early emission reductions and further reductions in non-CO₂ emissions can also lead to scenarios without net negative emissions in 2100, even in C1 and C3 (shown for the 85–95th percentile). In C1, avoidance of significant overshoot implies that immediate gross reductions are more relevant than long-term net negative emissions (explaining the lower number than in C2) but carbon dioxide removal (CDR) is still playing a role in compensating for remaining positive emissions in hard-to-abate sectors.

CH₄ and N₂O emissions are also reduced from C7 to C1, but this mostly occurs between C7 and C5. The main reason is the characteristics of abatement potential: technical measures can significantly reduce CH₄ and N₂O emissions at relatively low costs to about 50% of the current levels (e.g., by reducing CH₄ leaks from fossil fuel production and transport, reducing landfill emissions gazing, land management and introducing measures related to manure management, see also Chapter 7 and 11). However, technical potential estimates become exhausted even if the stringency of mitigation is increased (Harmsen et al. 2019a,b; Höglund-Isaksson et al. 2020). Therefore, further reduction may come from changes in activity levels, such as switching to a less meat-intensive diet, therefore reducing livestock (Stehfest et al. 2009; Willett et al. 2019; Ivanova et al. 2020) (Chapter 7). Other non-CO₂ GHG emissions (halogenated gases) are reduced to low levels for scenarios below 2.5°C.

Short-lived climate forcers (SLCFs) also play an important role in climate change, certainly for short-term changes (AR6 WGI, Figure SPM.2) (Shindell et al. 2012). These forcers consist of (i) substances contributing to warming, such as methane, black carbon and tropospheric ozone, and (ii) substances contributing to cooling (other aerosols, such as related to sulphur emissions). Most SLCFs are also air pollutants, and reducing their emissions provides additional co-benefits (Shindell et al. 2017a,b; Hanaoka and Masui 2020). In the case of the first group, emission reduction thus leads to both air pollution and climate benefits. For the second, group there is a possible trade-off (Shindell and Smith 2019; Lund et al. 2020). As aerosol emissions are mostly associated with fossil fuel combustion, the benefits of reducing CO₂ could, in the short term, be reduced as a result of lower aerosol cooling. There has been an active discussion on the exact climate contribution of SLCF-focused policies in the literature. This discussion partly emerged from different assumptions on possible reductions in the absence of ambitious climate policy and the uncertain global climate benefit from aerosol (black carbon) (Rogelj et al. 2014). The latter is now assessed to be smaller than originally thought (Takemura and Suzuki 2019; Smith et al. 2020b) (see also AR6 WGI Section 6.4). Reducing SLCF emissions is critical to meet long-term climate goals and might help reduce the rate of climate change in the short term. Deep SLCF emission reductions also increase the remaining carbon budget for a specific temperature goal (Rogelj et al. 2015a; Reisinger et al. 2021) (Box 3.4). A more detailed discussion can be found in AR6 WGI Chapters 5 and 6.

For accounting of emissions and the substitution of different gases as part of a mitigation strategy, typically, emission metrics are used to compare the climate impact of different gases. Most policies currently use Global Warming Potentials (GWPs) with a 100-year time horizon as this is also mandated for emissions reporting in the Paris Rulebook (for a wider discussion of GHG metrics, see Box 2.1 in Chapter 2 of this report, and AR6 WGI, Chapter 7, Section 7.6). Alternative metrics have also been proposed, such as those using a shorter or longer time horizon, or those that focus directly on the consequences of reaching a certain temperature target (Global Temperature Change Potential – GTP), allowing a more direct comparison with cumulative CO₂ emissions (Allen et al. 2016; Lynch et al. 2020) or focusing on damages (Global Damage Potential) (an overview is given in Chapter 2, and Cross-Chapter Box 3 in Chapter 3). Depending on the metric, the value attributed to reducing short-lived forcers such as methane can be lower in the near term (e.g., in the case of GTP) or higher (GWP with a short reference period). For most metrics, however, the impact on mitigation strategies is relatively small, among others, due to the marginal abatement cost curve of methane (low costs for low-to-medium mitigation levels; expensive for high levels). The timing of reductions across different gases impacts warming and the co-benefits (Harmsen et al. 2016; Cain et al. 2019). Nearly all scenarios in the literature use GWP-100 in cost-optimisation, reflecting the existing policy approach; the use of GWP-100 deviates from cost-optimal mitigation pathways by at most a few percent for temperature goals that limit warming to 2°C (>67%) or lower (Box 2.1).

Cumulative CO₂ emissions and temperature goals

The dominating role of CO₂ and its long lifetime in the atmosphere and some critical characteristics of the Earth System implies that there is a strong relationship between cumulative CO₂ emissions and temperature outcomes (Allen et al. 2009; Matthews et al. 2009; Meinshausen et al. 2009; MacDougall and Friedlingstein 2015). This is illustrated in Figure 3.13, which plots the cumulative CO₂ emissions against the projected outcome for global mean temperature, both until peak temperature and through to end of century (or 2100). The deviations from a linear relationship in Figure 3.13 are mostly caused by different non-CO₂ emission and forcing levels (see also Rogelj et al. 2015b). This means that reducing non-CO₂ emissions can play an important role in limiting peak warming: the smaller the residual non-CO₂ warming, the larger the carbon budget. This impact on carbon budgets can be substantial for stringent warming limits. For 1.5°C pathways, variations in non-CO₂ warming across different emission scenarios have been found to vary the remaining carbon budget by approximately 220 GtCO₂ (AR6 WGI Chapter 5, Section 5.5.2.2). In addition to reaching net zero CO₂ emissions, a strong reduction in methane emissions is the most critical component in non-CO₂ mitigation to keep the Paris climate goals in reach (Collins et al. 2018; van Vuuren et al. 2018) (see also AR6 WGI, Chapters 5, 6 and 7). It should be noted that the temperature categories (C1–C7) generally aligned with the horizontal axis, except for the end-of-century values for C1 and C2 that coincide.

Box 3.4 | Consistency of Remaining Carbon Budgets in the WGI Assessment and Cumulative CO₂ Emissions in WGIII Mitigation Pathways

Introduction

The WGI assessment has shown that the increase in global mean temperature has a near-linear relationship with cumulative CO₂ emissions (Chapter 5, Section 5.5, Box 5.3 of AR6 WGI report). Consistently, WGI has confirmed that net zero CO₂ emissions are required to halt CO₂-induced warming. This permits the estimation of carbon budgets consistent with specific temperature goals. In Chapter 3, we present the temperature outcomes and cumulative CO₂ emissions associated with different warming levels for around 1200 scenarios published in the literature and which were classified according to different warming levels (Section 3.2 and Annex III. II.3.2). In this box, we discuss the consistency of the assessments presented here and in IPCC AR6 WGI. The box summarises how the remaining carbon budgets assessed by AR6 WGI relate to the remaining cumulative CO₂ emissions until the time of net zero CO₂ emissions in mitigation pathways (Tables 3.2 and SPM.1) assessed by AR6 WGIII.

In its assessment, AR6 WGI uses a framework in which the various components of the remaining carbon budget are informed by various lines of evidence and assessed climate system characteristics. The AR6 WGIII, instead, uses around 1200 emission scenarios with estimated warming levels that cover the scenario range presented in AR6 WGI but also contain many more intermediate projections with varying emission profiles and a combination of CO₂ emissions and other greenhouse gases. In order to assess their climate outcomes, climate model emulators are used. The emulators are reduced complexity climate models that are provided by AR6 WGI, and which are calibrated to the AR6 WGI assessment of future warming for various purposes (a detailed description of the use of climate model emulators in the AR6 WGI and WGIII assessments can be found in Cross-Chapter Box 7.1 in the AR6 WGI report, with the connection of WGI and WGIII discussed in Annex III.2.5.1).

Remaining carbon budgets estimated by AR6 WGI

The AR6 WGI estimated the remaining carbon budgets from their assessment of (i) the transient climate response to cumulative emissions of carbon dioxide (TCRE), and estimates of (ii) the historical human-induced warming, (iii) the temperature change after reaching net zero CO₂ emissions, (iv) the contribution of future non-CO₂ warming (derived from the emissions scenarios assessed in the Special Report on 1.5°C Warming using WGI-calibrated emulators), and (v) the Earth System feedbacks (AR6 WGI Chapter 5.5, Box 5.2). For a given warming level, AR6 WGI assessed the remaining carbon budget from the beginning of 2020 onwards. These are 650/500/400 GtCO₂ for limiting warming to 1.5°C with 33%/50%/ 67% chance and 1350/1150 GtCO₂ for limiting warming to 2°C with 50%/67% chance. The estimates are subject to considerable uncertainty related to historical warming, future non-CO₂ forcing, and poorly quantified climate feedbacks. For instance, variation in non-CO₂ emissions across scenarios are estimated to either increase or decrease the remaining carbon budget estimates by 220 GtCO₂. The estimates of the remaining carbon budget assume that non-CO₂ emissions are reduced consistently with the tight temperature targets for which the budgets are estimated.

Cumulative CO₂ emissions until net zero estimated by AR6 WGIII

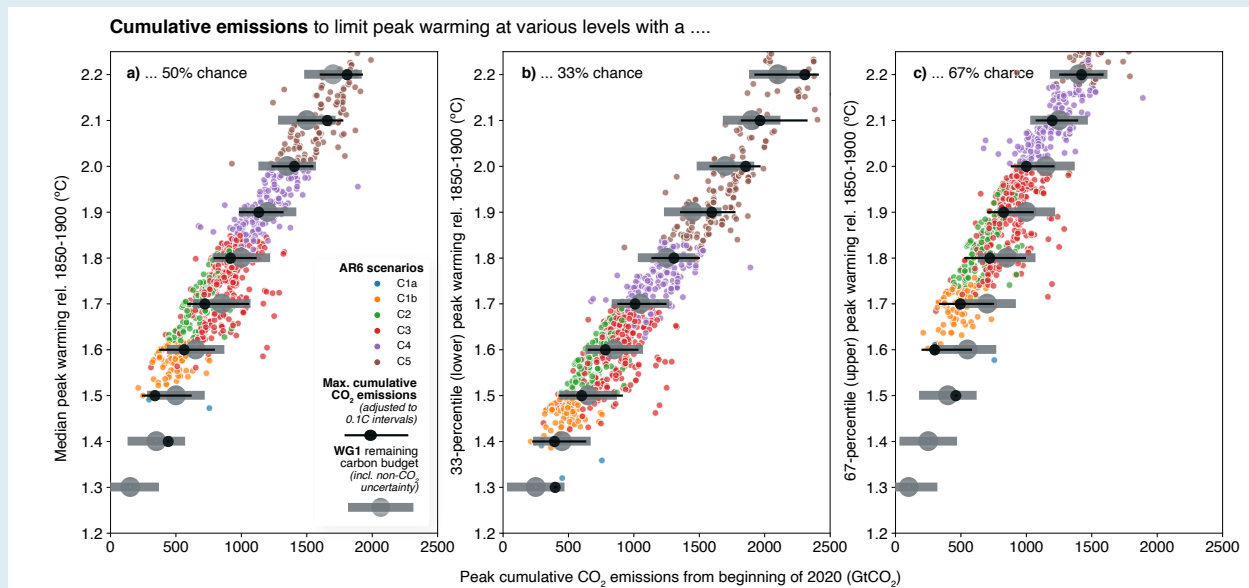

The AR6 WGIII provides estimates of cumulative net CO₂ emissions (from 2020 inclusive) until the time of reaching net zero CO₂ emissions (henceforth called 'peak cumulative CO₂ emissions') and until the end of the century for eight temperature classes that span a range of warming levels. The numbers can be found in Table 3.2 (330–710 GtCO₂ for C1; 530–930 for C2; and 640–1160 for C3).

Comparing the AR6 WGI remaining carbon budgets and remaining cumulative CO₂ emissions of the AR6 WGIII scenarios

A comparison between AR6 WGI and WGIII findings requires recognising that, unlike in WGI, cumulative emissions in WGIII are not provided for a specific peak-warming threshold or level but are instead provided for a set of scenarios in a category, representing a specific range of peak-temperature outcomes (for instance the C4 category contains scenarios with a median peak warming anywhere between approximately 1.8°C and up to 2°C). When accounting for this difference, the AR6 WGI and WGIII findings are very consistent for temperature levels below 2°C. Figure 1 compares the peak temperatures and associated cumulative CO₂ emissions (i.e., peak cumulative CO₂ emissions) for the WGIII scenarios to the remaining carbon budgets assessed by WGI. This shows only minor differences between the WGI and WGIII approaches.

After correcting for the categorisation, some (small) differences between the AR6 WGI and WGIII numbers arise from remaining differences between the outcomes of the climate emulators and their set-up (IPCC AR6 WGI Cross-Chapter Box 7.1) and the differences in the underlying scenarios. Moreover, the WGI assessment estimated the non-CO₂ warming at the time of net zero CO₂ emissions based on a relationship derived from the SR1.5 scenario database with historical emission estimates as in Meinshausen et al. (2020) (AR6 WGI Chapter 5). The WGIII assessment uses the same climate emulator with improved historical emissions estimates (Nicholls et al. 2021) (AR6 WGI Cross-Chapter Box 7.1). Annex III.2.5.1 further explores the effects of these factors on the relationship between non-CO₂ warming at peak cumulative CO₂ and peak surface temperature.

Box 3.4 (continued)

Box 3.4, Figure 1 | Cumulative CO₂ emissions from AR6 scenario categories (coloured dots), adjusted for distinct 0.1°C warming levels (black bars) in comparison to the WGI remaining carbon budgets (grey bars). The cumulative carbon emissions for the AR6 scenarios are shown for the median peak warming (a), the 33rd-percentile peak warming (b) and the upper 67th-percentile peak warming (c) calculated with the WGI-calibrated emulator MAGICC7 (IPCC AR6 WGI, Cross-Chapter Box 7.1). The adjustment to the nearest 0.1°C intervals is made using AR6 WGI TCRC (at the relevant percentile, e.g., the 67th-percentile TCRC is used to adjust the 67th-percentile peak warming), with the 5–95% range of adjusted scenarios provided by the black bar. The AR6 WGI remaining carbon budget is shown, including the WGI estimate of at least a ± 220 GtCO₂ uncertainty due to non-CO₂ emissions variations across scenarios (grey bars). For median peak warming (panel a) projections below 2°C relative to 1850–1900, the AR6 WGI assessment of cumulative carbon emissions tends to be slightly smaller than the remaining carbon budgets provided by WGI but well within the uncertainties. Note that only a few scenarios in WGI limit warming to below 1.5°C with a 50% chance, thus statistics for that specific threshold have low confidence.

Estimates of the remaining carbon budgets thus vary with the assumed level of non-CO₂ emissions, which are a function of policies and technology development. The linear relationship used in the AR6 WGI assessment between peak temperature and the warming as a result of non-CO₂ emissions (based on the SR1.5 data) is shown in the right panel of Figure 2 (dashed line). In the AR6 WGI approach, the non-CO₂ warming for each single scenario is based on the individual scenario characteristics. This is shown in the same figure by plotting the outcomes of scenario outcomes of a range of models (dots). The lines show the fitted data for individual models, emphasising the clear differences across models and the relationship with peak warming (policy level). In some scenarios, stringent non-CO₂ emission reductions provide an option to reach more stringent climate goals with the same carbon budget. This is especially the case for scenarios with a very low non-CO₂ warming, for instance, as a result of methane reductions through diet change. The left panel shows how these differences impact estimates of the remaining carbon budget. While the AR6 scenarios database includes a broad range of non-CO₂ emission projections the overall range is still very consistent with the WGI relationship and the estimated uncertainty with a ± 220 GtCO₂ range (see also Figure 5 in Annex III.II.2.5.1).

Overall, the slight differences between the cumulative emissions in AR6 WGI and the carbon budget in AR6 WGI are because the non-CO₂ warming in the WGI scenarios is slightly lower than in the SR1.5 scenarios that are used for the budget estimates in WGI (Annex III.2.5.1). In addition, improved consistency with Cross-Chapter Box 7.1 in Chapter 7, AR6 WGI results in a non-CO₂-induced temperature difference of about 0.05K between the assessments. Recalculating the remaining carbon budget using the WGI methodology combined with the full AR6 WGI scenario database results in a reduction of the estimated remaining 1.5°C carbon budget by about 100 GtCO₂ (–20%), and a reduction of about 40 GtCO₂ (–3%) for 2°C. Accounting also for the categorisation effect, the difference between the WGI and WGI estimates is found to be small and well within the uncertainty range (Figure 1). This means that the cumulative CO₂ emissions presented in WGI and the WGI carbon budgets are highly consistent.

A detailed comparison of the impact of different assessment steps (i.e., the new emulators, scenarios, and harmonisation methods), has been made and is presented in Figure 6 in Annex III.II.3.2.

Box 3.4 (continued)

Box 3.4, Figure 2 | (a) Differences in regressions of the relationship between peak surface temperature and associated cumulative CO₂ emissions from 2020 derived from scenarios of eight integrated assessment model frameworks. The coloured lines show the regression at median for scenarios of the eight modelling frameworks, each with more than 20 scenarios in the database and a detailed land-use representation. The red dotted lines indicate the non-CO₂ uncertainty range of AR6 WGI Chapter 5 (± 220 GtCO₂), here visualised around the median of the eight model framework lines. Carbon budgets from 2020 until 1.5°C (0.43K above 2010–2019 levels) and 2.0°C (0.93K above 2010–2019 levels) are shown for minimum and maximum model estimates at the median, rounded to the nearest 10 GtCO₂. Panel (b) shows the relationship between the estimated non-CO₂ warming in mitigation scenarios that reach net zero and the associated peak surface temperature outcomes. The coloured lines show the regression at median for scenarios of the eight modelling frameworks with more than 20 scenarios in the database and a detailed land-use representation. The black dashed line indicates the non-CO₂ relationship based on the scenarios and climate emulator setup as was assessed in AR6 WGI Chapter 5.

Policy implications

The concept of a finite carbon budget means that the world needs to get to net zero CO₂, no matter whether global warming is limited to 1.5°C or well below 2°C (or any other level). Moreover, exceeding the remaining carbon budget will have consequences by overshooting temperature levels. Still, the relationship between the timing of net zero and temperature targets is a flexible one, as discussed further in Cross-Chapter Box 3 in this chapter. It should be noted that the national-level inventory as used by UNFCCC for the land use, land-use change and forestry sector is different from the overall concept of anthropogenic emissions employed by IPCC AR6 WGI. For emissions estimates based on these inventories, the remaining carbon budgets must be correspondingly reduced by approximately 15%, depending on the scenarios (Grassi et al., 2021) (Chapter 7).

One of the uncertainties of the remaining carbon budget is the level of non-CO₂ emissions which is a function of policies and technology development. This represents a point of leverage for policies rather than an inherent geophysical uncertainty. Stringent non-CO₂ emission reductions hence can provide – to some degree – an option to reach more stringent climate goals with the same carbon budget.

The near-linear relationship implies that cumulative CO₂ emissions are critically important for climate outcomes (Collins et al. 2013). The maximum temperature increase is a direct function of the cumulative emissions until net zero CO₂ emissions is reached (the emission budget) (Figure 3.13, left side). The end-of-century temperature correlates well with cumulative emissions across the century (right panel). For long-term climate goals, positive emissions in the first half of the century can be offset by net removal of CO₂ from the atmosphere (net negative emissions) at the cost of a temporary overshoot of the target (Tokarska et al. 2019). The bottom panels of Figure 3.13 show the contribution of net negative CO₂ emissions.

Focusing on cumulative emissions, the right-hand panel of Figure 3.12b shows that for high-end scenarios (C6–C7), most emissions originate from fossil fuels, with a smaller contribution from net deforestation. For C5 and lower, there is also a negative contribution to emissions from both AFOLU emissions and energy

systems. For the energy systems, these negative emissions originate from bioenergy with carbon capture and storage (BECCS), while for AFOLU, they originate from reforestation and afforestation. For C3–C5, reforestation has a larger CDR contribution than BECCS, mostly due to considerably lower costs (Rochedo et al. 2018). For C1 and C2, the tight carbon budgets imply in many scenarios more CDR use (Riahi et al. 2021). Please note that net negative emissions are not so relevant for peak-temperature targets, and thus the C1 category, but CDR can still be used to offset the remaining positive emissions (Riahi et al. 2021). While positive CO₂ emissions from fossil fuels are significantly reduced, inertia and hard-to-abate sectors imply that in many C1–C3 scenarios, around 800–1000 GtCO₂ of net positive cumulative CO₂ emissions remain. This is consistent with literature estimates that current infrastructure is associated with 650 GtCO₂ (best estimate) if operated until the end of its lifetime (Tong et al. 2019). These numbers are considerably above the estimated carbon budgets for 1.5°C estimated in AR6 WGI, hence explaining CDR reliance (either to offset emissions immediately or later in time).

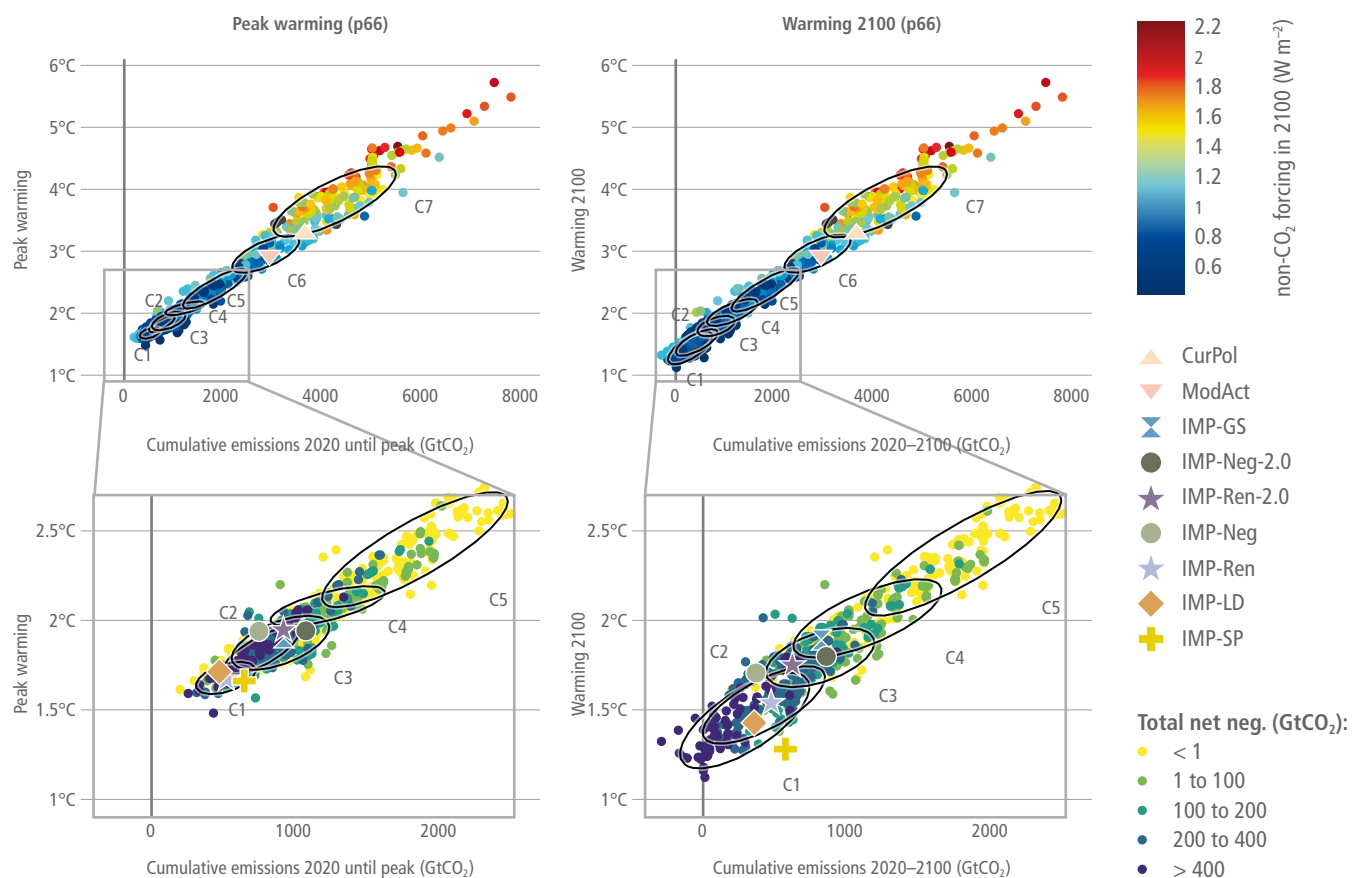

Figure 3.13 | The near-linear relationship between cumulative CO₂ emissions and temperature. The left panel shows cumulative emissions until net zero emission is reached. The right panel shows cumulative emissions until the end of the century, plotted against peak and end-of-century temperature, respectively. Both are shown as a function of non-CO₂ forcing and cumulative net negative CO₂ emissions. Position temperature categories (circles) and IPs are also indicated, including two 2°C sensitivity cases for *Neg* (Neg-2.0) and *Ren* (Ren-2.0).

Creating net negative emissions can thus be an important part of a mitigation strategy to offset remaining emissions or compensate for emissions earlier in time. As indicated above, there are different ways to potentially achieve this, including reforestation and afforestation and BECCS (as often covered in IAMs) but also soil carbon enhancement, direct air carbon capture and storage (DACCS) and ocean alkalisation (Chapter 12). Except for reforestation, these options have not been tested at large scale and often require more R&D. Moreover, the reliance on CDR in scenarios has been discussed given possible consequences of land use related to biodiversity loss and food security (BECCS and afforestation), the reliance on uncertain storage potentials (BECCS and DACCS), water use (BECCS), energy use (DACCS), the risks of possible temperature overshoot and the consequences for meeting Sustainable Development Goals (SDGs) (Anderson and Peters 2016; Smith et al. 2016; Venton 2016; Peters and Geden 2017; van Vuuren et al. 2017; Honegger et al. 2021). In the case of BECCS, it should be noted that bioenergy typically is associated with early-on positive CO₂ emissions and net negative effects are only achieved in time (carbon debt), and its potential is limited (Cherubini et al. 2013; Hanssen et al. 2020); most IAMs have only a very limited representation of these time dynamics. Several scenarios have therefore explored how reliance on net negative CO₂ emissions can be reduced or even avoided by alternative emission strategies (Grubler et al. 2018; van Vuuren et al. 2018) or early reductions by more stringent emission reduction in the short term (Rogelj et al. 2019b; Riahi et al. 2021). A more in-depth discussion of land-based mitigation options can be found in Chapter 7. It needs to be emphasised that even in strategies with net negative CO₂ emissions, the emission reduction via more conventional mitigation measures (efficiency improvement, decarbonisation of energy supply) is much larger than the CDR contribution (Tsutsui et al. 2020).

3.3.2.3 The Timing of Net Zero Emissions

In addition to the constraints on change in global mean temperature, the Paris Agreement also calls for reaching a balance of sources and sinks of GHG emissions (Art. 4). Different interpretations of the concept related to balance have been published (Rogelj et al. 2015c; Fuglestad et al. 2018). Key concepts include that of net zero CO₂ emissions (anthropogenic CO₂ sources and sinks equal zero) and net zero greenhouse gas emissions (see Annex I: Glossary, and Box 3.3). The same notion can be used for all GHG emissions, but here ranges also depend on the use of equivalence metrics (Box 2.1). Moreover, it should be noted that while reaching net zero CO₂ emissions typically coincides with the peak in temperature increase; net zero GHG emissions (based on GWP-100) imply a decrease in global temperature (Riahi et al. 2021) and net zero GHG emissions typically require negative CO₂ emissions to compensate for the remaining emissions from other GHGs. Many countries have started to formulate climate policy in the year that net zero emissions (either CO₂ or all greenhouse gases) are reached – although, at the moment, formulations are often still vague (Rogelj et al. 2021). There has been increased attention on the timing of net zero emissions in the scientific literature and ways to achieve it.

Figure 3.14 shows that there is a relationship between the temperature target, the cumulative CO₂ emissions budget, and the net zero year for CO₂ emissions (panel a) and the sum of greenhouse gases (panel b) for the scenarios published in the literature. In other words, the temperature targets from the Paris Agreement can, to some degree, be translated into a net-zero emission year (Tanaka and O'Neill 2018). There is, however, a considerable spread. In addition to the factors influencing the emission budget (AR6 WGI and Section 3.3.2.2), this is influenced by the emission trajectory until net zero is reached, decisions related to temperature overshoot and non-CO₂ emissions (especially for the moment CO₂ reaches net zero emissions). Scenarios with limited or no net negative emissions and rapid near-term emission reductions can allow small positive emissions (e.g., in hard-to-abate-sectors). They may therefore have a later year that net zero CO₂ emissions are achieved. High emissions in the short term, in contrast, require an early net zero year.

For the scenarios in the C1 category (limit warming to 1.5°C (>50% with no or limited overshoot, the net zero year for CO₂ emissions is typically around 2035–2070. For scenarios in C3 (limiting warming to 2°C (>67%)), CO₂ emissions reach net zero around after 2050. Similarly, also the years for net zero GHG emissions can be calculated (see Fig 3.14b). The GHG net zero emissions year is typically around 10–40 years later than the carbon neutrality. Residual non-CO₂ emissions at the time of reaching net zero CO₂ range between 5–11 GtCO₂-eq in pathways that limit warming to 2°C (>67%) or lower. In pathways limiting warming to 2°C (>67%), methane is reduced by around 19% (3–46%) in 2030 and 46% (29–64%) in 2050, and in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot by around 34% (21–57%) in 2030 and a similar 51% (35–70%) in 2050. Emissions-reduction potentials assumed in the pathways become largely exhausted when limiting warming to 2°C (>50%). N₂O emissions are reduced too, but similar to CH₄, emission reductions saturate for stringent climate goals. In the mitigation pathways, the emissions of cooling aerosols are reduced due to reduced use of fossil fuels. The overall impact on non-CO₂-related warming combines these factors.

In cost-optimal scenarios, regions will mostly achieve net zero emissions as a function of options for emission reduction, CDR, and expected baseline emission growth (van Soest et al. 2021b). This typically implies relatively early net zero emission years in scenarios for the Latin America region and relatively late net zero years for Asia and Africa (and average values for OECD countries). However, an allocation based on equity principles (such as responsibility, capability and equality) might result in different net zero years, based on the principles applied – with often earlier net zero years for the OECD (Fyson et al. 2020; van Soest et al. 2021b). Therefore, the emission trajectory until net zero emissions is a critical determinant of future warming (Section 3.5). The more CO₂ is emitted until 2030, the less CO₂ can be emitted after that to stay below a warming limit (Riahi et al. 2015). As discussed before, also non-CO₂ forcing plays a key role in the short term.

Figure 3.14 | Net zero year for CO₂ and all GHGs (based on AR6 GWP100) as a function of remaining carbon budget and temperature outcomes (note that scenarios that stabilise (near) zero are also included in determining the net zero year).

Cross-Chapter Box 3 | Understanding Net Zero CO₂ and Net Zero GHG Emissions

This Cross-Chapter Box surveys scientific, technical and policy aspects of net zero carbon dioxide (CO₂) and net zero greenhouse gas (GHG) emissions, with a focus on timing, the relationship with warming levels, and sectoral and regional characteristics of net zero emissions. Assessment of net zero GHG emissions additionally requires consideration of non-CO₂ gases and choice of GHG emission metrics used to aggregate emissions and removals of different GHGs (Cross-Chapter Box 2 in Chapter 2 and Cross-Chapter Box 7 in Chapter 10). The following considers net zero CO₂ and GHG emissions globally, followed by regional and sectoral dimensions.

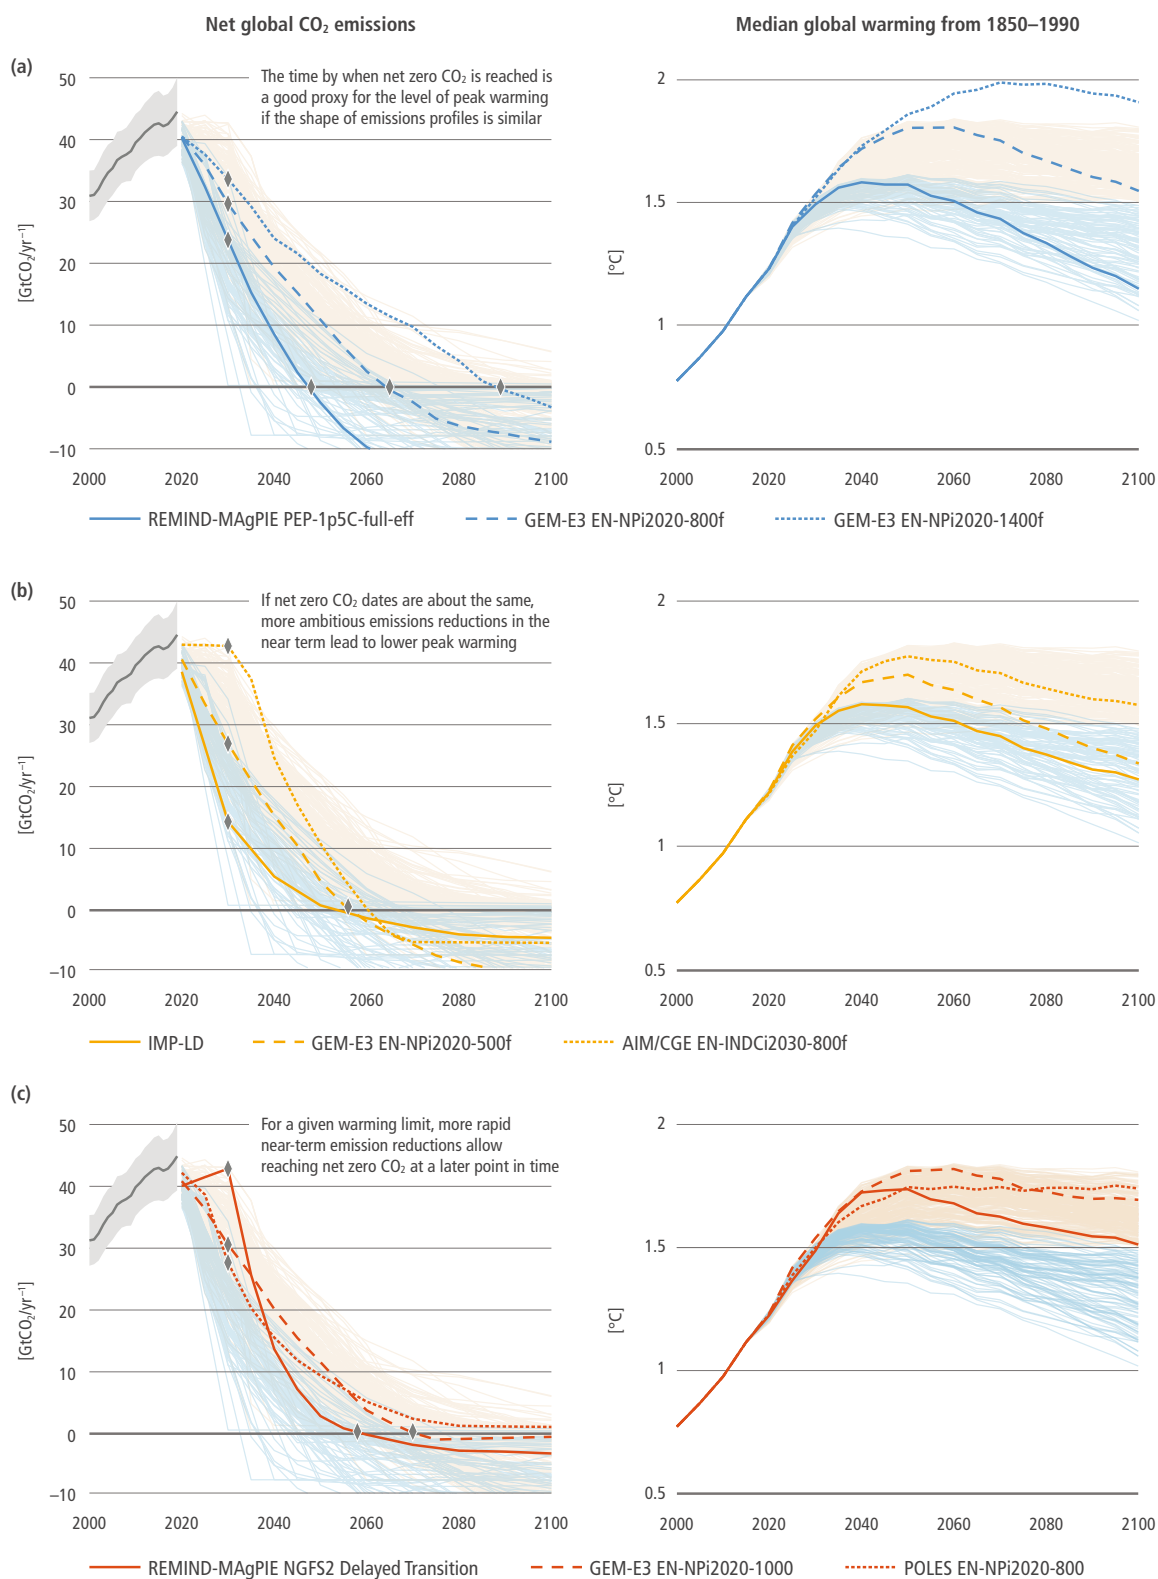

Net zero CO₂ emissions

Reaching net zero CO₂ emissions globally is necessary for limiting global warming to any level. At the point of net zero CO₂, the amount of CO₂ human activity is putting into the atmosphere equals the amount of CO₂ human activity is removing from the atmosphere (see Annex I: Glossary). Reaching and sustaining net zero CO₂ emissions globally stabilizes CO₂-induced warming. Reaching net zero CO₂ emissions and then moving to net negative CO₂ emissions globally leads to a peak and decline in CO₂-induced warming (AR6 WGI Sections 5.5 and 5.6).

Limiting warming to 1.5°C (>50%) or to 2°C (>67%) requires deep, rapid, and sustained reductions of other greenhouse gases including methane alongside rapid reductions of CO₂ emissions to net zero. This ensures that the warming contributions from non-CO₂ forcing agents as well as from CO₂ emissions are both limited at low levels. The AR6 WGI estimated remaining carbon budgets until the time of reaching net zero CO₂ emissions for a range of warming limits, taking into account historical CO₂ emissions and projections of the warming from non-CO₂ forcing agents (Box 3.4 in Section 3.3, AR6 WGI Section 5.5).

The earlier global net zero CO₂ emissions are reached, the lower the cumulative net amount of CO₂ emissions and human-induced global warming, all else being equal (Figure 1a in this Cross-Chapter Box). For a given net zero date, a variation in the shape of the CO₂ emissions profile can lead to a variation in the cumulative net amount of CO₂ emissions until the time of net zero CO₂ and as a result to different peak-warming levels. For example, cumulative net CO₂ emissions until the time of reaching net zero CO₂ will be smaller, and peak warming lower, if emissions are reduced steeply and then more slowly compared to reducing emissions slowly and then more steeply (Figure 1b in this Cross-Chapter Box).

Cross-Chapter Box 3 (continued)

Cross-Chapter Box 3, Figure 1 | Selected global CO₂ emissions trajectories with similar shape and different net zero CO₂ date (a), different shape and similar net zero CO₂ date (b), and similar peak warming, but varying shapes and net zero CO₂ dates (c). Funnels show pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (light blue) and limiting warming to 2°C (>67%) (beige). Historic CO₂ emissions from Section 2.2 (EDGAR v6).

Cross-Chapter Box 3 (continued)

Net zero CO₂ emissions are reached between 2050–2055 (2035–2070) in global emissions pathways limiting warming to 1.5°C (>50%) with no or limited overshoot, and between 2070–2075 (2055–...) in pathways limiting warming to 2°C (>67%) as reported in the AR6 scenarios database (median five-year interval and 5–95th percentile ranges).⁵ The variation of non-CO₂ emissions in 1.5°C–2°C pathways varies the available remaining carbon budget which can move the time of reaching net zero CO₂ in these pathways forward or backward.⁶ The shape of the CO₂ emissions reduction profile also affects the time of reaching net zero CO₂ (Figure 1c in this Cross-Chapter Box). Global emission pathways that more than halve CO₂ emissions from 2020 to 2030 can follow this rapid reduction by a more gradual decline towards net zero CO₂ and still limit warming to 1.5°C with no or limited overshoot, reaching the point of net zero after 2050. The literature since SR1.5 included a larger fraction of such pathways than were available at the time of SR1.5. This is the primary reason for the small backward shift in the median estimate of reaching global net zero CO₂ emissions in 1.5°C pathways collected in the AR6 scenario database compared to SR1.5. This does not mean that the world is assessed to have more time to rapidly reduce current emissions levels compared to SR1.5. The assessment of emissions reductions by 2030 and 2040 in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot has not changed substantially. It only means that the exact timing of reaching net zero CO₂ after a steep decline of CO₂ emissions until 2030 and 2040 can show some variation, and the SR1.5 median value of 2050 is still close to the middle of the current range (Figure 1c in this Cross-Chapter Box).

Pathways following emissions levels projected from the implementation of Nationally Determined Contributions (NDCs) announced prior to COP26 until 2030 would result in substantially (>0.1°C) exceeding 1.5°C. They would have to reach net zero CO₂ around 5–10 years later⁷ than in pathways with no or limited overshoot in order to reach the net negative emissions that would then be required to return warming to 1.5°C (>50%) after a high overshoot by 2100. Those high overshoot pathways have higher transient warming and higher reliance on net negative CO₂ emissions towards the end of the 21st century. As they need to reach net zero CO₂ emissions in only limited amount of time but from much higher 2030 emissions levels, their post-2030 CO₂ emissions reduction rates are substantially higher (by around 30%) than in pathways limiting warming to 1.5°C with no or limited overshoot. (Section 3.5).

Pathways following emissions levels projected from the implementation of NDCs announced prior to COP26 until 2030 would have to reach net zero CO₂ around 5 years earlier⁸ than cost-effective pathways that limit warming to 2°C (>67%). While cost-effective pathways take around 50–55 years to reach net zero CO₂ emissions, those pathways would only have 35–40 years left for transitioning to net zero CO₂ from 2030 onwards, close to the transition times that 1.5°C pathways are faced with today. Current CO₂ emissions and 2030 emission levels projected under the NDCs announced prior to COP26 are in a similar range (Sections 3.5 and 4.2).

Net zero greenhouse gas (GHG) emissions

The amount of CO₂-equivalent emissions and the point when net zero GHG emissions are reached in multi-GHG emissions pathways depends on the choice of GHG emissions metric. Various GHG emission metrics are available for this purpose.⁹ GWP-100 is the most commonly used metric for reporting CO₂-equivalent emissions and is required for emissions reporting under the Rulebook of the Paris Agreement. (Cross-Chapter Box 2 in Chapter 2, Annex I and Annex II.9)

⁵ A small fraction of pathways in the AR6 scenarios database that limit warming to 2°C (7% for C3 and 14% for C4) do not reach net zero CO₂ emissions during the 21st century. This is not inconsistent with the fundamental scientific requirement to reach net zero CO₂ emissions for a stable climate, but reflects that in some pathways, concurrent reductions in non-CO₂ emissions temporarily compensate for ongoing warming from CO₂ emissions. These would have to reach net zero CO₂ emissions eventually after 2100 to maintain these warming limits. For the two classes of pathways, the 95th percentile cannot be deduced from the scenario database as more than 5% of them do not reach net zero CO₂ by 2100.

⁶ The AR6 WGI Section 5.5 estimates a variation of the remaining carbon budget by ± 220 GtCO₂ due to variations of the non-CO₂ warming contribution in 1.5°C–2°C pathways. This translates to a shift of the timing of net zero CO₂ by about ± 10 years, assuming global CO₂ emissions decrease linearly from current levels of around 40 GtCO₂ to net zero.

⁷ Pathways following emissions levels of NDCs announced prior to COP26 to 2030 and then returning warming to 1.5°C (>50%) after high overshoot by 2100 reach net zero during 2055–2060 (2045–2070) (median five-year interval and 5–95th percentile range).

⁸ Pathways that follow emission levels projected from the implementation of NDCs announced prior to COP26 until 2030 and that still limit warming to 2°C (>67%) reach net zero CO₂ emissions during 2065–2070 (2055–2090) compared with 2070–2075 (2055–...) in cost-effective pathways acting immediately to *likely* limit warming to 2°C (median five-year interval and 5–95th percentile range). See Footnote 5 for the lack of 95th percentile (Section 3.3 and Table 3.2).

⁹ Defining net zero GHG emissions for a basket of greenhouse gases (GHGs) relies on a metric to convert GHG emissions including methane (CH₄), nitrous oxide (N₂O), fluorinated gases (F-gases), and potentially other gases, to CO₂-equivalent emissions. The choice of metric ranges from global warming potentials (GWPs) and global temperature change potentials (GTP) to economically oriented metrics. All metrics have advantages and disadvantages depending on the context in which they are used (Cross-Chapter Box 2 in Chapter 2).

Cross-Chapter Box 3 (continued)

For most choices of GHG emissions metric, reaching net zero GHG emissions requires net negative CO₂ emissions in order to balance residual CH₄, N₂O and F-gas emissions. Under foreseen technology developments, some CH₄, N₂O and F-gas emissions from, for example, agriculture and industry, will remain over the course of this century. Net negative CO₂ emissions will therefore be needed to balance these remaining non-CO₂ GHG emissions to obtain net zero GHG emissions at a point in time after net zero CO₂ has been reached in emissions pathways. Both the amount of net negative CO₂ emissions and the time lag to reaching net zero GHG depend on the choice of GHG emission metric.

Reaching net zero GHG emissions globally in terms of GWP-100 leads to a reduction in global warming from an earlier peak. This is due to net negative CO₂ emissions balancing the GWP-100-equivalent emissions of short-lived GHG emissions, which by themselves do not contribute to further warming if sufficiently declining (Fuglestad et al. 2018; Rogelj et al. 2021). Hence, 1.5°C–2°C emissions pathways in the AR6 scenario database that reach global net zero GHG emissions in the second half of the century show warming being halted at some peak value followed by a gradual decline towards the end of the century (AR6 WGI Chapter 1, Box 1.4).

Global net zero GHG emissions measured in terms of GWP-100 are reached between 2095 and 2100 (2050–...)¹⁰ in emission pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (median and 5–95th percentile). Around 50% of pathways limiting warming to 1.5°C (>50%) with no or limited overshoot and 70% of pathways limiting warming to 2°C (>67%) do not reach net zero GHG emissions in terms of GWP-100 before 2100. These pathways tend to show less reduction in warming after the peak than pathways that reach net zero GHG emissions. For the subset of pathways that reach net zero GHG emissions before 2100, including around 90% of pathways that return warming to 1.5°C after a high overshoot (>0.1°C) by 2100, the time lag between reaching net zero CO₂ and net zero GHG is 12–14 (7–39) years and the amount of net negative CO₂ emissions deployed to balance non-CO₂ emissions at the time of net zero GHG is around -7 (–10 to –4) GtCO₂ (range of medians and lowest 5th to highest 95 percentile across the four scenario classes that limit median warming to 2°C or lower) (Section 3.3 and Table 3.2).

Sectoral and regional aspects of net zero

The timing of net zero CO₂ or GHG emissions may differ across regions and sectors. Achieving net zero emissions globally implies that some sectors and regions must reach net zero CO₂ or GHG ahead of the time of global net zero CO₂ or GHG if others reach it later. Similarly, some sectors and regions would need to achieve net negative CO₂ or GHG emissions to compensate for continued emissions by other sectors and regions after the global net zero year. Differences in the timing to reach net zero emissions between sectors and regions depend on multiple factors, including the potential of countries and sectors to reduce GHG emissions and undertake carbon dioxide removal (CDR), the associated costs, and the availability of policy mechanisms to balance emissions and removals between sectors and countries (Fyson et al. 2020; Streffler et al. 2021a; van Soest et al. 2021b). A lack of such mechanisms could lead to higher global costs to reach net zero emissions globally, but less interdependencies and institutional needs (Fajardy and Mac Dowell 2020). Sectors will reach net zero CO₂ and GHG emissions at different times if they are aiming for such targets with sector-specific policies or as part of an economy-wide net zero emissions strategy integrating emissions reductions and removals across sectors. In the latter case, sectors with large potential for achieving net negative emissions would go beyond net zero to balance residual emissions from sectors with low potential, which in turn would take more time compared to the case of sector-specific action. Global pathways project global AFOLU emissions to reach global net zero CO₂ the earliest, around 2030 to 2035 in pathways to limit warming to 2°C (>67%) or lower, by rapid reduction of deforestation and enhancing carbon sinks on land, although net zero GHG emissions from global AFOLU are typically reached 30 years later, if at all. The ability of global AFOLU CO₂ emissions to reach net zero as early as in the 2030s in modelled pathways hinges on optimistic assumptions about the ability to establish global cost-effective mechanisms to balance emissions reductions and removals across regions and sectors. These assumptions have been challenged in the literature and the *Special Report on Climate Change and Land* (IPCC SRCCL).

The adoption and implementation of net zero CO₂ or GHG emission targets by countries and regions also depends on equity and capacity criteria. The Paris Agreement recognises that peaking of emissions will occur later in developing countries (Art. 4.1). Just transitions to net zero CO₂ or GHG could be expected to follow multiple pathways, in different contexts. Regions may decide about net zero pathways based on their consideration of potential for rapid transition to low-carbon development pathways, the capacity to design and implement those changes, and perceptions of equity within and across countries. Cost-effective pathways from global models have been shown to distribute the mitigation effort unevenly and inequitably in the absence of financial support mechanisms and capacity building (Budolfson et al. 2021), and hence would require additional measures to become aligned with

¹⁰ The 95th percentile cannot be deduced from the scenario database as more than 5% of pathways do not reach net zero GHG by 2100 (Section 3.3 and Table 3.2.), hence denoted by -....

Cross-Chapter Box 3 (continued)

equity considerations (Fyson et al. 2020; van Soest et al. 2021b). Formulation of net zero pathways by countries will benefit from clarity on scope, roadmaps and fairness (Rogelj et al. 2021; Smith 2021). Achieving net zero emission targets relies on policies, institutions and milestones against which to track progress. Milestones can include emissions levels, as well as markers of technological diffusion.

The accounting of anthropogenic carbon dioxide removal on land matters for the evaluation of net zero CO₂ and net zero GHG strategies. Due to the use of different approaches between national inventories and global models, the current net CO₂ emissions are lower by 5.5 GtCO₂, and cumulative net CO₂ emissions in modelled 1.5°C–2°C pathways would be lower by 104–170 GtCO₂, if carbon dioxide removals on land are accounted based on national GHG inventories. National GHG inventories typically consider a much larger area of managed forest than global models, and on this area additionally consider the fluxes due to human-induced global environmental change (indirect effects) to be anthropogenic, while global models consider these fluxes to be natural. Both approaches capture the same land fluxes, only the accounting of anthropogenic vs natural emissions is different. Methods to convert estimates from global models to the accounting scheme of national GHG inventories will improve the use of emission pathways from global models as benchmarks against which collective progress is assessed. (Section 7.2.2.5).

Net zero CO₂ and carbon neutrality have different meanings in this assessment, as is the case for net zero GHG and GHG neutrality. They apply to different boundaries in the emissions and removals being considered. Net zero (GHG or CO₂) refers to emissions and removals under the direct control or territorial responsibility of the reporting entity. In contrast, (GHG or carbon) neutrality includes anthropogenic emissions and anthropogenic removals within and also those beyond the direct control or territorial responsibility of the reporting entity. At the global scale, net zero CO₂ and carbon neutrality are equivalent, as is the case for net zero GHG and GHG neutrality. The term ‘climate neutrality’ is not used in this assessment because the concept of climate neutrality is diffuse, used differently by different communities, and not readily quantified.

Table 3.2 summarises the key characteristics for all temperature categories in terms of cumulative CO₂ emissions, near-term emission reductions, and the years of peak emission and net zero CO₂ and GHG emissions. The table shows again that many pathways in the literature limit global warming to 2°C (>67%) or limit warming to 1.5°C (>50%) with no or limited overshoot compared to pre-industrial levels. Cumulative net CO₂ emissions from the year 2020 until the time of net zero CO₂ in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot are 510 (330–710) GtCO₂ and in pathways that limit warming to 2°C (>67%), 890 (640–1160) GtCO₂ (see also Cross-Chapter Box 3 in this chapter). Mitigation pathways that limit warming to 2°C (>67%) compared to pre-industrial levels are associated with net global GHG emissions of 44 (32–55) GtCO₂-eq yr⁻¹ by 2030 and 20 (13–26) GtCO₂-eq yr⁻¹ in 2050. These correspond to GHG emissions reductions of 21% (1–42%) by 2030, and 64% (53–77%) by 2050 relative to 2019 emission levels. Pathways that limit global warming to 1.5°C (>50%) with no or limited overshoot require a further acceleration in the pace of the transformation, with GHG emissions reductions of 43% (34–60%) by 2030 and 84% (73–98%) in 2050 relative to modelled 2019 emission levels. The likelihood of limiting warming to below 1.5°C (>50%) with no or limited overshoot of the most stringent mitigation pathways in the literature (C1) has declined since SR1.5. This is because emissions have risen since 2010 by about 9 GtCO₂ yr⁻¹, resulting in relatively higher near-term emissions of the AR6 pathways by 2030 and slightly later dates for reaching net zero CO₂ emissions compared to SR1.5.

Given the larger contribution of scenarios in the literature that aim to reduce net negative emissions, emission reductions are somewhat larger in the short term compared to similar categories in the IPCC SR1.5. At the same time, the year of net zero emissions is somewhat later (but only if these rapid, short-term emission reductions are achieved). The scenarios in the literature in C1–C3 show a peak in global emissions before 2025. Not achieving this requires a more rapid reduction after 2025 to still meet the Paris goals (Section 3.5).

Table 3.2 | GHG, CO₂ emissions and warming characteristics of different mitigation pathways submitted to the AR6 scenarios database and as categorised in the climate assessment.

p50 [p5–p95] ^a			GHG emissions Gt CO ₂ -eq/yr ^g			GHG emissions reductions from 2019 % ^h			Emissions milestones ^{ij}				Cumulative CO ₂ emissions Gt CO ₂ ^m		Cumulative net-negative CO ₂ emissions Gt CO ₂	Global mean temperature changes 50% probability ⁿ °C		Likelihood of peak global warming staying below (%) ^o			Time when specific global warming levels are reached (with a 50% probability)

Table 3.2 (continued):

^a Values in the table refer to the 50th and [5th–95th] percentile values across the pathways falling within a given category as defined in Box SPM.1. For emissions-related columns these values relate to the distribution of all the pathways in that category. Harmonised emissions values are given for consistency with projected global warming outcomes using climate emulators. Based on the assessment of climate emulators in AR6 WGI (WG1 Chapter 7, Box 7.1), two climate emulators are used for the probabilistic assessment of the resulting warming of the pathways. For the 'Temperature change' and 'Likelihood' columns, the single upper-row values represent the 50th percentile across the pathways in that category and the median [50th percentile] across the warming estimates of the probabilistic MAGICC climate model emulator. For the bracketed ranges, the median warming for every pathway in that category is calculated for each of the two climate model emulators (MAGICC and FaIR). Subsequently, the 5th and 95th percentile values across all pathways for each emulator are calculated. The coolest and warmest outcomes (i.e., the lowest p5 of two emulators, and the highest p95, respectively) are shown in square brackets. These ranges therefore cover both the uncertainty of the emissions pathways as well as the climate emulators' uncertainty.

^b For a description of pathways categories see Box SPM.1 and Table 3.1.

^c All global warming levels are relative to 1850–1900. (See footnote n below and Box SPM.1⁴⁵ for more details.)

^d C3 pathways are sub-categorised according to the timing of policy action to match the emissions pathways in Figure SPM.4. Two pathways derived from a cost-benefit analysis have been added to C3a, whilst 10 pathways with specifically designed near-term action until 2030, whose emissions fall below those implied by NDCs announced prior to COP26, are not included in either of the two subsets.

^e Alignment with the categories of the illustrative SSP scenarios considered in AR6 WGI, and the Illustrative (Mitigation) Pathways (IPs/IMPs) of WGIII. The IMPs have common features such as deep and rapid emissions reductions, but also different combinations of sectoral mitigation strategies. See Box SPM.1 for an introduction of the IPs and IMPs, and Chapter 3 for full descriptions. [3.2, 3.3, Annex III.II.2.4]

^f The Illustrative Mitigation Pathway 'Neg' has extensive use of carbon dioxide removal (CDR) in the AFOLU, energy and the industry sectors to achieve net negative emissions. Warming peaks around 2060 and declines to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as C3, it strongly exhibits the characteristics of C2 high-overshoot pathways, hence it has been placed in the C2 category. See Box SPM.1 for an introduction of the IPs and IMPs.

^g The 2019 range of harmonised GHG emissions across the pathways [53–58 GtCO₂-eq] is within the uncertainty ranges of 2019 emissions assessed in Chapter 2 [53–66 GtCO₂-eq].⁴⁹ (Figure SPM.1, Figure SPM.2, Box SPM.1)

^h Rates of global emission reduction in mitigation pathways are reported on a pathway-by-pathway basis relative to harmonised modelled global emissions in 2019 rather than the global emissions reported in SPM Section B and Chapter 2; this ensures internal consistency in assumptions about emission sources and activities, as well as consistency with temperature projections based on the physical climate science assessment by WGI.⁴⁹ [Annex III.II.2.5]. Negative values (e.g., in C7, C8) represent an increase in emissions.

ⁱ Emissions milestones are provided for five-year intervals in order to be consistent with the underlying five-year time-step data of the modelled pathways. Peak emissions (CO₂ and GHGs) are assessed for five-year reporting intervals starting in 2020. The interval 2020–2025 signifies that projected emissions peak as soon as possible between 2020 and at latest before 2025. The upper five-year interval refers to the median interval within which the emissions peak or reach net zero. Ranges in square brackets underneath refer to the range across the pathways, comprising the lower bound of the 5th percentile five-year interval and the upper bound of the 95th percentile five-year interval. Numbers in round brackets signify the fraction of pathways that reach specific milestones.

^j Percentiles reported across all pathways in that category include those that do not reach net zero before 2100 (fraction of pathways reaching net zero is given in round brackets). If the fraction of pathways that reach net zero before 2100 is lower than the fraction of pathways covered by a percentile (e.g., 0.95 for the 95th percentile), the percentile is not defined and denoted with '...'. The fraction of pathways reaching net zero includes all with reported non-harmonised, and/or harmonised emissions profiles that reach net zero. Pathways were counted when at least one of the two profiles fell below 100 MtCO₂ yr⁻¹ until 2100.

^k The timing of net zero is further discussed in SPM C2.4 and Cross-Chapter Box 3 in Chapter 3 on net zero CO₂ and net zero GHG emissions.

^l For cases where models do not report all GHGs, missing GHG species are infilled and aggregated into a Kyoto basket of GHG emissions in CO₂-eq defined by the 100-year global warming potential. For each pathway, reporting of CO₂, CH₄, and N₂O emissions was the minimum required for the assessment of the climate response and the assignment to a climate category. Emissions pathways without climate assessment are not included in the ranges presented here. [See Annex III.II.2.5]

^m Cumulative emissions are calculated from the start of 2020 to the time of net zero and 2100, respectively. They are based on harmonised net CO₂ emissions, ensuring consistency with the WGI assessment of the remaining carbon budget.⁵⁰ [Box 3.4]

ⁿ Global mean temperature change for category (at peak, if peak temperature occurs before 2100, and in 2100) relative to 1850–1900, based on the median global warming for each pathway assessed using the probabilistic climate model emulators calibrated to the AR6 WGI assessment.¹² (See also Box SPM.1) [Annex III.II.2.5; WGI Cross-Chapter Box 7.1]

^o Probability of staying below the temperature thresholds for the pathways in each category, taking into consideration the range of uncertainty from the climate model emulators consistent with the AR6 WGI assessment. The probabilities refer to the probability at peak temperature. Note that in the case of temperature overshoot (e.g., category C2 and some pathways in C1), the probabilities of staying below at the end of the century are higher than the probabilities at peak temperature.

3.3.2.4 Mitigation Strategies

Detailed sectoral implications are discussed in Section 3.4 and Chapters 5–11 (see also Table 3.3). The stringency of climate policy has clear implications for mitigation action (Figure 3.15). There are a number of important commonalities of pathways limiting warming to 2°C (>67%) or lower: for instance, they all rely on significant improvement of energy efficiency, rapid decarbonisation of supply and, many of them, CDR (in energy supply or AFOLU), either in terms of net negative emissions or to compensate residual emissions. Still, there are also important differences and the (IMPs) show how different choices can steer the system into alternative directions with different combinations of response options. For decarbonisation of energy supply many options exist, including CCS, nuclear power, and renewables (Chapter 6). In the majority of the scenarios reaching low GHG targets, a considerable amount of CCS is applied (Figure 3.15d).

The share of renewables is around 30–70% in the scenarios that limit warming to 2°C (>67%) and clearly above 40% for scenarios that limit warming 1.5°C (>50%) (panel c). Scenarios have been published with 100% renewable energy systems even at a global scale, partly reflecting the rapid progress made for these technologies in the last decade (Creutzig et al. 2017; Jacobson et al. 2018; Breyer and Jefferson 2020). These scenarios do not show in the graph due to a lack of information from non-energy sources. There is a debate in the literature on whether it is possible to achieve a 100% renewable energy system by 2050 (Brook et al. 2018). This critically depends on assumptions made on future system integration, system flexibility, storage options, consequences for material demand and the ability to supply high-temperature functions and specific mobility functions with renewable energy. The range of studies published showing 100% renewable energy systems show that it is possible to design such systems in the context of energy system models (Hong et al.

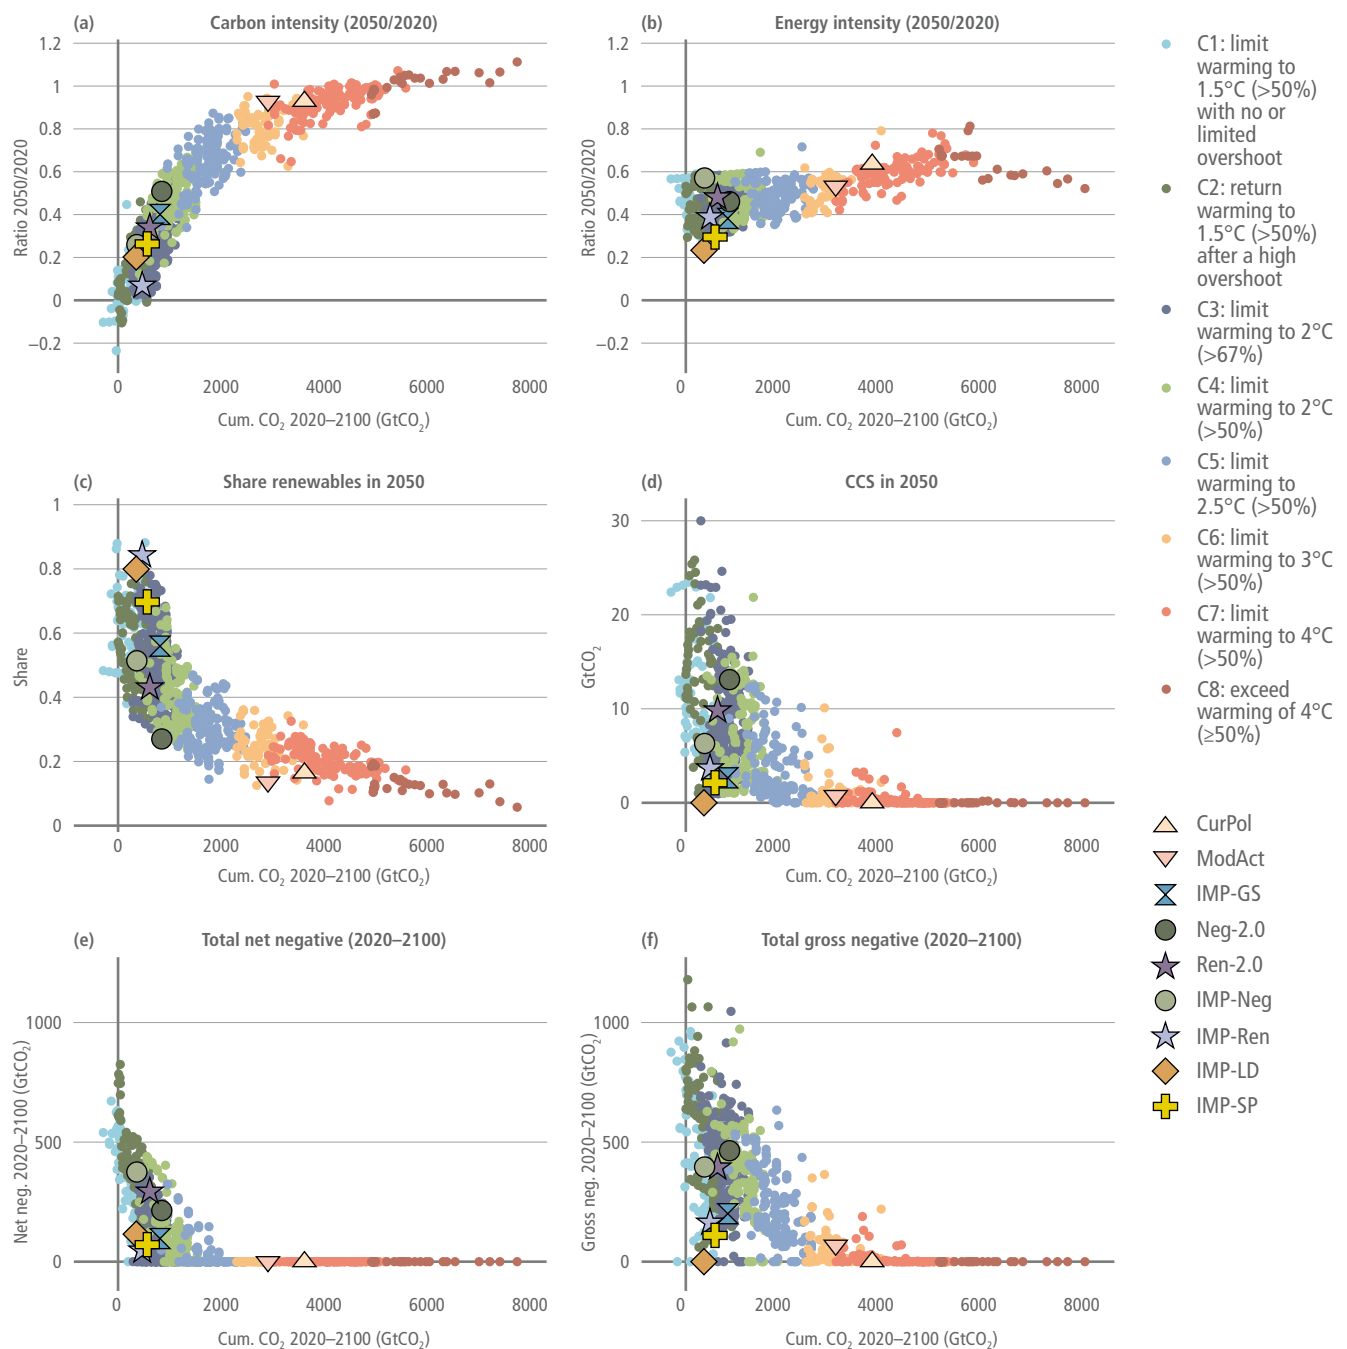

Figure 3.15 | Characteristics of scenarios as a function of the remaining carbon budget (mean decarbonisation rate is shown as the average reduction in the period 2010–2050 divided by 2010 emissions). The categories C1–C7 are explained in Table 3.1.

2014a,b; Lehtveer and Hedenus 2015a,b; Pfenninger and Keirstead 2015; Sepulveda et al. 2018; Zappa et al. 2019; IEA 2021b) (see also Box 6.6 on 100% renewables in net zero CO₂ systems). Panels e and f, finally, show the contribution of CDR – both in terms of net negative emissions and gross CDR. The contribution of total CDR obviously exceeds the net negative emissions. It should be noted that while a majority of scenarios rely on net negative emissions to reach stringent mitigation goals – this is not the case for all of them.

The spread shown in Figure 3.15 implies different mitigation strategies that could all lead to emissions levels consistent with the Paris Agreement (and reach zero emissions). The IMPs illustrate some

options for different decarbonisation pathways with heavy reliance on renewables (*IMP-Ren*), strong emphasis on energy-demand reductions (*IMP-LD*), widespread deployment of CDR methods coupled with CCS (BECCS and DACCS) (*IMP-Neg*), mitigation in the context of sustainable development (*IMP-SP*) (Figure 3.16). For example, in some scenarios, a small part of the energy system is still based on fossil fuels in 2100 (*IMP-Neg*), while in others, fossil fuels are almost or completely phased out (*IMP-Ren*). Nevertheless, in all scenarios, fossil fuel use is greatly reduced and unabated coal use is completely phased out by 2050. Also, nuclear power can be part of a mitigation strategy (however, the literature only includes some scenarios with high-nuclear contributions, such as Berger et al. 2017).

Figure 3.16 | Primary energy use and net emissions at net zero year for the different IMPs. Source: AR6 Scenarios Database.

This is explored further in Section 3.5. The different strategies are also clearly apparent in the way they scenarios reach net zero emissions. While *IMP-GS* and *IMP-Neg* rely significantly on BECCS and DACCS, their use is far more restricted in the other IMPs. Consistently, in these IMPs residual emissions are also significantly lower.

Mitigation pathways also have a regional dimension. In 2010, about 40% of emissions originated from the Developed Countries and Eastern Europe and West Central Asia regions. According to the projections shown in Figure 3.17, the share of the latter regions will further increase to about 70% by 2050. In the scenarios in the literature, emissions are typically almost equally reduced across the regions.

Figure 3.17¹¹ | Emissions by region (including 5–95th percentile range). Source: AR6 Scenarios Database.

3.3.3 Climate Impacts on Mitigation Potential

At the moment, climate change impact on mitigation potential is hardly considered in model-based scenarios. While a detailed overview of climate impacts is provided in IPCC AR6 WGII and Section 3.6 discusses the economic consequences, here we concentrate on the implications for mitigation potential. Climate change directly impacts the carbon budget via all kinds of feedbacks – which is included in the ranges provided for the carbon budget (e.g., 300–900 GtCO₂ for 17th–83rd percentile for not exceeding 1.5°C; see AR6 WGI Chapter 5, 2021). Climate change, however, alters the production and consumption of energy (Section 6.5). An overview of the literature is provided by Yalaw et al. (2020). In terms of supply, impacts could influence the cooling capacity of thermal plants, the potential and predictability of renewable energy, and energy infrastructure (van Vliet et al. 2016; Turner et al. 2017; Cronin et al. 2018a; Lucena et al. 2018; Yalaw et al. 2020; Gernaat et al. 2021). Although the outcomes of these studies differ, they seem to suggest that although impacts might be relatively small at the global scale, they could be substantial at the regional scale (increasing or decreasing potential). Climate change can also impact energy demand, with rising temperatures resulting in decreases in heating demand and increases in cooling demand (Isaac and van Vuuren 2009; Zhou et al. 2014; Labriet et al. 2015; McFarland et al. 2015; Auffhammer et al. 2017; Clarke et al. 2018; van Ruijven et al. 2019; Yalaw et al. 2020). As expected, the increase in cooling demand dominates the impact in warm regions and decreases in heating demand in cold regions (Isaac and van Vuuren 2009; Zhou et al. 2014; Clarke et al. 2018). Globally, most studies show a net increase in energy demand at the end of the century due to climate impacts (Isaac and van Vuuren 2009; Clarke et al. 2018; van Ruijven et al. 2019); however, one study shows a net decrease (Labriet et al. 2015). Only a few studies quantify the combined impacts of climate change on energy supply and energy demand (McFarland et al. 2015; Mima and Criqui 2015; Emodi et al. 2019;

Steinberg et al. 2020). These studies show increases in electricity generation in the USA (McFarland et al. 2015; Steinberg et al. 2020) and increases in CO₂ emissions in Australia (Emodi et al. 2019) or the USA (McFarland et al. 2015).

Climate change can impact the potential for AFOLU mitigation action by altering terrestrial carbon uptake, crop yields and bioenergy potential (Chapter 7). Carbon sequestration in forests may be positively or adversely affected by climate change and CO₂ fertilisation. On the one hand, elevated CO₂ levels and higher temperatures could enhance tree growth rates, carbon sequestration, and timber and biomass production (Beach et al. 2015; Kim et al. 2017; Anderegg et al. 2020). On the other hand, climate change could lead to greater frequency and intensity of disturbance events in forests, such as fires, prolonged droughts, storms, pests and diseases (Kim et al. 2017; Anderegg et al. 2020). The impact of climate change on crop yields could also indirectly impact the availability of land for mitigation and AFOLU emissions (Calvin et al. 2013; Bajželj and Richards 2014; Kyle et al. 2014; Beach et al. 2015; Meijl et al. 2018). The impact is, however, uncertain, as discussed in AR6 WGII Chapter 5. A few studies estimate the effect of climate impacts on AFOLU on mitigation, finding increases in carbon prices or mitigation costs by 1–6% in most scenarios (Calvin et al. 2013; Kyle et al. 2014).

In summary, a limited number of studies quantify the impact of climate on emissions pathways. The most important impact in energy systems might be through the impact on demand, although climate change could also impact renewable mitigation potential – certainly at the local and regional scale. Climate change might be more important for land-use related mitigation measures, including afforestation, bioenergy and nature-based solutions. The net effect of changes in climate and CO₂ fertilisation are uncertain but could be substantial (Chapter 7).

¹¹ The countries and areas classification in this figure deviate from the standard classification scheme adopted by AR6 WGIII as set out in Annex II.I.1.

3.4 Integrating Sectoral Analysis Into Systems Transformations

This section describes the role of sectors in long-term emissions pathways (Table 3.3). We discuss both sectoral aspects of IAM pathways and some insights from sectoral studies. Sectoral studies typically include more detail and additional mitigation options compared to IAMs. However, sectoral studies miss potential feedbacks and cross-sectoral linkages that are captured by IAMs. Additionally, since IAMs include all emissions sources, these models can be used to identify pathways to particular climate goals. In such pathways, emissions are balanced across sectors typically based on relative marginal abatement costs; as a result, some sectors are sources and some are sinks at the time of net zero CO₂ emissions. For these reasons, the mitigation observed in each sector in an IAM may differ from the potential in sectoral studies. Given the strengths and limitations of each type of model, IAMs and sectoral models are complementary, providing different perspectives.

Table 3.3 | Section 3.4 structure, definitions, and relevant chapters.

Section	Sector	What is included	Relevant chapter(s)
3.4.1	Cross-sector	Supply and demand, bioenergy, timing of net zero CO ₂ , other interactions among sectors	Chapters 5, 12
3.4.2	Energy supply	Energy resources, transformation (e.g., electricity generation, refineries, etc.)	Chapter 6
3.4.3	Buildings ^a	Residential and commercial buildings, other non-specified ^b	Chapter 9
3.4.4	Transportation ^a	Road, rail, aviation, and shipping	Chapter 10
3.4.5	Industry ^a	Industrial energy use and industrial processes	Chapter 11
3.4.6	AFOLU	Agriculture, forestry, and other land use	Chapter 7
3.4.7	Other CDR	CDR options not included in individual sectors (e.g., direct air carbon capture and sequestration, enhanced weathering)	Chapter 12

^a Direct energy use and direct emissions only; emissions do not include those associated with energy production.

^b Other non-specified fuel use, including military. Some models report this category in the buildings sector, while others report it in the 'Other' sector.

3.4.1 Cross-sector Linkages

3.4.1.1 Demand and Supply Strategies

Most IAM pathways rely heavily on supply-side mitigation strategies, including fuel switching, decarbonisation of fuels, and CDR (Creutzig et al. 2016; Bertram et al. 2018; Rogelj et al. 2018b; Mundaca et al. 2019). For demand-side mitigation, IAMs incorporate changes in energy efficiency, but many other demand-side options (e.g., behaviour and lifestyle changes) are often excluded from models (van Sluisveld et al. 2015; Creutzig et al. 2016; van den Berg et al. 2019; Wilson et al. 2019). In addition, this mitigation is typically price-driven and limited in magnitude (Yeh et al. 2017; Luderer et al. 2018; Wachsmuth and Duscha 2019; Sharmina et al. 2020). In contrast, bottom-up modelling studies show considerable potential for demand-side mitigation (Creutzig et al. 2016; Yeh et al. 2017; Mundaca et al. 2019; Wachsmuth and Duscha 2019) (Chapter 5), which can slow emissions growth and/or reduce emissions (Creutzig et al. 2016; Samadi et al. 2017).

A small number of mitigation pathways include stringent demand-side mitigation, including changes in thermostat set points (van Sluisveld et al. 2016; van Vuuren et al. 2018), more efficient or smarter appliances (van Sluisveld et al. 2016; Grubler et al. 2018; Napp et al. 2019), increased recycling or reduced industrial goods (Liu et al. 2018; van Sluisveld et al. 2016; Grubler et al. 2018; van de Ven et al. 2018; Napp et al. 2019), telework and travel avoidance (Grubler et al. 2018; van de Ven et al. 2018), shifts to public transit (van Sluisveld et al. 2016; Grubler et al. 2018; van Vuuren et al. 2018), reductions in food waste (van de Ven et al. 2018) and less meat-intensive diets (Liu et al. 2018; van de Ven et al. 2018; van Vuuren et al. 2018). These pathways show reduced dependence on CDR and reduced pressure on land (Grubler et al. 2018; Rogelj et al. 2018a; van de Ven et al. 2018; van Vuuren et al. 2018) (Section 5.3.3). However, the representation of these demand-side mitigation options in IAMs is limited, with most models excluding the costs of such changes (van Sluisveld et al. 2016), using stylised assumptions to represent them (van den Berg et al. 2019), and excluding rebound effects (Krey et al. 2019; Brockway et al. 2021). Furthermore, there are questions about the achievability of such pathways, including whether the behavioural changes included are feasible (Azevedo et al. 2021) and the extent to which development and demand can be decoupled (Steckel et al. 2013; Brockway et al. 2021; Keyßer and Lenzen 2021; Semieniuk et al. 2021).

Figure 3.18 shows indicators of supply- and demand-side mitigation in the IMPs, as well as the range across the database. Two of these IMPs (*IMP-SP*, *IMP-LD*) show strong reductions in energy demand, resulting in less reliance on bioenergy and limited CDR from energy supply. In contrast, *IMP-Neg* has higher energy demand, depending more on bioenergy and net negative CO₂ emissions from energy supply.

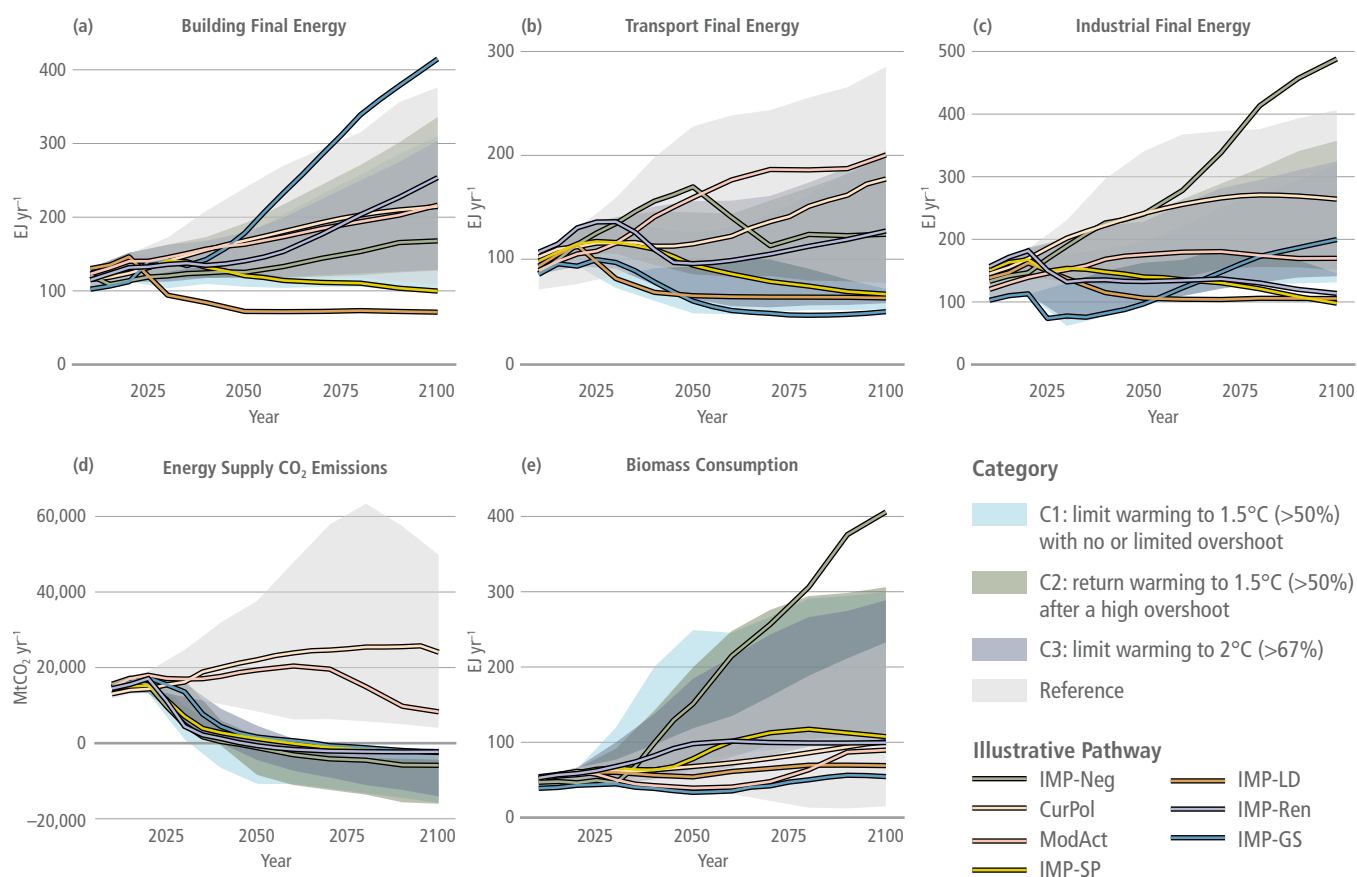

Figure 3.18 | Indicators of demand and supply-side mitigation in the Illustrative Pathways (lines) and the 5–95% range of Reference, 1.5°C and 2°C scenarios (shaded areas).

3.4.1.2 Sectoral Emissions Strategies and the Timing of Net Zero

Mitigation pathways show differences in the timing of decarbonisation (Figure 3.20) and the timing of net zero (Figure 3.19) across sectors and regions (*high confidence*); the timing in a given sector depends on the cost of abatement in it, the availability of CDR options, the scenario design, near-term emissions levels, and the amount of non-CO₂ abatement (Yeh et al. 2017; Emmerling et al. 2019; Rogelj et al. 2019a,b; Johansson et al. 2020; Azevedo et al. 2021; Ou et al. 2021; van Soest et al. 2021b) (Cross-Chapter Box 3 in this chapter). However, delaying emissions reductions, or more limited emissions reductions in one sector or region, involves compensating reductions in other sectors or regions if warming is to be limited (*high confidence*) (Price and Keppo 2017; Grubler et al. 2018; Rochedo et al. 2018; van Soest et al. 2021b).

At the time of net zero global CO₂ emissions, emissions in some sectors are positive and some negative. In cost-effective mitigation pathways, the energy supply sector typically reaches net zero CO₂ before the economy as a whole, while the demand sectors reach net zero CO₂ later, if at all (Pietzcker et al. 2014; Price and Keppo 2017; Luderer et al. 2018; Rogelj et al. 2018a,b; Méjean et al. 2019; Azevedo

et al. 2021) (Section 6.7). CO₂ emissions from transport, industry, and buildings are positive, and non-CO₂ GHG emissions are also positive at the time of global net zero CO₂ emissions (Figure 3.20).

So, while pathways indicate some flexibility in emissions reductions across sectors, all pathways involve substantial CO₂ emissions reductions in all sectors and regions (*high confidence*) (Luderer et al. 2018; Rogelj et al. 2018a,b; Méjean et al. 2019; Azevedo et al. 2021). Projected CO₂ emissions reductions between 2019 and 2050 in 1.5°C (>50%) pathways with no or limited overshoot are around 77% for energy demand, with a 5–95% range of 31–96%,¹² 115% for energy supply (90–167%), and 148% for AFOLU (94–387%). In pathways that limit warming to 2°C (>67%), projected CO₂ emissions are reduced between 2019 and 2050 by around 49% for energy demand, 97% for energy supply, and 136% for AFOLU (Sections 3.4.2–3.4.6). Almost 75% of GHG reductions at the time of net zero GHG are from the energy system, 13% are from AFOLU CO₂, and 13% from non-CO₂ (Figure 3.21). These reductions are achieved through a variety of sectoral strategies, illustrated in Figure 3.21 (Figure 3.21b), and described in Sections 3.4.2 to 3.4.7; the primary strategies include declines in fossil energy, increases in low-carbon energy use, and CDR to address residual emissions.

¹² Unless otherwise specified, the values in parentheses in Section 3.4 from this point forward indicate the 5–95th percentile range.

^a Values in the table refer to the 50th and (5–95th) percentile values.^b See category descriptions in Table 3.1.^c The warming profile of *IMP-Neg* peaks around 2060 and declines thereafter to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as a C3, it strongly exhibits the characteristics of C2 high-overshoot scenarios.^d Primary Energy as calculated in 'Direct Equivalent' terms according to IPCC reporting conventions.^e Low-carbon energy here defined to include: renewables (including biomass, solar, wind, hydro, geothermal, ocean); fossil fuels when used with CCS; and, nuclear power.

Figure 3.19 | Decade in which sectoral CO₂ emissions first reach net negative values. Each panel is a different temperature level. The colours indicate the decade in which CO₂ emissions go negative; the y-axis indicates the share of scenarios achieving net zero in that decade. Only scenarios that pass the vetting criteria are included (Section 3.2). Scenarios achieving net zero prior to 2020 are excluded.

Figure 3.20 | Greenhouse gas (GHG) emissions, including CO₂ emissions by sector and total non-CO₂ GHGs in 2050 (top left), 2100 (top middle), year of global net zero CO₂ (top right), cumulative CO₂ emissions from 2020–2100 (bottom left), and cumulative CO₂ emissions from 2020 until the year of net zero CO₂ for scenarios that limit warming to below 2°C. Scenarios are grouped by their temperature category. 'Industry' includes CO₂ emissions associated with industrial energy use only; sectors shown in this figure do not necessarily sum to total CO₂. In this, and other figures in Section 3.4, unless stated otherwise, only scenarios that pass the vetting criteria are included (Section 3.2). Boxes indicate the interquartile range, the median is shown with a horizontal black line, while vertical lines show the 5–95% interval.

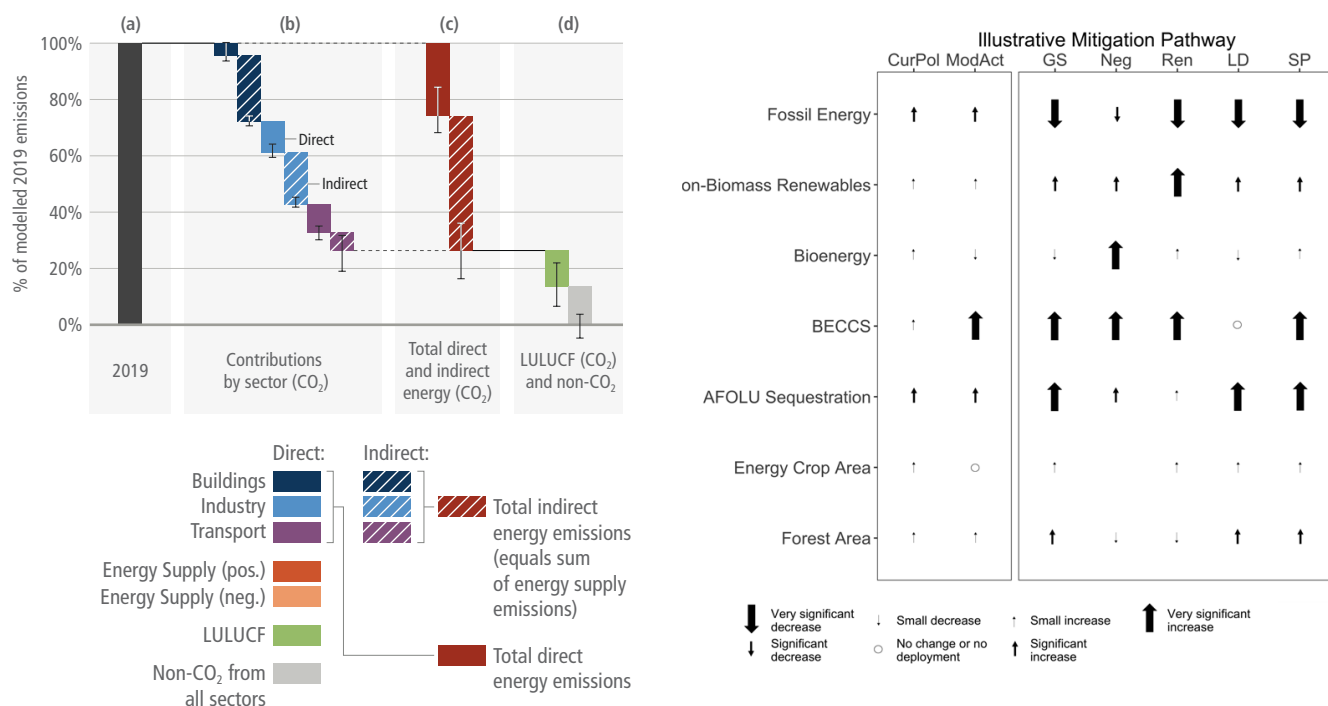

Figure 3.21 | Left panel: Greenhouse gas (GHG) emissions reductions from 2019 by sector at the year of net zero GHG for all scenarios that reach net zero GHG. Emissions reductions by sector for direct (demand) and indirect (upstream supply) are shown as the percent of total GHG reductions. **Right panel:** key indicators in 2050 for the IMPs. Definitions of significant and very significant are defined relative to 2019 and vary between indicators, as follows: fossil energy (significant >10%, very significant >50%), renewables (>150 EJ yr⁻¹, >200 EJ yr⁻¹), bioenergy (>100%, >200%), BECCS (>2.0 GtCO₂ yr⁻¹, >3.5 GtCO₂ yr⁻¹), AFOLU (>100% decline, >130% decline), energy crops (>150 million ha, >400 million ha), forest (>5% increase, >15% increase). Source: AR6 Scenarios Database.

In the context of mitigation pathways, only a few studies have examined solar radiation modification (SRM), typically focusing on Stratospheric Aerosol Injection (Arino et al. 2016; Emmerling and Tavoni 2018a,b; Heutel et al. 2018; Helweg et al. 2019; Rickels et al. 2020; Belaia et al. 2021). These studies find that substantial mitigation is required to limit warming to a given level, even if SRM is available (Moreno-Cruz and Smulders 2017; Emmerling and Tavoni 2018b; Belaia et al. 2021). SRM may reduce some climate impacts, reduce peak temperatures, lower mitigation costs, and extend the time available to achieve mitigation; however, SRM does not address ocean acidification and may involve risks to crop yields, economies, human health, or ecosystems (AR6 WGII Chapter 16; AR6 WGI TS and Chapter 5; SR1.5 SPM; and Cross-Working Group Box 4 in Chapter 14 of this report). There are also significant uncertainties surrounding SRM, including uncertainties on the costs and risks, which can substantially alter the amount of SRM used in modelled pathways (Tavoni et al. 2017; Heutel et al. 2018; IPCC 2018; Helweg et al. 2019; NASEM 2021). Furthermore, the degree of international cooperation can influence the amount of SRM deployed in scenarios, with uncoordinated action resulting in larger SRM deployment and consequently larger risks/impacts from SRM (Emmerling and Tavoni 2018a). Bridging research and governance involves consideration of the full range of societal choices and ramifications (Sugiyama et al. 2018). More information on SRM, including the caveats, risks, uncertainties, and governance issues is found in AR6 WGI Chapter 4; AR6 WGIII Chapter 14; and Cross-Working Group Box 4 in Chapter 14 of this report.

3.4.1.3 Linkages Among Sectors

Mitigation in one sector can be dependent upon mitigation in another sector, or may involve trade-offs between sectors. Mitigation in energy demand often includes electrification (Pietzcker et al. 2014; Luderer et al. 2018; Sharmina et al. 2020; DeAngelo et al. 2021), however such pathways only result in reduced emissions *if* the electricity sector is decarbonised (Zhang and Fujimori 2020) (Chapter 12). Relatedly, the mitigation potential of some sectors (e.g., transportation) depends on the decarbonisation of liquid fuels, for example, through biofuels (Pietzcker et al. 2014; Wise et al. 2017; Sharmina et al. 2020) (Chapter 12). In other cases, mitigation in one sector results in reduced emissions in another sector. For example, increased recycling can reduce primary resource extraction; planting trees or green roofs in urban areas can reduce the energy demand associated with space cooling (Chapter 12).

Mitigation in one sector can also result in additional emissions in another. One example is electrification of end use which can result in increased emissions from energy supply. However, one comparatively well-researched example of this linkage is bioenergy. An increase in demand for bioenergy within the energy system has the potential to influence emissions in the AFOLU sector through the intensification of land and forest management and/or via land-use change (Daioglou et al. 2019; Smith et al. 2019; Smith et al. 2020a; IPCC 2019a). The effect of bioenergy and BECCS on mitigation depends on a variety of factors in modelled pathways. In the energy system, the emissions mitigation depends on the scale of deployment, the conversion technology, and the fuel displaced (Calvin et al. 2021).

Limiting or excluding bioenergy and/or BECCS increases mitigation cost and may limit the ability of a model to reach a low warming level (Edmonds et al. 2013; Calvin et al. 2014b; Luderer et al. 2018; Muratori et al. 2020). In AFOLU, bioenergy can increase or decrease terrestrial carbon stocks and carbon sequestration, depending on the scale, biomass feedstock, land management practices, and prior land use (Calvin et al. 2014c; Wise et al. 2015; IPCC 2019a; Smith et al. 2019, 2020a; Calvin et al. 2021).

Pathways with very high biomass production for energy use typically include very high carbon prices in the energy system (Popp et al. 2017; Rogelj et al. 2018b), little or no land policy (Calvin et al. 2014b), a high discount rate (Emmerling et al. 2019), and limited non-BECCS CDR options (e.g., afforestation, DACCS) (Chen and Tavoni 2013; Calvin et al. 2014b; Marcucci et al. 2017; Realmonte et al. 2019; Fuhrman et al. 2020). Higher levels of bioenergy consumption are likely to involve trade-offs with mitigation in other sectors, notably in construction (i.e., wood for material and structural products) and AFOLU (carbon stocks and future carbon sequestration), as well as trade-offs with sustainability (Section 3.7) and feasibility concerns (Section 3.8). Not all of these trade-offs are fully represented in all IAMs. Based on sectoral studies, the technical potential for bioenergy, when constraints for food security and environmental considerations are included, are 5–50 EJ yr⁻¹ and 50–250 EJ yr⁻¹ in 2050 for residues and dedicated biomass production systems, respectively (Chapter 7). Bioenergy deployment in IAMs is within the range of these potentials,

with between 75 and 248 EJ yr⁻¹ in 2050 in pathways that limit warming to 1.5°C with no or limited overshoot. Finally, IAMs do not include all potential feedstock and management practices, and have limited representation of institutions, governance, and local context (Brown et al. 2019; Butnar et al. 2020; Calvin et al. 2021).

The inclusion of CDR options, like BECCS, can affect the timing of emissions mitigation in IAM scenarios, that is, delays in mitigations actions are compensated by net negative emissions in the second half of the century. However, studies with limited net negative emissions in the long term require very rapid declines in emissions in the near term (van Vuuren et al. 2017). Especially in forest-based systems, increased harvesting of forests can perturb the carbon balance of forestry systems, increasing emissions for some period; the duration of this period of increased emissions, preceding net emissions reductions, can be very variable (Mitchell et al. 2012; Lamers and Junginger 2013; Röder et al. 2019; Hanssen et al. 2020; Cowie et al. 2021). However, the factors contributing to differences in recovery time are known (Mitchell et al. 2012; Zanchi et al. 2012; Lamers and Junginger 2013; Laganière et al. 2017; Röder et al. 2019). Some studies that consider market-mediated effects find that an increased demand for biomass from forests can provide incentives to maintain existing forests and potentially to expand forest areas, providing additional carbon sequestration as well as additional biomass (Dwivedi et al. 2014; Kim et al. 2018; Baker et al. 2019; Favero et al. 2020). However, these responses are uncertain and likely to vary geographically.

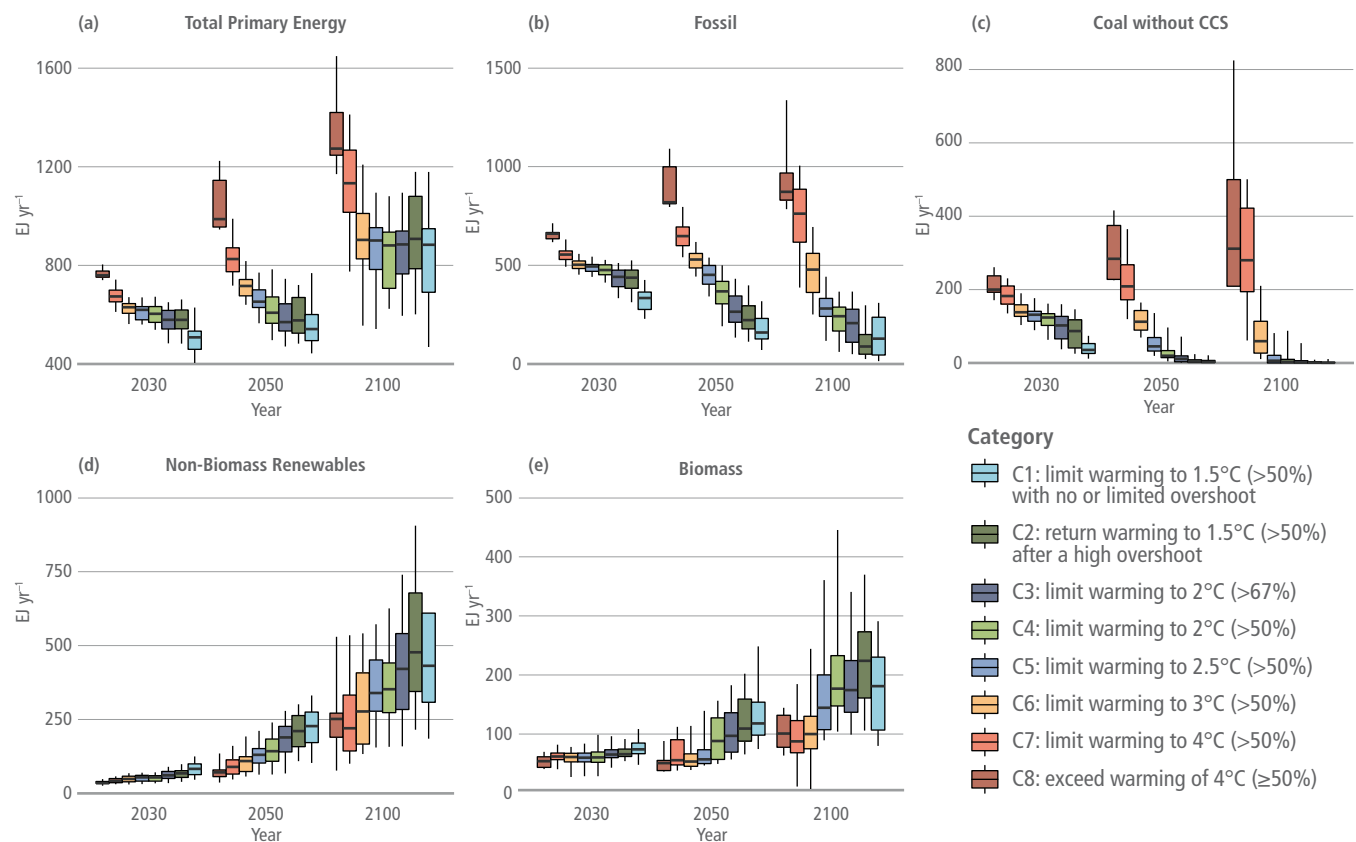

Figure 3.22 | Primary energy consumption across scenarios: total primary energy (a), fossil fuels (b), coal without CCS (c), non-biomass renewables (d), and biomass (e). Scenarios are grouped by their temperature category. Primary energy is reported in direct equivalent, where one unit of nuclear or non-biomass renewable energy output is reported as one unit of primary energy. Not all subcategories of primary energy are shown.

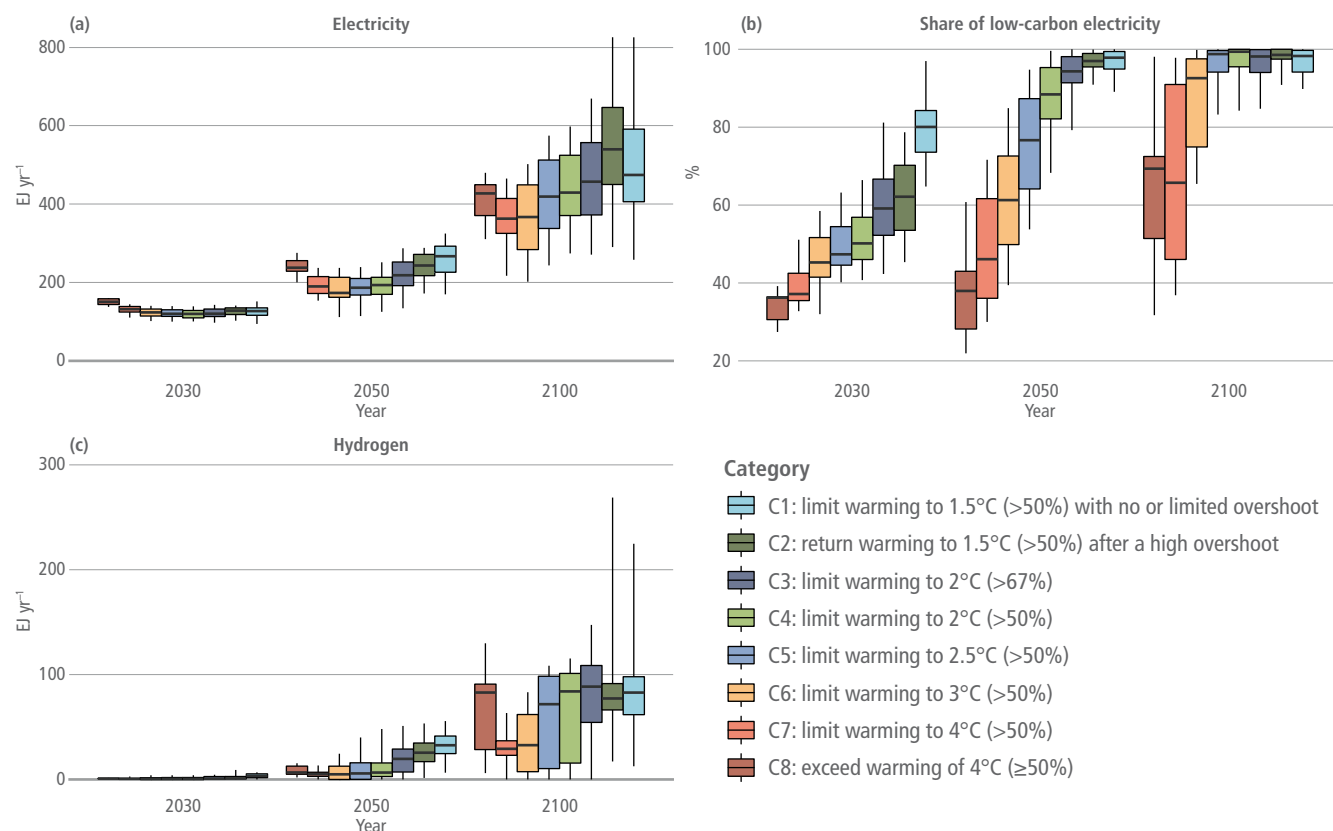

Figure 3.23 | Electricity (top left), share of low-carbon electricity (top right), and hydrogen (bottom left) production across all scenarios, grouped by the categories introduced in Section 3.2. Low carbon includes non-biomass renewables, biomass, nuclear, and CCS.

3.4.2 Energy Supply

Without mitigation, energy consumption and supply emissions continue to rise (*high confidence*) (Kriegler et al. 2016; Bauer et al. 2017; Riahi et al. 2017; Mcjeon et al. 2021) (Section 6.7). While the share of renewable energy continues to grow in reference scenarios, fossil fuel accounts for the largest share of primary energy (Bauer et al. 2017; Price and Keppo 2017; Riahi et al. 2017). In scenarios that limit warming to 2°C or lower, transition of the energy-supply sector to a low- or no-carbon system is rapid (Rogelj et al. 2016, 2018b; Grubler et al. 2018; Luderer et al. 2018; van Vuuren et al. 2018). CO₂ emissions from energy supply reach net zero around 2041 (2033–2057) in pathways limiting warming to 1.5°C (>50%) with no or limited overshoot and around 2053 (2040–2066) in pathways that limit warming to 2°C (>67%). Emissions reductions continue, with emissions reaching $-7.1 \text{ GtCO}_2 \text{ yr}^{-1}$ (–15 to $-2.3 \text{ GtCO}_2 \text{ yr}^{-1}$) in 2100 in all pathways that limit warming to 2°C (>67%) or lower.

All pathways that limit warming to 2°C (>67%) or lower show substantial reductions in fossil fuel consumption and a near elimination of the use of coal without CCS (*high confidence*) (Bauer et al. 2017; van Vuuren et al. 2018; Grubler et al. 2018; Luderer et al. 2018; Rogelj et al. 2018a,b; Azevedo et al. 2021; Mcjeon et al. 2021; Welsby et al. 2021) (Figure 3.22). In these pathways, the use of coal, gas and oil is reduced by 90%, 25%, and 41%, respectively, between 2019 and 2050 and 91%, 39%, and 78% between 2019 and 2100; coal without CCS is

further reduced to 99% below its 2019 levels in 2100. These pathways show an increase in low-carbon energy, with 88% (69–97%) of primary energy from low-carbon sources in 2100, with different combinations of low-carbon fuels (e.g., non-biomass renewables, biomass, nuclear, and CCS) (Rogelj et al. 2018a,b; van Vuuren et al. 2018) (Sections 3.4.1 and 6.7). Across all pathways that limit warming to 2°C and below, non-biomass renewables account for 52% (24–77%) of primary energy in 2100 (Creutzig et al. 2017; Pietzcker et al. 2017; Rogelj et al. 2018b) (Chapter 6 and Figure 3.22). There are some studies analysing the potential for 100% renewable energy systems (Hansen et al. 2019); however, there are a range of issues around such systems (Box 6.6).

Stringent emissions reductions at the level required to limit warming to 2°C (>67%) or 1.5°C are achieved through increased electrification of end use, resulting in increased electricity generation in all pathways (*high confidence*) (Rogelj et al. 2018a; Azevedo et al. 2021) (Figure 3.23). Nearly all electricity in pathways *likely* to limit warming to 2°C and below is from low- or no-carbon fuels (Rogelj et al. 2018a; Azevedo et al. 2021), with different shares of nuclear, biomass, non-biomass renewables, and fossil CCS across pathways. Low-emissions scenarios also show increases in hydrogen use (Figure 3.23).

3.4.3 Buildings

Global final energy use in the building sector increases in all pathways as a result of population growth and increasing affluence

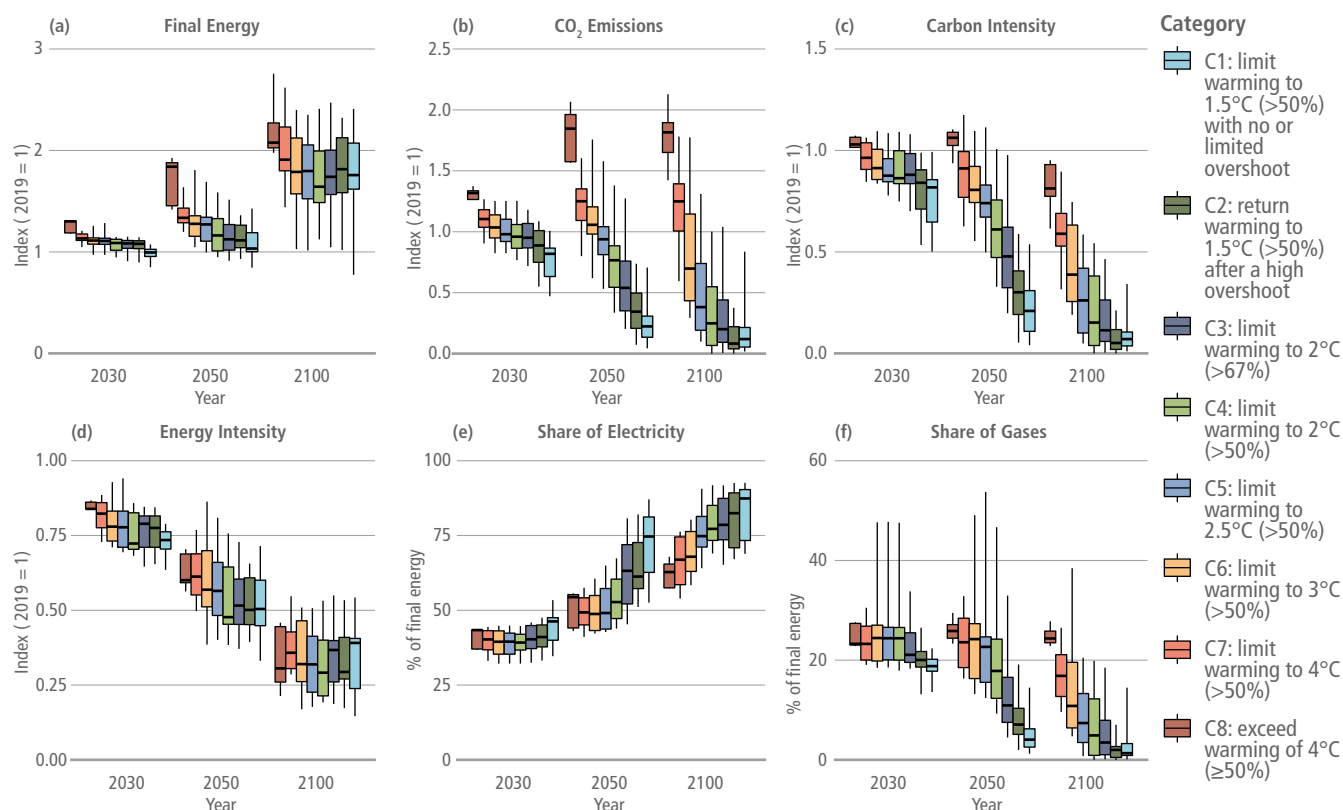

Figure 3.24 | Buildings final energy (a), CO₂ emissions (b), carbon intensity (c), energy intensity (d), share of final energy from electricity (e), and share of final energy from gases (f). Energy intensity is final energy per unit of GDP. Carbon intensity is CO₂ emissions per EJ of final energy. The first four indicators are indexed to 2019,¹² where values less than 1 indicate a reduction.

(Figure 3.24). There is very little difference in final energy intensity for the buildings sector across scenarios. Direct CO₂ emissions from the buildings sector vary more widely across temperature stabilisation levels than energy consumption. In 2100, scenarios above 3°C [C7–C8] still show an increase of CO₂ emissions from buildings around 29% above 2019, while all scenarios *likely* to limit warming to 2°C and below have emission reductions of around 85% (8–100%). Carbon intensity declines in all scenarios, but much more sharply as the warming level is reduced.

In all scenarios, the share of electricity in final energy use increases, a trend that is accelerated by 2050 for the scenarios *likely* to limit warming to 2°C and below (Figure 3.23). By 2100, the low-warming scenarios show large shares of electricity in final energy consumption for buildings. The opposite is observed for gases.

While several global IAM models have developed their buildings modules considerably over the past decade (Daioglou et al. 2012; Knobloch et al. 2017; Clarke et al. 2018; Edelenbosch et al. 2021; Mastrucci et al. 2021), the extremely limited availability of key sectoral variables in the AR6 scenarios database (such as floor space and energy use for individual services) prohibit a detailed analysis of sectoral dynamics. Individual studies in the literature often focus on single aspects of the buildings sector, though collectively providing a more comprehensive overview (Edelenbosch et al.

2020; Ürge-Vorsatz et al. 2020). For example, energy demand is driven by economic development that fulfills basic needs (Mastrucci et al. 2019; Rao et al. 2019a), but also drives up floor space in general (Daioglou et al. 2012; Levesque et al. 2018; Mastrucci et al. 2021) and ownership of energy-intensive appliances such as air conditioners (Isaac and van Vuuren 2009; Colelli and Cian 2020; Poblete-Cazenave et al. 2021). These dynamics are heterogeneous and lead to differences in energy demand and emission mitigation potential across urban/rural buildings and income levels (Krey et al. 2012; Poblete-Cazenave et al. 2021). Mitigation scenarios rely on fuel switching and technology (Knobloch et al. 2017; Dagnachew et al. 2020), efficiency improvement in building envelopes (Levesque et al. 2018; Edelenbosch et al. 2021) and behavioural changes (van Sluisveld et al. 2016; Niamir et al. 2018, 2020). The in-depth dynamics of mitigation in the building sector are explored in Chapter 9.

3.4.4 Transport

Reference scenarios show growth in transport demand, particularly in aviation and freight (Yeh et al. 2017; Sharmina et al. 2020; Müller-Casseres et al. 2021b). Energy consumption continues to be dominated by fossil fuels in reference scenarios, with some increases in electrification (Yeh et al. 2017; Edelenbosch et al. 2020; Yeh et al.

¹³ 2019 values are from model results and interpolated from other years when not directly reported.

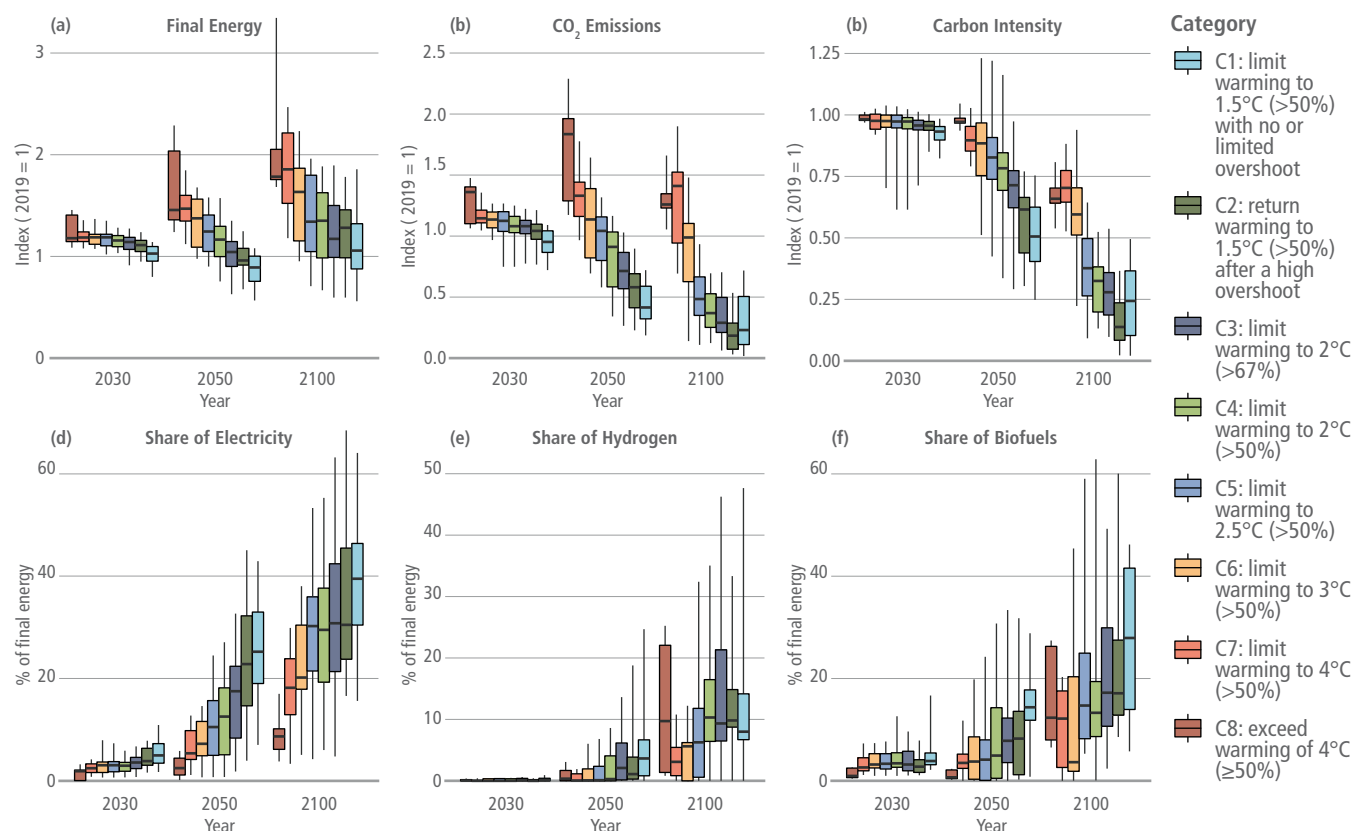

Figure 3.25 | Transport final energy (a), CO₂ emissions (b), carbon intensity (c) and share of final energy from electricity (d), hydrogen (e), and biofuels (f). See Chapter 10 for a discussion of energy intensity. Carbon intensity is CO₂ emissions per EJ of final energy. The first three indicators are indexed to 2019,¹³ where values less than 1 indicate a reduction.

2017). CO₂ emissions from transport increase for most models in reference scenarios (Yeh et al. 2017; Edelenbosch et al. 2020).

The relative contribution of demand-side reduction, energy-efficiency improvements, fuel switching, and decarbonisation of fuels, varies by model, level of mitigation, mitigation options available, and underlying socio-economic pathway (Longden 2014; Wise et al. 2017; Yeh et al. 2017; Luderer et al. 2018; Yeh et al. 2017; Edelenbosch et al. 2020; Müller-Casseres et al. 2021a,b). IAMs typically rely on technology-focused measures like energy-efficiency improvements and fuel switching to reduce carbon emissions (Pietzcker et al. 2014; Edelenbosch et al. 2017a; Yeh et al. 2017; Zhang et al. 2018a,b; Rogelj et al. 2018b; Zhang et al. 2018a,b; Sharmina et al. 2020). Many mitigation pathways show electrification of the transport system (Luderer et al. 2018; Pietzcker et al. 2014; Longden 2014; Luderer et al. 2018; Zhang et al. 2018a); however, without decarbonisation of the electricity system, transport electrification can increase total energy system emissions (Zhang and Fujimori 2020). A small number of pathways include demand-side mitigation measures in the transport sector; these studies show reduced carbon prices and reduced dependence on CDR (Grubler et al. 2018; Méjean et al. 2019; van de Ven et al. 2018; Zhang et al. 2018c; Méjean et al. 2019) (Section 3.4.1).

Across all IAM scenarios assessed, final energy demand for transport continues to grow, including in many stringent mitigation pathways (Figure 3.25). The carbon intensity of energy declines substantially by 2100 in *likely* 2°C (>67%) and below scenarios, leading to substantial declines in transport sector CO₂ emissions with increased electrification of the transport system (Figure 3.23).

The transport sector has more detail than other sectors in many IAMs (Edelenbosch et al. 2020); however, there is considerable variation across models. Some models (e.g., GCAM, IMAGE, MESSAGE-GLOBIOM) represent different transport modes with endogenous shifts across modes as a function of income, price, and modal speed (Edelenbosch et al. 2020).¹⁵ However, IAMs, including those with detailed transport, exclude several supply-side (e.g., synthetic fuels) and demand-side (e.g., behaviour change, reduced shipping, telework and automation) mitigation options (Pietzcker et al. 2014; Creutzig et al. 2016; Mittal et al. 2017; Davis et al. 2018; Köhler et al. 2020; Mittal et al. 2017; Gota et al. 2019; Wilson et al. 2019; Creutzig et al. 2016; Köhler et al. 2020; Sharmina et al. 2020; Pietzcker et al. 2014; Lefèvre et al. 2021; Müller-Casseres et al. 2021a,b).

¹⁴ 2019 values are from model results and interpolated from other years when not directly reported.

¹⁵ Some of these models are treated as global transport energy sectoral models (GTEMs) in Chapter 10.

As a result of these missing options and differences in how mitigation is implemented, IAMs tend to show less mitigation than the potential from national transport/energy models (Wachsmuth and Duscha 2019; Gota et al. 2019; Yeh et al. 2017; Gota et al. 2019; Wachsmuth and Duscha 2019; Edelenbosch et al. 2020). For the transport sector as a whole, studies suggest a mitigation potential of 4–5 GtCO₂ per year in 2030 (Edelenbosch et al. 2020) with complete decarbonisation possible by 2050 (Gota et al. 2019; Wachsmuth and Duscha 2019). However, in the scenarios assessed in this chapter that limit warming to below 1.5°C (>50%) with no or limited overshoot, transport sector CO₂ emissions are reduced by only 59% (28% to 81%) in 2050 compared to 2015. IAM pathways also show less electrification than the potential from other studies; pathways that limit warming to 1.5°C with no or limited overshoot show a median of 25% (7– to 43%) of final energy from electricity in 2050, while the IEA NZE scenario includes 45% (IEA 2021a).

3.4.5 Industry

Reference scenarios show declines in energy intensity, but increases in final energy use in the industrial sector (Edelenbosch et al. 2017b). These scenarios show increases in CO₂ emissions both for the total industrial sector (Edelenbosch et al. 2017b, 2020; Luderer et al. 2018) and individual subsectors such as cement and iron and steel (van Ruijven et al. 2016; van Sluisveld et al. 2021) or chemicals (Daioglou et al. 2014; van Sluisveld et al. 2021).

In mitigation pathways, CO₂ emissions reductions are achieved through a combination of energy savings (via energy-efficiency improvements and energy conservation), structural change, fuel switching, and decarbonisation of fuels (Edelenbosch et al. 2017b, 2020; Grubler et al. 2018; Luderer et al. 2018). Mitigation pathways show reductions in final energy for industry compared to the baseline (Edelenbosch et al. 2017b; Luderer et al. 2018; Edelenbosch et al. 2020) and reductions in the carbon intensity of the industrial sector through both fuel switching and the use of CCS (van Ruijven et al. 2016; Edelenbosch et al. 2017b, 2020; Luderer et al. 2018; Paltsev et al. 2021; van Sluisveld et al. 2021). The mitigation potential differs depending on the industrial subsector and the availability of CCS, with larger potential reductions in the steel sector (van Ruijven et al. 2016) and cement industry (Sanjuán et al. 2020) than in the

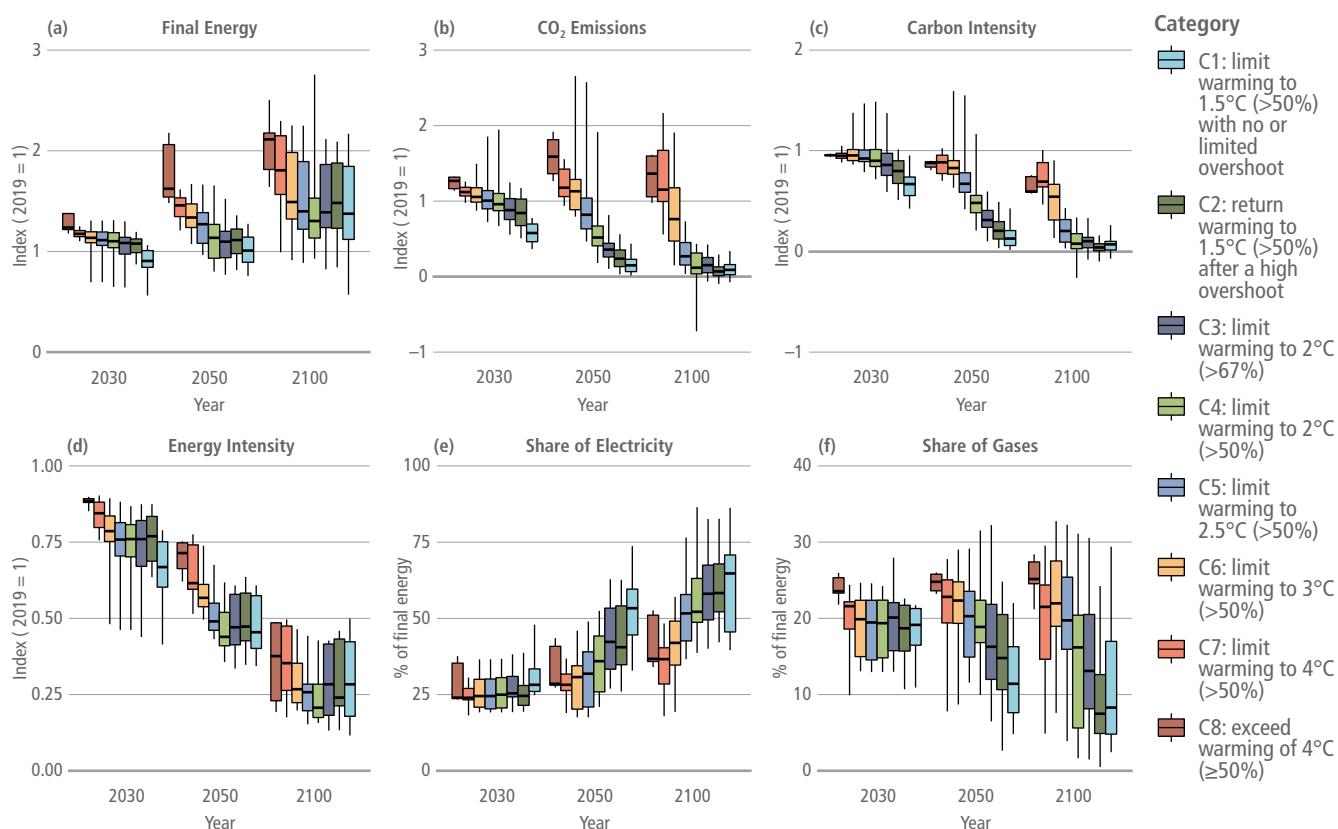

Figure 3.26 | Industrial final energy, including feedstocks (a), CO₂ emissions (b), carbon intensity (c), energy intensity (d), share of final energy from electricity (e), and share of final energy from gases (f). Energy intensity is final energy per unit of GDP. Carbon intensity is CO₂ emissions per EJ of final energy. The first four indicators are indexed to 2019,¹⁵ where values less than 1 indicate a reduction. Industrial sector CO₂ emissions include fuel combustion emissions only.

¹⁶ 2019 values are from model results and interpolated from other years when not directly reported.

chemicals sector (Daioglou et al. 2014). Many scenarios, including stringent mitigation scenarios, show continued growth in final energy; however, the carbon intensity of energy declines in all mitigation scenarios (Figure 3.26).

The representation of the industry sector is very aggregated in most IAMs, with only a small subset of models disaggregating key sectors such as cement, fertiliser, chemicals, and iron and steel (Daioglou et al. 2014; Edelenbosch et al. 2017b; Pauliuk et al. 2017; Napp et al. 2019; van Sluisveld et al. 2021). IAMs often account for both energy combustion and feedstocks (Edelenbosch et al. 2017b), but IAMs typically ignore material flows and miss linkages between sectors (Pauliuk et al. 2017; Kermeli et al. 2019). By excluding these processes, IAMs misrepresent the mitigation potential of the industry sector, for example by overlooking mitigation from material efficiency and circular economies (Sharmina et al. 2020), which can have substantial mitigation potential (Sections 5.3.4 and 11.3).

Sectoral studies indicate a large mitigation potential in the industrial sector by 2050, including the potential for net zero CO₂ emissions for steel, plastics, ammonia, and cement (Section 11.4.1). Detailed industry sector pathways show emissions reductions between 39% and 94% by mid-century compared to the present day¹⁷ (Section 11.4.2) and a substantial increase in direct electrification (IEA 2021a). IAMs show comparable mitigation potential to sectoral

studies with median reductions in CO₂ emissions between 2019 and 2050 of 70% in scenarios *likely* to limit warming to 2°C (>67%) and below and a maximum reduction of 96% (Figure 3.26). Some differences between IAMs and sectoral models can be attributed to differences in technology availability, with IAMs sometimes including more technologies (van Ruijven et al. 2016) and sometimes less (Sharmina et al. 2020).

3.4.6 Agriculture, Forestry and Other Land Use (AFOLU)

Mitigation pathways show substantial reductions in CO₂ emissions, but more modest reductions in AFOLU CH₄ and N₂O emissions (*high confidence*) (Popp et al. 2017; Roe et al. 2019; Reisinger et al. 2021) (Figure 3.27). Pathways limiting warming to *likely* 2°C or lower are projected to reach net zero CO₂ emissions in the AFOLU sector around 2033 (2024–2060); however, AFOLU CH₄ and N₂O emissions remain positive in all pathways (Figure 3.27). While IAMs include many land-based mitigation options, these models exclude several options with large mitigation potential, such as biochar, agroforestry, restoration/avoided conversion of coastal wetlands, and restoration/avoided conversion of peatland (IPCC 2019a; Smith et al. 2019) (Chapter 7 and Section 3.4). Sectoral studies show higher mitigation potential than IAM pathways, as

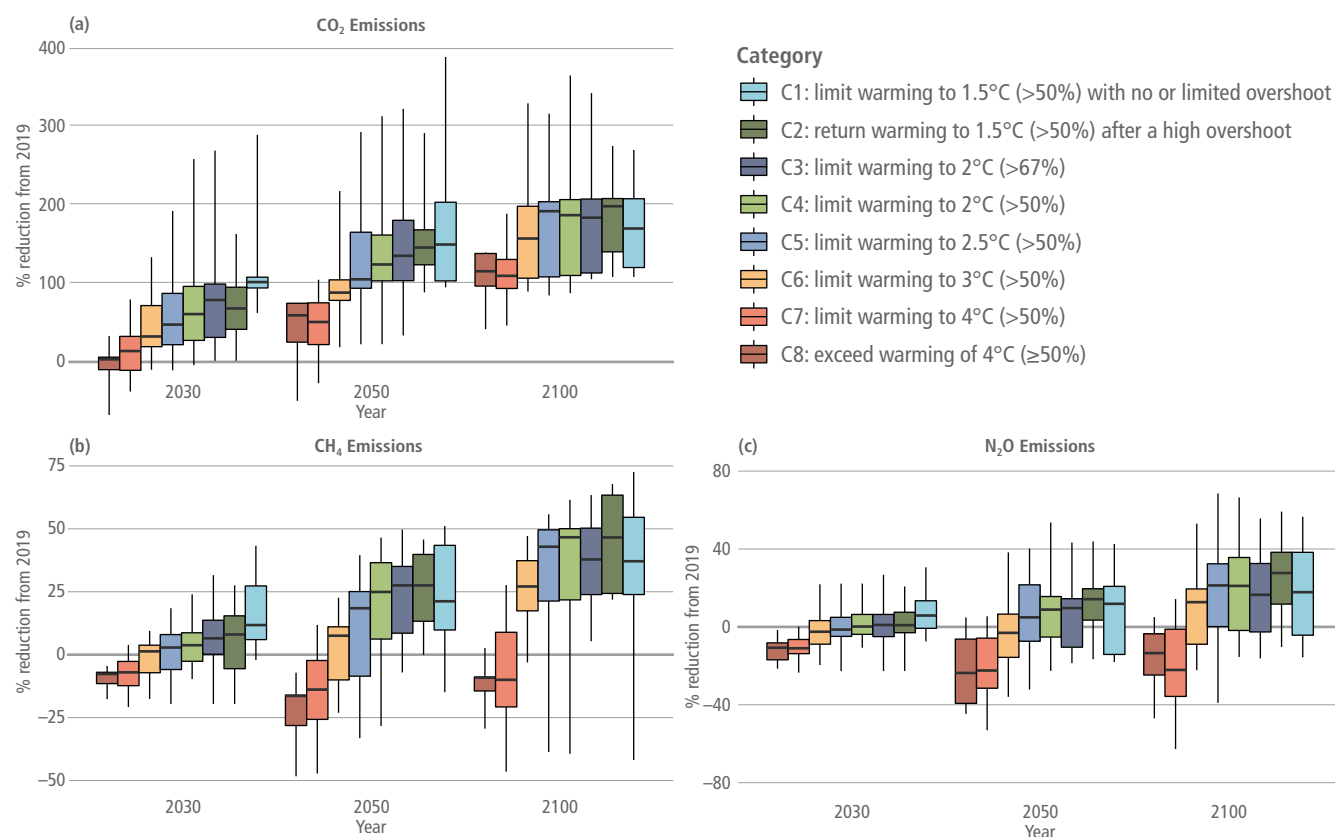

Figure 3.27 | Reduction in AFOLU GHG emissions from 2019. The AFOLU CO₂ estimates in this figure are not necessarily comparable with country GHG inventories (see Chapter 7).

¹⁷ Some studies calculate emissions reductions in 2050 compared to 2014, while others note emissions reductions in 2060 relative to 2018.

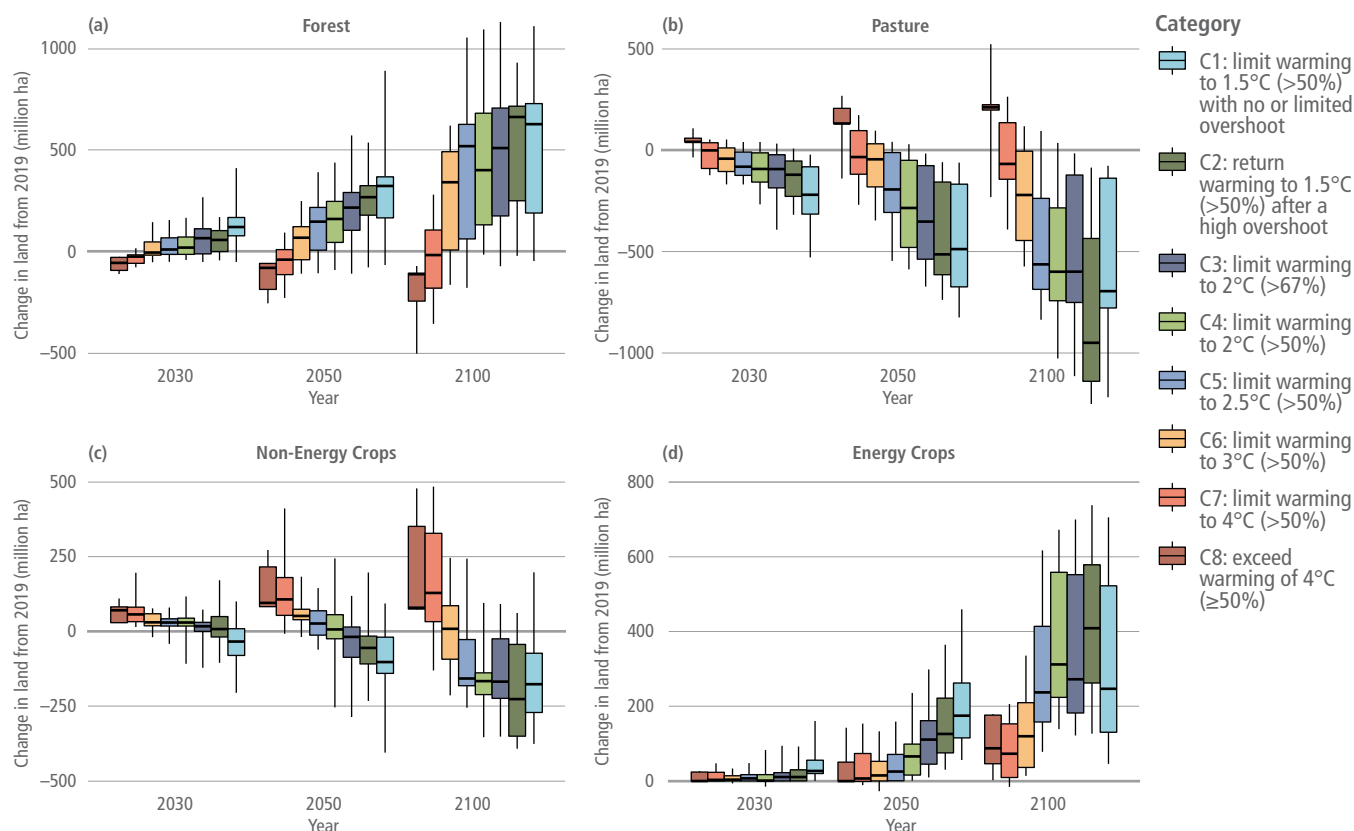

Figure 3.28 | Change in land cover from 2019 in million hectares. Positive values indicate an increase in area.

these studies include more mitigation options than IAMs (*medium confidence*) (Chapter 7).

Limiting warming to *likely* 2°C (>67%) or lower can result in large-scale transformation of the land surface (*high confidence*) (Popp et al. 2017; Rogelj et al. 2018a,b; Brown et al. 2019; Roe et al. 2019). The scale of land transformation depends, *inter alia*, on the temperature goal and the mitigation options included (Popp et al. 2017; Rogelj et al. 2018a; IPCC 2019a). Pathways with more demand-side mitigation options show less land transformation than those with more limited options (Grubler et al. 2018; van Vuuren et al. 2018; IPCC 2019a). Most of these pathways show increases in forest cover, with an increase of 322 million ha (–67 to 890 million ha) in 2050 in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, whereas bottom-up models portray an economic potential of 300–500 million ha of additional forest (Chapter 7). Many IAM pathways also include large amounts of energy cropland area, to supply biomass for bioenergy and BECCS, with 199 (56–482) million ha in 2050 in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. Large land transformations, such as afforestation/reforestation and widespread planting of energy crops, can have implications for biodiversity and sustainable development (Sections 3.7, 7.7.4 and 12.5).

Delayed mitigation has implications for land-use transitions (Hasegawa et al. 2021a). Delaying mitigation action can result in a temporary overshoot of temperature and large-scale deployment of CDR in the second half of the century to reduce temperatures from

their peak to a given level (Smith et al. 2019; Hasegawa et al. 2021a). IAM pathways rely on afforestation and BECCS as CDR measures, so delayed mitigation action results in substantial land-use change in the second half of the century with implications for sustainable development (Hasegawa et al. 2021a) (Section 3.7). Shifting to earlier mitigation action reduces the amount of land required for this, though at the cost of larger land-use transitions earlier in the century (Hasegawa et al. 2021a). Earlier action could also reduce climate impacts on agriculture and land-based mitigation options (Smith et al. 2019).

Some AFOLU mitigation options can enhance vegetation and soil carbon stocks such as reforestation, restoration of degraded ecosystems, protection of ecosystems with high carbon stocks and changes to agricultural land management to increase soil carbon (*high confidence*) (Griscom et al. 2017; de Coninck et al. 2018; Fuss et al. 2018; Smith et al. 2019) (AR6 WGIII Chapter 7). The time scales associated with these options indicate that carbon sinks in terrestrial vegetation and soil systems can be maintained or enhanced so as to contribute towards long-term mitigation (*high confidence*); however, many AFOLU mitigation options do not continue to sequester carbon indefinitely (Fuss et al. 2018; de Coninck et al. 2018; IPCC 2019a) (AR6 WGIII Chapter 7). In the very long term (the latter part of the century and beyond), it will become more challenging to continue to enhance vegetation and soil carbon stocks, so that the associated carbon sinks could diminish or even become sources (*high confidence*) (de Coninck et al. 2018; IPCC 2019a) (AR6 WGI Chapter 5). Sustainable forest management, including harvest and

forest regeneration, can help to remediate and slow any decline in the forest carbon sink, for example by restoring degraded forest areas, and so go some way towards addressing the issue of sink saturation (IPCC 2019) (AR6 WGI Chapter 5; and Chapter 7 in this report). The accumulated carbon resulting from mitigation options that enhance carbon sequestration (e.g., reforestation, soil carbon sequestration) is also at risk of future loss due to disturbances (e.g., fire, pests) (Boysen et al. 2017; de Coninck et al. 2018; Fuss et al. 2018; Smith et al. 2019; IPCC 2019a; Anderegg et al. 2020) (AR6 WGI Chapter 5). Maintaining the resultant high vegetation and soil carbon stocks could limit future land-use options, as maintaining these carbon stocks would require retaining the land use and land-cover configuration implemented to achieve the increased stocks.

Anthropogenic land CO₂ emissions and removals in IAM pathways cannot be directly compared with those reported in national GHG inventories (*high confidence*) (Grassi et al. 2018, 2021) (Section 7.2). Due to differences in definitions for the area of managed forests and which emissions and removals are considered anthropogenic, the reported anthropogenic land CO₂ emissions and removals differ by about 5.5 GtCO₂ yr⁻¹ between IAMs, which rely on bookkeeping approaches (e.g., Houghton and Nassikas 2017), and national GHG inventories (Grassi et al. 2021). Such differences in definitions can alter the reported time at which anthropogenic net zero CO₂ emissions are reached for a given emission scenario. Using national inventories would lead to an earlier reported time of net zero (van Soest et al. 2021b) or to lower calculated cumulative emissions until the time of net zero (Grassi et al. 2021) as compared to IAM pathways. The numerical differences are purely due to differences in the conventions applied for reporting the anthropogenic emissions and do not have any implications for the underlying land-use changes or mitigation measures in the pathways. Grassi et al. (Grassi et al. 2021) offer a methodology for adjusting to reconcile these differences and enable a more accurate assessment of the collective progress achieved under the Paris Agreement (Chapter 7 and Cross-Chapter Box 6 in Chapter 7).

(DACCS), enhanced weathering (EW), and ocean-based approaches, focusing on the role of these options in long-term mitigation pathways, using both IAMs (Chen and Tavoni 2013; Marcucci et al. 2017; Rickels et al. 2018; Fuhrman et al. 2019, 2020, 2021; Realmonte et al. 2019; Akimoto et al. 2021; Strefler et al. 2021a) and non-IAMs (Fuss et al. 2013; González and Ilyina 2016; Bednar et al. 2021; Shayegh et al. 2021). There are other options discussed in the literature, such as methane capture (Jackson et al. 2019), however, the role of these options in long-term mitigation pathways has not been quantified and is thus excluded here. Chapter 12 includes a more detailed description of the individual technologies, including their costs, potentials, financing, risks, impacts, maturity and upscaling.

Very few studies and pathways include other CDR options (Table 3.5). Pathways with DACCS include potentially large removal from DACCS (up to 37 GtCO₂ yr⁻¹ in 2100) in the second half of the century (Chen and Tavoni 2013; Marcucci et al. 2017; Realmonte et al. 2019; Fuhrman et al. 2020, 2021; Shayegh et al. 2021; Akimoto et al. 2021) and reduced cost of mitigation (Bistline and Blanford 2021; Strefler et al. 2021a). At large scales, the use of DACCS has substantial implications for energy use, emissions, land, and water; substituting DACCS for BECCS results in increased energy usage, but reduced land-use change and water withdrawals (Fuhrman et al., 2020, 2021) (Chapter 12.3.2; AR6 WGI Chapter 5). The level of deployment of DACCS is sensitive to the rate at which it can be scaled up, the climate goal or carbon budget, the underlying socio-economic scenario, the availability of other decarbonisation options, the cost of DACCS and other mitigation options, and the strength of carbon-cycle feedbacks (Chen and Tavoni 2013; Fuss et al. 2013; Honegger and Reiner 2018; Realmonte et al. 2019; Fuhrman et al. 2020; Bistline and Blanford 2021; Fuhrman et al. 2021; Strefler et al. 2021a) (AR6 WGI Chapter 5). Since DACCS consumes energy, its effectiveness depends on the type of energy used; the use of fossil fuels would reduce its sequestration efficiency (Creutzig et al. 2019; NASEM 2019; Babacan et al. 2020). Studies with additional CDR options in addition to DACCS (e.g., enhanced weathering, BECCS, afforestation, biochar, and soil carbon sequestration) find that CO₂ removal is spread across

Table 3.5 | Carbon dioxide removal in assessed pathways. Scenarios are grouped by temperature categories, as defined in Section 3.2.4. Quantity indicates the median and 5–95th percentile range of cumulative sequestration from 2020 to 2100 in GtCO₂. Count indicates the number of scenarios with positive values for that option. Source: AR6 Scenarios Database.

CDR option	C1: Limit warming to 1.5°C (>50%) with no or limited overshoot		C2: Return warming to 1.5°C (>50%) after a high overshoot		C3: Limit warming to 2°C (>67%)	
	Quantity	Count	Quantity	Count	Quantity	Count
CO ₂ removal on managed land including Afforestation/Reforestation ¹	262 (17–397)	64	330 (28–439)	82	209 (20–415)	196
BECCS	334 (32–780)	91	464 (226–842)	122	291 (174–653)	294
Enhanced weathering	0 (0–47)	2	0 (0–0)	1	0 (0–0)	1
DACCS	30 (0–308)	31	109 (0–539)	24	19 (0–253)	91

¹ Cumulative CDR from AFOLU cannot be quantified precisely because models use different reporting methodologies that in some cases combine gross emissions and removals, and use different baselines.

3.4.7 Other Carbon Dioxide Removal Options

This subsection includes other CDR options not discussed in the previous subsections, including direct air carbon capture and storage

available options (Holz et al. 2018; Strefler et al. 2021a). Similar to DACCS, the deployment of deep-ocean storage depends on cost and the strength of carbon-cycle feedbacks (Rickels et al. 2018).

3.5 Interaction Between Near-, Medium- and Long-term Action in Mitigation Pathways

This section assesses the relationship between long-term climate goals and short- to medium-term emissions reduction strategies based on the mitigation pathway literature. After an overview of this relationship (Section 3.5.1), it provides an assessment of what currently planned near-term action implies for limiting warming to 1.5°C–2°C (Section 3.5.2), and to what extent pathways with accelerated action beyond current NDCs can improve the ability to keep long-term targets in reach (Section 3.5.3).

The assessment in this section shows that if mitigation ambitions in NDCs announced prior to COP26¹⁸ are followed until 2030, leading to estimated emissions of 47–57 GtCO₂-eq in 2030¹⁹ (Section 4.2.2), it is no longer possible to limit warming to 1.5°C (>50%) with no or limited overshoot (*high confidence*). Instead, it would entail high overshoot (typically >0.1°C) and reliance on net negative CO₂ emissions with uncertain potential to return warming to 1.5°C (>50%) by the end of the century. It would also strongly increase mitigation challenges to limit warming to 2°C (>67%) (*high confidence*). GHG emissions reductions would need to abruptly increase after 2030 to an annual average rate of 1.4–2.0 GtCO₂-eq during the period 2030–2050, around 70% higher than in mitigation pathways assuming immediate action¹ to limit warming to 2°C (>67%). The higher post-2030 reduction rates would have to be obtained in an environment of continued buildup of fossil fuel infrastructure and less development of low-carbon alternatives until 2030. A lock-in to fossil fuel-intensive production systems (carbon lock-in) will increase the societal, economic and political strain of a rapid low-carbon transition after 2030 (*high confidence*).

The section builds on previous assessments in the IPCC's *Fifth Assessment Report* (Clarke et al. 2014) and the *IPCC Special Report on 1.5°C Warming* (Rogelj et al. 2018a). The literature assessed in these two reports has focused on delayed action until 2030 in the context of limiting warming to 2°C (den Elzen et al. 2010; van Vuuren and Riahi 2011; Luderer et al. 2013, 2016; Rogelj et al. 2013a; Kriegler et al. 2015; Riahi et al. 2015) and 1.5°C (Rogelj et al. 2013b; Luderer et al. 2018; Streffler et al. 2018). Here we provide an update of these assessments drawing on the most recent literature on global mitigation pathways. New studies have focused, *inter alia*, on constraining near-term developments by peak warming limits (Rogelj et al. 2019b; Riahi et al. 2021; Streffler et al. 2021b) and updating assumptions about near- and medium-term emissions developments based on national plans and long-term strategies (Roelfsema et al. 2020) (Section 4.2). Several studies have explored new types of pathways with accelerated action bridging between current policy plans and the goal of limiting warming below 2°C (Kriegler et al. 2018a; van Soest et al. 2021a) and looked at hybrid international policy regimes to phase in global collective action (Bauer et al. 2020).

3.5.1 Relationship Between Long-term Climate Goals and Near- to Medium-term Emissions Reductions

The close link between cumulative CO₂ emissions and warming has strong implications for the relationship between near-, medium-, and long-term climate action to limit global warming. The AR6 WGI Assessment has estimated a remaining carbon budget of 500 (400) GtCO₂ from the beginning of 2020 onwards for staying below 1.5°C with 50% (67%) likelihood, subject to additional uncertainties about historic warming and the climate response, and variations in warming from non-CO₂ climate forcers (Canadell and Monteiro 2019) (AR6 WGI Chapter 5, Section 5.5). For comparison, if current CO₂ emissions of more than 40 GtCO₂ are keeping up until 2030, more than 400 GtCO₂ will be emitted during 2021–2030, already exhausting the remaining carbon budget for 1.5°C by 2030.

The relationship between warming limits and near-term action is illustrated in Figure 3.29, using a set of 1.5°C–2°C scenarios with different levels of near-term action, overshoot and non-CO₂ warming contribution from a recent study (Riahi et al. 2021). In general, the more CO₂ is emitted until 2030, the less CO₂ can be emitted thereafter to stay within a remaining carbon budget and below a warming limit. Scenarios with immediate action to observe the warming limit give the longest time to exhaust the associated remaining carbon budget and reach net zero CO₂ emissions (see light blue lines in Figure 3.29 and Cross-Chapter Box 3 in this chapter). In comparison, following projected NDC emissions until 2030 would imply a more pronounced drop in emissions from 2030 levels to net zero to make up for the additional near-term emissions (see orange lines in Figure 3.29). If such a drop does not occur, the remaining carbon budget is exceeded and net negative CO₂ emissions are required to return global mean temperature below the warming limit (see black lines in Figure 3.29) (Clarke et al. 2014; Fuss et al. 2014; Rogelj et al. 2018a).

The relationship between warming limits and near-term action is also affected by the warming contribution of non-CO₂ greenhouse gases and other short-lived climate forcers (Section 3.3; AR6 WGI Section 6.7). The estimated budget values for limiting warming to 1.5°C–2°C already assume stringent reductions in non-CO₂ greenhouse gases and non-CO₂ climate forcing as found in 1.5°C–2°C pathways (Section 3.3 and Cross-Working Group Box 1 in this chapter; AR6 WGI Section 5.5 and Box 5.2 in Chapter 5). Further variations in non-CO₂ warming observed across 1.5°C–2°C pathways can vary the median estimate for the remaining carbon budget by 220 GtCO₂ (AR6 WGI Section 5.5). In 1.5°C–2°C pathways, the non-CO₂ warming contribution differs strongly between the near, medium and long term. Changes to the atmospheric composition of short-lived climate forcers (SLCFs) dominate the warming response in the near term (AR6 WGI Section 6.7). CO₂ reductions are combined with strong reductions in air pollutant emissions due to rapid reduction in fossil fuel combustion and in some cases the assumption of stringent air quality policies (Rao et al. 2017b; Smith et al. 2020c). As air pollutants exert a net-cooling effect,

¹⁸ Original NDCs refer to those submitted to the UNFCCC in 2015 and 2016. See Section 4.2.

¹⁹ In this section, the emissions range associated with NDCs announced prior to COP26 (or original NDCs) refer to the combined emissions ranges from the two cases of implementing only the unconditional elements of NDCs announced prior to COP26 (50–57 GtCO₂-eq) and implementing both unconditional and conditional elements of NDCs announced prior to COP26 (47–55 GtCO₂-eq), if not specified otherwise.

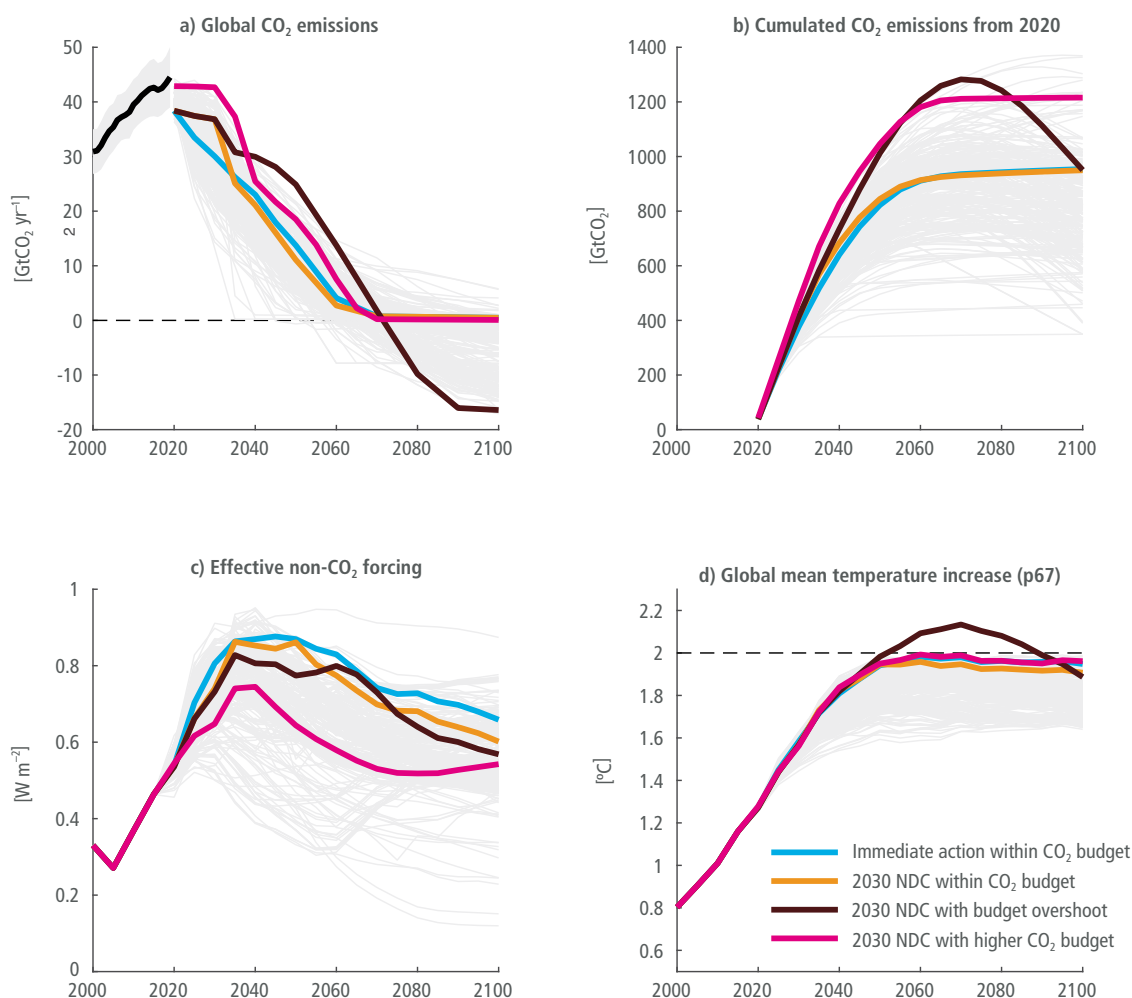

Figure 3.29 | Illustration of emissions and climate response in four mitigation pathways with different assumptions about near-term policy developments, global warming limit and non-CO₂ warming contribution drawn from Riahi et al. (2021). Shown are (a) CO₂ emissions trajectories, (b) cumulated CO₂ emissions, (c) effective non-CO₂ radiative forcing, and (d) the resulting estimate of the 67th percentile of global mean temperature response relative to 1850–1900. Light blue lines show a scenario that acts immediately on a remaining carbon budget of 900 GtCO₂ from 2020 without allowing net negative CO₂ emissions (i.e., temporary budget overshoot) (COFFEE 1.1, Scenario EN_NPi2020_900). Orange and black lines show scenarios drawn from the same model that follow the NDCs until 2030 and thereafter introduce action to stay within the same budget – in one case excluding net negative CO₂ emissions like before (orange lines; COFFEE 1.1, Scenario EN-INDCi2030_900) and in the other allowing for a temporary overshoot of the carbon budget until 2100 (black lines; COFFEE 1.1, Scenario EN-INDCi2030_900f). Light blue lines describe a scenario following the NDCs until 2030, and then aiming for a higher budget of 2300 GtCO₂ without overshoot (AIM/CGE 2.2, Scenario EN-INDCi2030_1200). It is drawn from another model which projects a lower anthropogenic non-CO₂ forcing contribution and therefore achieves about the same temperature outcome as the other two non-overshoot scenarios despite the higher CO₂ budget. Grey funnels include the trajectories from all scenarios that limit warming to 2°C (>67%) (category C3). Historical CO₂ emissions until 2019 are from Chapter SM.2.1 EDGAR v6.0.

their reduction drives up non-CO₂ warming in the near term, which can be attenuated by the simultaneous reduction of methane and black carbon (Shindell and Smith 2019; Smith et al. 2020b) (AR6 WGI Section 6.7). After 2030, the reduction in methane concentrations and associated reductions in tropospheric ozone levels tend to dominate so that a peak and decline in non-CO₂ forcing and non-CO₂-induced warming can occur before net zero CO₂ is reached (Figure 3.29) (Rogelj et al. 2018a). The more stringent the reductions in methane and other short-lived warming agents such as black carbon, the lower this peak and the earlier the decline of non-CO₂ warming, leading to a reduction of warming rates and overall warming in the near to medium term (Harmsen et al. 2020; Smith et al. 2020b). This is important for keeping warming below a tight warming limit that is already reached around mid-century as is the case in 1.5°C pathways (Xu and Ramanathan

2017). Early and deep reductions of methane emissions, and other short-lived warming agents such as black carbon, provide space for residual CO₂-induced warming until the point of net zero CO₂ emissions is reached (see purple lines in Figure 3.29). Such emissions reductions have also been advocated due to co-benefits for, for example, reducing air pollution (Rao et al. 2016; Shindell et al. 2017a, 2018; Shindell and Smith 2019; Rauner et al. 2020a; Vandyck et al. 2020).

The relationship between long-term climate goals and near-term action is further constrained by social, technological, economic and political factors (Cherp et al. 2018; van Sluisveld et al. 2018b; Aghion et al. 2019; Mercure et al. 2019; Trutnevyte et al. 2019b; Jewell and Cherp 2020). These factors influence path dependency and transition speed (Pahle et al. 2018; Vogt-Schilb et al. 2018). While detailed

integrated assessment modelling of global mitigation pathways accounts for technology inertia (Bertram et al. 2015a; Mercure et al. 2018) and technology innovation and diffusion (Wilson et al. 2013; van Sluisveld et al. 2018a; Luderer et al. 2021), there are limitations in capturing socio-technical and political drivers of innovation, diffusion and transition processes (Gambhir et al. 2019; Köhler et al. 2019; Hirt et al. 2020; Keppo et al. 2021). Mitigation pathways show a wide range of transition speeds that have been interrogated in the context of socio-technical inertia (Gambhir et al. 2017; Kefford et al. 2018; Kriegler et al. 2018a; Brutschin et al. 2021) vs accelerating technological change and self-enforcing socio-economic developments (Creutzig et al. 2017; Zenghelis 2019) (Section 3.8). Diagnostic analysis of detailed IAMs found a lag of 8–20 years between the convergence of emissions pricing and the convergence of emissions response after a period of differentiated emission prices (Harmsen et al. 2021). This provides a measure of the inertia to changing policy signals in the model response. It is about half the time scale of 20–40 years observed for major energy transitions (Grubb et al. 2021). Hence, the mitigation pathways assessed here capture socio-technical inertia in reducing emissions, but the limited modelling of socio-political factors may alter the extent and persistence of this inertia.

3.5.2 Implications of Near-term Emission Levels for Keeping Long-term Climate Goals Within Reach

The implications of near-term climate action for long-term climate outcomes can be explored by comparing mitigation pathways with different near-term emissions developments aiming for the same climate target (Riahi et al. 2015; Vrontisi et al. 2018; Roelfsema et al. 2020). A particular example is the comparison of cost-effective pathways with immediate action to limit warming to 1.5°C–2°C with mitigation pathways pursuing more moderate mitigation action until 2030. After the adoption of the Paris Agreement, near-term action was often modelled to reflect conditional and unconditional elements of originally submitted NDCs (2015–2019) (Fawcett et al. 2015; Fujimori et al. 2016a; Kriegler et al. 2018a; Vrontisi et al. 2018; Roelfsema et al. 2020). The most recent modelling studies also include submission of updated NDCs or announcements of planned updates in the first half of 2021 (Network for Greening the Financial System 2021; Riahi et al. 2021). Emissions levels under NDCs announced prior to COP26 are assessed to range between 47–57 GtCO₂-eq in 2030 (Section 4.2.2). This assessed range corresponds well to 2030 emissions levels in 2°C mitigation pathways in the literature that are designed to follow the original or updated NDCs until 2030.²⁰ For the 139 scenarios of this kind that are collected in the AR6 scenario database and that still limit warming to 2°C (>67%), the 2030 emissions range is 53 (45–58) GtCO₂-eq (based on native model reporting) and 52.5 (47–56.5) GtCO₂-eq, respectively (based on harmonised emissions data for climate assessment (Annex III.2.5.1); median and 5–95th percentile). This close match allows a robust assessment of the implications of implementing NDCs announced prior to COP26 for

post-2030 mitigation efforts and warming outcomes based on the literature and the AR6 scenarios database.

Without a strengthening of policies beyond those that are implemented by the end of 2020, GHG emissions are projected to rise beyond 2025, leading to a median global warming of 3.2 [2.2 to 3.5] °C by 2100. Modelled pathways that are consistent with NDCs announced prior to COP26 until 2030 and assume no increase in ambition thereafter have lower emissions, leading to a median global warming of 2.8°C [2.1–3.4°C] by 2100.

The assessed emission ranges from implementing the unconditional (unconditional and conditional) elements of NDCs announced prior to COP26 implies an emissions gap to cost-effective mitigation pathways of 19–26 (16–23) GtCO₂-eq in 2030 for limiting warming to 1.5°C (>50%) with no or limited overshoot and 10–16 (6–14) GtCO₂-eq in 2030 for limiting warming to 2°C (>67%) (Cross-Chapter Box 4 in Chapter 4). The emissions gap gives rise to a number of mitigation challenges (Kriegler et al. 2013a, 2018a,b; Luderer et al. 2013, 2018; Rogelj et al. 2013a; Fawcett et al. 2015; Riahi et al. 2015; Fujimori et al. 2016b; Streffer et al. 2018; Winning et al. 2019; SEI et al. 2020; UNEP 2020): (i) larger transitional challenges post-2030 to still remain under the warming limit, in particular higher CO₂ emissions reduction rates and technology transition rates required during 2030–2050; (ii) larger lock-in into carbon-intensive infrastructure and increased risk of stranded fossil fuel assets (Section 3.5.2.2); and (iii) larger reliance on CDR to reach net zero CO₂ more rapidly and compensate excess emissions in the second half of the century (Section 3.5.2.1). All these factors exacerbate the socio-economic strain of implementing the transition, leading to an increased risk of overshooting the warming and a higher risk of climate change impacts (Drouet et al. 2021).

The challenges are illustrated in Table 3.6 and Figure 3.30, surveying global mitigation pathways in the literature that were collected in the AR6 scenarios database. There is a clear trend of increasing peak warming with increasing 2030 GHG emission levels (Figure 3.30a,b). In particular, there is no mitigation pathway designed to follow the NDCs until 2030 that can limit warming to 1.5°C (>50%) with no or limited overshoot. Our assessment confirms the finding of the *IPCC Special Report on Global Warming of 1.5°C* (Rogelj et al. 2018) for the case of NDCs announced prior to COP26 that pathways following the NDCs until 2030 ‘would not limit global warming to 1.5°C, even if supplemented by very challenging increases in the scale and ambition of emissions reductions after 2030’ (SR1.5 SPM). This assessment is now more robust than in SR1.5 as it is based on a larger set of 1.5°C–2°C pathways with better representation of current trends and plans covering a wider range of post-2030 emissions developments. In particular, a recent multi-model study limiting peak cumulative CO₂ emissions for a wide range of carbon budgets and immediate vs NDC-type action until 2030 established a feasibility frontier for the existence of such pathways across participating models (Riahi et al. 2021).

²⁰ The intended design of mitigation pathways in the literature can be deduced from underlying publications and study protocols. This information was collected as part of this assessment to establish a categorisation of policy assumptions underpinning the mitigation pathways collected in the AR6 scenario database (Section 3.2 and Annex III.3.2.2).

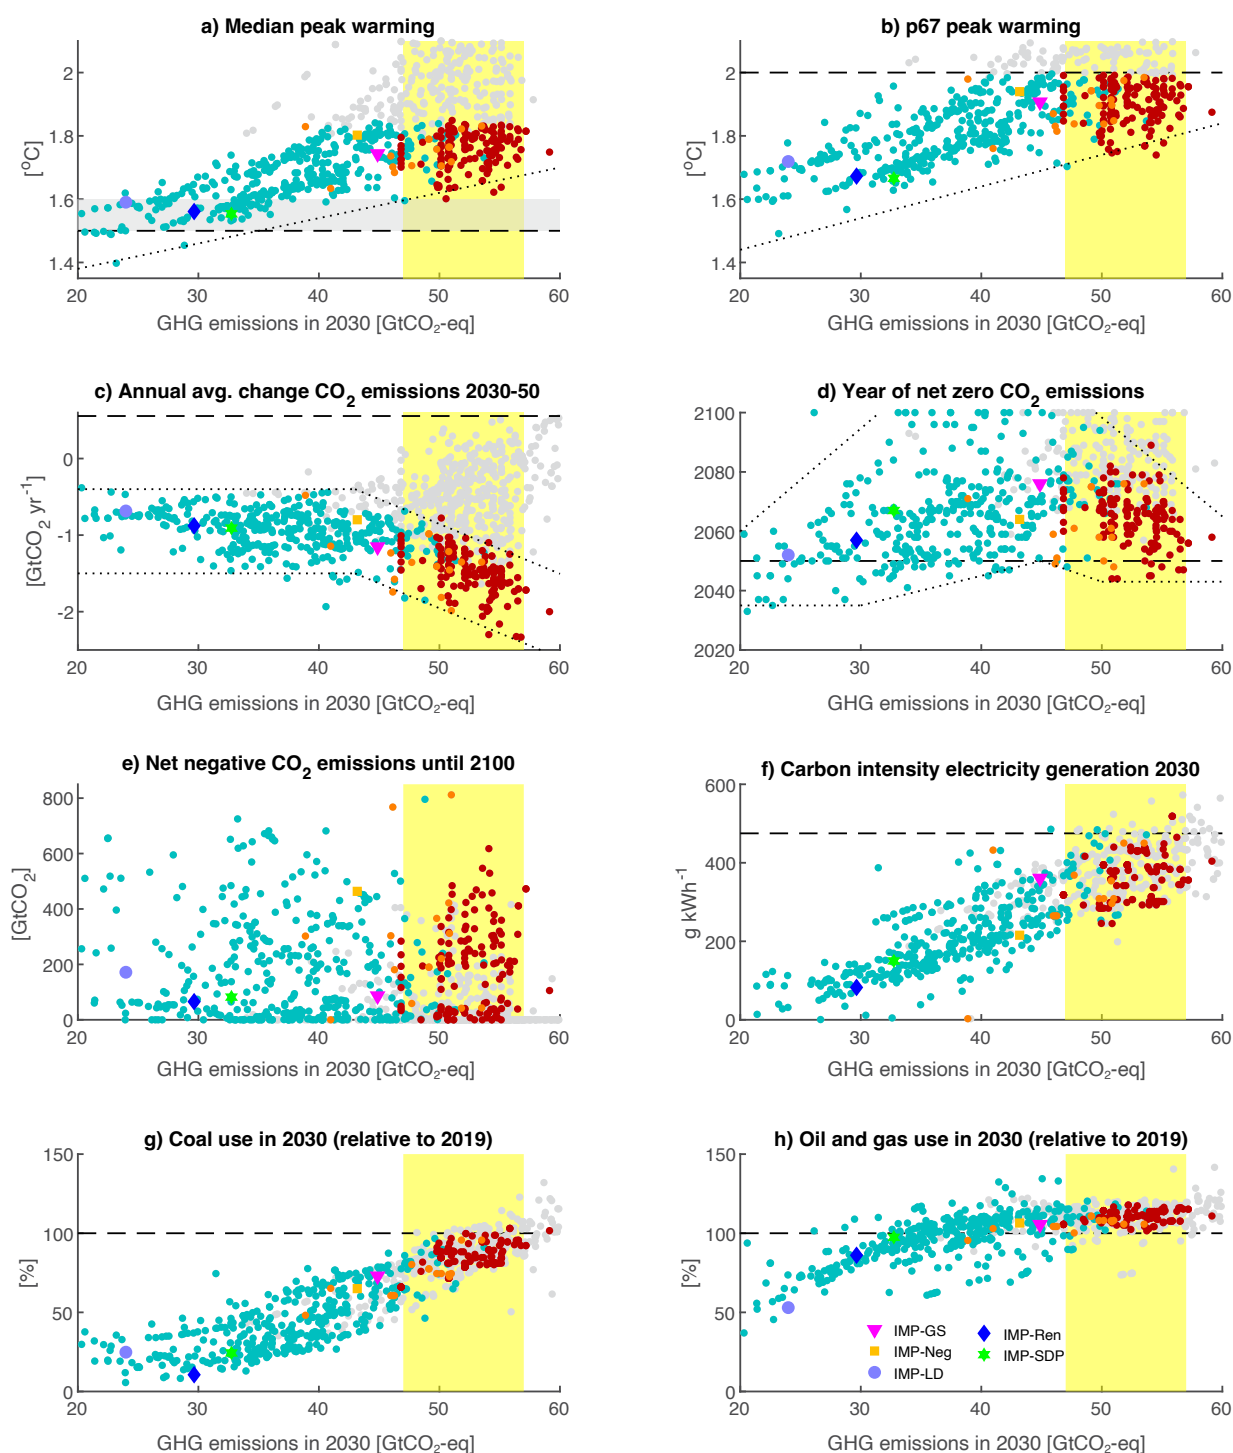

Figure 3.30 | Relationship between level of global GHG emissions in 2030 and selected indicators as listed in the panel titles for scenarios collected in the AR6 scenario database. Emissions data based on harmonised emissions used for the climate assessment. All scenarios that limit warming to 2°C (>67%) or lower are coloured blue or red (see p67 peak warming in panel (b)). The large majority of blue-coloured scenarios act immediately on the temperature target, while red-coloured scenarios depict all those that were designed to follow the NDCs or lesser action until 2030 and orange-coloured scenarios comprise a small set of pathways with additional regulatory action beyond NDCs (Section 3.5.3). Grey-coloured scenarios do not limit warming to 2°C (>67%) due to temporary overshoot or towards the end of the century. Large markers denote the five Illustrative Mitigation Pathways (IMPs) (legend in Panel (h); Section 3.2). Shaded yellow areas depict the estimated range of 2030 emissions from NDCs announced prior to COP26 (Section 4.2.2). Dotted lines are inserted in some panels to highlight trends in the dependency of selected output variables on 2030 GHG emissions levels (Section 3.5.2).

Table 3.6 | Comparison of key scenario characteristics for five scenario classes (see Table 3.2): (i) immediate action to limit warming to 1.5°C (>50%) with no or limited overshoot, (ii) near term action following the NDCs until 2030 and returning warming to below 1.5°C (>50%) by 2100 after a high overshoot, (iii) immediate action to limit warming to 2°C (>67%), (iv) near term action following the NDCs until 2030 followed by post-2030 action to limit warming to 2°C (>67%). Also shown are the characteristics for (v) the combined class of all scenarios that limit warming to 2°C (>67%). The classes (ii) and (iv) comprise the large majority of scenarios indicated by red dots, and the classes (i) and (iii) comprise the scenarios depicted by blue dots in Figure 3.30. Shown are median and interquartile ranges (in brackets) for selected global indicators. Emissions ranges are based on harmonized emissions data for the climate assessment with the exception of land use CO₂ emissions for which uncertainty in historic estimates is large. Numbers are rounded to the nearest 5, with the exception of cumulative CCS, BECCS, and net negative CO₂ emissions rounded to the nearest 10.

Global indicators	1.5°C	1.5°C (>50%) by 2100	2°C (>67%)		
	Immediate action, with no or limited overshoot (C1, 97 scenarios)	NDCs until 2030, with overshoot before 2100 (subset of 42 scenarios in C2)	Immediate action (C3a, 204 scenarios)	NDCs until 2030 (C3b; 97 scenarios)	All (C3; 311 scenarios)
Change in GHG emissions in 2030 (% rel to 2019)	–45 (–50,–40)	–5 (–5,0)	–25 (–35,–20)	–5 (–10,0)	–20 (–30,–10)

Change in carbon intensity of non-electric final energy consumption in 2030 (% rel to 2019)	–15 (–15,–10)	0 (–5,0)	–10 (–10,–5)	0 (–5,5)	–5 (–10,0)
in 2050 (% rel to 2019)	–50 (–55,–40)	–35 (–40,–30)	–30 (–35,–25)	–30 (–40,–20)	–30 (–35,–20)

The 2030 emissions levels in the NDCs announced prior to COP26 also tighten the remaining space to limit warming to 2°C (>67%). As shown in Figure 3.30b, the 67th percentile of peak warming reaches values above 1.7°C in pathways with 2030 emissions levels in this range. To still limit warming to 2°C (>67%), the global post-2030 GHG emission reduction rates would need to be abruptly raised in 2030 from 0–0.7 GtCO₂-eq yr⁻¹ to an average of 1.4–2.0 GtCO₂-eq yr⁻¹ during the period 2030–2050 (Figure 3.30c), around 70% higher than in immediate mitigation pathways confirming findings in the literature (Winning et al. 2019). Their average reduction rate of 0.6–1.4 GtCO₂ yr⁻¹ would already be unprecedented at the global scale and, with a few exceptions, national scale for an extended period of time (Riahi et al. 2015). For comparison, the impact of COVID-19 on the global economy is projected to have led to a decline of around 2.5–3 GtCO₂ of global CO₂ emissions from fossil fuels and industry in 2020 (Friedlingstein et al. 2020) (Section 2.2).

The increased post-2030 transition challenge in mitigation pathways with moderate near-term action is also reflected in the timing of reaching net zero CO₂ emissions (Figure 3.30d and Cross-Chapter Box 3 in this chapter). As 2030 emission levels and the cumulated CO₂ emissions until 2030 increase, the remaining time for dropping to net zero CO₂ and staying within the remaining carbon budget shortens (Figure 3.29). This gives rise to an inverted v-shape of the lower bound on the year of reaching net zero as a function of 2030 emissions levels. Reaching low emissions in 2030 facilitates reaching net zero early (left leg of the inverted v), but staying high until 2030 also requires reaching net zero CO₂ faster to compensate for higher emissions early on (right leg of the inverted v). Overall, there is a considerable spread of the timing of net zero CO₂ for any 2030 emissions level due to variation in the timing of spending the remaining carbon budget and the non-CO₂ warming contribution (Cross-Chapter Box 3 in this chapter).

There is also a profound impact on the underlying transition of energy and land use (Figure 3.30f–h and Table 3.6). Scenarios following NDCs until 2030 show a much smaller reduction in fossil fuel use, a slower growth in renewable energy use, and a smaller reduction in CO₂ and CH₄ land-use emissions in 2030 compared to immediate action scenarios. This is then followed by a much faster reduction of land-use emissions and fossil fuels, and a larger increase of nuclear energy, bioenergy and non-biomass renewable energy during the medium term in order to get close to the levels of the immediate action pathways in 2050. This is combined with a larger amount of net negative CO₂ emissions that are used to compensate the additional emissions before 2030. The faster transition during 2030–2050 is taking place from a greater investment in fossil fuel infrastructure and lower deployment of low-carbon alternatives in 2030, adding to the socio-economic challenges to realise the higher transition rates (Section 3.5.2.2). Therefore, these pathways also show higher mitigation costs, particularly during the period 2030–2050, than immediate action scenarios (Section 3.6.1 and Figure 3.34d) (Liu et al. 2016; Krieglner et al. 2018a; Vrontisi et al. 2018). Given these circumstances and the fact the modelling of socio-political and institutional constraints is limited in Integrated Assessment Models (IAMs) (Gambhir et al. 2019; Köhler et al. 2019; Hirt et al. 2020; Keppo et al. 2021), the feasibility of realising these scenarios is assessed to

be lower (Gambhir et al. 2017; Napp et al. 2017; Brutschin et al. 2021) (cf. Section 3.8), increasing the risk of an overshoot of climate goals.

3.5.2.1 Overshoot and Net Negative CO₂ Emissions

If near- to medium-term emissions developments deplete the remaining carbon budget, the associated warming limit will be overshoot. Some pathways that return warming to 1.5°C (>50%) by the end of the century show mid-century overshoots of up to 1.8°C median warming. The overshoot tends to be higher, the higher the 2030 emissions. Mitigation pathways with 2030 emissions levels in the NDCs announced prior to COP26 consistently overshoot 1.5°C by 0.15°C–0.3°C. This leads to higher risks from climate change impacts during the time of overshoot compared to pathways that limit warming to 1.5°C (>50%) with no or limited overshoot (Schleussner et al. 2016a; Mengel et al. 2018; Hofmann et al. 2019; Lenton et al. 2019; Tachiiri et al. 2019; Drouet et al. 2021). Furthermore, even if warming is reversed by net negative emissions, other climate changes such as sea level rise would continue in their current direction for decades to millennia (AR6 WGI Sections 4.6 and 5.6).

Returning warming to lower levels requires net negative CO₂ emissions in the second half of the century (Clarke et al. 2014; Fuss et al. 2014; Rogelj et al. 2018a). The amount of net negative CO₂ emissions in pathways limiting warming to 1.5°C–2°C climate goals varies widely, with some pathways not deploying net negative CO₂ emissions at all and others deploying up to –600 to –800 GtCO₂. The amount of net negative CO₂ emissions tends to increase with 2030 emissions levels (Figure 3.30e and Table 3.6). Studies confirmed the ability of net negative CO₂ emissions to reduce warming, but pointed to path dependencies in the storage of carbon and heat in the Earth System and the need for further research particularly for cases of high overshoot (Zickfeld et al. 2016, 2021; Keller et al. 2018a,b; Tokarska et al. 2019). The AR6 WGI assessed the reduction in global surface temperature to be approximately linearly related to cumulative CO₂ removal and, with lower confidence, that the amount of cooling per unit CO₂ removed is approximately independent of the rate and amount of removal (AR6 WGI TS.3.3.2). Still there remains large uncertainty about a potential asymmetry between the warming response to CO₂ emissions and the cooling response to net negative CO₂ emissions (Zickfeld et al. 2021). It was also shown that warming can adversely affect the efficacy of carbon dioxide removal measures and hence the ability to achieve net negative CO₂ emissions (Boysen et al. 2016).

Obtaining net negative CO₂ emissions requires massive deployment of carbon dioxide removal (CDR) in the second half of the century, on the order of 220 (160–370) GtCO₂ for each 0.1°C degree of cooling (based on the assessment of the *likely* range of the transient response to cumulative CO₂ emissions in AR6 WGI Section 5.5 in Chapter 5, not taking into account potential asymmetries in the temperature response to CO₂ emissions and removals). CDR is assessed in detail in Section 12.3 of this report (see also Cross-Chapter Box 8 in Chapter 12). Here we only point to the finding that CDR ramp-up rates and absolute deployment levels are tightly limited by technological, social, political, institutional and sustainability constraints (Smith et al. 2016; Boysen et al. 2017; Fuss et al. 2018, 2020; Nemet

et al. 2018; Hilaire et al. 2019; Jia et al. 2019) (Section 12.3). CDR therefore cannot be deployed arbitrarily to compensate any degree of overshoot. A fraction of models was not able to compute pathways that would follow the mitigation ambition in unconditional and conditional NDCs until 2030 and return warming to below 1.5°C by 2100 (Luderer et al. 2018; Roelfsema et al. 2020; Riahi et al. 2021). There exists a three-way trade-off between near-term emissions developments until 2030, transitional challenges during 2030–50, and long-term CDR deployment post-2050 (Sanderson et al. 2016; Holz et al. 2018; Streffler et al. 2018). For example, Streffler et al. (2018) find that if CO₂ emission levels stay at around 40 GtCO₂ until 2030, within the range of what is projected for NDCs announced prior to COP26, rather than being halved to 20 GtCO₂ until 2030, CDR deployment in the second half of the century would have to increase by 50–100%, depending on whether the 2030–2050 CO₂ emissions reduction rate is doubled from 6% to 12% or kept at 6% yr⁻¹. This three-way trade-off has also been identified at the national level (Pan et al. 2020).

In addition to enabling a temporary budget overshoot by net negative CO₂ emissions in the second half of the century, CDR can also be used to compensate – on an annual basis – residual CO₂ emissions from sources that are difficult to eliminate and to reach net zero CO₂ emissions more rapidly if deployed before this point (Kriegler et al. 2013b; Rogelj et al. 2018a). This explains its continued deployment in pathways that exclude overshoot and net negative CO₂ emissions (Riahi et al. 2021). However, given the time scales that would likely be needed to ramp-up CDR to gigatonne scale (Nemet et al. 2018), it can be expected to only make a limited contribution to reaching net zero CO₂ as fast as possible. In the vast majority (95%) of 1.5°C–2°C mitigation pathways assessed in this report, cumulative CDR deployment did not exceed 100 GtCO₂ until mid-century. This adds to the risk of excessively relying on CDR to compensate for weak mitigation action until 2030 by either facilitating massive net CO₂ emissions reduction rates during 2030–2050 or allowing a high temporary overshoot of 1.5°C until the end of the century. If international burden-sharing considerations are taken into account, the CDR penalty for weak action could increase further, in particular for developed countries (Fyson et al. 2020). Further assessment of CDR deployment in 1.5°C–2°C mitigation pathways is found in Section 3.4.7.

3.5.2.2 Carbon Lock-in and Stranded Assets

There already exists a substantial and growing carbon lock-in today, as measured by committed emissions associated with existing long-lived infrastructure (Section 2.7 and Figure 2.31). If existing fossil fuel infrastructure would continue to be operated as historically, it would entail CO₂ emissions exceeding the carbon budget for 1.5°C (Section 2.7.2 and Figure 2.32). However, owner-operators and societies may choose to retire existing infrastructure earlier than in the past, and committed emissions are thus contingent on the competitiveness of non-emitting alternative technologies and climate policy ambition. Therefore, in mitigation pathways, some infrastructure may become stranded assets. Stranded assets have been defined as ‘assets that have suffered from unanticipated or

premature write-downs, devaluations or conversion to liabilities’ (Caldecott 2017).

A systematic map of the literature on carbon lock-in has synthesized quantification of stranded assets in the mitigation pathways literature, and showed that (i) coal power plants are the most exposed to risk of becoming stranded, (ii) delayed mitigation action increases stranded assets, and (iii) sectoral distribution and the amount of stranded assets differ between countries (Fisch-Romito et al. 2021). There is high agreement that existing fossil fuel infrastructure would need to be retired earlier than historically, used less, or retrofitted with CCS, to stay within the remaining carbon budgets of limiting warming to 1.5°C or 2°C (Johnson et al. 2016; Kefford et al. 2018; Pfeiffer et al. 2018; Cui et al. 2019; Fofrich et al. 2020; Rogelj et al. 2018a). Studies estimate that cumulative early retired power plant capacities by 2060 can be up to 600 GW for gas and 1700 GW for coal (Iyer et al. 2015a; Kefford et al. 2018), that only 42% of the total capital stock of both operating and planned coal-fired power plants can be utilised to be compatible with the 2°C target (Pfeiffer et al. 2018), and that coal-fired power plants in scenarios consistent with keeping global warming below 2°C or 1.5°C retire one to three decades earlier than historically has been the case (Cui et al. 2019; Fofrich et al. 2020). After coal, electricity production based on gas is also projected to be phased out, with some capacity remaining as back-up (van Soest et al. 2017a). Kefford et al. (2018) find USD541 billion worth of stranded fossil fuel power plants could be created by 2060, with China and India the most exposed.

Some publications have suggested that stranded long-lived assets may be even more important outside of the power sector. While stranded power sector assets by 2050 could reach up to USD1.8 trillion in scenarios consistent with a 2°C target, Saygin et al. (2019) found a range of USD5–11 trillion in the buildings sector. Muldoon-Smith and Greenhalgh (2019) have even estimated a potential value at risk for global real estate assets up to USD21 trillion. More broadly, the set of economic activities that are potentially affected by a low-carbon transition is wide and includes also energy-intensive industries, transport and housing, as reflected in the concept of climate policy relevant sectors introduced in Battiston et al. (2017). The sectoral distribution and amount of stranded assets differ across countries (Fisch-Romito et al. 2021). Capital for fossil fuel production and distribution represents a larger share of potentially stranded assets in fossil fuel-producing countries such as the United States and Russia. Electricity generation would be a larger share of total stranded assets in emerging countries because this capital is relatively new compared to its operational lifetime. Conversely, buildings could represent a larger part of stranded capital in more developed countries and regions such as the USA, EU or even Russia because of high market value and low turnover rate.

Many quantitative estimates of stranded assets along mitigation pathways have focused on fossil fuel power plants in pathways characterised by mitigation ambition until 2030 corresponding to the NDCs followed by strengthened action afterwards to limit warming to 2°C (>67%) or lower (Bertram et al. 2015a; Iyer et al. 2015b; Lane et al. 2016; Farfan and Breyer 2017; van Soest et al. 2017a; Kriegler et al. 2018a; Luderer et al. 2018; Cui et al. 2019; Saygin et al.

2019; SEI et al. 2020). Pathways following NDCs announced prior to COP26 until 2030 do not show a significant reduction of coal, oil and gas use (Figure 3.30f–h and Table 3.6) compared to immediate action pathways. Stranded coal power assets are evaluated to be higher by a factor of two to three if action is strengthened after 2030 rather than now (Iyer et al. 2015b; Cui et al. 2019). There is high agreement that the later climate policies are implemented, the higher the expected stranded assets and the societal, economic and political strain of strengthening action. Associated price increases for carbon-intensive goods and transitional macro-economic costs have been found to scale with the emissions gap in 2030 (Kriegler et al. 2013a). At the aggregate level of the whole global economy, Rozenberg et al. (2015) showed that each year of delaying the start of mitigation decreases the required CO₂ intensity of new production by 20–50 gCO₂ per USD. Carbon lock-in can have a long-lasting effect on future emissions trajectories after 2030. Luderer et al. (2018) compared cost-effective pathways with immediate action to limit warming to 1.5°C–2°C with pathways following the NDCs until 2030 and adopting the pricing policy of the cost-effective pathways thereafter, and found that the majority of additional CO₂ emissions from carbon lock-in occur after 2030, reaching a cumulative amount of 290 (160–330) GtCO₂ by 2100 (Section 2.7.2). Early action and avoidance of investments in new carbon-intensive assets can minimise these risks.

The risk of stranded assets has implications for workers depending on those assets, asset owners, assets portfolio managers, financial institutions and the stability of the financial system. Chapter 6 assesses the risks and implications of stranded assets for energy systems (Section 6.7.3 and Box 6.11) and fossil fuels (Section 6.7.4). The implications of stranded assets for inequality and Just Transition are assessed in Chapter 17 (Section 17.3.2.3). Chapter 15 assesses the literature on those implications for the financial system as well as on coping options (Sections 15.5.2 and 15.6.1).

On the other hand, mitigation, by limiting climate change, reduces the risk of destroyed or stranded assets from the physical impacts of climate change on natural and human systems, from more frequent, intense or extended extreme events and from sea level rise (O'Neill et al. 2020a). The literature on mitigation pathways rarely includes an evaluation of stranded assets from climate change impacts. Unruh (2019) suggest that these are the real stranded assets of carbon lock-in and could prove much more costly.

3.5.3 Global Accelerated Action Towards Long-term Climate Goals

A growing literature explores long-term mitigation pathways with accelerated near-term action going beyond the NDCs (Graichen et al. 2017; Jiang et al. 2017; Kriegler et al. 2018a; Roelfsema et al. 2018; Fekete et al. 2021; van Soest et al. 2021a). Global accelerated action pathways are designed to transition more gradually from implemented policies and planned implementation of NDCs onto a 1.5°C–2°C pathway and at the same time alleviate the abrupt transition in 2030 that would be caused by following the NDCs until 2030 and strengthening towards limiting warming to 2°C thereafter (Section 3.5.2). Therefore, they have sometimes been called bridging

scenarios/pathways in the literature (IEA 2011; Spencer et al. 2015; van Soest et al. 2021a). They rely on regionally differentiated regulatory and pricing policies to gradually strengthening regional and sectoral action beyond the mitigation ambition in the NDCs. There are limitations to this approach. The tighter the warming limit, the more likely it is that disruptive action becomes inevitable to achieve the speed of transition that would be required (Kriegler et al. 2018a). Cost-effective pathways already have abrupt shifts in deployments, investments and prices at the time a stringent warming limit is imposed, reflecting the fact that the overall response to climate change has so far been misaligned with long-term climate goals (Fawcett et al. 2015; Rogelj et al. 2016; Schleussner et al. 2016b; Geiges et al. 2020). Disruptive action can help to break lock-ins and enable transformative change (Vogt-Schilb et al. 2018).

The large literature on accelerating climate action was assessed in the *IPCC Special Report on Global Warming of 1.5°C* (de Coninck et al. 2018) and is taken up in this report primarily in Chapters 4, 13, and 14. Accelerating climate action and facilitating transformational change requires a perspective on socio-technical transitions (Geels et al. 2016a; Geels et al. 2016b; Geels 2020), a portfolio of policy instruments to manage technological and environmental change (Fischer and Newell 2008; Goulder and Parry 2008; Acemoglu et al. 2012, 2016), a notion of path dependency and policy sequencing (Pierson 2000; Meckling et al. 2017; Pahle et al. 2018) and the involvement of polycentric governance layers of institutions and norms in support of the transformation (Dietz et al. 2003; Leach et al. 2007; Messner 2015). This subsection is focused on an assessment of the emerging quantitative literature on global accelerated action pathways towards 1.5°C–2°C, which to a large extent abstracts from the underlying processes and uses a number of stylised approaches to generate these pathways. A representative of accelerated action pathways has been identified as one of the Illustrative Mitigation Pathways (IMPs) in this assessment (*IMP-GS*, Figure 3.31).

One approach relies on augmenting initially moderate emissions-pricing policies with robust anticipation of ratcheting up climate action in the future (Spencer et al. 2015). If announcements of strong future climate policies are perceived to be credible, they can help to prevent carbon lock-in as investors anticipating high future costs of GHG emissions would reduce investment into fossil fuel infrastructure, such as coal power plants (Bauer et al. 2018b). However, the effectiveness of such announcements strongly hinges on their credibility. If investors believe that policymakers could drop them if anticipatory action did not occur, they may not undertake such action.

Another approach relies on international cooperation to strengthen near-term climate action. These studies build on international climate policy architectures that could incentivise a coalition of like-minded countries to raise their mitigation ambition beyond what is stated in their NDC (Graichen et al. 2017). Examples are the idea of climate clubs characterised by harmonised carbon and technology markets (Nordhaus 2015; Keohane et al. 2017; Paroussos et al. 2019; Pihl 2020) and the Powering Past Coal Alliance (PPCA) (Jewell et al. 2019). Paroussos et al. (2019) find economic benefits of joining a climate club despite the associated higher mitigation effort, in particular due

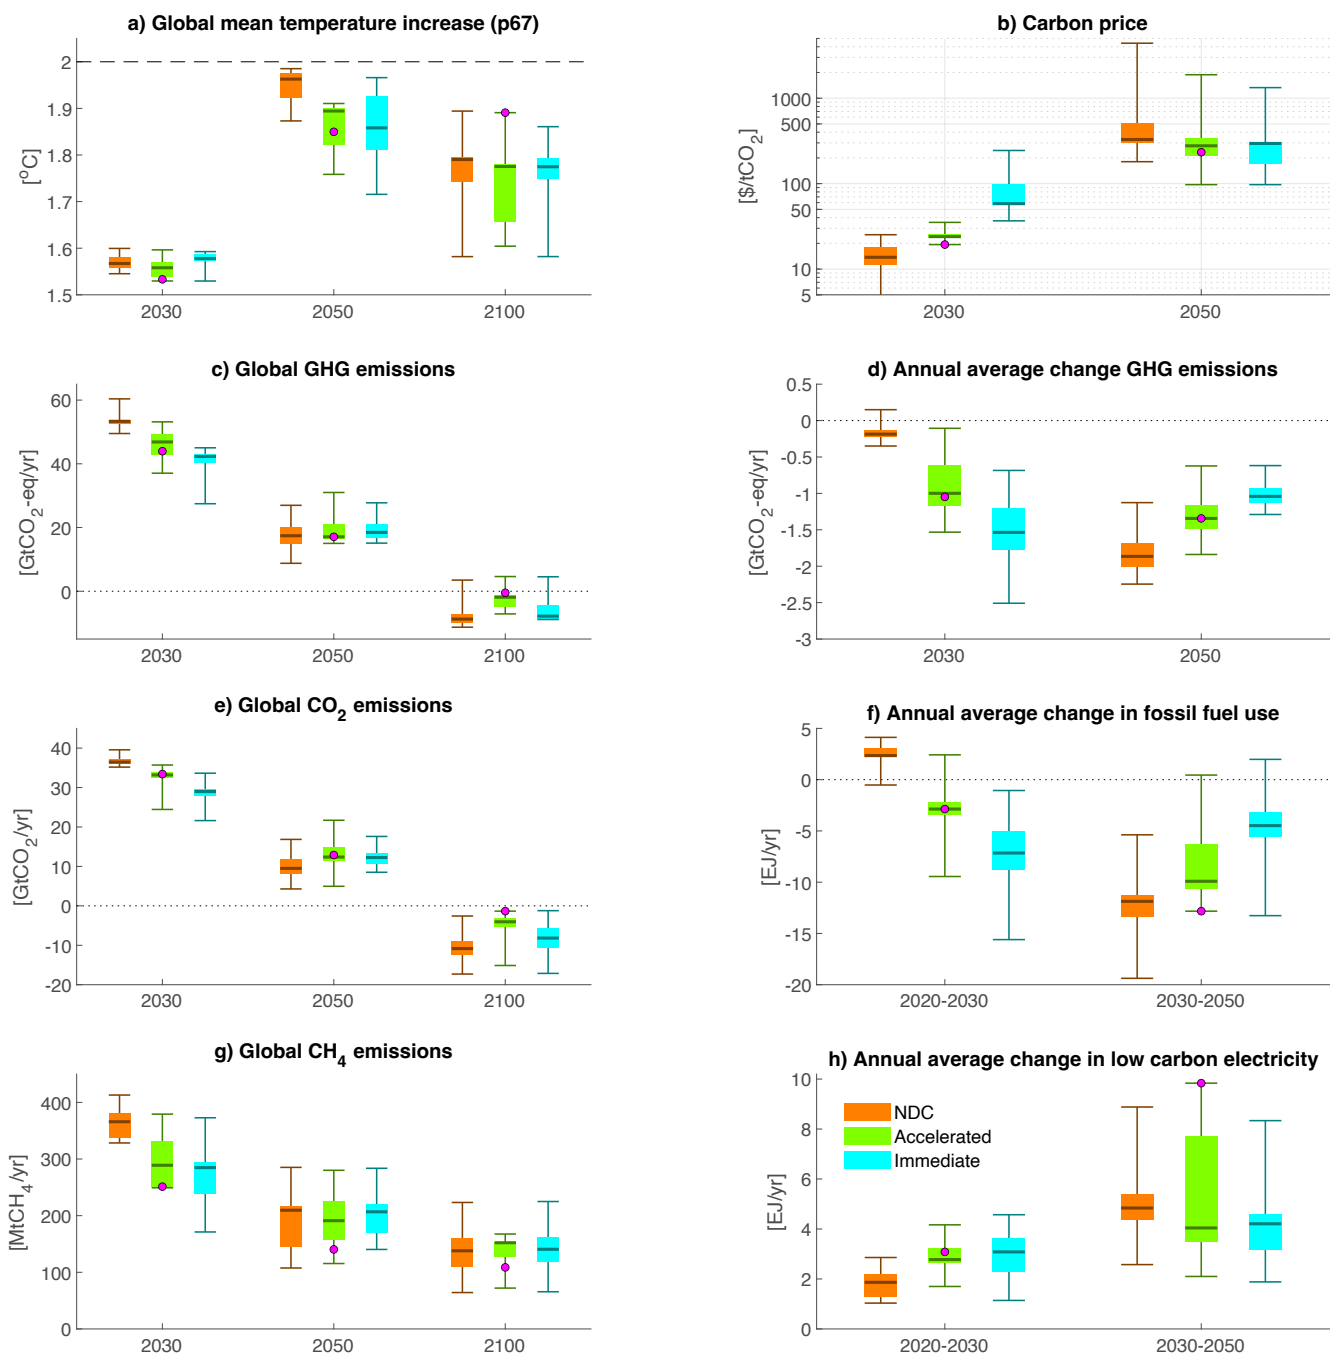

Figure 3.31 | Comparison of (i) pathways with immediate action to limit warming to 2°C (>67%) (Immediate, light blue), (ii) pathways following the NDCs until 2030 and limiting warming to 2°C (>67%) thereafter (NDC; orange), and (iii) pathways accelerating near-term action until 2030 beyond NDC ambition levels and limiting warming to 2°C (>67%) thereafter (accelerated) for selected indicators as listed in the panel titles, based on pathways from van Soest et al. (2021a). Low-carbon electricity comprises renewable and nuclear power. Indicator ranges are shown as box plots (full range, interquartile range, and median) for the years 2030, 2050 and 2100 (absolute values) and for the periods 2020–2030, 2030–2050 (change indicators). Ranges are based on nine models participating in van Soest et al. (2021a) with only seven models reporting emissions and climate results and eight models reporting carbon prices. The purple dot denotes the Illustrative Mitigation Pathway GS that was part of the study by van Soest et al.

to access to technology and climate finance. Graichen et al. (2017) find an additional reduction of 5–11 GtCO₂-eq compared to the mitigation ambition in the NDCs from the successful implementation of international climate initiatives. Other studies assess benefits from international transfers of mitigation outcomes (Stua 2017; Edmonds et al. 2021). Edmonds et al. (2021) find economic gains from sharing NDC emissions-reduction commitments compared to purely domestic implementation of NDCs. If reinvested in mitigation efforts, the study projects an additional reduction of 9 billion tonnes of CO₂ in 2030.

The most common approach relies on strengthening regulatory policies beyond current policy trends, also motivated by the finding that such policies have so far been employed more often than comprehensive carbon pricing (Kriegler et al. 2018a; Roelfsema et al. 2018; Fekete et al. 2021; IEA 2021a; van Soest et al. 2021a). Some studies have focused on generic regulatory policies such as low-carbon support policies, fossil fuel-sunset policies, and resource-efficiency policies (Bertram et al. 2015b; Hatfield-Dodds et al. 2017). Bertram et al. (2015b) found that a moderate carbon price combined with a coal moratorium and ambitious low-carbon support policies can limit efficiency losses until 2030 if emissions pricing is raised thereafter to limit warming to 2°C. They also showed that all three components are needed to achieve this outcome. Hatfield-Dodds et al. (2017) found that resource efficiency can lower 2050 emissions by an additional 15–20% while boosting near-term economic growth. The International Energy Agency (IEA 2021a) developed a detailed net zero scenario for the global energy sector characterised by a rapid phase-out of fossil fuels, a massive clean energy and electrification push, and the stabilisation of energy demand, leading to 10 GtCO₂ lower emissions from energy use in 2030 than in a scenario following the announced pledges.

The Paris Agreement has spurred the formulation of NDCs for 2030 and mid-century strategies around the world (cf. Chapter 4). This is giving researchers a rich empirical basis to formulate accelerated policy packages taking national decarbonisation pathways as a starting point (Graichen et al. 2017; Jiang et al. 2017; van Soest et al. 2017b; Waisman et al. 2019). The concept is to identify good practice policies that had demonstrable impact on pushing low-carbon options or reducing emissions in a country or region and then consider a wider roll out of these policies taking into account regional specificities (den Elzen et al. 2015; Fekete et al. 2015, 2021; Kriegler et al. 2018a; Kuramochi et al. 2018; Roelfsema et al. 2018). A challenge for this approach is to account for the fact that policy effectiveness varies with different political environments in different geographies. As a result, a global roll out of good practice policies to close the emissions gap will still be an idealised benchmark, but it is useful to understand how much could be gained from it.

Accelerated action pathways derived with this approach show considerable scope for narrowing the emissions gap between pathways reflecting the ambition level of the NDCs and cost-effective mitigation pathways in 2030. Kriegler et al. (2018a) find around 10 GtCO₂-eq lower emissions compared to original NDCs from a global roll out of good practice plus net zero policies and a moderate increase in regionally differentiated carbon pricing. Fekete et al. (2021) show that global replication of sector progress in five major economies would reduce GHG emissions in 2030 by

about 20% compared to a current policy scenario. These findings were found in good agreement with a recent model comparison study based on results from nine integrated assessment models (IAMs) (van Soest et al. 2021a). Based on these three studies, implementing accelerated action in terms of a global roll out of regulatory and moderate pricing policies is assessed to lead to global GHG emissions of 48 (38–52) GtCO₂-eq in 2030 (median and 5–95th percentile based on 10 distinct modelled pathways). This closes the implementation gap for the NDCs, and in addition falls below the emissions range implied by implementing unconditional and conditional elements of NDCs by 2–9 GtCO₂-eq. However, it does not close the emissions gap to immediate action pathways that limit warming to 2°C (>67%), and, based on our assessment in Section 3.5.2, emission levels above 40 GtCO₂-eq in 2030 still have a very low prospect for limiting warming to 1.5°C (>50%) with no or limited overshoot.

Figure 3.31 shows the intermediate position of accelerated action pathways derived by van Soest et al. (2021a) between pathways that follow the NDCs until 2030 and immediate action pathways limiting warming to 2°C (>67%). Accelerated action is able to reduce the abrupt shifts in emissions, fossil fuel use and low-carbon power generation in 2030 and also limits peak warming more effectively than NDC pathways. But primarily due to the moderate carbon price assumptions (Figure 3.31b), the reductions in emissions and particular fossil fuel use are markedly smaller than what would be obtained in the case of immediate action. The assessment shows that accelerated action until 2030 can have significant benefits in terms of reducing the mitigation challenges from following the NDCs until 2030. But putting a significant value on GHG emissions reductions globally remains a key element of moving onto 1.5°C–2°C pathways. The vast majority of pathways that limit warming to 2°C (>67%) or lower, independently of their differences in near-term emission developments, converge to a global mitigation regime putting a significant value on GHG emission reductions in all regions and sectors.

3.6 Economics of Long-term Mitigation and Development Pathways, Including Mitigation Costs and Benefits

A complete appraisal of economic effects and welfare effects at different temperature levels would include the macroeconomic impacts of investments in low-carbon solutions and structural change away from emitting activities, co-benefits and adverse side effects of mitigation, (avoided) climate damages, as well as (reduced) adaptation costs, with high temporal, spatial and social heterogeneity using a harmonised framework. If no such complete appraisal in a harmonised framework exists, key elements are emerging from the literature, and assessed in the following subsections: on aggregated economy-wide global mitigation costs (Section 3.6.1), on the economic benefits of avoiding climate impacts (Section 3.6.2), on economic benefits and costs associated with mitigation co-benefits and co-harms (Section 3.6.3) and on the distribution of economic implications between economic sectors and actors (Section 3.6.4).

3.6.1 Economy-wide Implications of Mitigation

3.6.1.1 Global Economic Effects of Mitigation and Carbon Values in Mitigation Pathways

Box 3.5 | Concepts and Modelling Frameworks Used for Quantifying Macroeconomic Effects of Mitigation

Most studies that have developed mitigation pathways have used a cost-effectiveness analysis (CEA) framework, which aim to compare the costs of different mitigation strategies designed to meet a given climate change mitigation goal (e.g., an emission-reduction target or a temperature stabilisation target) but does not represent economic impacts from climate change itself, nor the associated economic benefits of avoided impacts. Other studies use modelling frameworks that represent the feedback of damages from climate change on the economy in a cost-benefit analysis (CBA) approach, which balances mitigation costs and benefits. This second type of study is represented in Section 3.6.2.

The marginal abatement cost of carbon, also called carbon price, is determined by the mitigation target under consideration: it describes the cost of reducing the last unit of emissions to reach the target at a given point in time. Total macroeconomic mitigation costs (or gains) aggregate the economy-wide impacts of investments in low-carbon solutions and structural changes away from emitting activities. The total macroeconomic effects of mitigation pathways are reported in terms of variations in economic output or consumption levels, measured against a reference scenario, also called baseline, at various points in time or discounted over a given time period. Depending on the study, the reference scenario reflects specific assumptions about patterns of socio-economic development and assumes either no-climate policies or the climate policies in place or planned at the time the study was carried out. When available in the AR6 scenarios database, this second type of reference scenario, with trends from implemented policies until the end of 2020, has been chosen for computation of mitigation costs. In the vast majority of studies that have produced the body of work on the cost of mitigation assessed here, and in particular in all studies that have submitted global scenarios to the AR6 scenarios database except (Schultes et al. 2021), the feedbacks of climate change impacts on the economic development pathways are not accounted for. This omission of climate impacts leads to overly optimistic economic projections in the reference scenarios, in particular in reference scenarios with no or limited mitigation action where the extent of global warming is the greatest. Mitigation cost estimates computed against no or limited policy reference scenarios therefore omit economic benefits brought by avoided climate change impact along mitigation pathways, and should be interpreted with care (Grant et al. 2020). When aggregate economic benefits from avoided climate change impacts are accounted for, mitigation is a welfare-enhancing strategy (Section 3.6.2).

If GDP or consumption in mitigation pathways are below the reference scenario levels, they are reported as losses or macroeconomic costs. Such cost estimates give an indication of how economic activity slows relative to the reference scenario; they do not necessarily describe, in absolute terms, a reduction of economic output or consumption levels relative to previous years along the pathway. Aggregate mitigation costs depend strongly on the modelling framework used and the assumptions about the reference scenario against which mitigation costs are measured, in particular whether the reference scenario is, or not, on the efficiency frontier of the economy. If the economy is assumed to be at the efficiency frontier in the reference scenario, mitigation inevitably leads to actual costs, at least in the short-run until the production frontier evolves with technical and structural change. Starting from a reference scenario that is not on the efficiency frontier opens the possibility to simultaneously reduce emissions and obtain macroeconomic gains, depending on the design and implementation of mitigation policies. A number of factors can result in reference scenarios below the efficiency frontier, for instance distorting labour taxes and/or fossil fuel subsidies, misallocation or under-utilisation of production factors such as involuntary unemployment, imperfect information or non-rational behaviours. Although these factors are pervasive, the modelling frameworks used to construct mitigation pathways are often limited in their ability to represent them (Köberle et al. 2021).

The absolute level of economic activity and welfare also strongly depends on the socio-economic pathway assumptions regarding, *inter alia*, evolutions in demography, productivity, education levels, inequality, and technical change and innovation. The GDP or consumption indicators reported in the database of scenarios, and synthesized below, represent the absolute level of aggregate economic activity or consumption but do not reflect welfare and well-being (Roberts et al. 2020), that notably depend on human-needs satisfaction, distribution within society and inequality (Section 3.6.4).

Chapter 1 and Annex III.I give further details of the economic concepts and modelling frameworks, including their limitations, used in this report, respectively.

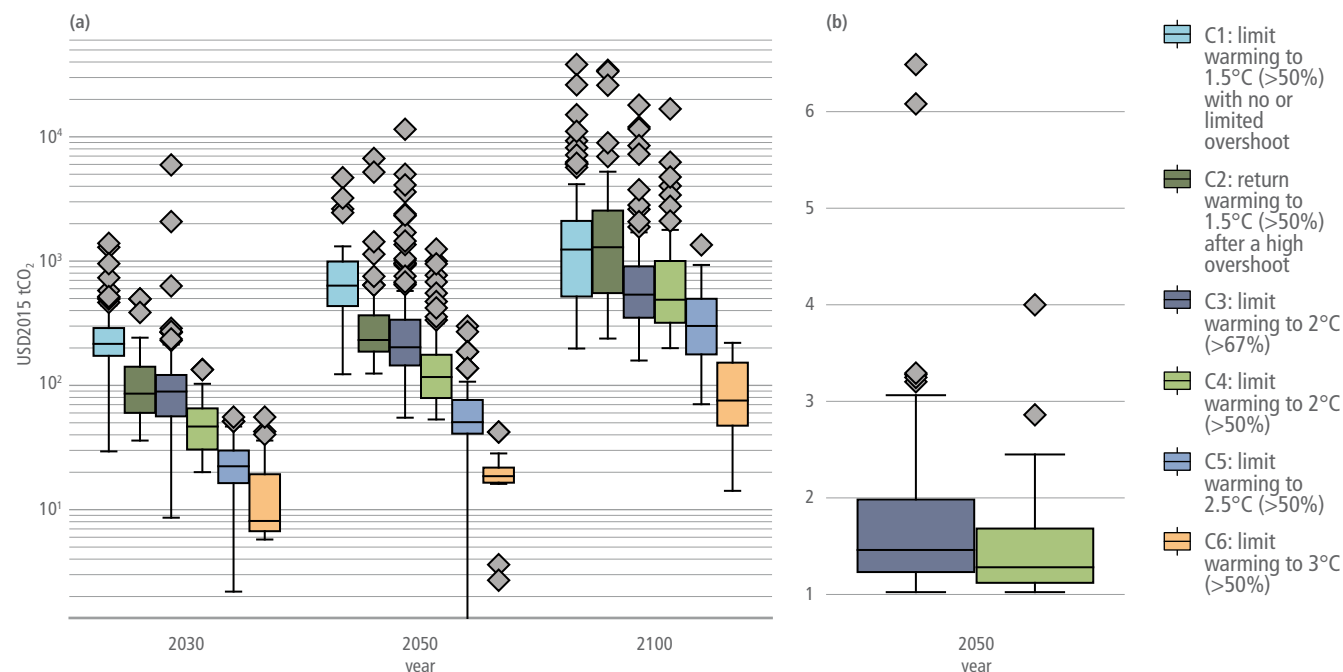

Figure 3.32 | Marginal abatement cost of carbon in 2030, 2050 and 2100 for mitigation pathways with immediate global mitigation action (a), and ratio in 2050 between pathways that correspond to NDCs announced prior to COP26 in 2030 and strengthen action after 2030 and pathways with immediate global mitigation action, for C3 and C4 temperature categories (b).

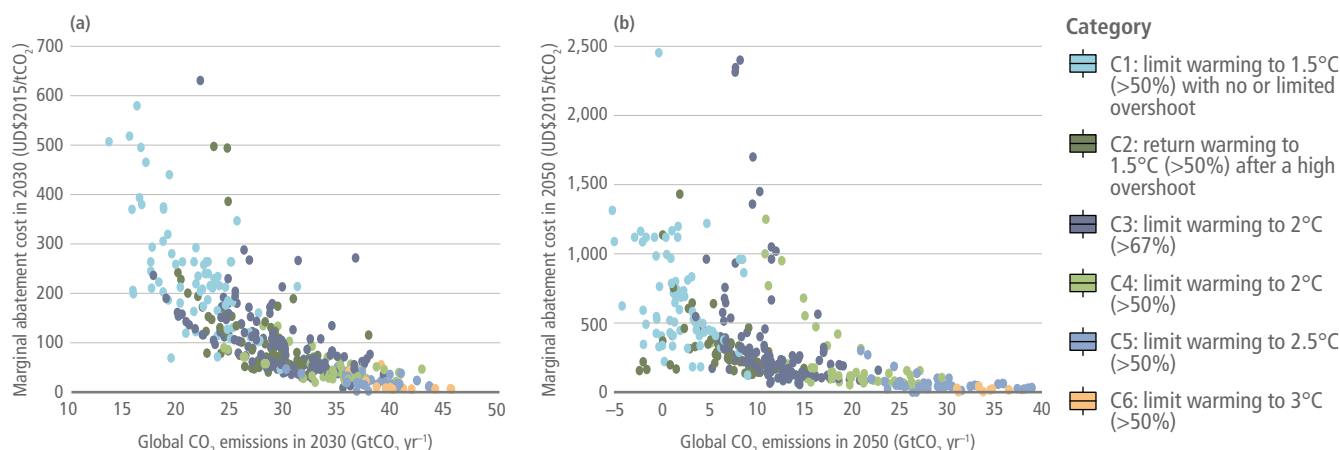

Figure 3.33 | Marginal abatement cost of carbon with respect to CO₂ emissions for mitigation pathways with immediate global mitigation action, in 2030 (a) and 2050 (b).

Estimates for the marginal abatement cost of carbon in mitigation pathways vary widely, depending on the modelling framework used and socio-economic, technological and policy assumptions. However, it is robust across modelling frameworks that the marginal abatement cost of carbon increases for lower temperature categories, with a higher increase in the short term than in the longer term (Figure 3.32, left panel) (*high confidence*). The marginal abatement cost of carbon increases non-linearly with the decrease of CO₂ emissions level, but the uncertainty in the range of estimates also increases (Figure 3.33). Mitigation pathways with low-energy consumption patterns exhibit lower carbon values (Méjean et al. 2019; Meyer et al. 2021). In the context of the COVID-19 pandemic recovery, Kikstra et al. (2021a) also show that a low-energy-demand recovery scenario reduces carbon prices for a 1.5°C-consistent pathway by 19% compared to a scenario with energy demand trends restored to pre-pandemic levels.

For optimisation modelling frameworks, the time profile of marginal abatement costs of carbon depends on the discount rate, with lower discount rates implying higher carbon values in the short term but lower values in the long term (Emmerling et al. 2019) (see also 'Discounting' in Annex I: Glossary, and Annex III.1.2). In that case, the discount rate also influences the shape of the emissions trajectory, with low discount rates implying more emissions reduction in the short term and, for low-temperature categories, limiting CDR and temperature overshoot.

Pathways that correspond to NDCs announced prior to COP26 in 2030 and strengthen action after 2030 imply higher marginal abatement costs of carbon in the longer run than pathways with stronger immediate global mitigation action (Figure 3.32b) (*high confidence*).

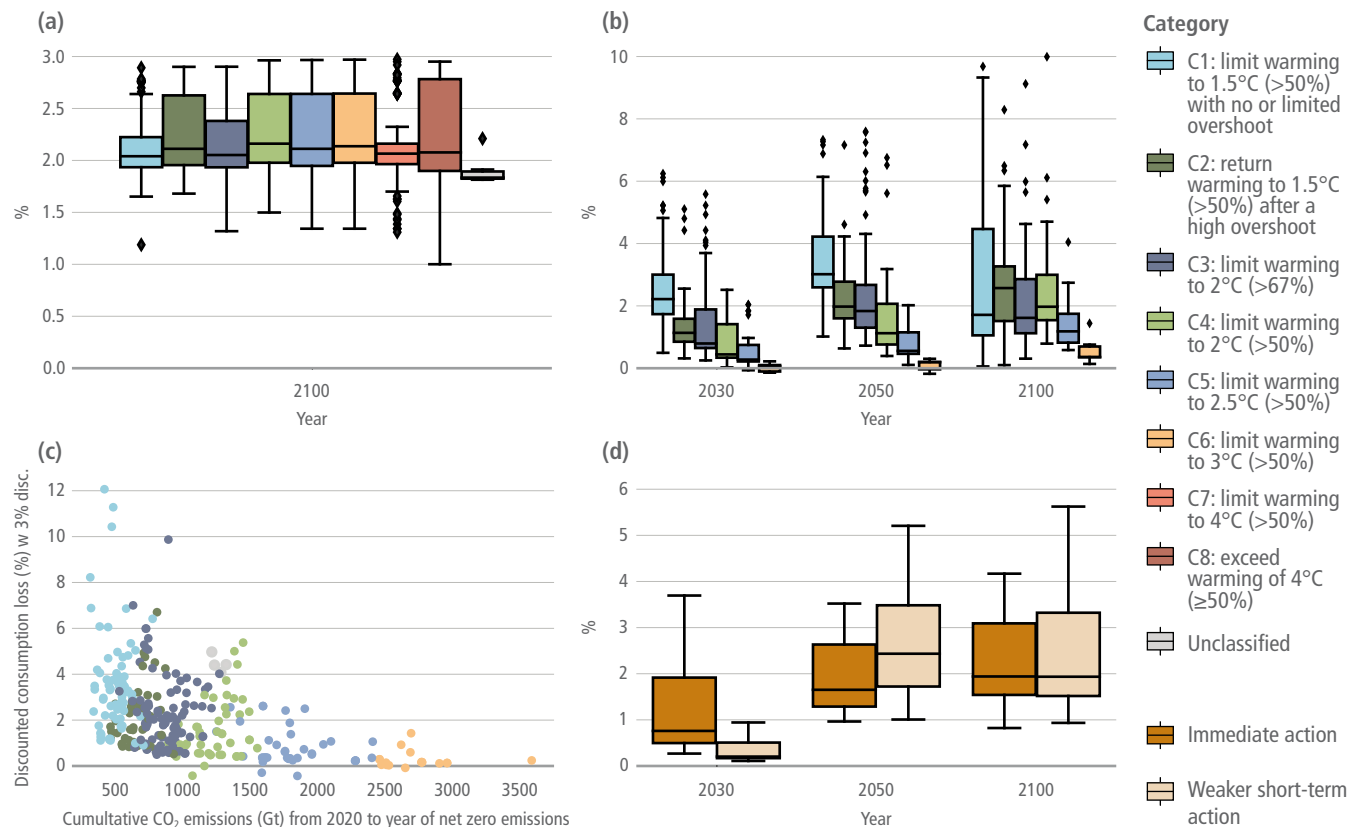

Figure 3.34 (a) Mean annual global consumption growth rate over 2020–2100 for the mitigation pathways in the AR6 scenarios database. (b) Global GDP loss compared to baselines (not accounting for climate change damages) in 2030, 2050 and 2100 for mitigation pathways with immediate global action. (c) Total discounted consumption loss (with a 3% discount rate) in mitigation scenarios with respect to their corresponding baseline (not accounting for climate change damages) as a function of cumulative CO₂ emissions until date of net zero CO₂. (d) Comparison of GDP losses compared to baselines (not accounting for climate change damages) in 2030, 2050 and 2100 for pairs of scenarios depicting immediate action pathways and delayed action pathways. Source: AR6 Scenarios Database.

Aggregate economic activity and consumption levels in mitigation pathways are primarily determined by socio-economic development pathways but are also influenced by the stringency of the mitigation goal and the policy choices to reach the goal (*high confidence*). Mitigation pathways in temperature categories C1 and C2 entail losses in global consumption with respect to their baselines – not including benefits of avoided climate change impacts nor co-benefits or co-harms of mitigation action – that correspond to an annualised reduction of consumption growth by 0.04 (median value) (interquartile range [0.02–0.06]) percentage points over the century. For pathways in temperature categories C3 and C4 this reduction in global consumption growth is 0.03 (median value) (interquartile range [0.01–0.05]) percentage points over the century. In the majority of studies that focus on the economic effects of mitigation without accounting for climate damages, global economic growth and consumption growth is reduced compared to baseline scenarios (that omit damages from climate change), but mitigation pathways do not represent an absolute decrease of economic activity level (Figure 3.34b,c).

However, the possibility for increased economic activity following mitigation action, and conversely the risk of large negative economic effects, are not excluded. Some studies find that mitigation increases the speed of economic growth compared to baseline scenarios (Pollitt and Mercure 2018; Mercure et al. 2019). These studies are based on a macroeconomic modelling framework that represent baselines

below the efficiency frontier, based on non-equilibrium economic theory, and assume that mitigation is undertaken in such a way that green investments do not crowd out investment in other parts of the economy – and therefore offers an economic stimulus. In the context of the recovery from the COVID-19 crisis, it is estimated that a green investment push would initially boost the economy while also reducing GHG emissions (IMF 2020; Pollitt et al. 2021). Conversely, several studies find that only a GDP non-growth/degrowth or post-growth approach enable reaching climate stabilisation below 2°C (Hardt and O’Neill 2017; D’Alessandro et al. 2020; Hickel and Kallis 2020; Nieto et al. 2020), or to minimise the risks of reliance on high energy-GDP decoupling, large-scale CDR and large-scale renewable energy deployment (Keyßer and Lenzen 2021). Similarly, feedbacks of financial system risk amplifying shocks induced by mitigation policy and lead to a higher impact on economic activity (Stolbova et al. 2018).

Mitigation costs increase with the stringency of mitigation (Hof et al. 2017; Vrontisi et al. 2018) (Figure 3.34b,c), but are reduced when energy demand is moderated through energy efficiency and lifestyle changes (Fujimori et al. 2014; Bibas et al. 2015; Liu et al. 2018; Méjean et al. 2019), when sustainable transport policies are implemented (Zhang et al. 2018c), and when international technology cooperation is fostered (Schultes et al. 2018; Paroussos et al. 2019). Mitigation costs also depend on assumptions on availability and costs of technologies (Clarke et al. 2014; Bosetti et al. 2015; Dessens et al. 2016; Creutzig et al.

2018; Napp et al. 2019; Giannousakis et al. 2021), on the representation of innovation dynamics in modelling frameworks (Hoekstra et al. 2017; Rengs et al. 2020) (Chapter 16), as well as the representation of investment dynamics and financing mechanisms (Iyer et al. 2015c; Mercure et al. 2019; Battiston et al. 2021). In particular, endogenous and induced innovation reduce technology costs over time, create path dependencies and reduce the macroeconomic cost of reaching a mitigation target (Section 1.7.1.2). Mitigation costs also depend on socio-economic assumptions (Hof et al. 2017; van Vuuren et al. 2020).

Mitigation pathways with early emissions reductions represent higher mitigation costs in the short-run but bring long-term gains for the economy compared to delayed transition pathways (*high confidence*). Pathways with earlier mitigation action bring higher long-term GDP than pathways reaching the same end-of-century temperature with weaker early action (Figure 3.34d). Comparing counterfactual history scenarios, Sanderson and O'Neill (2020) also find that delayed mitigation action leads to higher peak costs. Rogelj et al. (2019b) and Riahi et al. (2021) also show that pathways with earlier timing of net zero CO₂ lead to higher transition costs but lower long-term mitigation costs, due to dynamic effects arising from lock-in avoidance and learning effects. For example, Riahi et al. (2021) find that for a 2°C target, the GDP losses (compared to a reference scenario without impacts from climate change) in 2100 are 5–70% lower in pathways that avoid net negative CO₂ emissions and temperature overshoot than in pathways with overshoot. Accounting also for climate change damage, van der Wijst et al. (2021a) show that avoiding net negative emissions leads to a small increase in total discounted mitigation costs over 2020–2100, between 5% and 14% in their medium assumptions, but does not increase mitigation costs when damages are high and when using a low discount rate, and becomes economically attractive if damages are not fully reversible. The modelled cost-optimal balance of mitigation action over time strongly depends on the discount rate used to compute or evaluate mitigation pathways: lower discount rates favour earlier mitigation, reducing both temperature overshoot and reliance on net negative carbon emissions (Emmerling et al.

2019; Riahi et al. 2021). Mitigation pathways with weak early action corresponding to NDCs announced prior to COP26 in 2030 and strengthening action after 2030 to reach end-of-century temperature targets imply limited mitigation costs in 2030, compared to immediate global action pathways, but faster increase in costs post-2030, with implications for intergenerational equity (Aldy et al. 2016; Liu et al. 2016; Vrontisi et al. 2018). Emissions trading policies reduce global aggregate mitigation costs, in particular in the context of achieving NDCs (Fujimori et al. 2015, 2016a; Böhringer et al. 2021; Edmonds et al. 2021), and change the distribution of mitigation costs between regions and countries (Section 3.6.1.2).

3.6.1.2 Regional Mitigation Costs and Effort-sharing Regimes

The economic repercussions of mitigation policies vary across countries (Aldy et al. 2016; Hof et al. 2017): regional variations exist in institutions, economic and technological development, and mitigation opportunities. For a globally uniform carbon price, carbon-intensive and energy-exporting countries bear the highest economic costs because of a deeper transformation of their economies and of trade losses in the fossil markets (Stern et al. 2012; Tavoni et al. 2015; Böhringer et al. 2021). This finding is confirmed in Figure 3.35. Since carbon-intensive countries are often poorer, uniform global carbon prices raise equity concerns (Tavoni et al. 2015). On the other hand, the climate economic benefits of mitigating climate change will be larger in poorer countries (Cross-Working Group Box 1 in this chapter). This reduces policy regressivity but does not eliminate it (Taconet et al. 2020; Gazzotti et al. 2021). Together with co-benefits, such as health benefits of improved air quality, the economic benefits of mitigating climate change are likely to outweigh mitigation costs in many regions (Li et al. 2018, 2019; Scovronick et al. 2021).

Regional policy costs depend on the evaluation framework (Budolfson et al. 2021), policy design, including revenue recycling, and on international coordination, especially among trade partners. By fostering technological change and finance, climate cooperation can

Figure 3.35 | a: regional mitigation costs in the year 2050 (expressed as GDP losses between mitigation scenarios and corresponding baselines, not accounting for climate change damages), under the assumption of immediate global action with uniform global carbon pricing and no international transfers, by climate categories for the 2°C (>67%) and 1.5°C (>50%) (with and without overshoot) categories. Right panel: policy costs in 2050 (as in panel a) for 2°C (>67%) climate category C3 for scenario pairs that represent either immediate global action ('immediate') or delayed global action ('delayed') with weaker action in the short term, strengthening to reach the same end-of-century temperature target.

generate economic benefits, both in large developing economies such as China and India (Paroussos et al. 2019) and industrialised regions such as Europe (Vrontisi et al. 2020). International coordination is a major driver of regional policy costs. Delayed participation in global mitigation efforts raises participation costs, especially in carbon-intensive economies (Figure 3.35a). Trading systems and transfers can deliver cost savings and improve equity (Rose et al. 2017a). On the other hand, measures that reduce imports of energy-intensive goods such as carbon-border tax adjustment may imply costs outside of the policy jurisdiction and have international equity repercussions, depending on how they are designed (Böhringer et al. 2012, 2017; Cosbey et al. 2019) (Section 13.6.6).

An equitable global emission-trading scheme would require very large international financial transfers, in the order of several hundred billion USD per year (Tavoni et al. 2015; Bauer et al. 2020; van den Berg et al. 2020). The magnitude of transfers depends on the stringency of the climate goals and on the burden-sharing principle. Some interpretations of equitable burden sharing compliant with the Paris Agreement leads to negative carbon allowances for developed countries and some developing countries by mid-century (van den Berg et al. 2020), more stringent than cost-optimal pathways. International transfers also depend on the underlying socio-economic development (Leimbach and Giannousakis 2019), as these drive the mitigation costs of meeting the Paris Agreement

(Rogelj et al. 2018b). By contrast, achieving equity without international markets would result in a large discrepancy in regional carbon prices, up to a factor of 100 (Bauer et al. 2020). The efficiency-sovereignty trade-off can be partly resolved by allowing for limited differentiation of regional carbon prices: moderate financial transfers substantially reduce inefficiencies by narrowing the carbon price spread (Bauer et al. 2020).

3.6.1.3 Investments in Mitigation Pathways

Figures 3.36 and 3.37 show increased investment needs in the energy sector in lower temperature categories, and a major shift away from fossil fuel generation and extraction towards electricity, including for system enhancements for electricity transmission, distribution and storage, and low-carbon technologies. Investment needs in the electricity sector are 2.3 trillion USD₂₀₁₅ yr⁻¹ over 2023–2050 on average for C1 pathways, 2 trillion USD for C2 pathways, 1.7 trillion USD for C3, 1.2 trillion USD for C4 and 0.9–1.1 billion USD for C5/C6/C7 (mean values for pathways in each temperature category). The regional pattern of power sector investments broadly mirrors the global picture. However, the bulk of investment requirements are in medium- and low-income regions. These results from the AR6 scenarios database corroborate the findings from McCollum et al. (2018a), Zhou et al. (2019) and Bertram et al. (2021).

Figure 3.36 | Global average yearly investments from 2023–2052 for nine electricity supply subcomponents and for extraction of fossil fuels (in billion USD₂₀₁₅), in pathways by temperature categories. T&D: transmission and distribution of electricity. Bars show the median values (number of pathways at the bottom), and whiskers show the interquartile ranges.

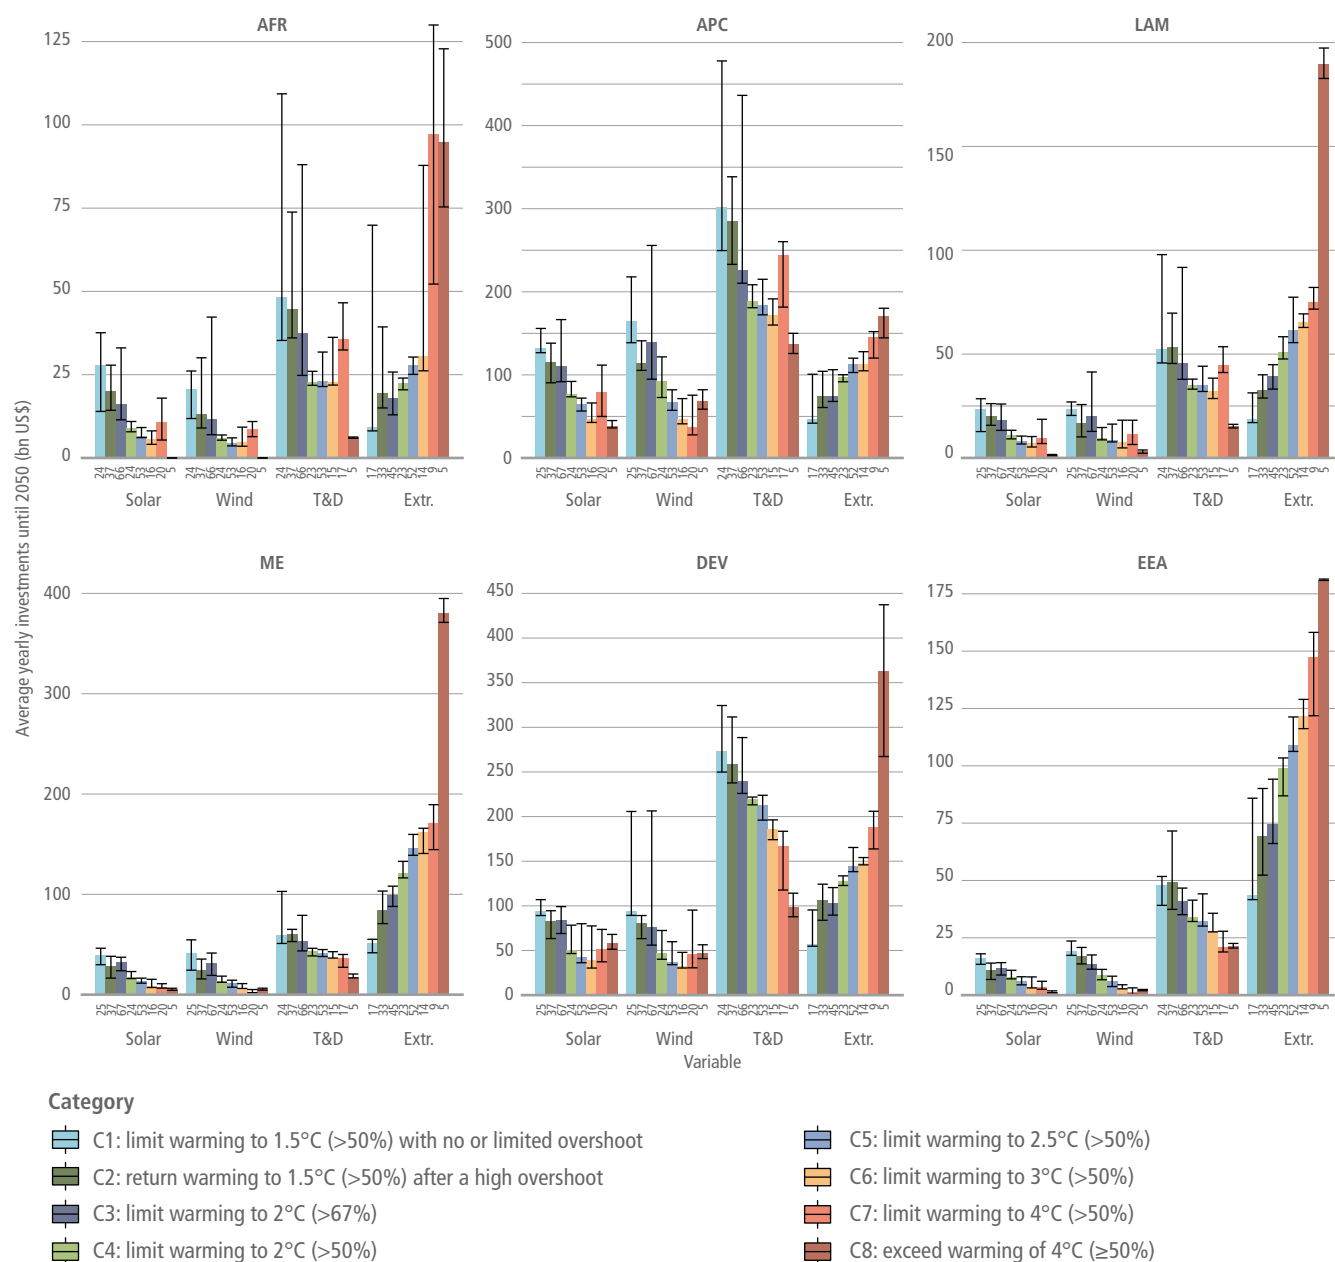

Figure 3.37 | Average yearly investments from 2023–2052 for the four subcomponents of the energy system representing the larger amounts (in billion USD2015), by aggregate regions, in pathways by temperature categories. T&D: transmissions and distribution of electricity. Extr.: extraction of fossil fuels. Bars show the median values (number of pathways at the bottom), and whiskers show the interquartile ranges. For definition of regional classifications used see Annex II Table 1.

In the context of the COVID-19 pandemic recovery, Kikstra et al. (2021a) show that a low-energy-demand recovery scenario reduces energy investments required until 2030 for a 1.5°C consistent pathway by 9% (corresponding to reducing total required energy investment by USD1.8 trillion) compared to a scenario with energy demand trends restored to pre-pandemic levels.

Few studies extend the scope of the investment needs quantification beyond the energy sector. Fisch-Romito and Guivarch (2019) and Ó Broin and Guivarch (2017) assess investment needs for transportation infrastructures and find lower investment needs in low-carbon pathways, due to a reduction in transport activity and a shift towards less road construction, compared to high-carbon

pathways. Rozenberg and Fay (2019) estimate the funding needs to close the service gaps in water and sanitation, transportation, electricity, irrigation, and flood protection in thousands of scenarios, showing that infrastructure investment paths compatible with full decarbonisation in the second half of the century need not cost more than more-polluting alternatives. Investment needs are estimated between 2% to 8% of GDP, depending on the quality and quantity of services targeted, the timing of investments, construction costs, and complementary policies.

Chapter 15 also reports investment requirements in global mitigation pathways in the near term, compares them to recent investment trends, and assesses financing issues.

3.6.2 Economic Benefits of Avoiding Climate Change Impacts

Cross-Working Group Box 1 | Economic Benefits from Avoided Climate Impacts Along Long-term Mitigation Pathways

Authors: Céline Guivarch (France), Steven Rose (the United States of America), Alaa Al Khourdajie (United Kingdom/Syria), Valentina Bosetti (Italy), Edward Byers (Austria/Ireland), Katherine Calvin (the United States of America), Tamma Carleton (the United States of America), Delavane Diaz (the United States of America), Laurent Drouet (France/Italy), Michael Grubb (United Kingdom), Tomoko Hasegawa (Japan), Alexandre C. Köberle (Brazil/United Kingdom), Elmar Kriegler (Germany), David McCollum (the United States of America), Aurélie Méjean (France), Brian O'Neill (the United States of America), Franziska Piontek (Germany), Julia Steinberger (United Kingdom/Switzerland), Massimo Tavoni (Italy)

Mitigation reduces the extent of climate change and its impacts on ecosystems, infrastructure, and livelihoods. This box summarises elements from the AR6 WGII report on aggregate climate change impacts and risks, putting them into the context of mitigation pathways. AR6 WGII provides an assessment of current lines of evidence regarding potential climate risks with future climate change, and therefore, the avoided risks from mitigating climate change. Regional and sectoral climate risks to physical and social systems are assessed (AR6 WGII Chapters 2–15). Over 100 of these are identified as Key Risks (KRs) and further synthesised by WGII Chapter 16 into eight overarching Representative Key Risks (RKR) relating to low-lying coastal systems; terrestrial and ocean ecosystems; critical physical infrastructure, networks and services; living standards; human health; food security; water security; and peace and mobility (AR6 WGII Section 16.5.2). The RKR assessment finds that risks increase with global warming level, and also depend on socio-economic development conditions, which shape exposure and vulnerability, and adaptation opportunities and responses. 'Reasons For Concern', another WGII aggregate climate-impacts risk framing, are also assessed to increase with climate change, with increasing risk for unique and threatened systems, extreme weather events, distribution of impacts, global aggregate impacts, and large-scale singular events (AR6 WGII Chapter 16). For human systems, in general, the poor and disadvantaged are found to have greater exposure level and vulnerability for a given hazard. With some increase in global average warming from today expected regardless of mitigation efforts, human and natural systems will be exposed to new conditions and additional adaptation will be needed (AR6 WGII Chapter 18). The range of dates for when a specific warming level could be reached depends on future global emissions, with significant overlap of ranges across emissions scenarios due to climate system response uncertainties (AR6 WGI Tables 4.2 and 4.5). The speed at which the climate changes is relevant to adaptation timing, possibilities, and net impacts.

The AR6 WGII also assesses the growing literature estimating the global aggregate economic impacts of climate change and the social cost of carbon dioxide and other greenhouse gases (AR6 WGII Cross-Working Box ECONOMIC: Estimating Global Economic Impacts from Climate Change and the Social Cost of Carbon in AR6 WGII Chapter 16). The former represents aggregate estimates that inform assessment of the economic benefits of mitigation. This literature is characterised by significant variation in the estimates, including for today's level of global warming, due primarily to fundamental differences in methods, but also differences in impacts included, representation of socio-economic exposure, consideration of adaptation, aggregation approach, and assumed persistence of damages. The AR6 WGII's assessment identifies different approaches to quantification of aggregated economic impacts of climate change, including: physical modelling of impact processes, such as projected mortality rates from climate risks such as heat, vector- or waterborne diseases that are then monetised; structural economic modelling of impacts on production, consumption, and markets for economic sectors and regional economies; and statistical estimation of impacts based on observed historical responses to weather and climate. The AR6 WGII finds that variation in estimated global economic impacts increases with warming in all methodologies, indicating higher risk in terms of economic impacts at higher temperatures (*high confidence*). Many estimates are non-linear with marginal economic impacts increasing with temperature, although some show declining marginal economic impacts with temperature, and functional forms cannot be determined for all studies. The AR6 WGII's assessment finds that the lack of comparability between methodologies does not allow for identification of robust ranges of global economic impact estimates (*high confidence*). Further, AR6 WGII identifies evaluating and reconciling differences in methodologies as a research priority for facilitating use of the different lines of evidence (*high confidence*). However, there are estimates that are higher than AR5, indicating that global aggregate economic impacts could be higher than previously estimated (*low confidence* due to the lack of comparability across methodologies and lack of robustness of estimates) (AR6 WGII Cross-Working Box ECONOMIC).

Conceptually, the difference in aggregate economic impacts from climate change between two given temperature levels represents the aggregate economic benefits arising from avoided climate change impacts due to mitigation action. A subset of the studies whose estimates were evaluated by AR6 WGII (5 of 15) are used to derive illustrative estimates of aggregate economic benefits in 2100 arising

Cross-Working Group Box 1 (continued)

Cross-Working Group Box 1, Figure 1 | Global aggregate economic benefits of mitigation from avoided climate change impacts in 2100 corresponding to shifting from a higher temperature category (4°C (3.75°C–4.25°C), 3°C (2.75°C–3.25°C), or above 2°C (2°C–2.5°C), to below 2°C (1.5°C–2°C), as well as from below 2°C to below 1.5°C (1°C–1.5°C)), from the five studies discussed in the text. Panel (a) is adapted from AR6 WGII Cross-Working Group Box ECONOMIC, Figure 1, showing global aggregate economic impact estimates (% global GDP loss relative to GDP without additional climate change) by temperature change level. All estimates are shown in grey. Estimates used for the computation of estimated benefits in 2100 in panel (b) are coloured for the selected studies, which provide results for different temperature change levels. See the AR6 WGII Cross-Working Group Box ECONOMIC for discussion and assessment of the estimates in panel (a) and the differences in methodologies. For B18 and T19, median estimates in the cluster are considered. Shape distinguishes the baseline scenarios. Temperature ranges are highlighted. HS17 estimates are based on their preferred model –50th percentile of non-catastrophic damage. Panel (b) shows the implied aggregate economic benefits in 2100 of a lower temperature increase. Economic benefits for point estimates are computed as a difference, while economic benefits from the curve HS17 are computed as ranges from the segment differences.

from avoided climate change (Howard and Sterner 2017; Burke et al. 2018; Pretis et al. 2018; Kahn et al. 2019; Takakura et al. 2019). Burke et al. (2018), Pretis et al. (2018) and Kahn et al. (2019) are examples of statistical estimations of historical relationships between temperature and economic growth, whereas Takakura et al. (2019) is an example of structural modelling, which evaluates selected impact channels (impacts on agriculture productivity, undernourishment, heat-related mortality, labour productivity, cooling/heating demand, hydro-electric and thermal power generation capacity and fluvial flooding) with a general equilibrium model. Howard and Sterner (2017) and Rose et al. (2017b) estimate damage functions that can be used to compute the economic benefits of mitigation from avoiding a given temperature level for a lower one. Howard and Sterner (2017) estimate a damage function from a meta-analysis of aggregate economic impact studies, while Rose et al. (2017b) derive global functions by temperature and socio-economic drivers from stylised aggregate cost-benefit-analysis (CBA) integrated assessment models (IAMs) using diagnostic experiments. Cross-Working Group Box 1, Figure 1 summarises the global aggregate economic benefits in 2100 of avoided climate change impacts from individual studies corresponding to shifting from a higher temperature category (above 3°C, below 3°C or below 2.5°C) to below 2°C, as well as from below 2°C to below 1.5°C. Benefits are positive and increase with the temperature gap for any given study, and this result is robust across socio-economic scenarios. The Figure provides evidence of a wide range of quantifications, and illustrates the important differences associated with methods. Panel a puts the studies used to calculate aggregate economic benefits arising from avoided impacts into the context of the broader set of studies assessed in WGII (Section 16.6.2 of this report, AR6 WGII Cross-Working Group Box ECONOMIC,). However, economic benefits in 2100 arising from avoided impacts cannot be directly computed from damage estimates across this broader set of studies, due to inconsistencies – different socio-economic assumptions, scenario designs, and counterfactual reference scenarios across studies. Furthermore, these types of estimates cannot be readily compared to mitigation cost estimates. The comparison would require a framework that ensures consistency in assumptions and dynamics and allows for consideration of benefits and costs along the entire pathway.

Aggregate benefits from avoided impacts expressed in GDP terms, as in Figure 1, do not encompass all avoided climate risks, adaptation possibilities, and do not represent their influence on well-being and welfare (AR6 WGII Cross-Working Group Box ECONOMIC). Methodological challenges for economic impact estimates include representing uncertainty and variability, capturing interactions and spillovers, considering distributional effects, representing micro- and macro-adaptation processes, specifying non-gradual damages and non-linearities, and improving understanding of potential long-run growth effects. In addition, the economic benefits aggregated

Cross-Working Group Box 1 (continued)

at the global scale provide limited insights into regional heterogeneity. Global economic impact studies with regional estimates find large differences across regions in absolute and percentage terms, with developing and transitional economies typically more vulnerable. Furthermore, (avoided) impacts for poorer households and poorer countries can represent a smaller share in aggregate quantifications expressed in GDP terms or monetary terms, compared to their influence on well-being and welfare (Hallegatte et al. 2020; Markhvida et al. 2020). Finally, as noted by AR6 WGII, other lines of evidence regarding climate risks, beyond monetary estimates, should be considered in decision-making, including Key Risks and Reasons for Concern.

Cost-benefit analyses (CBA) aim to balance all costs and benefits in a unified framework (Nordhaus, 2008). Estimates of economic benefits from avoided climate change impacts depend on the types of damages accounted for, the assumed exposure and vulnerability to these damages as well as the adaptation capacity, which in turn are based on the development pathway assumed (Cross-Working Group Box 1 in this chapter). CBA IAMs raised criticism, in particular for omitting elements of dynamic realism, such as inertia, induced innovation and path dependence, in their representation of mitigation (Grubb et al. 2021), and for underestimating damages from climate change, missing non-monetary damages, the uncertain and heterogeneous nature of damages and the risk of catastrophic damages (Stern 2013, 2016; Diaz and Moore 2017; NASEM 2017; Pindyck 2017; Stoerk et al. 2018; Stern and Stiglitz 2021). Emerging literature has started to address those gaps, and integrated into cost-benefit frameworks the account of heterogeneity of climate damage and inequality (Dennig et al. 2015; Budolfson et al. 2017; Fleurbaey et al. 2019; Kornek et al. 2021), damages with higher persistence, including damages on capital and growth (Moyer et al. 2014; Dietz and Stern 2015; Moore and Diaz 2015; Guivarch and Pottier 2018; Ricke et al. 2018; Piontek et al. 2019), risks of tipping points (Cai et al. 2015, 2016; Lontzek et al. 2015; Lemoine and Traeger 2016; van der Ploeg and de Zeeuw 2018; Cai and Lontzek 2019; Nordhaus 2019; Yumashev et al. 2019; Taconet et al. 2021) and damages to natural capital and non-market goods (Tol 1994; Sterner and Persson 2008; Bastien-Olvera and Moore 2020; Drupp and Hänsel 2021).

Each of these factors, when accounted for in a CBA framework, tends to increase the welfare benefit of mitigation, thus leading to stabilisation at a lower temperature in optimal mitigation pathways. The limitations in CBA modelling frameworks remain significant, their ability to represent all damages incomplete, and the uncertainty in estimates remains large. However, emerging evidence suggests that, even without accounting for co-benefits of mitigation on other sustainable development dimensions (see Section 3.6.3 for further details about on co-benefits), global benefits of pathways that limit warming to 2°C outweigh global mitigation costs over the 21st century: depending on the study, the reason for this result lies in assumptions of economic damages from climate change in the higher end of available estimates (Moore and Diaz 2015; Ueckerdt et al. 2019; Brown and Saunders 2020; Glanemann et al. 2020), in the introduction of risks of tipping points (Cai and

Lontzek 2019), in the consideration of damages to natural capital and non-market goods (Bastien-Olvera and Moore 2020) or in the combination of updated representations of carbon cycle and climate modules, updated damage estimates and/or updated representations of economic and mitigation dynamics (Dietz and Stern 2015; Hänsel et al. 2020; Wei et al. 2020; van der Wijst et al. 2021b). In the studies cited above that perform a sensitivity analysis, this result is found to be robust to a wide range of assumptions on social preferences (in particular, on inequality aversion and pure rate-of-time preference) and holds except if assumptions of economic damages from climate change are in the lower end of available estimates and the pure rate-of-time preference is in the higher range of values usually considered (typically above 1.5%). However, although such pathways bring net benefits over time (in terms of aggregate discounted present value), they involve distributional consequences and transition costs (Brown et al. 2020; Brown and Saunders 2020) (Sections 3.6.1.2 and 3.6.4).

The standard discounted utilitarian framework dominates CBA, thus often limiting the analysis to the question of discounting. CBA can be expanded to accommodate a wider variety of ethical values to assess mitigation pathways (Fleurbaey et al. 2019). The role of ethical values with regard to inequality and the situation of the worse off (Adler et al. 2017), risk (van den Bergh and Botzen 2014; Drouet et al. 2015), and population size (Scovronick et al. 2017; Méjean et al. 2020) has been explored. In most of these studies, the optimal climate policy is found to be more stringent than the one obtained using a standard discounted utilitarian criterion.

Comparing economic costs and benefits of mitigation raises a number of methodological and fundamental difficulties. Monetising the full range of climate change impacts is extremely hard, if not impossible (AR6 WGII Chapter 16), as is aggregating costs and benefits over time and across individuals when values are heterogeneous (Chapter 1; AR5 WGIII Chapter 3). Other approaches should thus be considered in supplement for decision-making (Chapter 1 and Section 1.7), in particular cost-effectiveness approaches that analyse how to achieve a defined mitigation objective at least cost or while also reaching other societal goals (Koomey 2013; Kaufman et al. 2020; Köberle et al. 2021; Stern and Stiglitz 2021). In cost-effectiveness studies too, incorporating benefits from avoided climate damages influences the results and leads to more stringent mitigation in the short term (Drouet et al. 2021; Schultes et al. 2021).

3.6.3 Aggregate Economic Implication of Mitigation Co-benefits and Trade-offs

Mitigation actions have co-benefits and trade-offs with other sustainable development dimensions (Section 3.7) beyond climate change, which imply welfare effects and economic effects, as well as other implications beyond the economic dimension. The majority of quantifications of mitigation costs and benefits synthesized in Sections 3.6.1 and 3.6.2 do not account for these economic benefits and costs associated with co-benefits and trade-offs along mitigation pathways.

Systematic reviews of the literature on co-benefits and trade-offs from mitigation actions have shown that only a small portion of articles provide economic quantifications (Deng et al. 2017; Karlsson et al. 2020). Most economic quantifications use monetary valuation approaches. Improved air quality, and associated health effects, are the co-benefit category dominating the literature (Markandya et al. 2018; Vandyck et al. 2018; Scovronick et al. 2019; Howard et al. 2020; Karlsson et al. 2020b; Rauner et al. 2020a,b), but some studies cover other categories, including health effects from diet change (Springmann et al. 2016b) and biodiversity impacts (Rauner et al. 2020a). Regarding health effects from air quality improvement and from diet change, co-benefits are shown to be of the same order of magnitude as mitigation costs (Thompson et al. 2014; Springmann et al. 2016a,b; Markandya et al. 2018; Scovronick et al. 2019b; Howard et al. 2020; Rauner et al. 2020a,b; Liu et al. 2021; Yang et al. 2021). Co-benefits from improved air quality are concentrated sooner in time than economic benefits from avoided climate change impacts (Karlsson et al. 2020), such that when accounting both for positive health impacts from reduced air pollution and for the negative climate effect of reduced cooling aerosols, optimal GHG mitigation pathways exhibit immediate and continual net economic benefits (Scovronick et al. 2019a). However, AR6 WGI Chapter 6 (Section 6.7.3) shows a delay in air pollution reduction benefits when they come from climate change mitigation policies compared with air pollution reduction policies.

Achieving co-benefits is not automatic but results from coordinated policies and implementation strategies (Clarke et al. 2014; McCollum et al. 2018a). Similarly, avoiding trade-offs requires targeted policies (van Vuuren et al. 2015; Bertram et al. 2018). There is limited evidence of such pathways, but the evidence shows that mitigation pathways designed to reach multiple Sustainable Development Goals instead of focusing exclusively on emissions reductions, result in limited additional costs compared to the increased benefits (Cameron et al. 2016; McCollum et al. 2018b; Fujimori et al. 2020a; Sognaes et al. 2021).

3.6.4 Structural Change, Employment and Distributional Issues Along Mitigation Pathways

Beyond aggregate effects at the economy-wide level, mitigation pathways have heterogeneous economic implications for different sectors and different actors. Climate-related factors are only one driver of the future structure of the economy, of the future of

employment, and of future inequality trends, as overarching trends in demographics, technological change (innovation, automation, etc.), education and institutions will be prominent drivers. For instance, Rao et al. (2019b) and Benveniste et al. (2021) have shown that income inequality projections for the 21st century vary significantly, depending on socio-economic assumptions related to demography, education levels, social public spending and migrations. However, the sections below focus on climate-related factors, both climate-mitigation actions themselves and the climate change impacts avoided along mitigation pathways, effects on structural change, including employment, and distributional effects.

3.6.4.1 Economic Structural Change and Employment in Long-term Mitigation Pathways

Mitigation pathways entail transformation of the energy sector, with structural change away from fossil energy and towards low-carbon energy (Section 3.3), as well as broader economic structural change, including industrial restructuring and reductions in carbon-intensive activities in parallel to extensions in low-carbon activities.

Mitigation affects work through multiple channels, which impacts geographies, sectors and skill categories differently (Fankhaeser et al. 2008; Bowen et al. 2018; Malerba and Wiebe 2021). Aggregate employment impacts of mitigation pathways mainly depend on the aggregate macroeconomic effect of mitigation (Sections 3.6.1 and 3.6.2) and of mitigation policy design and implementation (Freire-González 2018) (Section 4.2.6.3). Most studies that quantify overall employment implications of mitigation policies are conducted at the national or regional scales (Section 4.2.6.3), or sectoral scales (e.g., see Chapter 6 for energy sector jobs). The evidence is limited at the multinational or global scale, but studies generally find small differences in aggregate employment in mitigation pathways compared to baselines: the sign of the difference depends on the assumptions and modelling frameworks used and the policy design tested, with some studies or policy design cases leading to small increases in employment (Chateau and Saint-Martin 2013; Pollitt et al. 2015; Barker et al. 2016; Garcia-Casals et al. 2019; Fujimori et al. 2020a; Vrontisi et al. 2020; Malerba and Wiebe 2021) and other studies or policy design cases leading to small decreases (Chateau and Saint-Martin 2013; Vandyck et al. 2016). The small variations in aggregate employment hide substantial reallocation of jobs across sectors, with jobs creation in some sectors and jobs destruction in others. Mitigation action through thermal renovation of buildings, installation and maintenance of low-carbon generation, and the expansion of public transit lead to job creation, while jobs are lost in fossil fuel extraction, energy supply and energy-intensive sectors in mitigation pathways (von Stechow et al. 2015, 2016; Barker et al. 2016; Fuso Nerini et al. 2018; Perrier and Quirion 2018; Pollitt and Mercure 2018; Dominish et al. 2019; Garcia-Casals et al. 2019). In the energy sector, job losses in the fossil fuel sector are found to be compensated by gains in wind and solar jobs, leading to a net increase in energy sector jobs in 2050 in a mitigation pathway compatible with stabilisation of the temperature increase below 2°C (Pai et al. 2021). Employment effects also differ by geographies, with energy-importing regions benefiting from net job creations but energy-exporting regions experiencing very small gains or suffering

from net job destruction (Barker et al. 2016; Pollitt and Mercure 2018; Garcia-Casals et al. 2019; Malerba and Wiebe 2021). Coal phase-out raises acute issues of just transition for the coal-dependent countries (Spencer et al. 2018; Jakob et al. 2020) (Section 4.5 and Box 6.2).

Mitigation action also affects employment through avoided climate change impacts. Mitigation reduces the risks to human health and associated impacts on labour and helps protect workers from the occupational health and safety hazards imposed by climate change (Kjellstrom et al. 2016, 2018, 2019; Levi et al. 2018; Day et al. 2019) (AR6 WGII Chapter 16).

3.6.4.2 Distributional Implications of Long-term Mitigation Pathways

Mitigation policies can have important distributive effects between and within countries, either reducing or increasing economic inequality and poverty, depending on policy instruments' design and implementation (see Section 3.6.1.2 for an assessment of the distribution of mitigation costs across regions in mitigation pathways; Sections 3.7 and 4.2.2.6, and Box 3.6 for an assessment of the fairness and ambition of NDCs; and Section 4.5 for an assessment of national mitigation pathways along the criteria of equity, including Just Transition, as well as Section 17.4.5 for equity in a Just Transition). For instance, emissions taxation has important distributive effects, both between and within income groups (Cronin et al. 2018b; Klenert et al. 2018; Pizer and Sexton 2019; Douenne 2020; Steckel et al. 2021). These effects are more significant in some sectors, such as transport, and depend on country-specific consumption structures (Dorband et al. 2019; Fullerton and Muehlegger 2019; Ohlendorf et al. 2021). However, revenues from emissions taxation can be used to lessen their regressive distributional impacts or even turn the policy into a progressive policy reducing inequality and/or leading to gains for lower-income households (Cameron et al. 2016; Jakob and Steckel 2016; Fremstad and Paul 2019; Fujimori et al. 2020b; Böhringer et al. 2021; Budolfson et al. 2021; Soergel et al. 2021b; Steckel et al. 2021). Mitigation policies may affect the poorest through effects on energy and food prices (Hasegawa et al. 2015; Fujimori et al. 2019). Markkanen and Anger-Kraavi (2019) and Lamb et al. (2020) synthesize evidence from the existing literature on social co-impacts of climate change mitigation policy and their implications for inequality. They show that most policies can compound or lessen inequalities depending on contextual factors, policy design and policy implementation, but that negative inequality impacts of climate policies can be mitigated (and possibly even prevented), when distributive and procedural justice are taken into consideration in all stages of policymaking, including policy planning, development and implementation, and when focusing on the carbon intensity of lifestyles, sufficiency and equity, well-being and decent living standards for all (Section 13.6).

Mitigation pathways also affect economic inequalities between and within countries, and poverty, through the reduction of climate change impacts that fall more heavily on low-income countries, communities and households, and exacerbate poverty (AR6 WGII Chapters 8 and 16). Higher levels of warming are projected to generate higher inequality between countries as well as within them

(AR6 WGII Chapter 16). Through avoiding impacts, mitigation thus reduces economic inequalities and poverty (*high confidence*).

A few studies consider both mitigation policies' distributional impacts and avoided climate change impacts on inequalities along mitigation pathways. Rezaei et al. (2018) find that unmitigated climate change impacts increase inequality, whereas mitigation has the potential to reverse this effect. Considering uncertainty in socio-economic assumptions, emission pathways, mitigation costs, temperature response, and climate damage, Taconet et al. (2020) show that the uncertainties associated with socio-economic assumptions and damage estimates are the main drivers of future inequalities between countries and that in most cases mitigation policies reduce future inequalities between countries. Gazzotti et al. (2021) show that inequality persists in 2°C-consistent pathways due to regressivity of residual climate damages. However, the evidence on mitigation pathways' implications for global inequality and poverty remains limited, and the modelling frameworks used have limited ability to fully represent the different dimensions of inequality and poverty and all the mechanisms by which mitigation affects inequality and poverty (Rao et al. 2017a; Emmerling and Tavoni 2021; Jafino et al. 2021).

3.7 Sustainable Development, Mitigation and Avoided Impacts

3.7.1 Synthesis Findings on Mitigation and Sustainable Development

Rapid and effective climate mitigation is a necessary part of sustainable development (*high confidence*) (Cross-Chapter Box 5 in Chapter 4), but the latter can only be realised if climate mitigation becomes integrated with sustainable development policies (*high confidence*). Targeted policy areas must include healthy nutrition, sustainable consumption and production, inequality and poverty alleviation, air quality and international collaboration (*high confidence*). Lower energy demand enables synergies between mitigation and sustainability, with lower reliance on CDR (*high confidence*).

This section covers the long-term interconnection of sustainable development and mitigation, taking forward the holistic vision of sustainable development described in the SDGs (Brandi 2015; Leal Filho et al. 2018). Recent studies have explored the aggregated impact of mitigation for multiple sustainable-development dimensions (Hasegawa et al. 2014; Bertram et al. 2018; Fuso Nerini et al. 2018; Grubler et al. 2018; McCollum et al. 2018b; Soergel et al. 2021a; van Vuuren et al. 2019). For instance, Figure 3.38 shows selected mitigation co-benefits and trade-offs based on a subset of models and scenarios, since so far many IAMs do not have a comprehensive coverage of SDGs (Rao et al. 2017a; van Soest et al. 2019). Figure 3.38 shows that mitigation *likely* leads to increased forest cover (SDG 15 – life on land) and reduced mortality from ambient PM_{2.5} pollution (SDG 3 – good health and well-being) compared to reference scenarios. However, mitigation policies can also cause higher food prices and an increased population at risk of hunger (SDG 2 – zero hunger) and relying on solid fuels (SDG 3 – good health and well-being; and SDG 7 – affordable and

clean energy) as side effects. These trade-offs can be compensated through targeted support measures and/or additional sustainable development policies (Cameron et al. 2016; Bertram et al. 2018; Fujimori et al. 2019; Soergel et al. 2021a).

The synthesis of the interplay between climate mitigation and sustainable development is shown in Figure 3.39. Panel a shows the reduction in population affected by climate impacts at 1.5°C compared to 3°C according to sustainability domains (Byers et al. 2018). Reducing warming reduces the population impacted by all impact categories shown (*high confidence*). The left panel does not take into account any side effects of mitigation efforts or policies to reduce warming: only reductions in climate impacts. This underscores that mitigation is an integral basis for comprehensive sustainable development (Watts et al. 2015).

Panels b and c of Figure 3.39 show the effects of 1.5°C mitigation policies compared to current national policies: narrow

mitigation policies (averaged over several models, middle panel), and policies integrating sustainability considerations (right panel of Figure 3.39, based on the Illustrative Mitigation Pathway 'Shifting Pathways' (*IMP-SP*) (Soergel et al. 2021a)). Note that neither middle nor right panels include climate impacts.

Areas of co-benefits include human health, ambient air pollution and other specific kinds of pollution, while areas of trade-off include food access, habitat loss and mineral resources (*medium confidence*). For example, action consistent with 1.5°C in the absence of energy-demand reduction measures require large quantities of CDR, which, depending on the type used, are likely to negatively impact both food availability and areas for biodiversity (Fujimori et al. 2018; Ohashi et al. 2019; Roelfsema et al. 2020).

Mitigation to 1.5°C reduces climate impacts on sustainability (left). Policies integrating sustainability and mitigation (right) have far fewer trade-offs than narrow mitigation policies (middle).

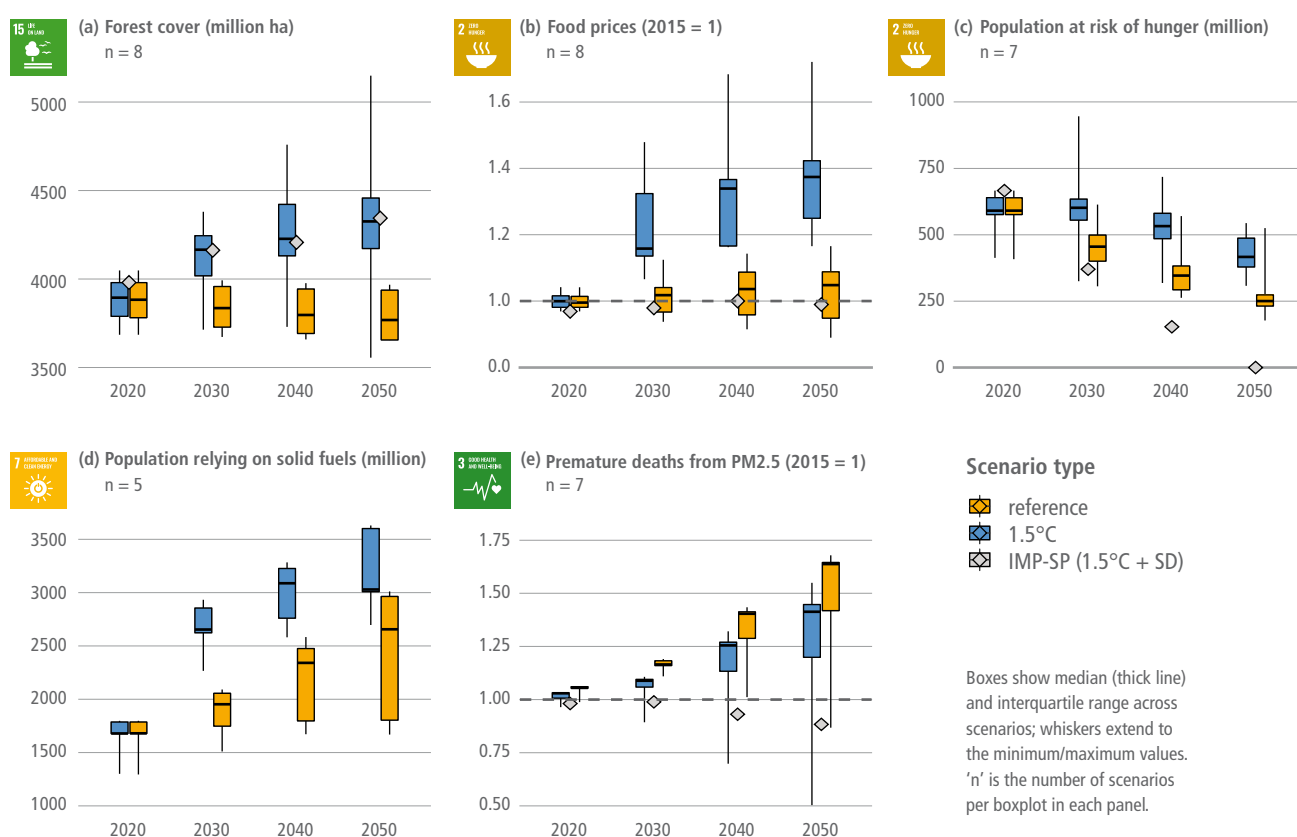

Figure 3.38 | Effect of climate change mitigation on different dimensions of sustainable development: shown are mitigation scenarios compatible with the 1.5°C target (blue) and reference scenarios (yellow). Blue box plots contain scenarios that include narrow mitigation policies from different studies (see below). This is compared to a sustainable development scenario (SP, Soergel et al. (2021a), grey diamonds) integrating mitigation and SD policies (e.g., zero hunger in 2050 by assumption). Scenario sources for box plots: single scenarios from: (i) Fujimori et al. (2020a); (ii) Soergel et al. (2021a); multi-model scenario set from CD-LINKS (McCollum et al. 2018b; Fujimori et al. 2019; Roelfsema et al. 2020). For associated methods, see also Cameron et al. (2016) and Rafaj et al. (2021). The reference scenario for Fujimori et al. (2020a) is no-policy baseline; for all other studies, it includes current climate policies. In the 'Food prices' and 'Risk of hunger' panels, scenarios from CD-LINKS include a price cap of USD200 tCO₂-eq for land-use emissions (Fujimori et al. 2019). For the other indicators, CD-LINKS scenarios without price cap (Roelfsema et al. 2020) are used due to SDG indicator availability. In the 'Premature deaths' panel, a well-below 2°C scenario from Fujimori et al. (2020a) is used in place of a 1.5°C scenario due to data availability, and all scenarios are indexed to their 2015 values due to a spread in reported levels between models. SDG icons were created by the United Nations.

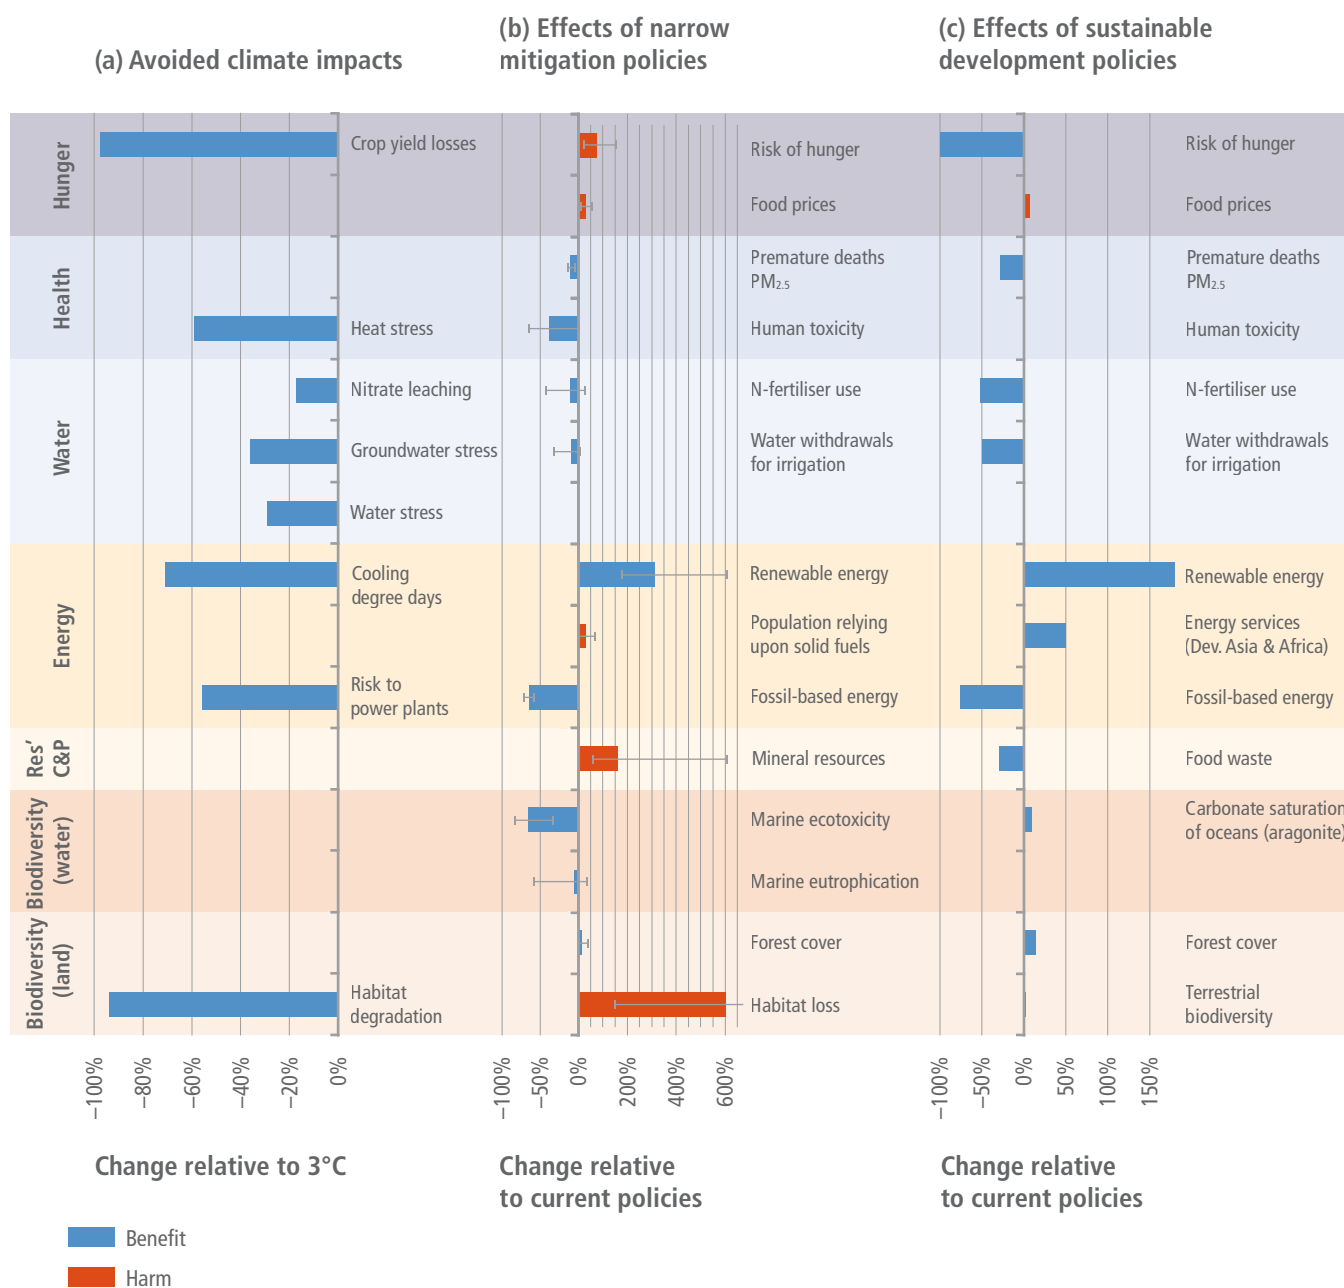

Figure 3.39 | Sustainable development effects of mitigation to 1.5°C. Panel (a): benefits of mitigation from avoided impacts. Panel (b): sustainability co-benefits and trade-offs of narrow mitigation policies (averaged over multiple models). Panel (c): sustainability co-benefits and trade-offs of mitigation policies integrating Sustainable Development Goals. Scale: 0% means no change compared to 3°C (left) or current policies (middle and right). Blue values correspond to proportional improvements, red values to proportional worsening. Note: only the left panel considers climate impacts on sustainable development; the middle and right panels do not. 'Res' C&P' stands for Responsible Consumption and Production (SDG 12). Data are from Byers et al. (2018) (left), *SP/Soergel et al. (2021a)* (right). Methods used in middle panel: for biodiversity, Ohashi et al. (2019); for ecotoxicity and eutrophication, Arvesen et al. (2018) and Pehl et al. (2017); for energy access, Cameron et al. (2016). 'Energy services' on the right is a measure of useful energy in buildings and transport. 'Food prices' and 'Risk of hunger' in the middle panel are the same as in Figure 3.38.

3.7.1.1 Policies Combining Mitigation and Sustainable Development

These findings indicate that holistic policymaking integrating sustainability objectives alongside mitigation will be important in attaining Sustainable Development Goals (van Vuuren et al. 2015, 2018; Bertram et al. 2018; Fujimori et al. 2018; Hasegawa et al. 2018; Liu et al. 2020a; Honegger et al. 2021; Soergel et al. 2021a). Mitigation policies which target direct sector-level regulation, early mitigation action, and lifestyle changes have beneficial sustainable development outcomes across air pollution, food, energy and water (Bertram et al. 2018).

These policies include ones around stringent air quality (Kinney 2018; Rafaj et al. 2018; Soergel et al. 2021a); efficient and safe demand-side technologies, especially cook stoves (Cameron et al. 2016); lifestyle changes (Bertram et al. 2018; Grubler et al. 2018; Soergel et al. 2021a); industrial and sectoral policy (Bertram et al. 2018); agricultural and food policies (including food waste) (van Vuuren et al. 2019; Soergel et al. 2021a); international cooperation (Soergel et al. 2021a); as well as economic policies described in Section 3.6. Recent research shows that mitigation is compatible with reductions in inequality and poverty (Box 3.6).

Lower demand – for example, for energy and land-intensive consumption such as meat – represents a synergistic strategy for achieving ambitious climate mitigation without compromising Sustainable Development Goals (*high confidence*) (Bertram et al. 2018; Grubler et al. 2018; van Vuuren et al. 2018; Kikstra et al. 2021b; Soergel et al. 2021a). This is especially true for reliance on BECCS (Hickel et al. 2021; Keyßer and Lenzen 2021). Options that reduce agricultural demand (e.g., dietary change, reduced food waste) can have co-benefits for adaptation through reductions in demand for land and water (Bertram et al. 2018; Grubler et al. 2018; IPCC 2019a; Soergel et al. 2021a).

While the impacts of climate change on agricultural output are expected to increase the population at risk of hunger, there is evidence suggesting population growth will be the dominant driver of hunger and undernourishment in Africa in 2050 (Hall et al. 2017). Meeting SDG 5, relating to gender equality and reproductive rights, could substantially lower population growth, leading to a global population lower than the 95% prediction range of the UN projections (Abel et al. 2016). Meeting SDG 5 (gender equality, including via voluntary family planning (O’Sullivan 2018)) could thus minimise the risks to SDG 2 (zero hunger) that are posed by meeting SDG 13 (climate action).

Box 3.6 | Poverty and Inequality

There is high confidence (*medium evidence, high agreement*) that the eradication of extreme poverty and universal access to energy can be achieved without resulting in significant GHG emissions (Tait and Winkler 2012; Chakravarty and Tavoni 2013; Pachauri et al. 2013; Pachauri 2014; Rao 2014; Hubacek et al. 2017b; Poble-Cazenave et al. 2021). There is also high agreement in the literature that a focus on well-being and decent living standards for all can reduce disparities in access to basic needs for services concurrently with climate mitigation (Section 5.2). Mitigation pathways in which national redistribution of carbon-pricing revenues is combined with international climate finance, achieve poverty reduction globally (Fujimori et al. 2020b; Soergel et al. 2021b). Carbon-pricing revenues in mitigation pathways consistent with limiting temperature increase to 2°C could also contribute to finance investment needs for basic infrastructure (Jakob et al. 2016) and the achievement of the SDGs (Franks et al. 2018).

Several studies conclude that reaching higher income levels globally, beyond exiting extreme poverty, and achieving more qualitative social objectives and well-being, are associated with higher emissions (Ribas et al. 2017, 2019; Hubacek et al. 2017b; Fischetti 2018; Scherer et al. 2018). Studies give divergent results on the effect of economic inequality reduction on emissions, with either an increase or a decrease in emissions (Berthe and Elie 2015; Lamb and Rao 2015; Grunewald et al. 2017; Hubacek et al. 2017a,b; Jorgenson et al. 2017; Knight et al. 2017; Mader 2018; Rao and Min 2018; Liu et al. 2019; Sager 2019; Baležentis et al. 2020; Liobikienė 2020; Liobikienė and Rimkuvienė 2020; Liu et al. 2020b; Millward-Hopkins and Oswald 2021). However, the absolute effect of economic inequality reduction on emissions remains moderate, under the assumptions tested. For instance, Sager (2019) finds that a full redistribution of income leading to equality among US households in a counterfactual scenario for 2009 would raise emissions by 2.3%; and Rao and Min (2018) limit to 8% the maximum plausible increase in emissions that would accompany the reduction of the global Gini coefficient from its current level of 0.55 to a level of 0.3 by 2050. Similarly, reduced income inequality would lead to a global energy-demand increase of 7% (Oswald et al. 2021). Reconciling mitigation and inequality reduction objectives requires policies that take into account both objectives at all stages of policymaking (Markkanen and Anger-Kraavi 2019), including focusing on the carbon intensity of lifestyles (Scherer et al. 2018), attention to sufficiency and equity (Fischetti 2018), and targeting the consumption of the richest and highest-emitting households (Otto et al. 2019).

In modelled mitigation pathways, inequality in per-capita emissions between regions are generally reduced over time, and the reduction is generally more pronounced in lower-temperature pathways (Box 3.6, Figure 1). Already in 2030, if NDCs from the Paris Agreement, announced prior to COP26, are fully achieved, inequalities in per-capita GHG emissions between countries would be reduced (Benveniste et al. 2018).

Box 3.6 (continued)

Box 3.6, Figure 1 | Difference in per-capita emissions of Kyoto gases between the highest emitting and the lowest emitting of the 10 regions, in 2030 and 2050, by temperature category of pathways.

Through avoiding impacts of climate change, which fall more heavily on low-income countries, communities and households, and exacerbate poverty, mitigation reduces inequalities and poverty (Section 3.6.4.2).

The remainder of this section covers specific domains of sustainable development: food (Section 3.7.2), water (Section 3.7.3), energy (Section 3.7.4), health (Section 3.7.5), biodiversity (Section 3.7.6) and multi-sector – cities, infrastructure, industry, production and consumption (Section 3.7.7). These represent the areas with the strongest research connecting mitigation to sustainable development. The links to individual SDGs are given within these sections. Each domain covers the benefits of avoided climate impacts and the implications (synergies and trade-offs) of mitigation efforts.

3.7.2 Food

The goal of SDG 2 is to achieve 'zero-hunger' by 2030. According to the UN (2015), over 25% of the global population currently experience food insecurity and nearly 40% of these experience severe food insecurity, a situation worsened by the COVID-19 pandemic (Paslakis et al. 2021).

3.7.2.1 Benefits of Avoided Climate Impacts Along Mitigation Pathways

Climate change will reduce crop yields, increase food insecurity, and negatively influence nutrition and mortality (*high confidence*) (AR6 WGII Chapter 5). Climate mitigation will thus reduce these impacts, and hence reduce food insecurity (*high confidence*). The yield reduction of global food production will increase food insecurity and influence nutrition and mortality (Hasegawa et al. 2014; Springmann et al. 2016a). For instance, Springmann et al. (2016a) estimate that climate change could lead to 315,000–736,000 additional deaths by 2050, though these could mostly be averted by stringent mitigation efforts. Reducing warming reduces the impacts of climate change, including extreme climates, on food production and risk of hunger (Hasegawa et al. 2014, 2021b).

3.7.2.2 Implications of Mitigation Efforts Along Pathways

Recent studies explore the effect of climate change mitigation on agricultural markets and food security (Havlik et al. 2014; Hasegawa et al. 2018; Doelman et al. 2019; Fujimori et al. 2019). Mitigation policies aimed at achieving 1.5°C–2°C, if not managed properly,

could negatively affect food security through changes in land and food prices (*high confidence*), leading to increases in the population at risk of hunger by 80–280 million people compared to baseline scenarios. These studies assume uniform carbon prices on AFOLU sectors (with some sectoral caps) and do not account for climate impacts on food production.

Mitigating climate change while ensuring that food security is not adversely affected requires a range of different strategies and interventions (*high confidence*). Fujimori et al. (2018) explore possible economic solutions to these unintended impacts of mitigation (e.g., agricultural subsidies, food aid, and domestic reallocation of income) with an additional small (<0.1%) change in global GDP. Targeted food-security support is needed to shield impoverished and vulnerable people from the risk of hunger that could be caused by the economic effects of policies narrowly focussed on climate objectives. Introducing more biofuels and careful selection of bioenergy feedstocks could also reduce negative impacts (FAO, IFAD, UNICEF, WFP and WHO, 2017). Reconciling bioenergy demands with food and biodiversity, as well as competition for land and water, will require changes in food systems – agricultural intensification, open trade, less consumption of animal products and reduced food losses – and advanced biotechnologies (Henry et al. 2018; Xu et al. 2019).

There are many other synergistic measures for climate mitigation and food security. Agricultural technological innovation can improve the efficiency of land use and food systems, thus reducing the pressure on land from increasing food demand (Foley et al. 2011; Popp et al. 2014; Obersteiner et al. 2016; Humpenöder et al. 2018; Doelman et al. 2019). Furthermore, decreasing consumption of animal products could contribute to SDG 3.4 by reducing the risk of non-communicable diseases (Garnett 2016).

Taken together, climate changes will reduce crop yields, increase food insecurity and influence nutrition and mortality (*high confidence*) (see 3.7.2.1). However, if measures are not properly designed, mitigating climate change will also negatively impact on food consumption and security. Additional solutions to negative impacts associated with climate mitigation on food production and consumption include a transition to a sustainable agriculture and food system that is less resource intensive, more resilient to a changing climate, and in line with biodiversity and social targets (Kayal et al. 2019).

3.7.3 Water

Water is relevant to SDG 6 (clean water and sanitation), SDG 15 (life on land), and SDG Targets 12.4 and 3.9 (water pollution and health). This section discusses water quantity, water quality, and water-related extremes. See Section 3.7.5 for water-related health effects.

3.7.3.1 Benefits of Avoided Climate Impacts Along Mitigation Pathways

Global precipitation, evapotranspiration, runoff and water availability increase with warming (Hanasaki et al. 2013; Greve et al. 2018) (AR6 WGII Chapter 4). Climate change also affects the occurrence

of and exposure to hydrological extremes (*high confidence*) (Arnell and Lloyd-Hughes 2014; Asadieh and Krakauer 2017; Dottori et al. 2018; Naumann et al. 2018; IPCC 2019a; Do et al. 2020) (AR6 WGII Chapter 4). Climate models project increases in precipitation intensity (*high confidence*), local flooding (*medium confidence*), and drought risk (*very high confidence*) (Arnell and Lloyd-Hughes 2014; Asadieh and Krakauer 2017; Dottori et al. 2018; IPCC 2019a) (AR6 WGII Chapter 4).

The effect of climate change on water availability and hydrological extremes varies by region (*high confidence*) due to differences in the spatial patterns of projected precipitation changes (Hanasaki et al. 2013; Schewe et al. 2014; Schlosser et al. 2014; Asadieh and Krakauer 2017; Dottori et al. 2018; Naumann et al. 2018; Koutroulis et al. 2019) (AR6 WGII Chapter 4). Global exposure to water stress is projected to increase with increased warming, but increases will not occur in all regions (Hanasaki et al. 2013; Schewe et al. 2014; Arnell and Lloyd-Hughes 2014; Gosling and Arnell 2016; IPCC 2019a).

Limiting warming could reduce water-related risks (*high confidence*) (O'Neill et al. 2017b; Byers et al. 2018; Hurlbert et al. 2019) (AR6 WGII Chapter 4) and the population exposed to increased water stress (Hanasaki et al. 2013; Arnell and Lloyd-Hughes 2014; Schewe et al. 2014; Gosling and Arnell 2016; IPCC 2019a).

The effect of climate change on water depends on the climate model, the hydrological model, and the metric (*high confidence*) stress (Hanasaki et al. (2013); Arnell and Lloyd-Hughes (2014); Schewe et al. (2014); Schlosser et al. (2014); Gosling and Arnell (2016); IPCC (2019a).

However, the effect of socio-economic development could be larger than the effect of climate change (*high confidence*) (Arnell and Lloyd-Hughes 2014; Schlosser et al. 2014; Graham et al. 2020).

Climate change can also affect water quality (both thermal and chemical) (Liu et al. 2017), leading to increases in stream temperature and nitrogen loading in rivers (Ballard et al. 2019).

3.7.3.2 Implications of Mitigation Efforts Along Pathways

The effects of mitigation on water demand depends on the mitigation technologies deployed (*high confidence*) (Chaturvedi et al. 2013a,b; Hanasaki et al. 2013; Kyle et al. 2013; Hejazi et al. 2014; Bonsch et al. 2016; Jakob and Steckel 2016; Mouratiadou et al. 2016; Fujimori et al. 2017; Maïzi et al. 2017; Bijl et al. 2018; Cui et al. 2018; Graham et al. 2018; Parkinson et al. 2019). Some mitigation options could increase water consumption (volume removed and not returned) while decreasing withdrawals (total volume of water removed, some of which may be returned) (Kyle et al. 2013; Fricko et al. 2016; Mouratiadou et al. 2016; Parkinson et al. 2019). Bioenergy and BECCS can increase water withdrawals and water consumption (*high confidence*) (Chaturvedi et al. 2013a; Kyle et al. 2013; Hejazi et al. 2014; Bonsch et al. 2016; Jakob and Steckel 2016; Mouratiadou et al. 2016; Fujimori et al. 2017; Maïzi et al. 2017; Séférian et al. 2018; Yamagata et al. 2018; Parkinson et al. 2019) (AR6 WGII Chapter 4). DACCS (Fuhrman et al. 2020) and CCS (Kyle et al. 2013; Fujimori

et al. 2017) could increase water demand; however, the implications of CCS depend on the cooling technology and when capture occurs (Magneschi et al. 2017; Maizi et al. 2017; Giannaris et al. 2020). Demand-side mitigation (e.g., dietary change, reduced food waste, reduced energy demand) can reduce water demand (Bajželj et al. 2014; Aleksandrowicz et al. 2016; Green et al. 2018; Springmann et al. 2018). Introducing specific measures (e.g., environmental flow requirements, improved efficiency, priority rules) can reduce water withdrawals (Bertram et al. 2018; Bijl et al. 2018; Parkinson et al. 2019).

The effect of mitigation on water quality depends on the mitigation option, its implementation, and the aspect of quality considered (*high confidence*) (Ng et al. 2010; Flörke et al. 2019; Sinha et al. 2019; Smith et al. 2019; Fuhrman et al. 2020; Karlsson et al. 2020; McElwee et al. 2020).

3.7.4 Energy

Energy is relevant to SDG 7 (affordable and clean energy). Access to sufficient levels of reliable, affordable and renewable energy is essential for sustainable development. Currently, over 1 billion people still lack access to electricity (Ribas et al. 2019).

3.7.4.1 Benefits of Avoided Climate Impacts Along Mitigation Pathways

Climate change alters the production of energy through changes in temperature (hydropower, fossil fuel, nuclear, solar, bioenergy, transmission and pipelines), precipitation (hydropower, fossil fuel, nuclear and bioenergy), windiness (wind and wave), and cloudiness (solar) (*high confidence*). Increases in temperature reduce efficiencies of thermal power plants (e.g., fossil fuel and nuclear plants) with air-cooled condensers by 0.4–0.7% per °C increase in ambient temperature (Cronin et al. 2018a; Simioni and Schaeffer 2019; Yalew, S.G. et al. 2020). Potentials and costs for renewable energy technologies are also affected by climate change, though with considerable regional variation and uncertainty (Gernaat et al. 2021). Biofuel yields could increase or decrease depending on the level of warming, changes in precipitation, and the effect of CO₂ fertilisation (Calvin et al. 2013; Kyle et al. 2014; Gernaat et al. 2021). Coastal energy facilities could potentially be impacted by sea level rise (Brown et al. 2014).

The energy sector uses large volumes of water (Fricko et al. 2016), making it highly vulnerable to climate change (Tan and Zhi 2016) (*high confidence*). Thermoelectric and hydropower sources are the most vulnerable to water stress (van Vliet et al. 2016). Restricted water supply to these power sources can affect grid security and affordable energy access (Koch et al. 2014; Ranzani et al. 2018; Zhang et al. 2018d). The hydropower facilities from high mountain areas of Central Europe, Iceland, Western USA/Canada, and Latin America (Hock et al. 2019), as well as Africa and China (Bartos and Chester 2015; Gaupp et al. 2015; Tarroja et al. 2016; Conway et al. 2017; Byers et al. 2018; Eyer and Wichman 2018; Ranzani et al. 2018; Savelsberg et al. 2018; Zhang et al. 2018d; Zhou et al. 2018; Wang et al. 2019) have experienced changes in seasonality and availability.

3.7.4.2 Implications of Mitigation Efforts Along Pathways

Extending energy access to all in line with SDG7 is compatible with strong mitigation consistent with the Paris Agreement (*high confidence*). The Low Energy Demand (LED) scenario projects that these twin goals can be achieved by relying heavily on energy efficiency and rapid social transformations (Grubler et al. 2018). The IEA's Sustainable Development Scenario (IEA 2020a) achieves development outcomes but with higher average energy use, and bottom-up modelling suggests that decent living standards could be provided to all in 2040–2050 with roughly 150 EJ, or 40% of current final energy use (Millward-Hopkins et al. 2020; Kikstra et al. 2021b). The trade-offs between climate mitigation and increasing energy consumption of the world's poorest are negligible (Rao and Min 2018; Scherer et al. 2018).

The additional energy demand to meet the basic cooling requirement in the Global South is estimated to be much larger than the electricity needed to provide basic residential energy services universally via clean and affordable energy, as defined by SDG 7 (IEA 2019; Mastrucci et al. 2019) (*high confidence*). If conventional air-conditioning systems are widely deployed to provide cooling, energy use could rise significantly (van Ruijven et al. 2019; Bezerra et al. 2021; Falchetta and Mistry 2021), thus creating a positive feedback further increasing cooling demand. However, the overall emissions are barely altered by the changing energy demand composition with reductions in heating demand occurring simultaneously (Isaac and van Vuuren 2009; Labriet et al. 2015; McFarland et al. 2015; Clarke et al. 2018). Some mitigation scenarios show price increases of clean cooking fuels, slowing the transition to clean cooking fuels (SDG 7.1) and leaving a billion people in 2050 still reliant on solid fuels in South Asia (Cameron et al. 2016).

In contrast, future energy infrastructure could improve reliability, thus lowering dependence on high-carbon, high-air pollution back-up diesel generators (Farquharson et al. 2018) that are often used to cope with unreliable power in developing countries (Maruyama Rentschler et al. 2019). There can be significant reliability issues where mini-grids are used to electrify rural areas (Numminen and Lund 2019). A stable, sustainable energy transition policy that considers national sustainable development in the short and long term is critical in driving a transition to an energy future that addresses the trilemma of energy security, equity, and sustainability (La Viña et al. 2018).

3.7.5 Health

SDG 3 (good health and well-being) aims to ensure healthy lives and promote well-being for all at all ages. Climate change is increasingly causing injuries, illnesses, malnutrition, threats to mental health and well-being, and deaths (AR6 WGII Chapter 7). Mitigation policies and technologies to reduce GHG emissions are often beneficial for human health on a shorter time scale than benefits in terms of slowing climate change (Limaye et al. 2020). The financial value of health benefits from improved air quality alone is projected to exceed the costs of meeting the goals of the Paris Agreement (Markandya et al. 2018).

3.7.5.1 Benefits of Avoided Climate Impacts Along Mitigation Pathways

The human health chapter of the WGII contribution to the AR6 concluded that climate change is increasingly affecting a growing number of health outcomes, with negative net impacts at the global scale and positive impacts only in a few limited situations. There are few estimates of economic costs of increases in climate-sensitive health outcomes. In the USA in 2012, the financial burden in terms of deaths, hospitalisations, and emergency department visits for ten climate-sensitive events across 11 states were estimated to be 10 (2.7–24.6) billion USD₂₀₁₈ (Limaye et al. 2019).

3.7.5.2 Implications of Mitigation Efforts Along Pathways

Transitioning toward equitable, low-carbon societies has multiple co-benefits for health and well-being (AR6 WGII Chapter 7). Health benefits can be gained from improvements in air quality through transitioning to renewable energy and active transport (e.g., walking and cycling); shifting to affordable low-meat, plant-rich diets; and green buildings and nature-based solutions, such as green-and-blue urban infrastructure, as shown in Figure 3.40 (Iacobucci 2016).

The avoided health impacts associated with climate change mitigation can substantially offset mitigation costs at the societal level (Ščasný et al. 2015; Schucht et al. 2015; Chang et al. 2017; Markandya et al. 2018). Models of health co-benefits show that a 1.5°C pathway could result in 152 million ± 43 million fewer premature deaths worldwide between 2020 and 2100 in comparison to a business-as-usual scenario, particularly due to reductions in exposure to PM_{2.5} (Shindell et al. 2018; Rauner et al. 2020a; Rafaj et al. 2021). Some of the most substantial health, well-being, and equity benefits associated with climate action derive from investing in basic infrastructure: sanitation, clean drinking water, clean energy, affordable healthy diets, clean public transport, and improved air quality from transformative solutions across economic sectors including agriculture, energy, transport and buildings (Chang et al. 2017).

The health co-benefits of the NDCs for 2040 were compared for two scenarios, one consistent with the goal of the Paris Agreement and the SDGs and the other also placing health as a central focus of the policies (i.e., health in all climate policies scenario) (Hamilton et al. 2021), for Brazil, China, Germany, India, Indonesia, Nigeria, South Africa, the UK, and the USA. Modelling of the energy, food and agriculture, and transport sectors, and associated risk factors

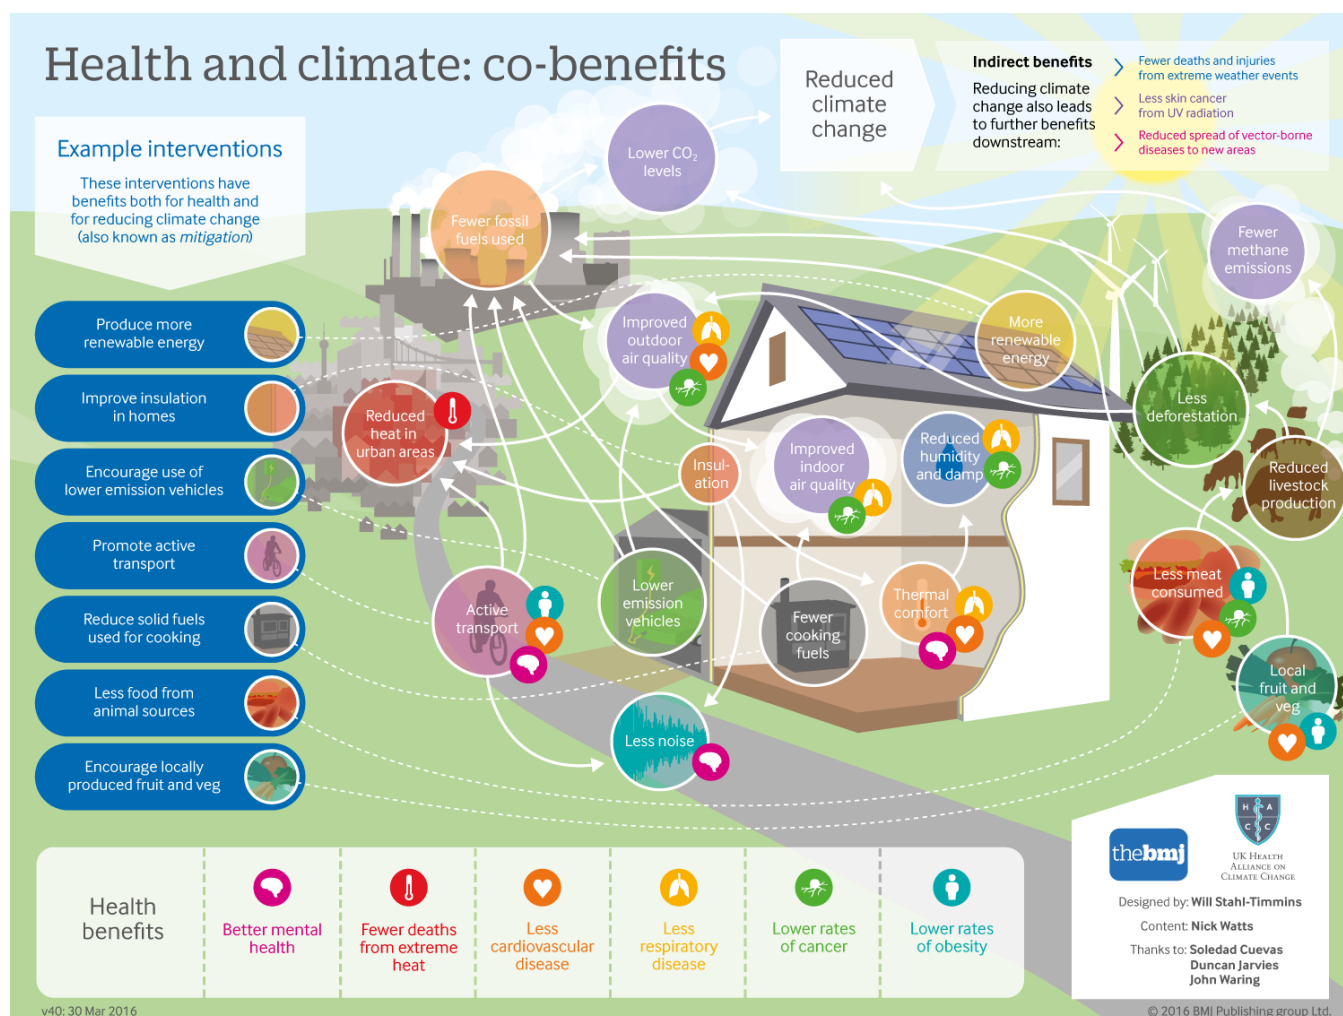

Figure 3.40 | Diagram showing the co-benefits between health and mitigation. Source: with permission from Iacobucci 2016.

related to mortality, suggested the sustainable pathways scenario could result in annual reductions of 1.18 million air pollution-related deaths, 5.86 million diet-related deaths, and 1.15 million deaths due to physical inactivity. Adopting the more ambitious health in all climate policies scenario could result in further reductions of 462,000 annual deaths attributable to air pollution, 572,000 annual deaths attributable to diet, and 943,000 annual deaths attributable to physical inactivity. These benefits were attributable to the mitigation of direct GHG emissions and the commensurate actions that reduce exposure to harmful pollutants, as well as improved diets and safe physical activity.

Cost-benefit analyses for climate mitigation in urban settings that do not account for health may underestimate the potential cost savings and benefits (Hess et al. 2020). The net health benefits of controlling air pollution as part of climate mitigation efforts could reach trillions of dollars annually, depending on the air quality policies adopted globally (Markandya et al. 2018; Scovronick et al. 2019b). Air pollution reductions resulting from meeting the Paris Agreement targets were estimated to provide health co-benefits-to-mitigation ratios of between 1.4 and 2.5 (Markandya et al. 2018). In Asia, the benefit of air pollution reduction through mitigation measures was estimated to reduce premature mortality by 0.79 million, with an associated health benefit of USD2.8 trillion versus mitigation costs of USD840 billion, equating to 6% and 2% of GDP, respectively (Xie et al. 2018). Similarly, stabilising radiative forcing to 3.4 W m^{-2} in South Korea could cost USD1.3–8.5 billion in 2050 and could lead to a USD23.5 billion cost reduction from the combined benefits of avoided premature mortality, health expenditures, and lost work hours (Kim et al. 2020). The health co-benefits related to physical exercise and reduced air pollution largely offset the costs of implementing low-CO₂-emitting urban mobility strategies in three Austrian cities (Wolking et al. 2018).

Just in the USA, over the next 50 years, a 2°C pathway could prevent roughly 4.5 million premature deaths, about 3.5 million hospitalisations and emergency room visits, and approximately 300 million lost workdays (Shindell 2020). The estimated yearly benefits of USD700 billion were more than the estimated cost of the energy transition.

3.7.6 Biodiversity (Land and Water)

Biodiversity covers life below water (SDG 14) and life on land (SDG 15). Ecosystem services are relevant to the goals of zero hunger (SDG 2), good health and well-being (SDG 3), clean water and sanitation (SDG 6) and responsible consumption and production (SDG 12), as well as being essential to human existence (IPBES 2019).

3.7.6.1 Benefits of Avoided Climate Impacts Along Mitigation Pathways

Terrestrial and freshwater aquatic ecosystems

Climate change is a major driver of species extinction and terrestrial and freshwater ecosystems destruction (*high confidence*) (AR6 WGII Chapter 2). Analysis shows that approximately half of all species with long-term records have shifted their ranges in elevation and about

two thirds have advanced their timing of spring events (Parmesan and Hanley 2015). Under 3.2°C warming, 49% of insects, 44% of plants and 26% of vertebrates are projected to be at risk of extinction. At 2°C, this falls to 18% of insects, 16% of plants and 8% of vertebrates and at 1.5°C, to 6% of insects, 8% of plants and 4% of vertebrates (Warren et al. 2018). Incidents of migration of invasive species, including pests and diseases, are also attributable to climate change, with negative impacts on food security and vector-borne diseases. Moreover, if climate change reduces crop yields, cropland may expand – a primary driver of biodiversity loss – in order to meet food demand (Molotoks et al. 2020). Land restoration and halting land degradation under all mitigation scenarios has the potential for synergy between mitigation and adaptation.

Marine and coastal ecosystems

Marine ecosystems are being affected by climate change and growing non-climate pressures including temperature change, acidification, land-sourced pollution, sedimentation, resource extraction and habitat destruction (*high confidence*) (Bindoff et al. 2019; IPCC 2019b). The impacts of climate drivers and their combinations vary across taxa (AR6 WGII Chapter 3). The danger of warming and acidification to coral reefs, rocky shores and kelp forests is well established (*high confidence*) (AR6 WGII Chapter 3). Migration towards optimal thermal and chemical conditions (Burrows et al. 2019) contributes to large-scale redistribution of fish and invertebrate populations, and major impacts on global marine biomass production and maximum sustainable yield (Bindoff et al. 2019).

3.7.6.2 Implications of Mitigation Efforts Along Pathways
