In a review of different approaches and attempts to map global land degradation, Gibbs and Salmon (2015) identified four main approaches to map the global extent of degraded lands: expert opinions (Oldeman and van Lynden 1998; Dregne 1998; Reed 2005; Bot et al. 2000), satellite observation of vegetation greenness (e.g., remote sensing of NDVI (Normalized Difference Vegetation Index), EVI (Enhanced Vegetation Index), PPI (Plant Phenology Index) (Yengoh et al. 2015; Bai et al. 2008c; Shi et al. 2017a; Abdi et al. 2019; JRC 2018), biophysical models (biogeographical/ topological) (Cai et al. 2011b; Hickler et al. 2005; Steinkamp and Hickler 2015; Stoorvogel et al. 2017) and inventories of land use/condition. Together they provide a relatively complete evaluation, but none on its own assesses the complexity of the process (Vogt et al. 2011; Gibbs and Salmon 2015). There is, however, a robust consensus that remote sensing and field-based methods are critical to assess and monitor land degradation, particularly over large areas (such as global, continental and sub-continental) although there are still knowledge gaps to be filled (Wessels et al. 2007, 2004; Prince 2016; Ghazoul and Chazdon 2017) as well as the problem of baseline (see 4.1.3).

Remote sensing can provide meaningful proxies of land degradation in terms of severity, temporal development, and areal extent. These proxies of land degradation include several indexes that have been used to assess land conditions and monitoring the changes of land condition, for example extent of gullies, severe forms of rill and sheet erosion, and deflation. The presence of open-access, quality controlled and continuously updated global databases of remote sensing data is invaluable, and is the only method for consistent monitoring of large areas over several decades (Sedano et al. 2016; Brandt et al. 2018b; Turner 2014).The NDVI, as a proxy for Net Primary Production (NPP, see glossary), is one of the most commonly used methods to assess land degradation, since it indicates land cover, an important factor for soil protection. Although NDVI is not a direct measure of vegetation biomass, there is a close coupling between NDVI integrated over a season and in situ NPP (*high agreement*, *robust evidence*) (see Higginbottom et al. 2014; Andela et al. 2013; Wessels et al. 2012).

Distinction between land degradation/improvement and the effects of climate variation is an important and contentious issue (Murthy and Bagchi 2018; Ferner et al. 2018). There is no simple and straightforward way to disentangle these two effects. The interaction of different determinants of primary production is not well understood. A key barrier to this is a lack of understanding of the inherent inter-annual variability of vegetation (Huxman et al. 2004; Knapp and Smith 2001; Ruppert et al. 2012; Bai et al. 2008a; Jobbágy and Sala 2000). One possibility is to compare potential land productivity modelled by vegetation models and actual productivity measured by remote sensing (Seaquist et al. 2009; Hickler et al. 2005; van der Esch et al. 2017), but the difference in spatial resolution, typically 0.5 degrees for vegetation models compared to 0.25–0.5 km for remote sensing data, is hampering the approach. Moderate-resolution Imaging Spectroradiometer, or MODIS, provides higher spatial resolution (up to 0.25 km), delivers data for the Enhanced Vegetation Index (EVI) which is calculated similarly to NDVI and have showed robust approach to estimate spatial patterns of global annual primary productivity (Shi et al. 2017b; Testa et al. 2018).

Another approach to disentangle the effects of climate and land use/management is to use the Rain Use Efficiency (RUE), defined as the biomass production per unit of rainfall, as an indicator (Le Houerou 1984; Prince et al. 1998; Fensholt et al. 2015). A variant of the RUE approach is the residual trend (RESTREND) of a NDVI time-series, defined as the fraction of the difference between the observed NDVI and the NDVI predicted from climate data (Yengoh et al. 2015; John et al. 2016). These two metrics aim to estimate the NPP, rainfall and the time dimensions. They are simple transforms of the same three variables: RUE shows the NPP relationship with rainfall for individual years, while RESTREND is the interannual change of RUE; also, both consider that rainfall is the only variable that affects biomass production. They are legitimate metrics when used appropriately, but in many cases they involve oversimplifications and yield misleading results (Fensholt et al. 2015; Prince et al. 1998).

Furthermore, increases in NPP do not always indicate improvement in land condition/reversal of land degradation, since this does not account for changes in vegetation composition. It could, for example, result from conversion of native forest to plantation, or due to bush encroachment, which many consider to be a form of land degradation (Ward 2005). Also, NPP may be increased by irrigation, which can enhance productivity in the short-medium term while increasing risk of soil salinisation in the long term (Niedertscheider et al. 2016).

Recent progress and expanding time series of canopy characterisations based on passive microwave satellite sensors have offered rapid progress in regional and global descriptions of forest degradation and recovery trends (Tian et al. 2017). The most common proxy is VOD (vertical optical depth) and has already been used to describe global forest/savannah carbon stock shifts over two decades, highlighting strong continental contrasts (Liu et al. 2015a) demonstrating the value of this approach to monitor forest degradation at large scales. Contrasting NDVI which is only sensitive to vegetation "greenness", from which primary production can be modelled, VOD is also sensitive to water in woody parts of the vegetation and hence provides a view of vegetation dynamics that can be complementary to NDVI. As well as the NDVI, VOD also needs to be corrected to take into account the rainfall variation (Andela et al. 2013).

Even though remote sensing offers much potential, its application to land degradation and recovery remains challenging as structural changes often occur at scales below the detection capabilities of most remote sensing technologies. Additionally, if the remote sensing is based on vegetation indexes data, other forms of land degradation, such as nutrient depletion, changes of soil physical or biological properties, loss of values for humans, among others, cannot be inferred indirectly by remote sensing. The combination of remotely sensed images and field based approach can give improved estimates of carbon stocks and tree biodiversity (Imai et al. 2012; Fujiki et al. 2016).

Additionally, the majority of trend techniques employed would be capable of detecting only the most severe of degradation processes, and would therefore not be useful as a degradation early-warning system (Higginbottom et al. 2014; Wessels et al. 2012). However, additional analyses using higher resolution imagery, such as the Landsat and SPOT satellites, would be well suited to provide further localized information on trends observed (Higginbottom et al. 2014). New approaches to assess land degradation using high spatial resolution are developing but the need for time series makes progress slow. The use of synthetic aperture radar (SAR) data has been shown to be advantageous for the estimation of soil surface characteristics, in particular surface roughness and soil moisture (Gao et al. 2017; Bousbih et al. 2017), and detecting and quantifying selective logging (Lei et al. 2018). It is still necessary to maintain the efforts to fully assess land degradation using remote sensing.

Computer simulation models can be used alone or combined with the remote sensing observations to assess land degradation. The RUSLE (Revised Universal Soil Loss Equation) can be used, to some extent, to predict the long-term average annual soil loss by water erosion. RUSLE has been constantly revisited to estimate soil loss based on the product of rainfall–runoff erosivity, soil erodibility, slope length and steepness factor, conservation factor, and support practice parameter (Nampak et al. 2018). Inherent limitations of RUSLE include data-sparse regions, inability to account for soil loss from gully erosion or mass wasting events, and that it does not predict sediment pathways from hillslopes to water bodies (Benavidez et al. 2018). Since RUSLE models only provide gross erosion, the integration of a further module in the RUSLE scheme to estimate the sediment yield from the modelled hillslopes is needed. The spatially distributed sediment delivery model WaTEM/SEDEM has been widely tested in Europe (Borrelli et al. 2018). Wind erosion is another factor that needs to be taken into account in the modelling of soil erosion (Webb et al. 2017a, 2016). Additional models need to be developed to include the limitations of the RUSLE models.

Regarding the field based approach to assess land degradation, there are multiple indicators that reflect functional ecosystem processes linked to ecosystem services and, thus, to the value for humans. These indicators are a composite set of measurable attributes from different factors, such as climate, soil, vegetation, biomass, management, among others, that can be used together or to develop indexes to better assess land degradation (Allen et al. 2011; Kosmas et al. 2014).

Declines in vegetation cover, changes in vegetation structure, decline in mean species abundances, decline in habitat diversity, changes in abundance of specific indicator species, reduced vegetation health and productivity, and vegetation management intensity and use, are the most common indicators in the vegetation condition of forest and woodlands (Stocking et al. 2001; Wiesmair et al. 2017; Ghazoul and Chazdon 2017; Alkemade et al. 2009).

Several indicators of the soil quality (soil organic matter, depth, structure, compaction, texture, pH, C:N ratio, aggregate size distribution and stability, microbial respiration, soil organic carbon, salinisation, among others) have been proposed (see also 2.2) (Schoenholtz et al. 2000). Among these, soil organic matter (SOM) directly and indirectly drives the majority of soil functions. Decreases in

SOM can lead to a decrease in fertility and biodiversity, as well as a loss of soil structure, causing reductions in water holding capacity, increased risk of erosion (both wind and water) and increased bulk density and hence soil compaction (Allen et al. 2011; Certini 2005; Conant et al. 2011a). Thus, indicators related with the quantity and quality of the SOM are necessary to identify land degradation (Pulido et al. 2017; Dumanski and Pieri 2000). The composition of the microbial community is *very likely* to be positive impacted by both climate change and land degradation processes (Evans and Wallenstein 2014; Wu et al. 2015; Classen et al. 2015), thus changes in microbial community composition can be very usefull to rapidly reflect land degradation (e.g. forest degradation increased the bacterial alpha-diversity indexes) (Flores-Rentería et al. 2016; Zhou et al. 2018). These indicators might be used as a set of indicators site-dependent, and in a plant-soil system (Ehrenfeld et al. 2005).

Useful indicators of degradation and improvement include changes in ecological processes and disturbance regimes that regulate the flow of energy and materials and that control ecosystem dynamics under a climate change scenario. Proxies of dynamics include spatial and temporal turnover of species and habitats within ecosystems (Ghazoul et al. 2015; Bahamondez and Thompson 2016). Indicators in agricultural lands include crop yield decreases and difficulty in maintaining yields (Stocking et al. 2001). Indicators of landscape degradation/improvement in fragmented forest landscapes include the extent, size, and distribution of remaining forest fragments, an increase in edge habitat, and loss of connectivity and ecological memory (Zahawi et al. 2015; Pardini et al. 2010).

In summary, as land degradation is such a complex and global process there is no single method by which land degradation can be estimated objectively and consistently over large areas (*very high confidence*). However, many approaches exist that can be used to assess different aspects of land degradation or provide proxies of land degradation. Remote sensing, complemented by other kinds of data (i.e., field observations, inventories, expert opinions), is the only method that can generate geographically explicit and globally consistent data over time scales relevant for land degradation (several decades).

4.3 Status and current trends of land degradation

The scientific literature on land degradation often excludes forest degradation, yet here we attempt to assess both issues. Because of the different bodies of scientific literature, we assess land degradation and forest degradation under different sub-headings, and where possible draw integrated conclusions.

4.3.1 Land degradation

There are no reliable global maps of the extent and severity of land degradation (Gibbs and Salmon 2015; Prince et al. 2018; van der Esch et al. 2017), despite the fact that land degradation is a severe problem (Turner et al. 2016). The reasons are both conceptual, i.e., how is land degradation defined, using what baseline (Herrick et al. 2019) or over what time period, and methodological, i.e. how can it be measured (Prince et al. 2018). Although there is a strong consensus that land degradation is a reduction in productivity of the land or soil, there are diverging views regarding the spatial and temporal scales at which land degradation occurs (Warren 2002), and how this can be quantified and mapped. Proceeding from the definition in this report, there are also diverging views concerning ecological integrity and the value to humans. A comprehensive treatment of the conceptual discussion about land degradation is provided by the recent report on land degradation from the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services, IPBES (Montanarella et al. 2018).

A review of different attempts to map global land degradation, based on expert opinion, satellite observations, biophysical models and a data base of abandoned agricultural lands, suggested that between <10 M km^2 to 60 M km^2 (corresponding to 8–45% of the ice-free land area) have been degraded globally (Gibbs and Salmon, 2015) (*very low confidence*).

One often used global assessment of land degradation used trends in NDVI as a proxy for land degradation and improvement during the period 1983 to 2006 (Bai et al. 2008b,c) with an update to 2011 (Bai et al. 2015). These studies, based on very coarse resolution satellite data (8 km NOAA AVHRR), indicated that between 22% and 24% of the global ice-free land area was subject to a downward trend, while about 16% showed an increasing trend. The study also suggested, contrary to earlier assessments (Middleton and Thomas 1997), that drylands were not among the most affected regions. Another study using a similar approach for the period 1981-2006 suggested that about 29% of the global land area is subject to 'land degradation hotspots', i.e. areas with acute land degradation in need of particular attention. These hotspot areas were distributed over all agro-ecological regions and land cover types. Two different studies have tried to link land degradation, identified by NDVI as a proxy, and number of people affected: Le et al. (2016) estimated that at least 3.2 billion people were affected, while Barbier and Hochard (2016, 2018) estimated that 1.33 billion people were affected, of which 95% were living in developing countries.

Yet another study, using a similar approach and type of remote sensing data, compared NDVI trends with biomass trends calculated by a global vegetation model over the period 1982-2010 and found that 17-36% of the land areas showed a negative NDVI trend while a positive or neutral trend was predicted in modelled vegetation (Schut et al. 2015). The World Atlas of Desertification (3rd edition) includes a global map of land productivity change over the period 1999 to 2013, which is one useful proxy for land degradation (Cherlet et al. 2018). Over that period about 20% of the global ice-free land area shows signs of declining or unstable productivity, whereas about 20% shows increasing productivity. The same report also summarized the productivity trends by land categories and found that most forest land showed increasing trends in productivity while rangelands had more declining trends than increasing trends (Fig 4.4). These productivity assessments, however, do not distinguish between trends due to climate change and trends due to other factors. A recent analysis of "greening" of the world using MODIS time series of NDVI 2000 – 2017, shows a striking increase in the greening over China and India. In China the greening is seen over both forested areas, 42%, and cropland areas, in which 32% is increasing (see Section 4.9.3). In India, the greening is almost entirely associated with cropland (82%) (Chen et al. 2019).

All the studies of vegetation trends referred to above show that there are regionally-differentiated trends of either decreasing or increasing vegetation. When comparing vegetation trends with trends in climatic variables, Schut et al. (2015) found very few areas (1-2%) where an increase in vegetation trend was independent of the climate drivers, and that study suggested that positive vegetation trends are primarily caused by climatic factors.

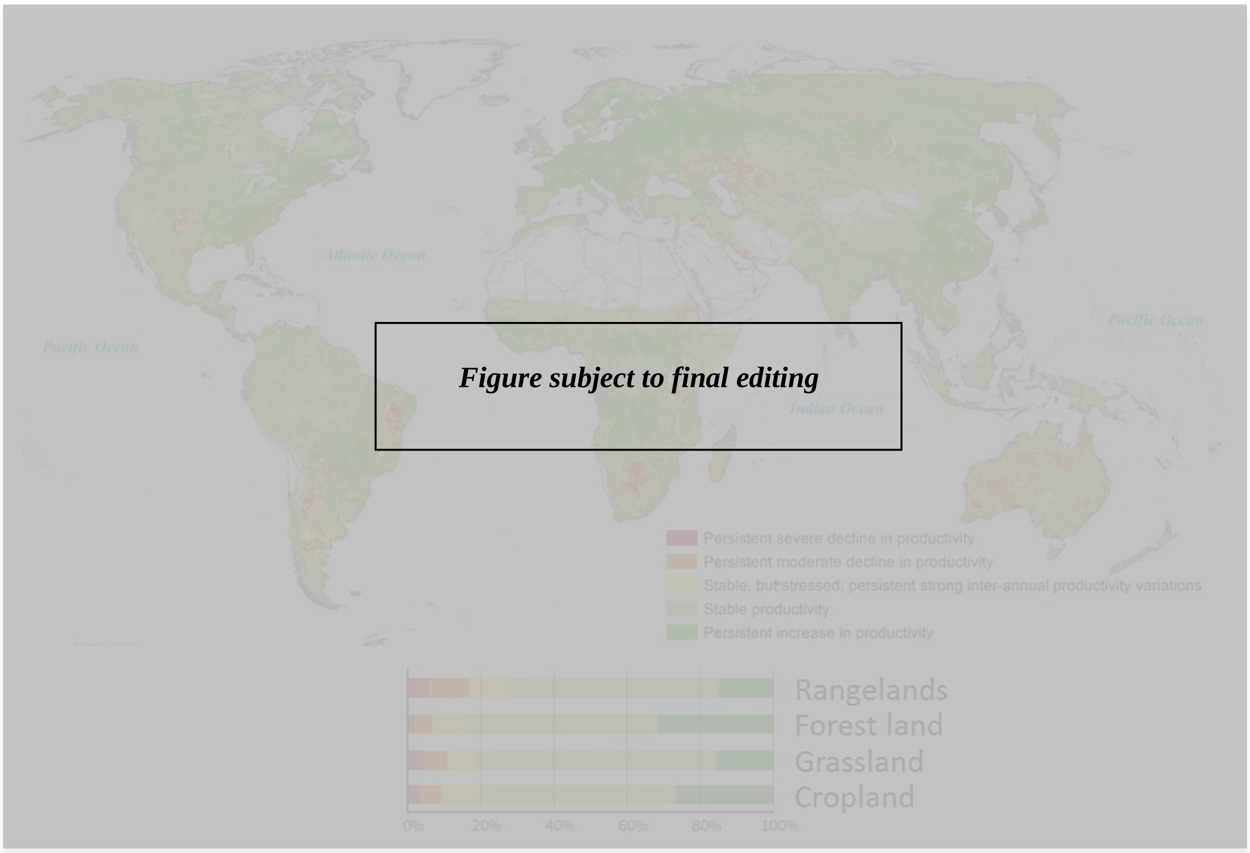

Figure 4.4. Proportional global land productivity trends by land cover/land use class. (Cropland includes arable land, permanent crops and mixed classes with over 50% crops; Grassland includes natural grassland and managed pasture land; Rangelands include shrub land, herbaceous and sparsely vegetated areas; Forest land includes all forest categories and mixed classes with tree cover greater than 40%). Data source: Copernicus Global Land SPOT VGT, 1999-2013.

In an attempt to go beyond the mapping of global vegetation trends for assessing land degradation, Borelli et al. (2017) used a soil erosion model (RUSLE) and suggested that soil erosion is mainly caused in areas of crop land expansion, particularly in sub-Saharan Africa, South America and Southeast Asia. The method is controversial for both conceptual reasons (i.e., the ability of the model to capture the most important erosion processes) and data limitations (i.e., the availability of relevant data at regional to global scales), and its validity for assessing erosion over large areas has been questioned by several studies (Baveye 2017; Evans and Boardman 2016a,b; Labrière et al. 2015).

An alternative to using remote sensing for assessing the state of land degradation is to compile field based data from around the globe (Turner et al. 2016). In addition to the problems of definitions and baselines, this approach is also hampered by the lack of standardized methods used in the field. An assessment of the global severity of soil erosion in agriculture, based on 1,673 measurements around the world (compiled from 201 peer reviewed articles), indicated that the global net median rate of soil formation (i.e., formation minus erosion) is about 0.004 mm yr^{-1} (~ 0.05 t $ha^{-1}yr^{-1}$) compared with the median net rate of soil loss in agricultural fields, 1.52 mm yr^{-1} (~ 18 t $ha^{-1}yr^{-1}$) in tilled fields and 0.065 mm yr^{-1} (~ 0.8 t $ha^{-1}yr^{-1}$) in no-till fields (Montgomery 2007a). This means that the rate of soil erosion from agricultural fields is in between 380 (conventional tilling) and 16 times (no-till) the natural rate of soil formation (*medium agreement, limited evidence*). These approximate figures are supported by another large meta-study including over 4000 sites around the world (see Figure 4.4) where the average soil loss from agricultural plots was ~ 21 t $ha^{-1}yr^{-1}$ (García-Ruiz et al. 2015). Climate change, mainly through the intensification of rainfall, will further increase these rates unless land management is improved (*high agreement, medium evidence*).

Soils contain about 1500 Gt of organic carbon (median across 28 different estimates presented by (Scharlemann et al. 2014)), which is about 1.8 times more carbon than in the atmosphere (Ciais et al. 2013) and 2.3 – 3.3 times more than what is held in the terrestrial vegetation of the world (Ciais et al. 2013). Hence, land degradation including land conversion leading to soil carbon losses has the potential to impact the atmospheric concentration of CO_2 substantially. When natural ecosystems are cultivated they lose soil carbon that accumulated over long time periods. The loss rate depends on the type of natural vegetation and how the soil is managed. Estimates of the magnitude of loss vary but figures between 20% and 59% have been reported in several meta studies (Poeplau and Don 2015; Wei et al. 2015; Li et al. 2012; Murty et al. 2002; Guo and Gifford 2002). The amount of soil carbon lost explicitly due to land degradation after conversion is hard to assess due to large variation in local conditions and management, see also Chapter 2.

From a climate change perspective, land degradation plays an important role in the dynamics of nitrous oxide (N_2O) and methane (CH_4). N_2O is produced by microbial activity in the soil and the dynamics are related to both management practices and weather conditions while CH_4 dynamics are primarily determined by the amount of soil carbon and to what extent the soil is subject to water logging (Palm et al. 2014), see also Chapter 2.

Several attempts have been made to map the human footprint on the planet (Čuček et al. 2012; Venter et al. 2016) but they in some cases confuse human impact on the planet with degradation. From our definition it is clear that human impact (or pressure) is not synonymous with degradation but information on the human footprint provides a useful mapping of potential non-climatic drivers of degradation.

In summary, there are no uncontested maps of the location, extent and severity of land degradation. Proxy estimates based on remote sensing of vegetation dynamics provide one important information source, but attribution of the observed changes in productivity to climate change, human activities, or other drivers is hard. Nevertheless, the different attempts to map the extent of global land degradation using remotely sensed proxies show some convergence and suggest that about a quarter of the ice free land area is subject to some form of land degradation (*limited evidence, medium agreement*) affecting about 3.2 billion people (*low confidence*). Attempts to estimate the severity of land degradation through soil erosion estimates suggest that soil erosion is a serious form of land degradation in croplands closely associated with unsustainable land management in combination with climatic parameters, some of which are subject to climate change (*limited evidence, high agreement*). Climate change is one among several causal factors in the status and current trends of land degradation (*limited evidence, high agreement*).

4.3.2 Forest degradation

Quantifying degradation in forests has also proven difficult. Indicators that remote sensing or inventory methods can measure more easily than reductions in biological productivity, losses of ecological integrity or value to humans include reductions in canopy cover or carbon stocks. However, the causes of reductions in canopy cover or carbon stocks can be many (Curtis et al. 2018), including natural disturbances (e.g., fires, insects and other forest pests), direct human activities (e.g., harvest, forest management) and indirect human impacts (such as climate change) and these may not reduce long-term biological productivity. In many boreal, some temperate and other forest types natural disturbances are common, and consequently these disturbance-adapted forest types are comprised of a mosaic of stands of different ages and stages of stand recovery following natural disturbances. In those managed forests where natural disturbances are uncommon or suppressed, harvesting is the primary determinant of forest age-class distributions.

Quantifying forest degradation as a reduction in productivity, carbon stocks or canopy cover also requires that an initial condition (or baseline) is established against which this reduction is assessed (see Section 4.1.4). In forest types with rare stand-replacing disturbances, the concept of “intact” or “primary” forest has been used to define the initial condition (Potapov et al. 2008) but applying a single metric can be problematic (Bernier et al. 2017). Moreover, forest types with frequent stand-replacing disturbances, such as wildfires, or with natural disturbances that reduce carbon stocks, such as some insect outbreaks, experience over time a natural variability of carbon stocks or canopy density making it more difficult to define the appropriate baseline carbon density or canopy cover against which to assess degradation. In these systems, forest degradation cannot be assessed at the stand level, but requires a landscape-level assessment that takes into consideration the stand age-class distribution of the landscape, which reflects natural and human disturbance regimes over past decades to centuries and also considers post-disturbance regrowth (van Wagner 1978; Volkova et al. 2018; Lorimer and White 2003).

The lack of a consistent definition of forest degradation also affects the ability to establish estimates of the rates or impacts of forest degradation because the drivers of degradation are not clearly defined (Sasaki and Putz 2009). Moreover, the literature at times confounds estimates of forest degradation and deforestation (i.e. the conversion of forest to non-forest land uses). Deforestation is a change in land use, while forest degradation is not, although severe forest degradation can ultimately lead to deforestation.

Based on empirical data provided by 46 countries, the drivers for deforestation (due to commercial agriculture) and forest degradation (due to timber extraction and logging) are similar in Africa, Asia and Latin America (Hosonuma et al. 2012). More recently, global forest disturbance over the period 2001 – 2015 was attributed to commodity driven deforestation (27 ± 5%), forestry (26 ± 4%), shifting agriculture (24 ± 3%) and wildfire (23 ± 4%). The remaining 0.6 ± 0.3% was attributed to the expansion of urban centers (Curtis et al. 2018).

The trends of productivity shown by several remote sensing studies (see previous section) are largely consistent with mapping of forest cover and change using a 34 year time series of coarse resolution satellite data (NOAA AVHRR) (Song et al. 2018). This study, based on a thematic classification of satellite data, suggests that (i) global tree canopy cover increased by 2.24 million km² between 1982 and 2016 (corresponding to +7.1%) but with regional differences that contribute a net loss in the tropics and a net gain at higher latitudes, and (ii) the fraction of bare ground decreased by 1.16 million km² (corresponding to -3.1%), mainly in agricultural regions of Asia (Song et al. 2018), see Figure 4.5. Other tree or land cover datasets show opposite global net trends (Li et al. 2018b), but high agreement in terms of net losses in the tropics and large net gains in the temperate and boreal zones (Li et al. 2018b; Song et al. 2018; Hansen et al. 2013). Differences across global estimates are further discussed in Chapter 1 (1.1.2.3) and Chapter 2.

The changes detected from 1982 to 2016 were primarily linked to direct human action, such as land-use changes (about 60% of the observed changes), but also to indirect effects, such as human induced climate change (about 40% of the observed changes) (Song et al. 2018), a finding also supported by a more recent study (Chen et al. 2019). The climate induced effects were clearly discernible in some regions, such as forest decline in the US Northwest due to increasing pest infestation and increasing fire frequency (Lesk et al. 2017; Abatzoglou and Williams 2016; Seidl et al. 2017), warming induced vegetation increase in the Arctic region, general greening in the Sahel probably as a result of increasing rainfall and atmospheric CO_2, and advancing treelines in mountain regions (Song et al. 2018).

Keenan et al.(Keenan et al. 2015) and Sloan and Sayer (2015) studied the 2015 Forest Resources Assessment (FRA) of the FAO (FAO 2016) and found that the total forest area from 1990 to 2015 declined by 3%, an estimate that is supported by a global remote sensing assessment of forest area change that found a 2.8% decline between 1990-2010 (D’Annunzio et al. 2017; Lindquist and D’Annunzio 2016). The trend in deforestation is, however, contradicting between these two global assessments with FAO (2016) suggesting deforestation is slowing down while the remote sensing assessments finds it to be accelerating (D'Annunzio et al. 2017). Recent estimates (Song et al. 2018) owing to semantic and methodological differences (see Chapter 1, section 1.1.2.3) suggest global tree cover to have increased over the period 1982-2016, which contradicts the forest area dynamics assessed by FAO (2016, Lindquist and D'Annunzio 2016). The loss rate in tropical forest areas from 2010 to 2015 is 55 000 km^2 yr^{-1}. According to the FRA the global natural forest area also declined from 39.61 M km^2 to 37.21 M km^2 during the period 1990 to 2015 (Keenan et al. 2015).

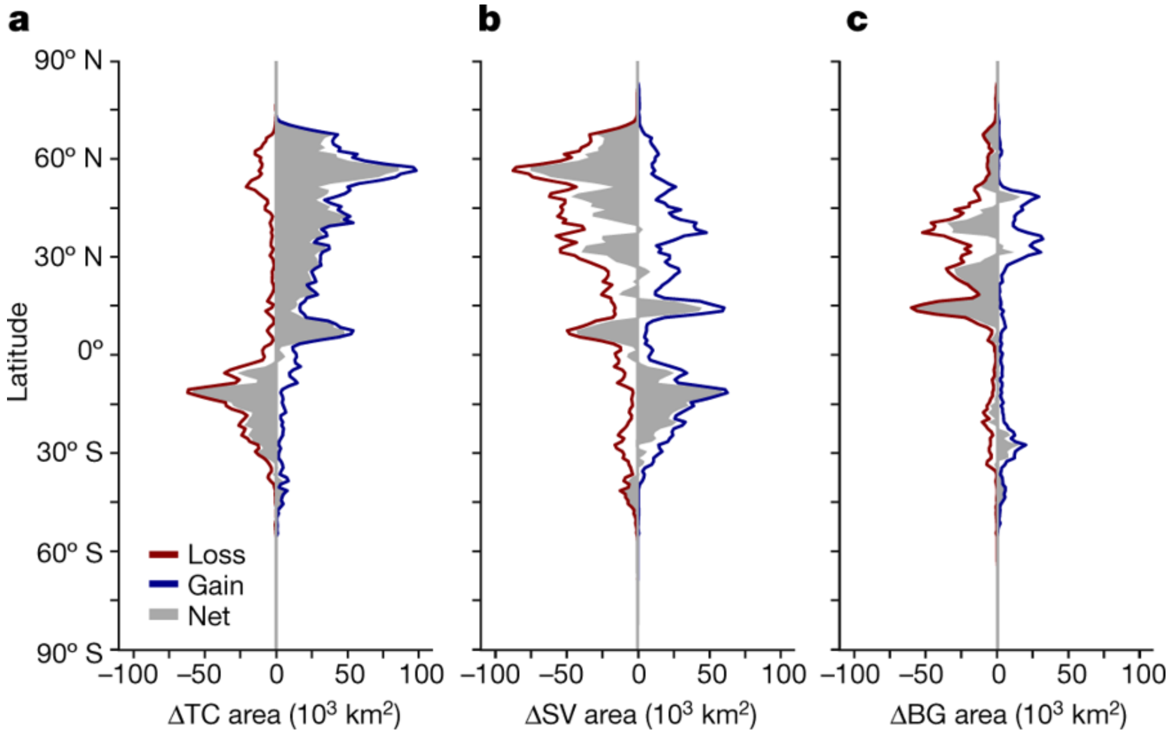

Figure 4.5. Diagrams showing latitudinal profiles of land cover change over the period 1982 to 2016 based on analysis of time-series of NOAA AVHRR imagery: a, Tree canopy cover change (ΔTC). b, Short vegetation cover change (ΔSV). c, Bare ground cover change (ΔBG). Area statistics were calculated for every 1° of latitude (Song et al. 2018). Source of data: NOAA AVHRR.

Since 1850, deforestation globally contributed 77% of the emissions from land-use and land-cover change (LULCC) while degradation contributed 10% (with the remainder originating from non-forest land uses) (Houghton and Nassikas 2018). That study also showed large temporal and regional differences with northern mid-latitude forests currently contributing carbon sinks due to increasing forest area and forest management. However, the contribution to carbon emissions of degradation as percentage of total forest emissions (degradation and deforestation) are uncertain, with estimates varying from 25% (Pearson et al. 2017) to nearly 70% of carbon losses (Baccini et al. 2017). The 25% estimate refers to an analysis of 74 developing countries within tropical and subtropical regions covering 22 million km^2 for the period 2005-2010 while the 70% estimate refers to an analysis of the tropics for the period 2003-2014, but by and large the scope of these studies is the same. Pearson et al. (2017) estimated annual gross emissions of 2.1 Gt CO_2, of which 53% were derived from timber harvest, 30% from wood fuel harvest and 17% from forest fire. Estimating gross emissions only, creates a distorted representation of human impacts on the land sector carbon cycle. While forest harvest for timber and fuel wood and land–use change (deforestation) contribute to gross emissions, to quantify impacts on the atmosphere it is necessary to estimate net emissions, i.e. the balance of gross emissions and gross removals of carbon from the atmosphere through forest regrowth (Chazdon et al. 2016a; Poorter et al. 2016; Sanquetta et al. 2018).

Current efforts to reduce atmospheric CO_2 concentrations can be supported by reductions in forest-related carbon emissions and increases in sinks, which requires that the net impact of forest management on the atmosphere be evaluated (Griscom et al. 2017). Forest management and the use of wood products in GHG mitigation strategies result in changes in forest ecosystem C stocks, changes in harvested wood product C stocks, and potential changes in emissions resulting from the use of wood products and forest biomass that substitute for other emissions-intensive materials such as concrete, steel and fossil fuels (Kurz et al. 2016; Lemprière et al. 2013; Nabuurs et al. 2007). The net impact of these changes on GHG emissions and removals, relative to a scenario without forest mitigation actions needs to be quantified, (e.g. Werner et al. 2010; Smyth et al. 2014; Xu et al. 2018). Therefore, reductions in forest ecosystem C stocks alone are an incomplete estimator of the impacts of forest management on the atmosphere (Nabuurs et al. 2007; Lemprière et al. 2013; Kurz et al. 2016; Chen et al. 2018b). The impacts of forest management and the carbon storage in long-lived products and landfills vary greatly by region, however, because of the typically much shorter life-span of wood products produced from tropical regions compared to temperate and boreal regions (Earles et al. 2012; Lewis et al. 2019; Iordan et al. 2018) (see also section 4.8.4).

Assessments of forest degradation based on remote sensing of changes in canopy density or land cover, (e.g., (Hansen et al. 2013; Pearson et al. 2017) quantify changes in aboveground biomass C stocks and require additional assumptions or model-based analyses to also quantify the impacts on other ecosystem carbon pools including belowground biomass, litter, woody debris and soil carbon. Depending on the type of disturbance, changes in aboveground biomass may lead to decreases or increases in other carbon pools, for example, windthrow and insect induced tree mortality may result in losses in aboveground biomass that are (initially) off-set by corresponding increases in dead organic matter carbon pools (Yamanoi et al. 2015; Kurz et al. 2008), while deforestation will reduce the total ecosystem carbon pool (Houghton et al. 2012).

A global study of current vegetation carbon stocks (450 Gt C), relative to a hypothetical condition without land-use (916 Gt C), attributed 42-47% of carbon stock reductions to land management effects without land-use change, while the remaining 53-58% of carbon stock reductions were attributed to deforestation and other land-use changes (Erb et al. 2018). While carbon stocks in European forests are lower than hypothetical values in the complete absence of human land use, forest area and carbon stocks have been increasing over recent decades (McGrath et al. 2015; Kauppi et al. 2018). Studies of Gingrich et al. (2015) on the long-term trends in land-use over nine European countries (Albania, Austria, Denmark, Germany, Italy, the Netherlands, Romania, Sweden and the United Kingdom) also show an increase in forest land and reduction in cropland and grazing land from the 19th century to the early 20th century. However, the extent to which human activities have affected the productive capacity of forest lands is poorly understood. Biomass Production Efficiency (BPE), i.e. the fraction of photosynthetic production used for biomass production, was significantly higher in managed forests (0.53) compared to natural forests (0.41) (and it was also higher in managed (0.44) compared to natural (0.63) grasslands) (Campioli et al. 2015). Managing lands for production may involve trade-offs. For example, a larger proportion of Net Primary Production in managed forests is allocated to biomass carbon storage, but lower allocation to fine roots is hypothesised to reduce soil C stocks in the long-term (Noormets et al. 2015). Annual volume increment in Finnish forests has more than doubled over the last century, due to increased growing stock, improved forest management and environmental changes (Henttonen et al. 2017).

As economies evolve, the patterns of land-use and C stock changes associated with human expansion into forested areas often include a period of rapid decline of forest area and carbon stocks, recognition of the need for forest conservation and rehabilitation, and a transition to more sustainable land management that is often associated with increasing carbon stocks, (e.g. Birdsey et al. 2006). Developed and developing countries around the world are in various stages of forest transition

(Kauppi et al. 2018; Meyfroidt and Lambin 2011). Thus, opportunities exist for sustainable forest management to contribute to atmospheric carbon targets through reduction of deforestation and degradation, forest conservation, forest restoration, intensification of management, and enhancements of carbon stocks in forests and harvested wood products (Griscom et al. 2017) (*medium evidence, medium agreement*).

4.4 Projections of land degradation in a changing climate

Land degradation will be affected by climate change in both direct and indirect ways, and land degradation will to some extent also feed-back into the climate system. The direct impacts are those in which climate and land interact directly in time and space. Examples of direct impacts are when increasing rainfall intensity exacerbates soil erosion, or when prolonged droughts reduce the vegetation cover of the soil making it more prone to erosion and nutrient depletion. The indirect impacts are those where climate change impacts and land degradation are separated in time and/or space. Examples of such impacts are when declining agricultural productivity due to climate change drives an intensification of agriculture elsewhere, which may cause land degradation. Land degradation, if sufficiently widespread, may also feed back into the climate system by reinforcing ongoing climate change.

Although climate change is exacerbating many land degradation processes (*high to very high confidence*), prediction of future land degradation is challenging because land management practices determine to a very large extent the state of the land. Scenarios of climate change in combination with land degradation models can provide useful knowledge on what kind and extent of land management will be necessary to avoid, reduce and reverse land degradation.

4.4.1 Direct impacts on land degradation

There are two main levels of uncertainty in assessing the risks of future climate change induced land degradation. The first level, where uncertainties are comparatively low, is the changes of the degrading agent, such as erosive power of precipitation, heat stress from increasing temperature extremes (HÜVE et al. 2011), water stress from droughts, and high surface wind speed. The second level of uncertainties, and where the uncertainties are much larger, relates to the above and belowground ecological changes as a result of changes in climate, such as rainfall, temperature, and increasing level of CO_2. Vegetation cover is crucial to protect against erosion (Mullan et al. 2012; García-Ruiz et al. 2015).

Changes in rainfall patterns, such as distribution in time and space, and intensification of rainfall events will increase the risk of land degradation, both in terms of likelihood and consequences (*high agreement, medium evidence*). Climate induced vegetation changes will increase the risk of land degradation in some areas (where vegetation cover will decline) (*medium confidence*). Landslides are a form of land degradation that is induced by extreme rainfall events. There is a strong theoretical reason for increasing landslide activity due to intensification of rainfall, but the empirical evidence is so far lacking that climate change has contributed to landslides (Crozier 2010; Huggel et al. 2012; Gariano and Guzzetti 2016), human disturbance may be a more important future trigger than climate change (Froude and Petley 2018).

Erosion of coastal areas as a result of sea level rise will increase worldwide (*very high confidence*). In cyclone prone areas (such as the Caribbean, Southeast Asia, and the Bay of Bengal) the combination of sea level rise and more intense cyclones (Walsh et al. 2016b), and in some areas also land subsidence (Yang et al. 2019; Shirzaei and Bürgmann 2018; Wang et al. 2018; Fuangswasdi et al. 2019; Keogh and Törnqvist 2019), will pose a serious risk to people and livelihoods (*very high confidence*), in some cases even exceeding limits to adaption, see further section 4.8.4.1, 4.9.6, 4.9.8.

4.4.1.1 Changes in water erosion risk due to precipitation changes

The hydrological cycle is intensifying with increasing warming of the atmosphere. The intensification means that the number of heavy rainfall events is increasing while the total number of rainfall events tends to decrease (Trenberth 2011; Li and Fang 2016; Kendon et al. 2014; Guerreiro et al. 2018; Burt et al. 2016a; Westra et al. 2014; Pendergrass and Knutti 2018) *(robust evidence, high agreement*). Modelling of changes in land degradation as a result of climate change alone is hard because of the importance of local contextual factors. As shown above, actual erosion rate is extremely dependent on local conditions, primarily vegetation cover and topography (García-Ruiz et al. 2015). Nevertheless, modelling of soil erosion risks has advanced substantially in recent decades and such studies are indicative of future changes in the risk of soil erosion while actual erosion rates will still primarily be determined by land management. In a review article, Li & Fang (Li and Fang 2016) summarised 205 representative modelling studies around the world where erosion models had been used in combination with down-scaled climate models to assess future (between 2030 to 2100) erosion rates. The meta-study by Li & Fang considered, where possible, climate change in terms of temperature increase and changing rainfall regimes and their impacts on vegetation and soils. Almost all of the sites had current soil loss rates above 1t ha^{-1} (assumed to be the upper limit for acceptable soil erosion in Europe) and 136 out of 205 studies predicted increased soil erosion rates. The percentage increase in erosion rates varied between 1.2% to as much as over 1600%, whereas 49 out of 205 studies projected more than 50% increase. Projected soil erosion rates varied substantially between studies because the important of local factors, hence climate change impacts on soil erosion should preferably be assessed at the local to regional scale, rather than the global (Li and Fang 2016).

Mesoscale convective systems (MCS), typically thunder storms, have increased markedly in recent 3-4 decades in the USA and Australia and they are projected to increase substantially (Prein et al. 2017). Using a climate model with the ability to represent MCS, Prein and colleagues were able to predict future increases in frequency, intensity, and size of such weather systems. Findings include the 30% decrease in number of MCS of <40 mm h^{-1}, but a sharp increase of 380% in the number of extreme precipitation events of >90 mm h^{-1} over the North American continent. The combined effect of increasing precipitation intensity and increasing size of the weather systems implies that the total amount of precipitation from these weather systems is expected to increase by up to 80% (Prein et al. 2017), which will substantially increase the risk of land degradation in terms of landslides, extreme erosion events, flashfloods etc.

The potential impacts of climate change on soil erosion can be assessed by modelling the projected changes in particular variables of climate change known to cause erosion, such as erosivity of rainfall. A study of the conterminous United States based on three climate models and three scenarios (A2, A1B, and B1) found that rainfall erosivity will increase in all scenarios, even if there are large spatial differences – strong increase in NE and NW, and either weak or inconsistent trends in the SW and mid-West (Segura et al. 2014).

In a study of how climate change will impact future soil erosion processes in the Himalayas, Gupta and Kumar (2017) estimated that soil erosion will increase by about 27% in the near term (2020s) and 22% in the medium term (2080s), with little difference between scenarios. A study from Northern Thailand estimated that erosity will increase by 5% in the near term (2020s) and 14% in the medium term (2080s), which would result in a similar increase of soil erosion, all other factors being constant (Plangoen and Babel 2014). Observed rainfall erosivity has increased significantly in the lower Niger Basin (Nigeria) and are predicted to increase further based on statistical downscaling of four General Circulation Models (GCM) scenarios, with an estimated increase of 14%, 19% and 24% for the 2030s, 2050s, and 2070s respectively (Amanambu et al. 2019).

Many studies from around the world where statistical downscaling of GCM results have been used in combination with process based erosion models show a consistent trend of increasing soil erosion

Using a comparative approach Serpa et al. (2015) studied two Mediterranean catchments (one dry and one humid) using a spatially explicit hydrological model (SWAT) in combination with land use and climate scenarios for 2071-2100. Climate change projections showed, on the one hand, decreased rainfall and streamflow for both catchments whereas sediment export decreased only for the humid catchment; projected land use change, from traditional to more profitable, on the other hand resulted in increase in streamflow. The combined effect of climate and land use change resulted in reduced sediment export for the humid catchment (-29% for A1B; -22% for B1) and increased sediment export for the dry catchment (+222% for A1B; +5% for B1). Similar methods have been used elsewhere, also showing the dominant effect of land use/land cover for runoff and soil erosion (Neupane and Kumar 2015).

A study of future erosion rates in Northern Ireland, using a spatially explicit erosion model in combination with downscaled climate projections (with and without sub-daily rainfall intensity changes), showed that erosion rates without land management changes would decrease by 2020s, 2050s and 2100s irrespective of changes in intensity, mainly as a result of a general decline in rainfall (Mullan et al. 2012). When land management scenarios were added to the modelling, the erosion rates started to vary dramatically for all three time periods, ranging from a decrease of 100% for no-till land use, to an increase of 3621% for row crops under annual tillage and sub-days intensity changes (Mullan et al. 2012). Again, it shows how crucial land management is for addressing soil erosion, and the important role of rainfall intensity changes.

There is a large body of literature based on modelling future land degradation due to soil erosion concluding that in spite of the increasing trend of erosive power of rainfall (*medium evidence*, *high agreement*) land degradation is primarily determined by land management (*very high confidence*).

4.4.1.2 Climate induced vegetation changes, implications for land degradation

The spatial mosaic of vegetation is determined by three factors: the ability of species to reach a particular location, how species tolerate the environmental conditions at that location (e.g. temperature, precipitation, wind, the topographic and soil conditions), and the interaction between species (including above/below ground species (Settele et al. 2015). Climate change is projected to alter the conditions and hence impact the spatial mosaic of vegetation, which can be considered a form of land degradation. Warren et al. (2018) estimated that only about 33% of globally important biodiversity conservation areas will remain intact if global mean temperature increases to 4.5°C, while twice that area (67%) will remain intact if warming is restricted to 2°C. According to AR5, the clearest link between climate change and ecosystem change is when temperature is the primary driver, with changes of Arctic tundra as a response to significant warming as the best example (Settele et al. 2015). Even though distinguishing climate induced changes from land use changes is challenging, Boit et al. (2016) suggest that 5-6% of biomes in South America will undergo biome shifts until 2100, regardless of scenario, attributed to climate change. The projected biome shifts are primarily forests shifting to shrubland and dry forests becoming fragmented and isolated from more humid forests (Boit et al. 2016). Boreal forests are subject to unprecedented warming in terms of speed and amplitude (IPCC 2013b), with significant impacts on their regional distribution (Juday et al. 2015). Globally, tree lines are generally expanding northward and to higher elevations, or remaining stable, while a reduction in tree line was rarely observed and only where disturbances occurred (Harsch et al. 2009) There is *limited evidence* of a slow northward migration of the boreal forest in eastern North America (Gamache and Payette 2005). The thawing of permafrost may increase drought induced tree mortality throughout the circumboreal zone (Gauthier et al. 2015).

Forests are a prime regulator of hydrological cycling, both fluxes of atmospheric moisture and precipitation, hence climate and forests are inextricably linked (Ellison et al. 2017; Keys et al. 2017). Forest management influences the storage and flow of water in forested watersheds, particularly harvesting, thinning and construction of roads increase the likelihood of floods as an outcome of extreme climate events (Eisenbies et al. 2007). Water balance of at least partly forested landscapes is to a large extent controlled by forest ecosystems (Sheil and Murdiyarso 2009; Pokam et al. 2014). This includes surface runoff, as determined by evaporation and transpiration and soil conditions, and water flow routing (Eisenbies et al. 2007). Water use efficiency (i.e., the ratio of water loss to biomass gain) is increasing with increased CO_2 levels (Keenan et al. 2013), hence transpiration is predicted to decrease which in turn will increase surface runoff (Schlesinger and Jasechko 2014). However, the interaction of several processes makes predictions challenging (Frank et al. 2015; Trahan and Schubert 2016). Surface runoff is an important agent in soil erosion.

Generally, removal of trees through harvesting or forest death (Anderegg et al. 2012) will reduce transpiration and hence increase the runoff during the growing season. Management induced soil disturbance (such as skid trails and roads) will affect water flow routing to rivers and streams (Zhang et al. 2017; Luo et al. 2018; Eisenbies et al. 2007).

Climate change affects forests in both positive and negative ways (Trumbore et al. 2015; Price et al. 2013) and there will be regional and temporal differences in vegetation responses (Hember et al. 2017; Midgley and Bond 2015). Several climate change related drivers interact in complex ways, such as warming, changes in precipitation and water balance, CO_2 fertilisation, and nutrient cycling, which makes projections of future net impacts challenging (see 2.3.1.2) (Kurz et al. 2013; Price et al. 2013). In high latitudes, a warmer climate will extend the growing seasons which however, could be constrained by summer drought (Holmberg et al. 2019) while increasing levels of atmospheric CO_2 will increase water use efficiency but not necessarily tree growth (Giguère-Croteau et al. 2019). Improving one growth limiting factor will only enhance tree growth if other factors are not limiting (Norby et al. 2010; Trahan and Schubert 2016; Xie et al. 2016; Frank et al. 2015). Increasing forest productivity has been observed in most of Fennoscandia (Kauppi et al. 2014; Henttonen et al. 2017), Siberia and the northern reaches of North America as a response to a warming trend (Gauthier et al. 2015) but increased warming may also decrease forest productivity and increase risk of tree mortality and natural disturbances (Price et al. 2013; Girardin et al. 2016; Beck et al. 2011; Hember et al. 2016; Allen et al. 2011). The climatic conditions in high latitudes are changing at a magnitude faster than the ability of forests to adapt with detrimental, yet unpredictable, consequences (Gauthier et al. 2015).

Negative impacts dominate, however, and have already been documented (Lewis et al. 2004; Bonan et al. 2008; Beck et al. 2011) and are predicted to increase (Miles et al. 2004 ; Allen et al. 2010; Gauthier et al. 2015; Girardin et al. 2016; Trumbore et al. 2015). Several authors have emphasized a concern that tree mortality (forest dieback) will increase due to climate induced physiological stress as well as interactions between physiological stress and other stressors, such as insect pests, diseases, and wildfires (Anderegg et al. 2012; Sturrock et al. 2011; Bentz et al. 2010; McDowell et al. 2011). Extreme events such as extreme heat and drought, storms, and floods also pose increased threats to forests in both high and low latitude forests (Lindner et al. 2010; Mokria et al. 2015). However, comparing observed forest dieback with modelled climate induced damages did not show a general link between climate change and forest dieback (Steinkamp and Hickler 2015). Forests are subject to increasing frequency and intensity of wildfires which is projected to increase substantially with continued climate change (see also Cross-Chapter Box 3: Fire and climate change, Chapter 2) (Price et al. 2013). In the tropics, interaction between climate change, CO_2 and fire could lead to abrupt shifts between woodland and grassland dominated states in the future (Shanahan et al. 2016).

Within the tropics, much research has been devoted to understanding how climate change may alter regional suitability of various crops. For example coffee is expected to be highly sensitive to both temperature and precipitation changes, both in terms of growth and yield and in terms of increasing problems of pests (Ovalle-Rivera et al. 2015). Some studies conclude that the global area of coffee production will decrease by 50% (Bunn et al. 2015). Due to increased heat stress, the suitability of Arabica coffee is expected to deteriorate in Mesoamerica, while it can improve in high altitude areas in South America. The general pattern is that the climatic suitability for Arabica coffee will deteriorate at low altitudes of the tropics as well as at the higher latitudes (Ovalle-Rivera et al. 2015). This means that climate change in and of itself can render unsustainable previously sustainable land use and land management practices and vice versa (Laderach et al. 2011).

Rangelands are projected to change in complex ways due to climate change. Increasing levels of atmospheric CO_2 stimulate directly plant growth and can potentially compensate negative effects from drying by increasing rain use efficiency. But the positive effect of increasing CO_2 will be mediated by other environmental conditions, primarily water availability but also nutrient cycling, fire regimes and invasive species. Studies over the North American rangelands suggest, for example, that warmer and dryer climatic conditions will reduce NPP in the southern Great Plains, the Southwest, and northern Mexico, but warmer and wetter conditions will increase NPP in the northern Plains and southern Canada (Polley et al. 2013).

4.4.1.3 Coastal erosion

Coastal erosion is expected to increase dramatically by sea level rise and in some areas in combination with increasing intensity of cyclones (highlighted in Section 4.9.6). Cyclone induced coastal erosion). Coastal regions are also characterised by high population density, particularly in Asia (Bangladesh, China, India, Indonesia, Vietnam), whereas the highest population increase in coastal regions is projected in Africa (East Africa, Egypt, and West Africa) (Neumann et al. 2015). For coastal regions worldwide, and particularly in developing countries with high population density in low-lying coastal areas, limiting the warming to 1.5˚C to 2.0 ˚C will have major socio-economic benefits compared with higher temperature scenarios (IPCC 2018a; Nicholls et al. 2018). For more in-depth discussions on coastal process, please refer to Chapter 4 of the upcoming IPCC Special Report on The Ocean and Cryosphere in a Changing Climate (IPCC SROCC).

Despite the uncertainty related to the responses of the large ice sheets of Greenland and west Antarctica, climate change-induced sea level rise is largely accepted and represents one of the biggest threats faced by coastal communities and ecosystems (Nicholls et al. 2011; Cazenave and Cozannet 2014; DeConto and Pollard 2016; Mengel et al. 2016). With significant socio-economic effects, the physical impacts of projected sea level rise, notably coastal erosion, have received considerable scientific attention (Nicholls et al. 2011; Rahmstorf 2010; Hauer et al. 2016).

Rates of coastal erosion or recession will increase due to rising sea levels and in some regions also in combination with increasing oceans waves (Day and Hodges 2018; Thomson and Rogers 2014; McInnes et al. 2011; Mori et al. 2010), lack or absence of sea-ice (Savard et al. 2009; Thomson and Rogers 2014) and thawing of permafrost (Hoegh-Guldberg et al. 2018), and changing cyclone paths (Tamarin-Brodsky and Kaspi 2017; Lin and Emanuel 2016a). The respective role of the different climate factors in the coastal erosion process will vary spatially. Some studies have shown that the role of sea level rise on the coastal erosion process can be less important than other climate factors, like wave heights, changes in the frequency of the storms, and the cryogenic processes (Ruggiero 2013; Savard et al. 2009). Therefore, in order to have a complete picture of the potential effects of sea level rise on rates of coastal erosion, it is crucial to consider the combined effects of the aforementioned climate controls and the geomorphology of the coast under study.

Coastal wetlands around the world are sensitive to sea-level rise. Projections of the impacts on global coastlines are inconclusive, with some projections suggesting that 20% to 90% (depending on sea-level rise scenario) of present day wetlands will disappear during the 21st century (Spencer et al. 2016). Another study, which included natural feed-back processes and management responses suggested that coastal wetlands may actually increase (Schuerch et al. 2018b).

Low-lying coastal areas in the tropics are particularly subject to the combined effect of sea-level rise and increasing intensity of tropical cyclones, conditions which in many cases pose limits to adaptation, see section 4.8.5.1.

Many large coastal deltas are subject to the additional stress of shrinking deltas as a consequence of the combined effect of reduced sediment loads from rivers due to damming and water use, and land subsidence resulting from extraction of ground water or natural gas, and aquaculture (Higgins et al. 2013; Tessler et al. 2016; Minderhoud et al. 2017; Tessler et al. 2015; Brown and Nicholls 2015; Szabo et al. 2016; Yang et al. 2019; Shirzaei and Bürgmann 2018; Wang et al. 2018; Fuangswasdi et al. 2019). In some cases the rate of subsidence can outpace the rate of sea level rise by one order of magnitude (Minderhoud et al. 2017) or even two (Higgins et al. 2013). Recent findings from the Mississippi Delta raises the risk of a systematic underestimation of the rate of land subsidence in coastal deltas (Keogh and Törnqvist 2019)

In sum, from a land degradation point of view, low lying coastal areas are particularly exposed to the nexus of climate change and increasing concentration of people (Elliott et al. 2014) (*robust evidence, high agreement*) and the situation will become particularly acute in delta areas shrinking from both reduced sediment loads and land subsidence (*robust evidence, high agreement*).

4.4.2 Indirect impacts on land degradation

Indirect impacts of climate change on land degradation are difficult to quantify because of the many conflating factors. The causes of land-use change are complex, combining physical, biological and socioeconomic drivers (Lambin et al. 2001; Lambin and Meyfroidt 2011). One such driver of land-use change is the degradation of agricultural land, which can result in a negative cycle of natural land being converted to agricultural land to sustain production levels. The intensive management of agricultural land can lead to a loss of soil function, negatively impacting the many ecosystem services provided by soils including maintenance of water quality and soil carbon sequestration (Smith et al. 2016a). The degradation of soil quality due to cropping is of particular concern in tropical regions, where it results in a loss of productive potential of the land, affecting regional food security and driving conversion of non-agricultural land, such as forestry, to agriculture (Lambin et al. 2003; Drescher et al. 2016; Van der Laan et al. 2017). Climate change will exacerbate these negative cycles unless sustainable land managed practices are implemented.

Climate change impacts on agricultural productivity (see Chapter 5) will have implications for the intensity of land use and hence exacerbate the risk of increasing land degradation. There will be both localised effects (i.e., climate change impacts on productivity affecting land use in the same region) and teleconnections (i.e., climate change impacts and land-use change are spatially and temporally separate) (Wicke et al. 2012; Pielke et al. 2007). If global temperature increases beyond 3°C it will have negative yield impacts on all crops (Porter et al. 2014) which, in combination with a doubling of demands by 2050 (Tilman et al. 2011), and increasing competition for land from the expansion of negative emissions technologies (IPCC 2018a; Schleussner et al. 2016), will exert strong pressure on agricultural lands and food security.

In sum, reduced productivity of most agricultural crops will drive land-use changes worldwide (*robust evidence, medium agreement*), but predictions of how this will impact land degradation is challenging because of several conflating factors. Social change, such as widespread changes in dietary preferences will have a huge impact on agriculture and hence land degradation (*medium evidence, high agreement*).

4.5 Impacts of bioenergy and technologies for CO_2 removal (CDR) on land degradation

4.5.1 Potential scale of bioenergy and land-based CDR

In addition to the traditional land use drivers (e.g. population growth, agricultural expansion, forest management), a new driver will interact to increase competition for land throughout this century: the potential large-scale implementation of land-based technologies for CO_2 removal (CDR). Land-based CDR include afforestation and reforestation, bioenergy with carbon capture and storage (BECCS), soil carbon management, biochar and enhanced weathering (Smith et al., 2015; Smith 2016)

Most scenarios, including two of the four pathways in the IPCC Special Report on 1.5°C (IPCC 2018a), compatible with stabilisation at 2°C involve substantial areas devoted to land-based CDR, specifically afforestation/ reforestation and BECCS (Schleussner et al. 2016; Smith et al. 2016b; Mander et al. 2017). Even larger land areas are required in most scenarios aimed at keeping average global temperature increases to below 1.5 °C , and scenarios that avoid BECCS also require large areas of energy crops in many cases (IPCC 2018b), although some options with strict demand-side management avoid this need (Grubler et al. 2018). Consequently, the addition of carbon capture and storage (CCS) systems to bioenergy facilities enhances mitigation benefits because it increases the carbon retention time and reduces emissions relative to bioenergy facilities without CCS. The IPCC SR15 states that "When considering pathways limiting warming to 1.5°C with no or limited overshoot, the full set of scenarios shows a conversion of 0.5 – 11 M km^2 of pasture into 0 – 6 M km^2 for energy crops, a 2 M km^2 reduction to 9.5 M km^2 increase forest, and a 4 M km^2 decrease to a 2.5 M km^2 increase in non-pasture agricultural land for food and feed crops by 2050 relative to 2010." (Rogelj et al., 2018, p. 145) . For comparison, the global cropland area in 2010 was 15.9 M km^2 (Table 1.1), and (Woods et al. 2015) estimate the area of abandoned and degraded land potentially available for energy crops (or afforestation/reforestation) exceeds 5 M km^2. However, the area of available land has long been debated, as much marginal land is subject customary land tenure and used informally often by impoverished communities (Baka 2013, 2014; Haberl et al. 2013; Young 1999). Thus, as noted in the SR15, "The implementation of land-based mitigation options would require overcoming socio-economic, institutional, technological, financing and environmental barriers that differ across regions" (IPCC, 2018a, p. 18).

The wide range of estimates reflects the large differences among the pathways, availability of land in various productivity classes, types of NET implemented, uncertainties in computer models, and social and economic barriers to implementation (Fuss et al. 2018; Nemet et al. 2018; Minx et al. 2018).

4.5.2 Risks of land degradation from expansion of bioenergy and land-based CDR

The large-scale implementation of high intensity dedicated energy crops, and harvest of crop and forest residues for bioenergy, could contribute to increases in the area of degraded lands: intensive land management can result in nutrient depletion, over fertilisation and soil acidification, salinisation (from irrigation without adequate drainage), wet ecosystems drying (from increased evapotranspiration), as well as novel erosion and compaction processes (from high impact biomass harvesting disturbances) and other land degradation processes described in Section 4.2.1.

Global integrated assessment models used in the analyses of mitigation pathways vary in their approaches to modelling CDR (Bauer et al. 2018) and the outputs have large uncertainties due to their limited capability to consider site-specific details (Krause et al. 2018). Spatial resolutions vary from 11 world regions to 0.25 degrees gridcells (Bauer et al. 2018). While model projections identify potential areas for CDR implementation (Heck et al. 2018), the interaction with climate change induced biome shifts, available land and its vulnerability to degradation are unknown. The crop/forest types and management practices that will be implemented are also unknown, and will be influenced by local incentives and regulations. While it is therefore currently not possible to project the area at risk of degradation from the implementation of land-based CDR, there is a clear risk that expansion of energy crops at the scale anticipated could put significant strain on land systems, biosphere integrity, freshwater supply and biogeochemical flows (Heck et al. 2018). Similarly, extraction of biomass for energy from existing forests, particularly where stumps are utilized, can impact soil health (de Jong et al. 2017). Reforestation and afforestation present a lower risk of land degradation and may in fact reverse degradation (see Section 4.5.3) although potential adverse hydrological and biodiversity impacts will need to be managed (Caldwell et al. 2018; Brinkman et al. 2017). Soil carbon management can deliver negative emissions while reducing or reversing land degradation. Chapter 6 discusses the significance of context and management in determining environmental impacts of implementation of land-based options.

4.5.3 Potential contributions of land-based CDR to reducing and reversing land degradation

Although large-scale implementation of land-based CDR has significant potential risks, the need for negative emissions and the anticipated investments to implement such technologies can also create significant opportunities. Investments into land-based CDR can contribute to halting and reversing land degradation, to the restoration or rehabilitation of degraded and marginal lands (Chazdon and Uriarte 2016; Fritsche et al. 2017) and can contribute to the goals of land degradation neutrality (Orr et al. 2017a).

Estimates of the global area of degraded land range from less than 10 to 60 M km^2 (Gibbs and Salmon 2015), see also section 4.3.1. Additionally, large areas are classified as marginal lands and may be suitable for the implementation of bioenergy and land-based CDR (Woods et al. 2015). The yield per hectare of marginal and degraded lands is lower than on fertile lands, and if CDR will be implemented on marginal and degraded lands this will increase the area demand and costs per unit area of achieving negative emissions (Fritsche et al. 2017). Selection of lands suitable for CDR must be considered carefully to reduce conflicts with existing users, to assess the possible trade-offs in biodiversity contributions of the original and the CDR land uses, to quantify the impacts on water budgets, and to ensure sustainability of the CDR land use.

Land use and land condition prior to the implementation of CDR affect the climate change benefits (Harper et al. 2018). Afforestation/ reforestation on degraded lands can increase C stocks in vegetation and soil, increase carbon sinks (Amichev et al. 2012), and deliver co-benefits for biodiversity and ecosystem services particularly if a diversity of local species are used. Afforestation and reforestation on native grasslands can reduce soil carbon stocks, although the loss is typically more than compensated by increases in biomass and dead organic matter C stocks (Bárcena et al. 2014; Li et al. 2012; Ovalle-Rivera et al. 2015; Shi et al. 2013), and may impact biodiversity (Li et al. 2012) (see also 4.4.1: Large scale forest cover expansion, what can be learned in context of the SRCCL).

Strategic incorporation of energy crops into agricultural production systems, applying an integrated landscape management approach, can provide co-benefits for management of land degradation and other environmental objectives. For example, buffers of Miscanthus and other grasses can enhance soil carbon and reduce water pollution (Cacho et al. 2018; Odgaard et al. 2019), and strip-planting of short rotation tree crops can reduce the water table where crops are affected by dryland salinity (Robinson et al. 2006). Shifting to perennial grain crops has the potential to combine food production with carbon sequestration at a higher rate than with annual grain crops and avoid the trade-off between food production and climate change mitigation (Crews, Carton, & Olsson, 2018; de Oliveira, Brunsell, Sutherlin, Crews, & DeHaan, 2018; Ryan et al., 2018, see also 4.9.2).

Changes in land cover can affect surface reflectance, water balances and emissions of volatile organic compounds and thus the non-GHG impacts on the climate system from afforestation/reforestation or planting energy crops (Anderson et al. 2011; Bala et al. 2007; Betts 2000; Betts et al. 2007), (see Section 4.6 for further details). Some of these impacts reinforce the GHG mitigation benefits, while others off-set the benefits, with strong local (slope, aspect) and regional (boreal vs. tropical biomes) differences in the outcomes (Li et al. 2015). Adverse effects on albedo from afforestation with evergreen conifers in boreal zones can be reduced through planting of broadleaf deciduous species (Astrup et al. 2018; Cai et al. 2011a; Anderson et al. 2011).

Combining CDR technologies may prove synergistic. Two soil management techniques with an explicit focus on increasing the soil carbon content rather than promoting soil conservation more broadly have been suggested: Addition of biochar to agricultural soils (see 4.9.5) and addition of ground silicate minerals to soils in order to take up atmospheric CO_2 through chemical weathering (Taylor et al. 2017; Haque et al. 2019; Beerling 2017; Strefler et al. 2018). The addition of biochar is comparatively well understood and also field tested at large scale, see section 4.9.5 for a comprehensive discussion. The addition of silicate minerals to soils is still highly uncertain in terms of its potential (from 95 $GtCO_2\ yr^{-1}$ (Strefler et al. 2018) to only 2-4 $GtCO_2\ yr^{-1}$ (Fuss et al. 2018)) and costs (Schlesinger and Amundson 2018).

Effectively addressing land degradation through implementation of bioenergy and land-based CDR will require site-specific local knowledge, matching of species with the local land, water balance, nutrient and climatic conditions, and ongoing monitoring and, where necessary, adaptation of land management to ensure sustainability under global change (Fritsche et al. 2017). Effective land governance mechanisms including integrated land-use planning, along with strong sustainability standards could support deployment of energy crops and afforestation/reforestation at appropriate scales and geographical contexts (Fritsche et al. 2017). Capacity-building and technology transfer through the international cooperation mechanisms of the Paris Agreement could support such efforts. Modelling to inform policy development is most useful when undertaken with close interaction between model developers and other stakeholders including policymakers to ensure that models account for real world constraints (Dooley and Kartha 2018).

International initiatives to restore lands, such as the Bonn Challenge (Verdone and Seidl 2017) and the New York Declaration on Forests (Chazdon et al. 2017), and interventions undertaken for Land Degradation Neutrality and implementation of NDCs (see Glossary) can contribute to NET objectives. Such synergies may increase the financial resources available to meet multiple objectives (see section 4.8.4).

4.5.4 Traditional biomass provision and land degradation

Traditional biomass (fuelwood, charcoal, agricultural residues, animal dung) used for cooking and heating by some 2.8 billion people (38% of global population) in non-OECD countries accounts for more than half of all bioenergy used worldwide (IEA 2017; REN21 2018; see Cross-Chapter Box 7 on Bioenergy, Chapter 6). Cooking with traditional biomass has multiple negative impacts on human health, particularly for women, children and youth (Machisa et al. 2013; Sinha and Ray 2015; Price 2017; Mendum and Njenga 2018; Adefuye et al. 2007) and on household productivity including high workloads for women and youth (Mendum and Njenga 2018; Brunner et al. 2018; Hou et al. 2018; Njenga et al. 2019). Traditional biomass is land-intensive due to reliance on open fires, inefficient stoves and overharvesting of woodfuel, contributing to land degradation, losses in biodiversity and reduced ecosystem services (IEA 2017; Bailis et al. 2015; Masera et al. 2015; Specht et al. 2015; Fritsche et al. 2017; Fuso Nerini et al. 2017). Traditional woodfuels account for 1.9-2.3% of global GHG emissions, particularly in “hotspots” of land degradation and fuelwood depletion in eastern Africa and South Asia, such that one-third of traditional woodfuels globally are harvested unsustainably (Bailis et al. 2015). Scenarios to significantly reduce reliance on traditional biomass in developing countries present multiple co-benefits (*high evidence*, *high agreement*), including reduced emissions of black carbon, a short-lived climate forcer that also causes respiratory disease (Shindell et al. 2012).

A shift from traditional to modern bioenergy, especially in the African context, contributes to improved livelihoods and can reduce land degradation and impacts on ecosystem services (Smeets et al. 2012; Gasparatos et al. 2018; Mudombi et al. 2018). In Sub-Saharan Africa, most countries mention woodfuel in their Nationally Determined Contribution (NDC) but fail to identify transformational processes to make fuelwood a sustainable energy source compatible with improved forest management (Amugune et al. 2017). In some regions, especially in South and Southeast Asia, a scarcity of woody biomass may lead to excessive removal and use of agricultural wastes and residues, which contributes to poor soil quality and land degradation (Blanco-Canqui and Lal 2009; Mateos et al. 2017).

In sub-Saharan Africa, forest degradation is widely associated with charcoal production although in some tropical areas rapid re-growth can offset forest losses (Hoffmann et al. 2017; McNicol et al. 2018). Overharvesting of wood for charcoal contributes to the high rate of deforestation in sub-Saharan Africa, which is five times the world average, due in part to corruption and weak governance systems (Sulaiman et al. 2017). Charcoal may also be a by-product of forest clearing for agriculture, with charcoal sale providing immediate income when the land is cleared for food crops (Kiruki et al. 2017; Ndegwa et al. 2016). Besides loss of forest carbon stock, a further concern for climate change is methane and black carbon emissions from fuelwood burning and traditional charcoal-making processes (Bond et al. 2013; Patange et al. 2015; Sparrevik et al. 2015).

A fundamental difficulty in reducing environmental impacts associated with charcoal lies in the small-scale nature of much charcoal production in sub-Saharan Africa leading to challenges in regulating its production and trade, which is often informal, and in some cases illegal, but nevertheless widespread since charcoal is the most important urban cooking fuel (Zulu 2010; Zulu and Richardson 2013; Smith et al. 2015; World Bank 2009) (World Bank, 2009). Urbanisation combined with population growth has led to continuously increasing charcoal production. Low efficiency of traditional charcoal production results in a four-fold increase in raw woody biomass required and thus much greater biomass harvest (Hojas-Gascon et al. 2016; Smeets et al. 2012). With continuing urbanisation anticipated, increased charcoal production and use will probably contribute to increasing land pressures and increased land degradation, especially in sub-Saharan Africa *(medium evidence, high agreement)*.

Although it could be possible to source this biomass more sustainably, the ecosystem and health impacts of this increased demand for cooking fuel would be reduced through use of other renewable fuels or in some cases, non-renewable fuels (LPG), as well as through improved efficiency in end-use and through better resource and supply chain management (Santos et al. 2017; Smeets et al. 2012; Hoffmann et al. 2017). Integrated response options such as agro-forestry (see Chapter 6) and good governance mechanisms for forest and agricultural management (see Chapter 7) can support the transition to sustainable energy for households and reduce the environmental impacts of traditional biomass.

4.6 Impacts of land degradation on climate

While Chapter 2 has its focus on land cover changes and their impacts on the climate system, this chapter focuses on the influences of individual land degradation processes on climate (see cross chapter Table 4.1) which may or may not take place in association to land cover changes. The effects of land degradation on CO_2 and other greenhouse gases as well as those on surface albedo and other physical controls of the global radiative balance are discussed.

4.6.1 Impacts on greenhouse gases

Land degradation processes with direct impact on soil and terrestrial biota have great relevance in terms of CO_2 exchange with the atmosphere given the magnitude and activity of these reservoirs in the global C cycle. As the most widespread form of soil degradation, erosion detaches the surface soil material which typically hosts the highest organic C stocks, favoring the mineralisation and release as CO_2, yet complementary processes such as C burial may compensate this effect, making soil erosion a long-term C sink (*low agreement, limited evidence)*, (Wang et al. 2017b), but see also (Chappell et al. 2016). Precise estimation of the CO_2 released from eroded lands is challenged by the fact that only a fraction of the detached C is eventually lost to the atmosphere. It is important to acknowledge that a substantial fraction of the eroded material may preserve its organic C load in field conditions. Moreover, C sequestration may be favored through the burial of both the deposited material and the surface of its hosting soil at the deposition location (Quinton et al. 2010). The cascading effects of erosion on other environmental processes at the affected sites can often cause net CO_2 emissions through their indirect influence on soil fertility and the balance of organic C inputs and outputs, interacting with other non-erosive soil degradation processes such as nutrient depletion, compaction and salinisation, which can lead to the same net C effects (see Table 4.1) (van de Koppel et al. 1997).

As natural and human-induced erosion can result in net C storage in very stable buried pools at the deposition locations, degradation in those locations has a high C-release potential. Coastal ecosystems such as mangrove forests, marshes and seagrasses are a typical deposition locations and their degradation or replacement with other vegetation is resulting in a substantial C release (0.15 to 1.02 Gt C yr^{-1}) (Pendleton et al. 2012), which highlights the need for a spatially-integrated assessment of land degradation impacts on climate that considers in-situ but also ex-situ emissions.

Cultivation and agricultural management of cultivated land are relevant in terms of global CO_2 land-atmosphere exchange (see also 4.8.1). Besides the initial pulse of CO_2 emissions associated with the onset of cultivation and associated vegetation clearing (see Chapter 2), agricultural management practices can increase or reduce C losses to the atmosphere. Although global croplands are considered to be at relatively neutral stage in the current decade (Houghton et al. 2012), this results from a highly uncertain balance between coexisting net losses and gains. Degradation losses of soil and biomass carbon appear to be compensated by gains from soil protection and restoration practices such as cover crops, conservation tillage and nutrient replenishment favoring organic matter build-up. Cover crops, increasingly used to improve soils, have the potential to sequester 0.12 Gt C yr^{-1} on global croplands with a saturation time of more than 150 years (Poeplau and Don 2015). No-till practices (i.e. tillage elimination favoring crop residue retention in the soil surface) which were implemented to protect soils from erosion and reduce land preparation times, were also seen with optimism as a C sequestration option, which today is considered more modest globally and, in some systems, even less certain (VandenBygaart 2016; Cheesman et al. 2016; Powlson et al. 2014). Among soil fertility restoration practices, lime application for acidity correction, increasingly important in tropical regions, can generate a significant net CO_2 source in some soils (Bernoux et al. 2003, Alemu et al 2017).

Land degradation processes in seminatural ecosystems driven by unsustainable uses of their vegetation through logging or grazing lead to reduced plant cover and biomass stocks, causing net C releases from soils and plant stocks. Degradation by logging activities is particularly important in developing tropical and subtropical regions, involving C releases that exceed by far the biomass of harvested products, including additional vegetation and soil sources that are estimated to reach 0.6 Gt C yr^{-1} (Pearson et al. 2014, 2017). Excessive grazing pressures pose a more complex picture with variable magnitudes and even signs of C exchanges. A general trend of higher C losses in humid overgrazed rangelands suggests a high potential for C sequestration following the rehabilitation of those systems (Conant and Paustian 2002) with a global potential sequestration of 0.045 Gt C yr^{-1}. A special case of degradation in rangelands are those processes leading to the woody encroachment of grass-dominated systems, which can be responsible of declining animal production but high C sequestration rates (Asner et al. 2003, Maestre et al. 2009).

Fire regime shifts in wild and seminatural ecosystems can become a degradation process in itself, with high impact on net C emission and with underlying interactive human and natural drivers such as burning policies (Van Wilgen et al. 2004), biological invasions (Brooks et al. 2009), and plant pest/disease spread (Kulakowski et al. 2003). Some of these interactive processes affecting unmanaged forests have resulted in massive C release, highlighting how degradation feedbacks on climate are not restricted to intensively used land but can affect wild ecosystems as well (Kurz et al. 2008).

Agricultural land and wetlands represent the dominant source of non-CO_2 greenhouse gases (Chen et al. 2018d). In agricultural land, the expansion of rice cultivation (increasing CH_4 sources), ruminant stocks and manure disposal (increasing CH_4, N_2O and NH_3 fluxes) and nitrogen over-fertilisation combined with soil acidification (increasing N_2O fluxes) are introducing the major impacts (*medium agreement, medium evidence*) and their associated emissions appear to be exacerbated by global warming (*medium agreement and medium evidence)* (Oertel et al. 2016).

As the major sources of global N_2O emissions, over-fertilisation and manure disposal are not only increasing in-situ sources but also stimulating those along the pathway of dissolved inorganic nitrogen transport all the way from draining waters to the ocean (*high agreement, medium evidence*). Current budgets of anthropogenically fixed nitrogen on the Earth System (Tian et al. 2015; Schaefer et al. 2016; Wang et al. 2017a) suggest that N_2O release from terrestrial soils and wetlands accounts for 10-15% of the inputs, yet many further release fluxes along the hydrological pathway remain uncertain, with emissions from oceanic "dead-zones" being a major aspect of concern (Schlesinger 2009; Rabalais et al. 2014).

Environmental degradation processes focused on the hydrological system, which are typically manifested at the landscape scale, include both drying (as in drained wetlands or lowlands) and wetting trends (as in waterlogged and flooded plains). Drying of wetlands reduces CH_4 emissions (Turetsky et al. 2014) but favors pulses of organic matter mineralization linked to high N_2O release (Morse and Bernhardt 2013; Norton et al. 2011). The net warming balance of these two effects is not resolved and may be strongly variable across different types of wetlands. In the case of flooding of non-wetland soils, a suppression of CO_2 release is typically over compensated in terms of net greenhouse impact by enhanced CH_4 fluxes, that stem from the lack of aeration but are aided by the direct effect of extreme wetting on the solubilisation and transport of organic substrates (McNicol and Silver 2014). Both wetlands rewetting/restoration and artificial creation can increase CH_4 release (Altor and Mitsch 2006; Fenner et al. 2011). Permafrost thawing is another major source of CH_4 release with substantial long-term contributions to the atmosphere that are starting to get globally quantified (Christensen et al. 2004; Schuur et al. 2015; Walter Anthony et al. 2016).

4.6.2 Physical impacts

Among the physical effects of land degradation, surface albedo changes are those with the most evident impact on the net global radiative balance and net climate warming/cooling. Degradation processes affecting wild and semi-natural ecosystems such as fire regime changes, woody encroachment, logging and overgrazing can trigger strong albedo changes before significant biogeochemical shifts take place, in most cases these two types of effects have opposite signs in terms of net radiative forcing, making their joint assessment critical for understanding climate feedbacks (Bright et al. 2015).

In the case of forest degradation or deforestation, the albedo impacts are highly dependent on the latitudinal/climatic belt to which they belong. In boreal forests the removal or degradation of the tree cover increases albedo (net cooling effect)(*medium evidence, high agreement*) as the reflective snow cover becomes exposed, which can exceed the net radiative effect of the associated C release to the atmosphere (Davin et al. 2010; Pinty et al. 2011). On the other hand, progressive greening of boreal and temperate forests has contributed to net albedo declines (*medium agreement, medium evidence*) (Planque et al. 2017; Li et al. 2018a). In the northern treeless vegetation belt (tundra), shrub encroachment leads to the opposite effect as the emergence of plant structures above the snow cover level reduce winter-time albedo (Sturm 2005).

The extent to which albedo shifts can compensate carbon storage shifts at the global level has not been estimated. A significant but partial compensation takes place in temperate and subtropical dry ecosystems in which radiation levels are higher and C stocks smaller compared to their more humid counterparts (*medium agreement, medium evidence*). In cleared dry woodlands half of the net global warming effect of net C release has been compensated by albedo increase (Houspanossian et al. 2013), whereas in afforested dry rangelands albedo declines cancelled one fifth of the net C sequestration (Rotenberg and Yakir 2010). Other important cases in which albedo effects impose a partial compensation of C exchanges are the vegetation shifts associated to wild fires, as shown for the savannahs, shrublands and grasslands of sub-Saharan Africa (Dintwe et al. 2017). Besides the net global effects discussed above, albedo shifts can play a significant role on local climate (*high agreement, medium evidence*), as exemplified by the effect of no-till agriculture reducing local heat extremes in European landscapes (Davin et al. 2014) and the effects of woody encroachment causing precipitation rises in the North American Great Plains (Ge and Zou 2013). Modeling efforts that integrate ground data from deforested areas worldwide accounting for both physical and biogeochemical effects, indicate that massive global deforestation would have a net warming impact (Lawrence and Vandecar 2015) at both local and global levels with highlight non-linear effects of forest loss on climate variables.

Beyond the albedo effects presented above, other physical impacts of land degradation on the atmosphere can contribute to global and regional climate change. Of particular continental to global relevance are the net cooling effects of dust emissions (*low agreement, medium evidence*) (Lau and Kim 2007), but see also (Huang et al. 2014). Anthropogenic emission of mineral particles from degrading land appear to have a similar radiative impact than all other anthropogenic aerosols (Sokolik and Toon 1996). Dust emissions may explain regional climate anomalies through reinforcing feedbacks, as suggested for the amplification of the intensity, extent and duration of the low precipitation anomaly of the North American “Dust Bowl” in the 1930s (Cook et al. 2009). Another source of physical effects on climate are surface roughness changes which, by affecting atmospheric drag, can alter cloud formation and precipitation (*low agreement, low evidence*), as suggested by modeling studies showing how the massive deployment of solar panels in the Sahara could increase rainfall in the Sahel (Li et al. 2018c) or how woody encroachment in the Arctic tundra could reduce cloudiness and raise temperature (Cho et al. 2018). The complex physical effects of deforestation, as explored through modeling, converge into general net regional precipitation declines, tropical temperature increases and boreal temperature declines, while net global effects are less certain (Perugini et al. 2017). Integrating all the physical effects of land degradation and its recovery or reversal is still challenge, yet modeling attempts suggest that over the last three decades the slow but persistent net global greening caused by the average increase of leaf area in the land has caused a net cooling of the Earth, mainly through the raise of evapotranspiration (Zeng et al. 2017) (*low confidence*).

4.7 Impacts of climate-related land degradation on poverty and livelihoods

Unravelling the impacts of climate-related land degradation on poverty and livelihoods is highly challenging. This complexity is due to the interplay of multiple social, political, cultural, and economic factors, such as markets, technology, inequality, population growth, (Barbier and Hochard 2018) each of which interact and shape the ways in which social-ecological systems respond (Morton 2007). We find *limited evidence* attributing the impacts of climate-related land degradation to poverty and livelihoods, with climate often not distinguished from any other driver of land degradation. Climate is nevertheless frequently noted as a risk multiplier for both land degradation and poverty (*high agreement, robust evidence*) and is one of many stressors people live with, respond to and adapt to in their daily lives (Reid and Vogel 2006). Climate change is considered to exacerbate land degradation and potentially accelerate it due to heat stress, drought, changes to evapotranspiration rates and biodiversity, as well as a result of changes to environmental conditions that allow new pests and diseases to thrive (Reed and Stringer 2016b). In general terms, the climate (and climate change) can increase human and ecological communities' sensitivity to land degradation. Land degradation then leaves livelihoods more sensitive to the impacts of climate change and extreme climatic events (*high agreement, robust evidence*). If human and ecological communities exposed to climate change and land degradation are sensitive and cannot adapt, they can be considered vulnerable to it; if they are sensitive and can adapt, they can be considered resilient (Reed and Stringer 2016b). The impacts of land degradation will vary under a changing climate both spatially and temporally, leading some communities and ecosystems to be more vulnerable or more resilient than others under different scenarios. Even within communities, groups such as women and the youth are often more vulnerable than others.

4.7.1 Relationships between land degradation, climate change and poverty

This section sets out the relationships between land degradation and poverty, and climate change and poverty, leading to inferences about the 3-way links between them. Poverty is multidimensional and includes a lack of access to the whole range of capital assets that can be used to pursue a livelihood. Livelihoods constitute the capabilities, assets, and activities that are necessary to make a living (Chambers and Conway 1992; Olsson et al. 2014b).

The literature shows *high agreement* in terms of speculation that there are <u>potential</u> links between land degradation and poverty. However, studies have not provided robust quantitative assessments of the extent and incidence of poverty within land degradation affected populations (Barbier and Hochard 2016). Some researchers, e.g. Nachtergaele et al. (2011) estimate that 1.5 billion people were dependent upon degraded land to support their livelihoods in 2007, while >42 % of the world's poor population inhabit degraded areas. However, there is overall *low confidence* in the evidence base, a lack of studies that look beyond the past and present, and the literature calls for more in-depth research to be undertaken on these issues (Gerber et al. 2014). Recent work by Barbier and Hochard (Barbier and Hochard 2018) points to biophysical constraints such as poor soils and limited rainfall which interact to limit land productivity, suggesting that those farming in climatically less favourable agricultural areas are challenged by poverty. Studies such as those by (Coomes et al. 2011), focusing on an area in the Amazon, highlight the importance of the initial conditions of land holding in the dominant (shifting) cultivation system in terms of long-term effects on household poverty and future forest cover, showing initial land tenure and socio-economic aspects can make some areas less favourable too.

Much of the qualitative literature is focused on understanding the livelihood and poverty impacts of degradation through a focus on subsistence agriculture, where farms are small, under traditional or informal tenure and where exposure to environmental (including climate) risks is high (Morton 2007). In these situations, the poor lack access to assets (financial, social, human, natural and physical) and in the absence of appropriate institutional supports and social protection, this leaves them sensitive and unable to adapt, so a vicious cycle of poverty and degradation can ensue. To further illustrate the complexity, livelihood assessments often focus on a single snapshot in time, livelihoods are dynamic and people alter their livelihood activities and strategies depending the on internal and external stressors to which they are responding (O'Brien et al. 2004). When certain livelihood activities and strategies become no longer tenable as a result of land degradation (and may push people into poverty), it can have further effects on issues such as migration (Lee 2009), as people adapt by moving (see Section 4.7.3); and may result in conflict (see Section 4.7.3), as different groups within society compete for scarce resources, sometimes through non-peaceful actions. Both migration and conflict can lead to land use changes elsewhere that further fuel climate change through increased emissions.

Similar challenges as for understanding land degradation-poverty linkages are experienced in unravelling the relationship between climate change and poverty. A particular issue in examining climate change-poverty links relates to the common use of aggregate economic statistics like GDP, as the assets and income of the poor constitute such as minor proportion of national wealth (Hallegatte et al. 2018). Aggregate quantitative measures also fail to capture the distributions of costs and benefits from climate change. Furthermore, people fall into and out of poverty, with climate change being one of many factors affecting these dynamics, through its impacts on livelihoods. Much of the literature on climate change and poverty tends to look backward rather than forward (Skoufias et al. 2011), providing a snap-shot of current or past relationships, (for example, (Dell et al. 2009) who examine the relationship between temperature and income (GDP) using cross-sectional data from countries in the Americas). Yet, simulations of future climate change impacts on income or poverty are largely lacking.

Noting the *limited evidence* that exists that explicitly focuses on the relationship between land degradation, climate change and poverty, Barbier and Hochard (2018b) suggest that those people living in less favoured agricultural areas face a poverty-environment trap that can result in increased land degradation under climate change conditions. The emergent relationships between land degradation, climate change and poverty are shown in Figure 4.6 (see also Figure 6.1).

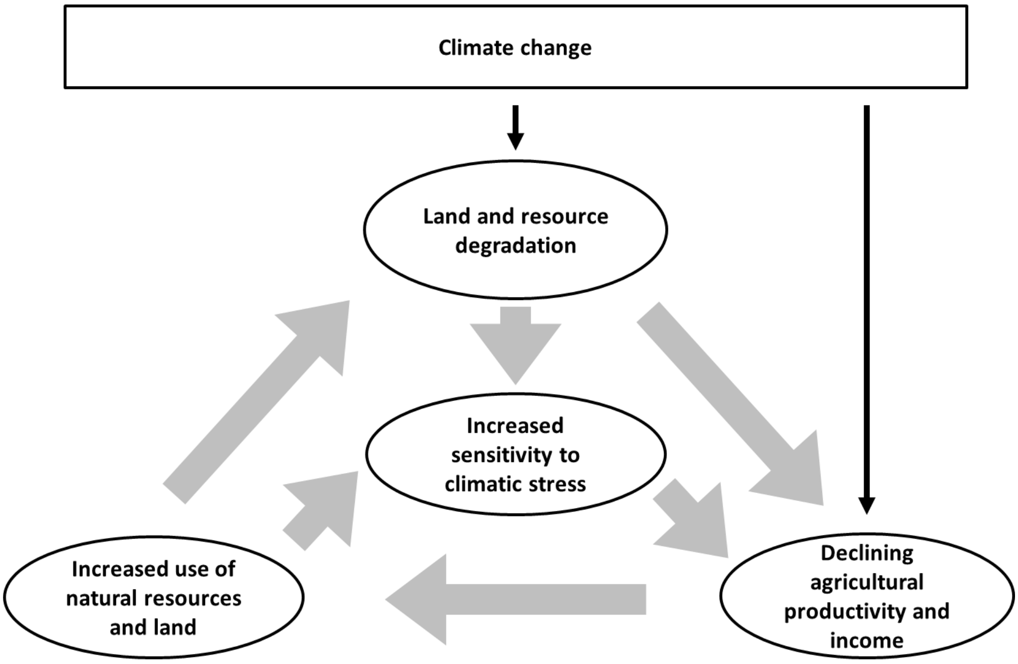

Figure 4.6 Schematic representation of links between climate change, land management and socio-economic conditions.

The poor have access to few productive assets, so land, and the natural resource base more widely, plays a key role in supporting the livelihoods of the poor. It is however, hard to make generalisations about how important income derived from the natural resource base is for rural livelihoods in the developing world (Angelsen et al. 2014) with studies focusing on forest resources having shown that approximately one quarter of the total rural household income in developing countries stems from forests, with forest-based income shares being tentatively higher for low-income households (Vedeld et al. 2007; Angelsen et al. 2014). Different groups use land in different ways within their overall livelihood portfolios and are therefore at different levels of exposure and sensitivity to climate shocks and stresses. The literature nevertheless displays *high evidence* and *high agreement* that those populations whose livelihoods are more sensitive to climate change and land degradation are often more dependent on environmental assets, and these people are often the poorest members of society. There is further *high evidence and high agreement* that both climate change and land degradation can affect livelihoods and poverty through their threat multiplier effect. Research in Bellona, in the Solomon Islands in the south Pacific (Reenberg et al. 2008) examined event-driven impacts on livelihoods, taking into account weather events as one of many drivers of land degradation and links to broader land-use and land cover changes that have taken place. Geographical locations experiencing land degradation are often the same locations that are directly affected by poverty, and are also affected by extreme events linked to climate change and variability.

Much of the assessment presented above has considered placed-based analyses examining the relationships between poverty, land degradation and climate change in the locations in which these outcomes have occurred. Altieri and Nicholls (2017) note that due to the globalised nature of markets and consumption systems, the impacts of changes in crop yields linked to climate-related land degradation (manifest as lower yields) will be far reaching, beyond the sites and livelihoods experiencing degradation. Despite these teleconnections, farmers living in poverty in developing countries will be especially vulnerable due to their exposure, dependence on the environment for income and limited options to engage in other ways to make a living (Rosenzweig and Hillel 1998). In identifying ways in which these interlinkages can be addressed, (Scherr 2000) observes that key actions that can jointly address poverty and environmental improvement often seek to increase access to natural resources, enhance the productivity of the natural resource assets of the poor, and to engage stakeholders in addressing public natural resource management issues. In this regard, it is increasingly recognised that those suffering from and being vulnerable to land degradation and poverty need to have a voice and play a role in the development of solutions, especially where the natural resources and livelihood activities they depend on are further threatened by climate change.

4.7.2 Impacts of climate related land degradation on food security

How and where we grow food compared to where and when we need to consume it is at the crux of issues surrounding land degradation, climate change and food security, especially because more than 75% of the global land surface (excluding Antarctica) faces rain-fed crop production constraints (Fischer et al. 2009), see also Chapter 5. Taken separately, knowledge on land degradation processes and human-induced climate change has attained a great level of maturity. However, their combined effects on food security, notably food supply, remain underappreciated (Webb et al. 2017b), and quantitative information is lacking. Just a few studies have shown how the interactive effects of the aforementioned challenging, interrelated phenomena can impact crop productivity and hence food security and quality (Karami et al. 2009; Allen et al. 2001; Högy and Fangmeier 2008) (*low evidence*). Along with socio-economic drivers climate change accelerates land degradation due to its influence on land-use systems (Millennium Assessment 2005; UNCCD 2017), potentially leading to a decline in agri-food system productivity, particularly on the supply side. Increases in temperature and changes in precipitation patterns are expected to have impacts on soil quality, including nutrient availability and assimilation (St.Clair and Lynch 2010). Those climate-related changes are expected to have net negative impacts on agricultural productivity, particularly in tropical regions, though the magnitude of impacts depends on the models used. Anticipated supply side issues linked to land and climate relate to biocapacity factors (including e.g. whether there is enough water to support agriculture); production factors (e.g. chemical pollution of soil and water resources or lack of soil nutrients) and distribution issues (e.g. decreased availability of and/or accessibility to the necessary diversity of quality food where and when it is needed) (Stringer et al. 2011). Climate sensitive transport infrastructure is also problematic for food security (Islam et al. 2017), and can lead to increased food waste, while poor siting of roads and transport links can lead to soil erosion and forest loss (Xiao et al. 2017), further feeding back into climate change.

Over the past decades, crop models have been useful tools for assessing and understanding climate change impacts on crop productivity and food security (White et al. 2011; Rosenzweig et al. 2014). Yet, the interactive effects of soil parameters and climate change on crop yields and food security remain limited, with *low evidence* of how they play out in different economic and climate settings (e.g. Sundström et al. 2014). Similarly, there have been few meta-analyses focusing on the adaptive capacity of land-use practices such as conservation agriculture in light of climate stress (see e.g. Steward et al. 2018), as well as *low evidence* quantifying the role of wild foods and forests (and by extension forest degradation) in both the global food basket and in supporting household scale food security (Bharucha and Pretty 2010; Hickey et al. 2016)

To be sustainable, any initiative aiming at addressing food security – encompassing supply, diversity and quality - must take into consideration the interactive effects between climate and land degradation in a context of other socio-economic stressors. Such socio-economic factors are especially important if we look at demand side issues too, which include lack of purchasing power, large scale speculation on global food markets leading to exponential price rises (Tadesse et al. 2014), competition in appropriation of supplies and changes to per capita food consumption (Stringer et al. 2011; see also Chapter 5). Lack of food security, combined with lack of livelihood options, is often an important manifestation of vulnerability, and can act as a key trigger for people to migrate. In this way, migration becomes an adaptation strategy.

4.7.3 Impacts of climate-related land degradation on migration and conflict

Land degradation may trigger competition for scarce natural resources potentially leading to migration and/or conflict, though even with *medium evidence* there is *low agreement* in the literature. Linkages between land degradation and migration occur within a larger context of multi-scale interaction of environmental and non-environmental drivers and processes, including resettlement projects, searches for education and/or income, land shortages, political turmoil, and family-related reasons (McLeman 2017; Hermans and Ide 2019). The complex contribution of climate to migration and conflict hampers retrieving any level of confidence on climate-migration and climate-conflict linkages, therefore constituting a major knowledge gap (Cramer et al. 2014; Hoegh-Guldberg et al. 2018).

There is *low evidence* on the causal linkages between climate change, land degradation processes (other than desertification) and migration. Existing studies on land degradation and migration – particularly in drylands – largely focus on the effect of rainfall variability and drought and shows how migration serves as adaptation strategy (Piguet et al. 2018; McLeman 2017; chapter 3). For example, in the Ethiopian highlands severe topsoil erosion and forest degradation is a major environmental stressor which is amplified by re-occurring droughts, with migration being an important household adaptation strategy (Morrissey 2013). In the humid tropics, land degradation, mainly as a consequence of deforestation, has been a reported reason for people leaving their homes during the Amazonian colonisation (Hecht 1983) but was also observed more recently, for example in Guatemala, where soil degradation was one of the most frequently cited migration pushes (López-Carr 2012) and Kenya, where households respond to low soil quality by sending temporary migrants for additional income generation (Gray 2011). In contrast, in the Andean highlands and the Pacific coastal plain, migration increased with land quality, probably because revenues from additional agricultural production was invested in costly forms of migration (Gray and Bilsborrow 2013). These mixed results illustrate the complex, non-linear relationship of land degradation-migration linkages and suggest explaining land degradation-migration linkages requires considering a broad socio-ecological embedding (McLeman 2017).

In addition to people moving away from an area due to "lost" livelihood activities, climate related land degradation can also reduce the availability of livelihood safety nets – environmental assets that people use during times of shocks or stress. For example, Barbier (2000) notes that wetlands in north-east Nigeria around Hadejia–Jama'are floodplain provide dry season pastures for seminomadic herders, agricultural surpluses for Kano and Borno states, groundwater recharge of the Chad formation aquifer and 'insurance' resources in times of drought. The floodplain also supports many migratory bird species. As climate change and land degradation combine, delivery of these multiple services can be undermined, particularly as droughts become more widespread, reducing the utility of this wetland environment as a safety net for people and wildlife alike.

Early studies conducted in Africa hint at a significant causal link between land degradation and violent conflict (Homer-Dixon et al. 1993). For example, Percival and Homer-Dixon (1995) identified land degradation as one of the drivers of the crisis in Rwanda in the early 1990s which allowed radical forces to stoke ethnic rivalries. With respect to the Darfur conflict, some scholars and UNEP concluded that land degradation, together with other environmental stressors, constitute a major security threat for the Sudanese people (Byers and Dragojlovic 2004; Sachs 2007; UNEP 2007). Recent studies show *low agreement*, suggesting that climate change can increase the likelihood of civil violence if certain economic, political and social factors, including low development and weak governance mechanisms, are present (Scheffran et al. 2012; Benjaminsen et al. 2012). In contrast, Raleigh (Raleigh and Urdal 2007) found in a global study that land degradation is a weak predictor for armed conflict. As such, studies addressing possible linkages between climate change – a key driver of land degradation – and the risks of conflict have yielded contradictory results and it remains largely unclear whether land degradation resulting from climate change leads to conflict or cooperation (Salehyan 2008; Solomon et al. 2018).

Land degradation-conflict linkages can be bi-directional. Research suggests that households experiencing natural resource degradation often engage in migration for securing livelihoods (Kreamer 2012), which potentially triggers land degradation at the destination leading to conflict there (Kassa et al. 2017). While this indeed holds true for some cases it may not for others given the complexity of processes, contexts and drivers. Where conflict and violence do ensue, it is often as a result of a lack of appreciation for the cultural practices of others.

4.8 Addressing land degradation in the context of climate change

Land degradation in the form of soil carbon loss is estimated to have been ongoing for at least 12,000 years, but increased exponentially in the last 200 years (Sanderman et al. 2017). Before the advent of modern sources of nutrients, it was imperative for farmers to maintain and improve soil fertility through the prevention of runoff and erosion, and management of nutrients through vegetation residues and manure. Many ancient farming systems were sustainable for hundreds and even thousands of years, such as raised field agriculture in Mexico (Crews and Gliessman 1991), tropical forest gardens in SE Asia and Central America (Ross 2011; Torquebiau 1992; Turner and Sabloff 2012), terraced agriculture in East Africa, Central America, Southeast Asia and the Mediterranean basin (Turner and Sabloff 2012; Preti and Romano 2014; Widgren and Sutton 2004; Håkansson and Widgren 2007; Davies and Moore 2016; Davies 2015), and integrated rice-fish cultivation in East Asia (Frei and Becker 2005).

Such long-term sustainable farming systems evolved in very different times and geographical contexts, but they share many common features, such as: the combination of species and structural diversity in time, and space (horizontally and vertically) in order to optimise the use of available land; recycling of nutrients through biodiversity of plants, animals, and microbes; harnessing the full range of site-specific micro-environments (e.g. wet and dry soils); biological interdependencies which helps suppression of pests; reliance on mainly local resources; reliance on local varieties of crops and sometimes incorporation of wild plants and animals; the systems are often labour and knowledge intensive (Rudel et al. 2016; Beets 1990; Netting 1993; Altieri and Koohafkan 2008). Such farming systems have stood the test of time and can provide important knowledge for adapting farming systems to climate change (Koohafkann and Altieri 2011).

In modern agriculture the importance of maintaining the biological productivity and ecological integrity of farm land has not been a necessity in the same way as in pre-modern agriculture because nutrients and water have been supplied externally. The extreme land degradation in the US Midwest during the Dust Bowl period in the 1930s became an important wake-up call for agriculture and agricultural research and development, from which we can still learn much in order to adapt to ongoing and future climate change (McLeman et al. 2014; Baveye et al. 2011; McLeman and Smit 2006).

Sustainable Land Management (SLM) is a unifying framework for addressing land degradation and can be defined as the stewardship and use of land resources, including soils, water, animals and plants, to meet changing human needs, while simultaneously ensuring the long-term productive potential of these resources and the maintenance of their environmental functions. ‘It is a comprehensive approach comprising technologies combined with social, economic and political enabling conditions (Nkonya et al. 2011). It is important to stress that farming systems are informed by both scientific and local/traditional knowledge. The power of SLM in small-scale diverse farming was demonstrated effectively in Nicaragua after the severe cyclone Mitch in 1998 (Holt-Giménez 2002). Pairwise analysis of 880 fields with and without implementation of SLM practices showed that the SLM fields systematically fared better than the fields without SLM in terms of more topsoil remaining, higher field moisture, more vegetation, less erosion and lower economic losses after the cyclone. Furthermore the difference between fields with and without SLM increased with increasing levels of storm intensity, increasing slope gradient, and increasing age of SLM (Holt-Giménez 2002).

When addressing land degradation through SLM and other approaches it is important to consider feedbacks that impact climate change. Table 4.2 shows some of the most important land degradation issues, their potential solutions, and their impacts on climate change. This table provides a link between the comprehensive lists of land degradation processes (Table 4.1) and land management solutions (Table 4.2).

Table 4.2 (Cross-chapter Ch 3 and Ch 4) Interaction of human and climate drivers can exacerbate desertification and land degradation

Climate change exacerbates the rate and magnitude of several ongoing land degradation and desertification processes. Human drivers of land degradation and desertification include expanding agriculture, agricultural practices and forest management. In turn land degradation and desertification are also drivers of climate change through the emission of greenhouse gases, reduced rates of carbon uptake and reduced capacity of ecosystems to act as carbon sinks into the future.

Human driver	Climate driver
Grazing pressure	Warming trend
Agriculture practices	Extreme temperatures
Expansion of agriculture	Drying trend
Forest clearing	Extreme rainfall
Wood fuel	Shifting rains
	Intensifying cyclones
	Sea level rise

Issue/syndrome	Impact on climate change	Human driver	Climate driver	Land management options	References	
Erosion of agricultural soils	Emission: CO_2, N_2O			Increase soil organic matter, no till, perennial crops, erosion control, agroforestry, dietary change	{3.2.4, 3.5.1, 3.6.2, 3.8.1, 4.9.1, 4.9.5, 4.10.2, 4.10.5}	{3.1.4,3.4.1, 3.5.2,3.7.1,4.8.1,4.8.5, 4.9.2,4.9.5}
Deforestation	Emission of CO_2			Forest protection, sustainable forest management and dietary change	{4.2.5, 4.6, 4.9.3, 4.9.4, 4.10.3}	{4.1.5,4.5,4.8.3,4.8.4,4.9.3}
Forest degradation	Emission of CO_2 Reduced carbon sink			Forest protection, sustainable forest management	{4.2.5, 4.6, 4.9.3, 4.9.4, 4.10.3}	{4.1.5,4.5,4.8.3,4.8.4,4.9.3}
Overgrazing	Emission: CO_2, CH_4 Increasing albedo			Controlled grazing, rangeland management	{3.2.4.2, 3.5.1, 3.7.1, 3.8.1, 4.9.1.4}	{3.1.4.2,3.4.1,3.6.1,3.7.1,4.8.1.4}
Firewood and charcoal production	Emission: CO_2, CH_4 Increasing albedo			Clean cooking (health co-benefits, particularly for women and children)	{3.7.3, 4.6.4, 4.9.3, 4.9.4}	{3.6.3,4.5.4,4.8.3,4.8.4}
Increasing fire frequency and intensity	Emission: CO_2, CH_4, N_2O Emission: aerosols, increasing albedo			Fuel management, fire management	{3.2.4, 3.7.1, 4.2.5, 4.9.3, Cross chapter box 3}	{3.1.4,3.6.1,4.1.5,4.8.3, Cross chapter box 3}
Degradation of tropical peat soils	Emission: CO_2, CH_4			Peatland restoration, erosion control, regulating the use of peat soils	{4.10.4}	{4.9.4}
Thawing of perma-frost	Emission: CO_2, CH_4			relocation of settlement and infrastructure	{4.9.5.1}	{4.8.5.1}
Coastal erosion	Emission: CO_2, CH_4			Wetland and coastal restoration, mangrove conservation, long term land use planning	{4.10.6, 4.10.7, 4.10.8}	{4.9.6,4.9.7,4.9.8}
Sand and dust storms, wind erosion	Emission: aerosols			Vegetation management, afforestation, windbreaks	{3.4.1, 3.5.1, 3.7.1, 3.8.1, 3.8.2}	{3.3.1,3.4.1,3.6.1,3.7.1,3.7.2}
Bush encroachment	Capturing: CO_2, Decreasing albedo			Grazing land management, fire management	{3.7.1.3, 3.8.3.2}	{3.6.1.3,3.7.3.2}

4.8.1 Actions on the ground to address land degradation

Concrete actions on the ground to address land degradation are primarily focused on soil and water conservation. In the context of adaptation to climate change, actions relevant for addressing land degradation are sometimes framed as ecosystem based adaptation (EBA) (Scarano 2017) or Nature Based Solutions (NBS) (Nesshöver et al. 2017), and in an agricultural context, agroecology (see glossary) provides an important frame. The site-specific biophysical and social conditions, including local and indigenous knowledge, are important for successful implementation of concrete actions.

Responses to land degradation generally take the form of agronomic measures (methods related to managing the vegetation cover), soil management (methods related to tillage, nutrient supply), and mechanical methods (methods resulting in durable changes to the landscape) (Morgan 2005a). Measures may be combined to reinforce benefits to land quality, as well as improving carbon sequestration that supports climate change mitigation. Some measures offer adaptation options and other co-benefits, such as agroforestry involving planting fruit trees that can support food security in the face of climate change impacts (Reed and Stringer 2016a) or application of compost or biochar that enhances soil water holding capacity, so increases resilience to drought.

There are important differences in terms of labour and capital requirements for different technologies, and also implications for land tenure arrangements. Agronomic measures and soil management require generally little extra capital input and comprise activities repeated annually, so have no particular implication for land tenure arrangements. Mechanical methods require substantial upfront investments in terms of capital and labour, resulting in long lasting structural change requiring more secure land tenure arrangements (Mekuriaw et al. 2018). Agroforestry is a particularly important strategy for SLM in the context of climate change because the large potential to sequester carbon in plants and soil and enhance resilience of agricultural systems (Zomer et al. 2016).

Implementation of sustainable land management practices has been shown to increase the productivity of land (Branca et al. 2013) and to provide good economic returns on investment in many different settings around the world (Mirzabaev et al. 2015). Giger et al (2018) showed in a meta study of 363 projects over the period 1990 to 2012 that 73% of the projects were perceived to have a positive or at least neutral cost/benefit ratio in the short term, and 97% were perceived to have a positive or very positive cost/benefit ratio in the long term (*robust evidence, high agreement*). Despite the positive effects, uptake is far from universal. Local factors, both biophysical conditions (e.g. soils, drainage, and topography) and socio-economic conditions (e.g. land tenure, economic status, and land fragmentation) play decisive roles in the interest in, capacity to undertake, and successful implementation of sustainable land management practices (Teshome et al. 2016; Vogl et al. 2017; Tesfaye et al. 2016; Cerdà et al. 2018; Adimassu et al. 2016). From a landscape perspective, sustainable land management can generate benefits, including adaptation to and mitigation of climate change, for entire watersheds, but challenges remain regarding coordinated and consistent implementation (Kerr et al. 2016; Wang et al. 2016a). (*medium evidence, medium agreement*)

4.8.1.1 Agronomic and soil management measures

Rebuilding soil carbon is an important goal of SLM, particularly in the context of climate change (Rumpel et al. 2018). The two most important reasons why agricultural soils have lost 20-60% of the soil carbon they contained under natural ecosystem conditions are the frequent disturbance through tillage and harvesting and the change from deep rooted perennial plants to shallow rooted annual plants (Crews and Rumsey 2017). Practices that build soil carbon are those that increase organic matter input to soil, or reduce decomposition of soil organic matter.

Agronomic practices can alter the carbon balance significantly, by increasing organic inputs from litter and roots into the soil. Practices include retention of residues, use of locally-adapted varieties, inter-cropping, crop rotations, and green manure crops that replace the bare field fallow during winter and are eventually ploughed before sowing next main crop (Henry et al., 2018). Cover crops (green manure crops and catch crops that are grown between the main cropping seasons) can increase soil carbon stock by between 0.22 and 0.4 t C $ha^{-1}yr^{-1}$ (Poeplau and Don 2015; Kaye and Quemada 2017).

Reduced tillage (or no-tillage) is an important strategy for reducing soil erosion and nutrient loss by wind and water (Van Pelt et al. 2017; Panagos et al. 2015; Borrelli et al. 2016). But the evidence that no-till agriculture also sequesters carbon is not compelling (VandenBygaart 2016). Soil sampling of only the upper 30 cm can give biased results suggesting that soils under no-till practices have higher carbon content than soils under conventional tillage (Baker et al. 2007; Ogle et al. 2012; Fargione et al. 2018; VandenBygaart 2016).

Changing from annual to perennial crops can increase soil carbon content (Culman et al. 2013; Sainju et al. 2017). A perennial grain crop (intermediate wheatgrass) was on average over four years a net carbon sink of about 13.5 t CO_2 $ha^{-1}yr^{-1}$ (de Oliveira et al. 2018). Sprunger et al. (2018) compared an annual winter wheat crop with a perennial grain crop (intermediate wheatgrass) and found that the perennial grain root biomass was 15 times larger than winter wheat, however, there was no significant difference in soil carbon pools after the four-year experiment. Exactly how much, and over what time period, carbon can be sequestered through changing from annual to perennial crops depends on the degree of soil carbon depletion and other local biophysical factors (see also section 4.9.2).

Integrated soil fertility management is a sustainable approach to nutrient management that uses a combination of chemical and organic amendments (manure, compost, biosolids, biochar), rhizobial nitrogen fixation, and liming materials to address soil chemical constraints (Henry et al., 2018). In pasture systems, management of grazing pressure, fertilisation, diverse species including legumes and perennial grasses can reduce erosion and enhance soil carbon (Conant et al. 2017).

4.8.1.2 Mechanical soil and water conservation

In hilly and mountainous terrain terracing is an ancient but still practiced soil conservation method worldwide (Preti and Romano 2014) in climatic zones from arid to humid tropics (Balbo 2017). By reducing the slope gradient of hillsides, terraces provide flat surfaces and deep, loose soils that increase infiltration, reduce erosion and thus sediment transport. They also decrease the hydrological connectivity and thus reduce hillside runoff (Preti et al. 2018; Wei et al. 2016; Arnáez et al. 2015; Chen et al. 2017). In terms of climate change, terraces are a form of adaptation which helps both in cases where rainfall is increasing or intensifying (by reducing slope gradient and the hydrological connectivity), and where rainfall is decreasing (by increasing infiltration and reducing runoff) (*robust evidence*, *high agreement*). There are several challenges, however, to continued maintenance and construction of new terraces, such as the high costs in terms of labour and/or capital (Arnáez et al. 2015) and disappearing local knowledge for maintaining and constructing new terraces (Chen et al. 2017). The propensity of farmers to invest in mechanical soil conservation methods varies with land tenure, farmers with secure tenure arrangements are more willing to invest in durable practices such as terraces (Lovo 2016; Sklenicka et al. 2015; Haregeweyn et al. 2015). Where the slope is less severe, erosion can be controlled by contour banks, and the keyline approach (Duncan 2016; Stevens et al. 2015) to soil and water conservation.

4.8.1.3 Agroforestry

Agroforestry is defined as a collective name for land-use systems in which woody perennials (trees, shrubs, etc.) are grown in association with herbaceous plants (crops, pastures) and/or livestock in a spatial arrangement, a rotation, or both, and in which there are both ecological and economic interactions between the tree and non-tree components of the system (Young, 1995, p. 11). At least since the 1980s agroforestry has been widely touted as an ideal land management practice in areas vulnerable to climate variations and subject to soil erosion. Agroforestry holds the promise of improving of soil and climatic conditions while generating income from wood energy, timber, and non-timber products – sometimes presented as a synergy of adaptation and mitigation of climate change (Mbow et al. 2014).

There is strong scientific consensus that a combination of forestry with agricultural crops and/or livestock, agroforestry systems can provide additional ecosystem services when compared with monoculture crop systems (Waldron et al. 2017; Sonwa et al. 2011a, 2014, 2017; Charles et al. 2013). Agroforestry can enable sustainable intensification by allowing continuous production on the same unit of land with higher productivity without the need to use shifting agriculture systems to maintain crop yields (Nath et al. 2016). This is especially relevant where there is a regional requirement to find a balance between the demand for increased agricultural production and the protection of adjacent natural ecosystems such as primary and secondary forests (Mbow et al. 2014). For example, the use of agroforestry for perennial crops such as coffee and cocoa are increasingly promoted as offering a route to sustainable farming with important climate change adaptation and mitigation co-benefits (Sonwa et al. 2001; Kroeger et al. 2017). Reported co-benefits of agroforestry in cocoa production include increased carbon sequestration in soils and biomass, improved water and nutrient use efficiency and the creation of a favourable micro-climate for crop production (Sonwa et al. 2017; Chia et al. 2016). Importantly, the maintenance of soil fertility using agroforestry has the potential to reduce the practice of shifting-agriculture (of cocoa) which results in deforestation (Gockowski and Sonwa 2011). However, positive interactions within these systems can be ecosystem and/or species specific, but co-benefits such as increased resilience to extreme climate events, or improved soil fertility are not always observed (Blaser et al. 2017; Abdulai et al. 2018). These contrasting outcomes indicate the importance of field scale research programs to inform agroforestry system design, species selection and management practices (Sonwa et al. 2014) .

Despite the many proven benefits, adoption of agroforestry has been low and slow (Toth et al. 2017; National Research Centre for Agroforestry et al. 1999; Pattanayak et al. 2003; Jerneck and Olsson 2014). There are several reasons for the slow uptake, but the perception of risks and the time lag between adoption and realisation of benefits are often important (Pattanayak et al. 2003; Mercer 2004; Jerneck and Olsson 2013).

An important question for agroforestry is whether it supports poverty alleviation, or if it favours comparatively affluent households. Experiences from India suggest that the overall adoption is (s)low and differential between rich and poor households. Brockington el al. (2016), studied agroforestry adoption over many years in South India, they found that overall only 18% of the households adopted agroforestry but among the relatively rich households who adopted agroforestry, 97% of them were still practicing it after 6-8 years and some had expanded their operations. Similar results were obtained in Western Kenya, that food secure households were much more willing to adopt agroforestry than food insecure households (Jerneck and Olsson 2013, 2014). Other experiences from sub-Saharan Africa illustrate the difficulties (such as local institutional support) of having a continued engagement of communities in agroforestry (Noordin et al. 2001; Matata et al. 2013; Meijer et al. 2015).

4.8.1.4 Crop-livestock interaction as an approach to manage land degradation

The integration of crop and livestock production into “mixed farming” for smallholders in developing countries became an influential model, particularly for Africa, in the early 1990s (Pritchard et al. 1992; McIntire et al. 1992). Crop-livestock integration under this model was seen as founded on three pillars; improved use of manure for crop fertility management; expanded use of animal traction (draught animals); and promotion of cultivated fodder crops. For Asia, emphasis was placed on draught power for land preparation, manure for soil fertility enhancement, and fodder production as an entry point for cultivation of legumes (Devendra and Thomas 2002). Mixed farming was seen as an evolutionary process to expand food production in the face of population increase, promote improvements in income and welfare, and protect the environment. The process could be further facilitated and steered by research, extension and policy (Pritchard et al. 1992; McIntire et al. 1992; Devendra 2002) (Pritchard et al., 1992; McIntire et al. 1992; Devendra 1992).

Scoones and Wolmer (2002) place this model in historical context, including concern about population pressure on resources and the view that mobile pastoralism was environmentally damaging. The latter view had already been critiqued by developing understandings of pastoralism, mobility and communal tenure of grazing lands (for example (Behnke 1994; Ellis 1994)). They set out a much more differentiated picture of crop livestock interactions, which can take place either within a single farm household, or between crop and livestock producers, in which case they will be mediated by formal and informal institutions governing the allocation of land, labour and capital, with the interactions evolving through multiple place-specific pathways (Ramisch et al. 2002; Scoones and Wolmer 2002). Promoting a diversity of approaches to crop-livestock interactions does not imply that the integrated model necessarily leads to land degradation, but increases the space for institutional support to local innovation (Scoones and Wolmer 2002).

However, specific managerial and technological practices that link crop and livestock production will remain an important part of the repertoire of on-farm adaptation and mitigation. Howden and coauthors (Howden et al. 2007) note the importance of innovation within existing integrated systems including use of adapted forage crops. Rivera-Ferre et al. (2016) list as adaptation strategies with high potential for grazing systems, mixed crop-livestock systems or both: crop-livestock integration in general; soil management including composting; enclosure and corralling of animal; improved storage of feed. Most of these are seen as having significant co-benefits for mitigation, and improved management of manure is seen as a mitigation measure with adaptation co-benefits.

4.8.2 Local and indigenous knowledge for addressing land degradation

In practice, responses are anchored both in scientific research, as well as local, indigenous and traditional knowledge and know-how. For example, studies in the Philippines Camacho et al. (2016) examine how traditional integrated watershed management by indigenous people sustain regulating services vital to agricultural productivity, while delivering co-benefits in the form of biodiversity and ecosystem resilience at a landscape scale. Although responses can be site specific and sustainable at a local scale, the multi-scale interplay of drivers and pressures can nevertheless cause practices that have been sustainable for centuries to become less so. Siahaya et al (2016) explore the traditional knowledge that has informed rice cultivation in the uplands of East Borneo, grounded in sophisticated shifting cultivation methods (gilir balik) which have been passed on for generations (more than 200 years) in order to maintain local food production. Gilir balik involves temporary cultivation of plots, after which, abandonment takes place as the land user moves to another plot, leaving the natural (forest) vegetation to return. This approach is considered sustainable if it has the support of other subsistence strategies, adapts to and integrates with the local context, and if the carrying capacity of the system is not surpassed (Siahaya et al. 2016). Often gilir balik cultivation involves intercropping of rice with bananas, cassava and other food crops. Once the abandoned plot has been left to recover such that soil fertility is restored, clearance takes place again and the plot is reused for cultivation. Rice cultivation in this way plays an important role in forest management, with several different types of succession forest being found in the study are of Siahaya et al (2016). Nevertheless, interplay of these practices with other pressures (large-scale land acquisitions for oil palm plantation, logging and mining), risk their future sustainability. Use of fire is critical in processes of land clearance, so there are also trade-offs for climate change mitigation which have been sparsely assessed.

Interest appears to be growing in understanding how indigenous and local knowledge inform land users' responses to degradation, as scientists engage farmers as experts in processes of knowledge co-production and co-innovation (Oliver et al. 2012; Bitzer and Bijman 2015). This can help to introduce, implement, adapt and promote the use of locally appropriate responses (Schwilch et al. 2011). Indeed, studies strongly agree on the importance of engaging local populations in both sustainable land and forest management. Meta-analyses in tropical regions that examined both forests in protected areas and community managed forests suggest that deforestation rates are lower, with less variation in deforestation rates presenting in community managed forests compared to protected forests (Porter-Bolland et al. 2012). This suggests that consideration of the social and economic needs of local human populations is vital in preventing forest degradation (Ward et al. 2018). However, while disciplines such as ethnopedology seek to record and understand how local people perceive, classify and use soil, and draw on that information to inform its management (Barrera-Bassols and Zinck 2003), links with climate change and its impacts (perceived and actual) are not generally considered.

4.8.3 Reducing deforestation and forest degradation and increasing afforestation

Improved stewardship of forests through reduction or avoidance of deforestation and forest degradation, and enhancement of forest carbon stocks can all contribute to land-based natural climate solutions (Angelsen et al. 2018; Sonwa et al. 2011b; Griscom et al. 2017). While estimates of annual emissions from tropical deforestation and forest degradation range widely from 0.5 to 3.5 Gt C yr^{-1} (Baccini et al. 2017; Houghton et al. 2012; Mitchard 2018, see also Chapter 2), they all indicate the large potential to reduce annual emissions from deforestation and forest degradation. Recent estimates of forest extent for Africa in 1900 may result in downward adjustments of historic deforestation and degradation emission estimates (Aleman et al. 2018). Emissions from forest degradation in non-Annex I countries have declined marginally from 1.1 $GtCO_2$ yr^{-1} in 2001-2010 to 1 $GtCO_2$ yr^{-1} in 2011-2015, but the relative emissions from degradation compared to deforestation have increased from a quarter to a third (Federici et al. 2015). Forest sector activities in developing countries were estimated to represent a technical mitigation potential in 2030 of 9 Gt CO_2 (Miles et al. 2015). This was partitioned into reduction of deforestation (3.5 Gt CO_2), reduction in degradation and forest management (1.7 Gt CO_2) and afforestation and reforestation (3.8 $GtCO_2$). The economic mitigation potential will be lower than the technical potential (Miles et al. 2015).

Natural regeneration of second-growth forests enhances carbon sinks in the global carbon budget (Chazdon and Uriarte 2016). In Latin America, Chazdon et al. (2016) estimated that in 2008, second-growth forests (1 to 60 years old) covered 2.4 M km^2 of land (28.1% of the total study area). Over 40 years, these lands can potentially accumulate 8.5 Gt C in aboveground biomass via low-cost natural regeneration or assisted regeneration, corresponding to a total CO_2 sequestration of 31.1 Gt CO_2 (Chazdon et al. 2016b). While aboveground biomass carbon stocks are estimated to be declining in the tropics, they are increasing globally due to increasing stocks in temperate and boreal forests (Liu et al. 2015b), consistent with the observations of a global land sector carbon sink (Le Quéré et al. 2013; Keenan et al. 2017; Pan et al. 2011).

Moving from technical mitigation potentials (Miles et al. 2015) to real reduction of emissions from deforestation and forest degradation required transformational changes (Korhonen-Kurki et al. 2018). This transformation can be facilitated by two enabling conditions: the presence of already initiated policy change; or the scarcity of forest resources combined with an absence of any effective forestry framework and policies. These authors and others (Angelsen et al. 2018) found that the presence of powerful transformational coalitions of domestic pro-REDD+ political actors combined with strong ownership and leadership, regulations and law enforcement, and performance-based funding, can provide a strong incentive for achieving REDD+ goals.

Implementing schemes such as REDD+ and various projects related to the voluntary carbon market is often regarded as a no-regrets investment (Seymour and Angelsen 2012) but the social and ecological implications (including those identified in the Cancun Safeguards) must be carefully considered for REDD+ projects to be socially and ecologically sustainable (Jagger et al. 2015). In 2018, 34 countries have submitted a REDD+ forest reference level and/or forest reference emission level to the UNFCCC. Of these REDD+ reference levels, 95% included the activity "reducing deforestation" while 34% included the activity "reducing forest degradation" (FAO 2018). Five countries submitted REDD+ results in the technical annex to their Biannual Update Report (BUR) totalling an emission reduction of 6.3 Gt CO_2 between 2006 and 2015 (FAO 2018).

Afforestation is another mitigation activity that increases carbon sequestration (see also Cross-Chapter Box 2: Implications of large-scale reforestation and afforestation, Chapter 1). Yet, it requires careful consideration about where to plant trees to achieve potential climatic benefits given an altering of local albedo and turbulent energy fluxes and increasing night-time land surface temperatures (Peng et al., 2014). A recent hydro-climatic modelling effort has shown that forest cover can account for about 40% of the observed decrease in annual runoff (Buendia et al. 2016). A meta-analysis of afforestation in Northern Europe (Bárcena and co-authors 2014) concluded that significant soil organic carbon sequestration in Northern Europe occurs after afforestation of croplands but not grasslands. Additional sequestration occurs in forest floors and biomass carbon stocks. Successful programmes of large scale afforestation activities in South Korea and China are discussed in-depth a special case study (Section 4.9.3).

The potential outcome of efforts to reduce emissions from deforestation and degradation in Indonesia through a 2011 moratorium on concessions to convert primary forests to either timber or palm oil uses was evaluated against rates of emissions over the period 2000 to 2010. The study concluded that less than 7% of emissions would have been avoided had the moratorium been implemented in 2000 because it only curtailed emissions due to a subset of drivers of deforestation and degradation (Busch et al. 2015).

In terms of ecological integrity of tropical forests, the policy focus on carbon storage and tree cover can be problematic if it leaves out other aspects of forests ecosystems, such as biodiversity – and particularly fauna (Panfil and Harvey 2016; Peres et al. 2016; Hinsley et al. 2015). Other concerns of forest based projects under the voluntary carbon market are potential negative socio-economic side effects (Edstedt and Carton 2018a; Carton and Andersson 2017; Osborne 2011; Scheidel and Work 2018; Richards and Lyons 2016; Borras and Franco 2018; Paladino and Fiske 2017) and leakage (particularly at the subnational scale), i.e. when interventions to reduce deforestation or degradation at one site displace pressures and increase emissions elsewhere (Atmadja and Verchot 2012; Phelps et al. 2010; Lund et al. 2017; Balooni and Lund 2014).

Maintaining and increasing forest area, in particular of native forests rather than monoculture and short-rotation plantations, contributes to the maintenance of global forest carbon stocks (Lewis et al. 2019) (*robust evidence, high agreement*).

4.8.4 Sustainable forest management and CO_2 removal technologies

While reducing deforestation and forest degradation may help directly meet mitigation goals, sustainable forest management aimed at providing timber, fiber, biomass and non-timber resources can provide long-term livelihood for communities, can reduce the risk of forest conversion to non-forest uses (settlement, crops, etc.), and can maintain land productivity, thus reducing the risks of land degradation (Putz et al. 2012; Gideon Neba et al. 2014; Sufo Kankeu et al. 2016; Nitcheu Tchiadje et al. 2016; Rossi et al. 2017).

Developing sustainable forest management strategies aimed at contributing towards negative emissions throughout this century requires an understanding of forest management impacts on ecosystem carbon stocks (including soils), carbon sinks, carbon fluxes in harvested wood, carbon storage in harvested wood products including landfills and the emission reductions achieved through the use of wood products and bioenergy (Nabuurs et al. 2007; Lemprière et al. 2013; Kurz et al. 2016; Law et al. 2018; Nabuurs et al. 2017). Transitions from natural to managed forest landscapes can involve a reduction in forest carbon stocks, the magnitude of which depends on the initial landscape conditions, the harvest rotation length relative to the frequency and intensity of natural disturbances and on the age-dependence of managed and natural disturbances (Harmon et al. 1990; Kurz et al. 1998a). Initial landscape conditions, in particular the age-class distribution and therefore C stocks of the landscape strongly affect the mitigation potential of forest management options (Ter-Mikaelian et al. 2013; Kilpeläinen et al. 2017). Landscapes with predominantly mature forests may experience larger reductions in carbon stocks during the transition to managed landscapes (Harmon et al. 1990;

Kurz et al. 1998b; Lewis et al. 2019) while in landscapes with predominantly young or recently disturbed forests sustainable forest management can enhance carbon stocks (Henttonen et al. 2017).

Forest growth rates, net primary productivity, and net ecosystem productivity are age-dependent with maximum rates of carbon removal from the atmosphere occurring in young to medium aged forests and declining thereafter (Tang et al. 2014). In boreal forest ecosystem, estimation of carbon stocks and carbon fluxes indicate that old growth stands are typically small carbon sinks or carbon sources (Gao et al. 2018; Taylor et al. 2014; Hadden and Grelle 2016). In tropical forests, carbon uptake rates in the first 20 years of forest recovery were 11 times higher than uptake rates in old-growth forests (Poorter et al. 2016). Age-dependent increases in forest carbon stocks and declines in forest carbon sinks mean that landscapes with older forests have accumulated more carbon but their sink strength is diminishing, while landscapes with younger forests contain less carbon but they are removing CO_2 from the atmosphere at a much higher rate (Volkova et al. 2017; Poorter et al. 2016). The rates of carbon removal are not just age-related but also controlled by many biophysical factors and human activities (Bernal et al. 2018) and in ecosystems with uneven-aged, multispecies forests the relationships between carbon stocks and sinks are more difficult and expensive to quantify.

Whether or not forest harvest and use of biomass is contributing to net reductions of atmospheric carbon depends on carbon losses during and following harvest, rates of forest regrowth, and the use of the harvested wood and the carbon retention in long-lived or short-lived products as well as the emission reductions achieved through the substitution of emissions-intensive products with wood products (Lemprière et al. 2013; Lundmark et al. 2014; Xu et al. 2018b; Olguin et al. 2018; Dugan et al. 2018; Chen et al. 2018b; Pingoud et al. 2018; Seidl et al. 2007). Studies that ignore changes in forest carbon stocks (such as some life cycle analyses that assume no impacts of harvest on forest carbon stocks), ignore changes in wood product pools (Mackey et al. 2013) or assume long-term steady state (Pingoud et al. 2018), or ignore changes in emissions from substitution benefits (Mackey et al. 2013; Lewis et al. 2019) will arrive at diverging conclusions about the benefits of sustainable forest management. Moreover, assessments of climate benefits of any mitigation action must also consider the time dynamics of atmospheric impacts as some actions will have immediate benefits (e.g. avoided deforestation) while others may not achieve net atmospheric benefits for decades or centuries. For example, the climate benefits of woody biomass use for bioenergy depend on several factors such as the source and alternate fate of the biomass, the energy type it substitutes and the rates of regrowth of the harvested forest (Laganière et al. 2017; Ter-Mikaelian et al. 2014; Smyth et al. 2017). Conversion of primary forests in regions of very low stand replacing disturbances to short-rotation plantations where the harvested wood is used for short-lived products with low displacement factors will increase emissions. In general, greater mitigation benefits are achieved if harvested wood products are used for products with long carbon retention time and high displacement factors.

With increasing forest age, carbon sinks in forests will diminish until harvest or natural disturbances such as wildfire remove biomass carbon or release it to the atmosphere (Seidl et al. 2017). While individual trees can accumulate carbon for centuries (Köhl et al. 2017), stand level carbon accumulation rates depend on both tree growth and tree mortality rates (Hember et al. 2016; Lewis et al. 2004). Sustainable forest management, including harvest and forest regeneration, can help maintain active carbon sinks by maintaining a forest age-class distribution that includes a share of young, actively growing stands (Volkova et al. 2018; Nabuurs et al. 2017). The use of the harvested carbon in either long-lived wood products (e.g. for construction), short-lived wood products (e.g., pulp and paper), or biofuels affects the net carbon balance of the forest sector (Lemprière et al. 2013; Matthews et al. 2018). The use of these wood products can further contribute to GHG emission reduction goals by avoiding the emissions from the products with higher embodied emissions that have been displaced (Nabuurs et al. 2007; Lemprière et al. 2013). In 2007 the IPCC concluded that "[i]n the long term, a sustainable forest management strategy aimed at maintaining or increasing forest carbon stocks, while producing an annual sustained yield of timber, fibre or energy from the forest, will generate the largest sustained mitigation benefit" (Nabuurs et al. 2007).–The apparent trade-offs between maximising forest C stocks and maximising ecosystem C sinks are at the origin of ongoing debates about optimum management strategies to achieve negative emissions (Keith et al. 2014; Kurz et al. 2016; Lundmark et al. 2014). Sustainable forest management, including the intensification of carbon-focussed management strategies, can make long-term contributions towards negative emissions if the sustainability of management is assured through appropriate governance, monitoring and enforcement. As specified in the definition of sustainable forest management, other criteria such as biodiversity must also be considered when assessing mitigation outcomes (Lecina-Diaz et al. 2018). Moreover, the impacts of changes in management on albedo and other non-GHG factors also need to be considered (Luyssaert et al. 2018) (See also Chapter 2). The contribution of sustainable forest management for negative emissions is strongly affected by the use of the wood products derived from forest harvest and the time horizon over which the carbon balance is assessed. Sustainable forest management needs to anticipate the impacts of climate change on future tree growth, mortality and disturbances when designing climate change mitigation and adaptation strategies (Valade et al. 2017; Seidl et al. 2017).

4.8.5 Policy responses to land degradation

The 1992 United Nations Conference on Environment and Development (UNCED), also known as the Rio de Janeiro Earth Summit, recognised land degradation as a major challenge to sustainable development, and led to the establishment of the United Nations Convention to Combat Desertification (UNCCD), which addressed specifically land degradation in the drylands. The UNCCD emphasizes sustainable land use to link poverty reduction on one hand and environmental protection on the other. The two other "Rio Conventions" emerging from the UNCED, the United Nations Framework Convention on Climate Change (UNFCCC) and the Convention on Biological Diversity (CBD), focus on climate change and biodiversity, respectively. The land has been recognized as an aspect of common interest to the three conventions, and sustainable land management (SLM) is proposed as a unifying theme for current global efforts on combating land degradation, climate change and loss of biodiversity, as well as facilitating land-based adaptation to climate change and sustainable development.

The Global Environmental Facility (GEF) funds developing countries to undertake activities that meet the goals of the conventions and deliver global environmental benefits. Since 2002, the GEF has invested in projects that support sustainable land management through its Land Degradation Focal Area Strategy, to address land degradation within and beyond the drylands.

Under the UNFCCC, parties have devised National Adaptation Plans (NAPs) that identify medium- and long-term adaptation needs. Parties have also developed their climate change mitigation plans, presented as Nationally Determined Contributions (NDCs). These programs have the potential of assisting the promotion of SLM. It is realised that the root causes of land degradation and successful adaptation will not be realised until holistic solutions to land management are explored. SLM can help address root causes of low productivity, land degradation, loss of income generating capacity as well as contribute to the amelioration of the adverse effects of climate change.

The "4 per 1000" (4p1000) initiative (Soussana et al. 2019) launched by France during the UNFCCC COP21 in 2015 aims at capturing CO_2 from the atmosphere through changes to agricultural and forestry practices at a rate that would increase the carbon content of soils by 0.4% per year (Rumpel et al. 2018). If global soil carbon content increases at this rate in the top 30-40 cm, the annual increase in atmospheric CO_2 would be stopped (Dignac et al. 2017). This is an illustration of how extremely important soils are for addressing climate change. The initiative is based on eight steps: stop carbon loss (priority #1 is peat soils); promote carbon uptake; monitor, report, and verify impacts; deploy technology for tracking soil carbon; test strategies for implementation and upscaling; involve communities; coordinate policies; provide support (Rumpel et al. 2018). Questions remain however, to what extent the 4p1000 is achievable as a universal goal (van Groenigen et al. 2017; Poulton et al. 2018; Schlesinger and Amundson 2018).

Land degradation neutrality (LDN) was introduced by the UNCCD at Rio +20, and adopted at UNCCD COP12 (UNCCD 2016a). LDN is defined as "a state whereby the amount and quality of land resources necessary to support ecosystem functions and services and enhance food security remain stable or increase within specified temporal and spatial scales and ecosystems". Pursuit of LDN requires effort to avoid further net loss of the land-based natural capital relative to a reference state, or baseline. LDN encourages a dual-pronged effort involving sustainable land management to reduce the risk of land degradation, combined with efforts in land restoration and rehabilitation, to maintain or enhance land-based natural capital, and its associated ecosystem services (Orr et al., 2017; Cowie et al. 2018;). Planning for LDN involves projecting the expected cumulative impacts of land use and land management decisions, then counterbalancing anticipated losses with measures to achieve equivalent gains, within individual land types (where land type is defined by land potential). Under LDN framework developed by UNCCD, three primary indicators are used to assess whether LDN is achieved by 2030: land cover change, net primary productivity and soil organic carbon (Cowie et al. 2018; Sims et al., 2019. Achieving LDN therefore requires integrated landscape management that seeks to optimize land use to meet multiple objectives (ecosystem health, food security, human well-being) (Cohen-Shacham, E., Walters, G., Janzen, C. and Maginnis 2016). The response hierarchy of Avoid > Reduce > Reverse land degradation articulates the priorities in planning LDN interventions. LDN provides the impetus for widespread adoption of SLM and efforts to restore or rehabilitate land. Through its focus LDN ultimately provides tremendous potential for mitigation of and adaptation to climate change by halting and reversing land degradation and transforming land from a carbon source to a sink. There are strong synergies between the concept of LDN and the Nationally Determined Contributions (NDCs) of many countries with linkages to national climate plans. LDN is also closely related to many Sustainable Development Goals (SDG) in the areas of poverty, food security, environmental protection and sustainable use of natural resources (UNCCD 2016b). The GEF is supporting countries to set LDN targets and implement their LDN plans through its land degradation focal area, which encourages application of integrated landscape approach to managing land degradation (GEF 2018).

The 2030 agenda for sustainable development, adopted by the United Nations in 2015, comprises 17 Sustainable Development Goals (SDGs). Goal 15 is of direct relevance to land degradation with the objective to protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification and halt and reverse land degradation and halt biodiversity loss. Target 15.3 specifically addresses land degradation neutrality. Other goals that are relevant for land degradation include goal 2 (Zero hunger), goal 3 (Good health and well-being), goal 7 (Affordable and clean energy), goal 11 (Sustainable cities and communities), and goal 12 (Responsible production and consumption). Sustainable management of land resources underpins the SDGs related to hunger, climate change and environment. Further goals of a cross-cutting nature include 1 (No poverty), 6 (Clean water and sanitation) and 13 (Climate action). It remains to be seen how these interconnections are dealt with in practice.

With a focus on biodiversity, IPBES published a comprehensive assessment of land degradation in 2018 (Montanarella et al. 2018). The IPBES report, together with this report focusing on climate change, may contribute to create synergy between the two main global challenges for addressing land degradation in order to help achieving the goals of SDG 15 (Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss).

Market based mechanisms like the Clean Development Mechanism (CDM) under the UNFCCC and the voluntary carbon market provide incentives to enhance carbon sinks on the land through afforestation and reforestation. Implications for local land use and food security have been raised as a concern and need to be assessed (Edstedt and Carton 2018b; Olsson et al. 2014b). Many projects aimed at reducing emissions from deforestation and forest degradations (not to be confused with the national REDD+ programs in accordance with the UNFCCC Warsaw Framework) are being planned and implemented primarily targeting countries with high forest cover and high deforestation rates. Some parameters of incentivising emissions reduction, quality of forest governance, conservation priorities, local rights and tenure frameworks, and sub-national project potential are being looked into with often very mixed results (Newton et al. 2016; Gebara and Agrawal 2017).

Besides international public initiatives, some actors in the private sector are increasingly aware of the negative environmental impacts of some global value chains producing food, fibre, and energy products (Lambin et al. 2018; van der Ven and Cashore 2018; van der Ven et al. 2018; Lyons-White and Knight 2018). While improvement is under way in many supply chains, measures implemented so far are often insufficient to be effective in reducing or stopping deforestation and forest degradation (Lambin et al. 2018). The GEF is investing in actions to reduce deforestation in commodity supply chains through its Food Systems, Land Use, and Restoration Impact Program (GEF 2018).

4.8.5.1 Limits to adaptation

SLM can be deployed as a powerful adaptation strategy in most instances of climate change impacts on natural and social systems, yet there are limits to adaptation (Klein, R.J.T., G.F. Midgley, B.L. Preston, M. Alam, F.G.H. Berkhout, K. Dow 2014; Dow et al. 2013a). Such limits are dynamic and interact with social and institutional conditions (Barnett et al. 2015; Filho and Nalau 2018). Exceeding adaptation limits will trigger escalating losses or require undesirable transformational change, such as forced migration. The rate of change in relation to the rate of possible adaptation is crucial (Dow et al. 2013b). How limits to adaptation are defined and how they can be measured is contextual and contested. Limits must be assessed in relation to the ultimate goals of adaptation, which is subject to diverse and differential values (Dow et al. 2013b; Adger et al. 2009). A particularly sensitive issue is whether migration is accepted as adaptation or not (Black et al. 2011; Tacoli 2009; Bardsley and Hugo 2010). If migration were understood and accepted as a form of successful adaptation, it would change the limits to adaptation by reducing or even avoiding future humanitarian crises caused by climate extremes (Adger et al. 2009; Upadhyay et al. 2017; Nalau et al. 2018).

In the context of land degradation potential limits to adaptation exist if land degradation becomes so severe and irreversible that livelihoods cannot be maintained, and if migration is either not acceptable or possible. Examples are coastal erosion where land disappears (Gharbaoui and Blocher 2016; Luetz 2018), collapsing livelihoods due to thawing of permafrost (Landauer and Juhola 2019), and extreme forms of soil erosion (e.g., landslides (Van der Geest and Schindler 2016) and gully erosion leading to badlands (Poesen et al. 2003)).

4.8.6 Resilience and thresholds

Resilience refers to the capacity of interconnected social, economic and ecological systems, such as farming systems, to absorb disturbance (e.g., drought, conflict, market collapse), and respond or reorganise, to maintain their essential function, identity and structure. Resilience can be described as "coping capacity". The disturbance may be a shock - sudden events such as a flood or disease epidemic – or it may be a trend that develops slowly, like a drought or market shift. The shocks and trends anticipated to occur due to climate change are expected to exacerbate risk of land degradation. Therefore, assessing and enhancing resilience to climate change is a critical component of designing sustainable land management strategies.

Resilience as an analytical lens is particularly strong in ecology and related research on natural resource management (Folke et al. 2010; Quinlan et al. 2016) while in the social sciences the relevance of resilience for studying social and ecological interactions is contested (Cote and Nightingale 2012; Olsson et al. 2015; Cretney 2014; Béné et al. 2012; Joseph 2013). In the case of adaptation to climate change (and particularly regarding limits to adaptation), a crucial ambiguity of resilience is the question whether resilience is a normative concept (i.e. resilience is good or bad) or is a descriptive characteristic of a system (i.e. neither good nor bad). Previous IPCC reports have defined resilience as a normative (positive) attribute (see AR5 Glossary), while the wider scientific literature is divided on this (Weichselgartner and Kelman 2015; Strunz 2012; Brown 2014; Grimm and Calabrese 2011; Thorén and Olsson 2018). For example, is outmigration from a disaster prone area considered a successful adaptation (high resilience) or a collapse of the livelihood system (lack of resilience) (Thorén and Olsson 2018)? In this report resilience is considered a positive attribute when it maintains capacity for adaptation, learning and/or transformation.

Furthermore, resilience and the related terms adaptation and transformation are defined and used differently by different communities (Quinlan et al. 2016). The relationship and hierarchy of resilience with respect to vulnerability and adaptive capacity are also debated, with different perspectives between the disaster management, and global change communities, (e.g., Cutter et al. 2008). Nevertheless, these differences in usage need not inhibit the application of “resilience thinking” in managing land degradation; researchers using these terms, despite variation in definitions, apply the same fundamental concepts to inform management of human-environment systems, to maintain or improve the resource base, and sustain livelihoods.

Applying resilience concepts involves viewing the land as a component of an interlinked social-ecological system; identifying key relationships that determine system function and vulnerabilities of the system; identifying thresholds or tipping points beyond which the system transitions to an undesirable state; and devising management strategies to steer away from thresholds of potential concern, thus facilitating healthy systems and sustainable production (Walker et al., 2009).

A threshold is a non-linearity between a controlling variable and system function, such that a small change in the variable causes the system to shift to an alternative state. Bestelmeyer et al. (2015) and Prince et al. (2018) illustrate this concept in the context of land degradation. Studies have identified various biophysical and socio-economic thresholds in different land-use systems. For example, 50% ground cover (living and dead plant material and biological crusts) is a recognised threshold for dryland grazing systems (e.g., (Tighe et al. 2012); below this threshold infiltration rate declines, risk of erosion causing loss of topsoil increases, a switch from perennial to annual grass species occurs and there is a consequential sharp decline in productivity. This shift to a lower-productivity state cannot be reversed without significant human intervention. Similarly, the combined pressure of water limitations and frequent fire can lead to transition from closed forest to savannah or grassland: if fire is too frequent trees do not reach reproductive maturity and post-fire regeneration will fail; likewise, reduced rainfall / increased drought prevents successful forest regeneration (Reyer et al. 2015; Thompson et al. 2009) see also Cross-chapter box 3 on Fire and climate change, Chapter 2.

In managing land degradation, it is important to assess the resilience of the existing system, and the proposed management interventions. If the existing system is in an undesirable state or considered unviable under expected climate trends, it may be desirable to promote adaptation or even transformation to a different system that is more resilient to future changes. For example, in an irrigation district where water shortages are predicted, measures could be implemented to improve water use efficiency, for example by establishing drip irrigation systems for water delivery, although transformation to pastoralism or mixed dryland cropping/livestock production may be more sustainable in the longer term, at least for part of the area. Application of sustainable land management practices, especially those focussed on ecological functions (e.g., agroecology, ecosystem-based approaches, regenerative agriculture, organic farming), can be effective in building resilience of agro-ecosystems (Henry et al. 2018). Similarly, the resilience of managed forests can be enhanced by sustainable forest management that protects or enhances biodiversity, including assisted migration of tree species within their current range limit (Winder et al. 2011; Pedlar et al. 2012) or increasing species diversity in plantation forests (Felton et al. 2010; Liu et al. 2018a). The essential features of a resilience approach to management of land degradation under climate change are described by (O'Connell et al. 2016; Simonsen et al. 2014).

Consideration of resilience can enhance effectiveness of interventions to reduce or reverse land degradation (*medium agreement, limited evidence*). This approach will increase the likelihood that SLM/SFM and land restoration/rehabilitation interventions achieve long-term environmental and social benefits. Thus, consideration of resilience concepts can enhance the capacity of land systems to cope with climate change and resist land degradation, and assist land use systems to adapt to climate change.

4.8.7 Barriers to implementation of sustainable land management

There is a growing recognition that addressing barriers and designing solutions to complex environmental problems, such as land degradation, requires awareness of the larger system into which the problems and solutions are embedded (Laniak et al. 2013). An ecosystem approach to SLM based on understanding of the processes of land degradation has been recommended that can separate multiple drivers, pressures and impacts (Kassam et al. 2013), but large uncertainty in model projections of future climate, and associated ecosystem processes (IPCC 2013a) pose additional challenges to the implementation of SLM. As discussed earlier in this chapter, many SLM practices, including both technologies and approaches, are available that can increase yields and contribute to closing the yield gap between actual and potential crop or pasture yield, while also enhancing resilience to climate change (Yengoh and Ardö 2014; WOCAT). However, there are often systemic barriers to adoption and scaling up of SLM practices, especially in developing countries.

Uitto (2016) identified areas that the GEF, the financial mechanism of the UNCCD, UNFCCC and other multilateral environmental agreements, can address to solve global environmental problems. This includes removal of barriers related to knowledge and information; strategies for implementation of technologies and approaches; and institutional capacity. Strengthening these areas would drive transformational change leading to behavioral change and broader adoption of sustainable environmental practices. Detailed analysis of barriers as well as strategies, methods and approaches to scale up SLM have been undertaken for GEF programs in Africa, China and globally (Tengberg and Valencia 2018; Liniger et al. 2011; Tengberg et al. 2016). A number of interconnected barriers and bottlenecks to the scaling up of SLM have been identified in this context and are related to:

- Limited access to knowledge and information, including new SLM technologies and problem-solving capacities;
- Weak enabling environment, including the policy, institutional and legal framework for SLM, and land tenure and property rights;
- Inadequate learning and adaptive knowledge management in the project cycle, including monitoring and evaluation of impacts; and
- Limited access to finance for scaling up, including public and private funding, innovative business models for SLM technologies and financial mechanisms and incentives, such as payments for ecosystem services (PES), insurance and micro-credit schemes (see also Shames et al 2014).

Adoption of innovations and new technologies are increasingly analysed using the transition theory framework (Geels 2002), the starting point being the recognition that many global environmental problems cannot be solved by technological change alone but require more far-reaching change of social-ecological systems. Using transition theory makes it possible to analyse how adoption and implementation follow the four stages of sociotechnical transitions, from predevelopment of technologies and approaches at the niche level, take-off and acceleration, to regime shift and stabilisation at the landscape level. According to a recent review of sustainability transitions in developing countries (Wieczorek 2018), three internal niche processes are important, including the formation of networks that support and nurture innovation, the learning process and the articulation of expectations to guide the learning process. While technologies are important, institutional and political aspects form the major barriers to transition and upscaling. In developing and transition economies, informal institutions play a pivotal role and transnational linkages are also important, such as global value chains. In these countries, it is therefore more difficult to establish fully coherent regimes or groups of individuals who share expectations, beliefs or behavior, as there is a high level of uncertainty about rules and social networks or dominance of informal institutions, which creates barriers to change. This uncertainty is further exacerbated by climate change. Landscape forces comprise a set of slow changing factors, such as broad cultural and normative values, long-term economic effects such as urbanisation, and shocks such as war and crises that can lead to change.

A study on SLM in the Kenyan highlands using transition theory concluded that barriers to adoption of SLM included high poverty levels, a low input-low output farming system with limited potential to generate income, diminishing land sizes and low involvement of the youth in farming activities. Coupled with a poor coordination of government policies for agriculture and forestry, these barriers created negative feedbacks in the SLM transition process. Other factors to consider include gender issues and lack of secure land tenure. Scaling up of SLM technologies would require collaboration of diverse stakeholders across multiple scales, a more supportive policy environment and substantial resource mobilisation (Mutoko et al. 2014). Tengberg and Valencia (2018) analysed the findings from a review of the GEF integrated natural resources management portfolio of projects using the transition theory framework (Figure 4.7). They concluded that to remove barriers to SLM, an agricultural innovations systems approach that supports co-production of knowledge with multiple stakeholders, institutional innovations, a focus on value chains and strengthening of social capital to facilitate shared learning and collaboration could accelerate the scaling up of sustainable technologies and practices from the niche to the landscape level. Policy integration and establishment of financial mechanisms and incentives could contribute to overcoming barriers to a regime shift. The new SLM regime could in turn be stabilised and sustained at the landscape level by multi-stakeholder knowledge platforms and strategic partnerships. However, transitions to more sustainable regimes and practices are often challenged by lock-in mechanisms in the current system (Lawhon and Murphy 2012), such as economies of scale, investments already made in equipment, infrastructure and competencies, lobbying, shared beliefs, and practices, which could hamper wider adoption of SLM.

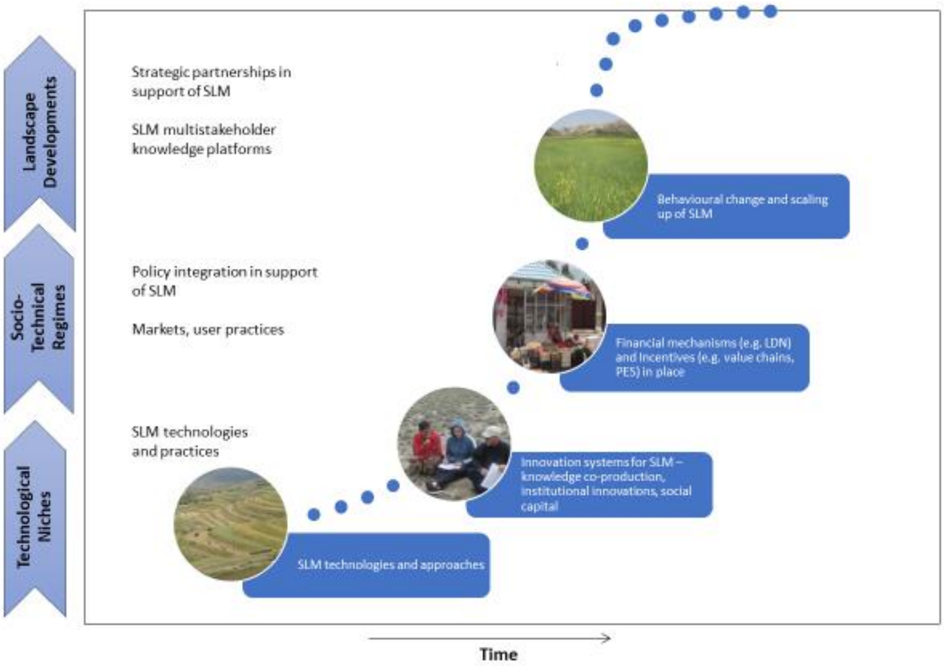

Figure 4.7 The transition from SLM niche adoption to regime shift and landscape development (figure draws inspiration from (Geels 2002)). Adapted from (Tengberg and Valencia 2018)

Adaptive, multi-level and participatory governance of social-ecological systems is considered important for regime shifts and transitions to take place (Wieczorek 2018) and essential to secure the capacity of environmental assets to support societal development over longer time periods (Folke et al. 2005). There is also recognition that effective environmental policies and programs need to be informed by a comprehensive understanding of the biophysical, social, and economic components and processes of a system, their complex interactions, and how they respond to different changes (Kelly (Letcher) et al. 2013). But blueprint policies will not work due to the wide diversity of rules and informal institutions used across sectors and regions of the world, especially in traditional societies (Ostrom 2009).

The most effective way of removing barriers to funding of SLM has been mainstreaming of SLM objectives and priorities into relevant policy and development frameworks and combining SLM best practices with economic incentives for land users. As the short-term costs for establishing and maintaining SLM measures are generally high and constitute a barrier to adoption, land users may need to be compensated for generation of longer-term public goods, such as ecosystem services. Cost-benefit analyses can be conducted on SLM interventions to facilitate such compensations (Liniger et al. 2011; Nkonya et al. 2016; Tengberg et al. 2016). The landscape approach is a means to reconcile competing demands on the land and remove barriers to implementation of SLM (e.g. Sayer et al. 2013; Bürgi et al. 2017). It involves an increased focus on participatory governance, development of new SLM business models, and innovative funding schemes including insurance (Shames et al. 2014). The Land Degradation Neutrality (LDN) Fund takes a landscape approach and raises private finance for SLM and promotes market-based instruments, such as Payment for Ecosystem Services (PES), certification and carbon trading, that can support scaling up of SLM to improve local livelihoods, sequester carbon and enhance the resilience to climate change.

4.9 Case-studies

Climate change impacts on land degradation can be avoided, reduced or even reversed, but need to be addressed in a context sensitive manner. Many of the responses described in this section can also provide synergies of adaptation and mitigation. In this section we provide more in-depth analysis of a number of salient aspects of how land degradation and climate change interact. Table 4.3 is a synthesis of how of these case studies relate to climate change and other broader issues in terms of co-benefits.

Table 4.3 Synthesis of how the case studies interact with climate change and a broader set of co-benefits

Case studies (4.10) (4.9)	Mitigation benefits and potential	Adaptation benefits	Co-benefits		Legend
Urban green infrastructure (4.10.1) (4.9.1) An increasing majority of the world population live in cities and land degradation is an urgent matter for urban areas			human health, recreation		carbon sink
Perennial grains (4.10.2) (4.9.2) After 40 years of breeding, perennial grains now seem to have the potential of reducing climate impacts of agriculture while increasing its overall sustainability			reduced use of herbicides, reduced soil erosion and nutrient leakage		reduced emission
Reforestation (4.10.3) (4.9.3) Two cases of successful reforestation serve as illustrations of the potential of sustained efforts into reforestation			economic return from sustainable forestry, reduced flood risk downstream		
Managment of peat soils (4.10.4) (4.9.4) Degradation of peat soils in tropical and arctic regions is a major source of greenhouse gases, hence an urgent mitigation option			improved air quality in tropical regions		reduced flood risk
Biochar (4.10.5) (4.9.5) Biochar is a land managent technique of high potential, but controversial			improved soil fertility		reduced heat stress
Protection against hurricane damages (4.10.6) (4.9.6) More severe tropical cyclones increase the risk of land degradation in some areas, hence the need for increased adaptation			reduced losses (human lives, livelihoods, and assets)		drought resistance
Responses to salt water intrusion (4.10.7) (4.9.7) The combined effect of climate induced sealevel rise and land use change in coastal regions increases the risk of saltwater intrusion in many coastal regions			improved food and water security,		storm protection
Avoiding coastal maladaptation (4.10.8) (4.9.8) Low lying coastal areas are in urgent need of adaptation, but examples have resulted in maladaptation			reduced losses (human lives, livelihoods, and assets)		protection against sea level rise

4.9.1 Urban green infrastructure

Over half the world's population now lives in towns and cities, a proportion that is predicted to increase to ~70% by the middle of the century (United Nations 2015). Rapid urbanisation is a severe threat to land and the provision of ecosystem services (Seto et al. 2012). However, as cities expand, the avoidance of land degradation, or the maintenance/enhancement of ecosystem services is rarely considered in planning processes. Instead economic development and the need for space for construction is prioritised, which can result in substantial pollution of air and water sources, the degradation of existing agricultural areas and indigenous, natural or semi-natural ecosystems both within and outside of urban areas. For instance, urban areas are characterised by extensive impervious surfaces. Degraded, sealed soils beneath these surfaces do not provide the same quality of water retention as intact soils. Urban landscapes comprising 50-90% impervious surfaces can therefore result in 40-83% of rainfall becoming surface water runoff (Pataki et al. 2011). With rainfall intensity predicted to increase in many parts of the world under climate change (Royal Society 2016), increased water runoff is going to get worse. Urbanisation, land degradation and climate change are therefore strongly interlinked, suggesting the need for common solutions (Reed and Stringer 2016b).

There is now a large body of research and application demonstrating the importance of retaining urban green infrastructure (UGI) for the delivery of multiple ecosystem services (DG Environment News Alert Service, 2012; Wentworth, 2017) as an important tool to mitigate and adapt to climate change. UGI can be defined as all green elements within a city, including but not limited to retained indigenous ecosystems, parks, public greenspaces, green corridors, street trees, urban forests, urban agriculture, green roofs/walls and private domestic gardens (Tzoulas et al. 2007). The definition is usually extended to include 'blue' infrastructure, such as rivers, lakes, bioswales and other water drainage features. The related concept of Nature Based Solutions (defined as: living solutions inspired by, continuously supported by and using nature, which are designed to address various societal challenges in a resource-efficient and adaptable manner and to provide simultaneously economic, social, and environmental benefits) has gained considerable traction within the European Commission as one approach to mainstreaming the importance of UGI (Maes and Jacobs 2017; European Union 2015).

Through retaining existing vegetation and ecosystems, revegetating previous developed land or integrating vegetation into buildings in the form of green walls and roofs, UGI can play a direct role in mitigating climate change through carbon sequestration. However, compared to overall carbon emissions from cities, effects will be small. Given that UGI necessarily involves the retention and management of non-sealed surfaces, co-benefits for land degradation (e.g. soil compaction avoidance, reduced water run-off, carbon storage and vegetation productivity; (Davies et al. 2011; Edmondson et al. 2011, 2014; Yao et al. 2015) will also be apparent. Although not currently a priority, its role in mitigating land degradation could be substantial. For instance, appropriately managed innovative urban agricultural production systems, such as vertical farms, could have the potential to both meet some of the food needs of cities and reduce the production (and therefore degradation) pressure on agricultural land in rural areas, although thus far this is unproven (for a recent review (Wilhelm and Smith 2018)).

The importance of UGI as part of a climate change adaptation approach has received greater attention and application (Gill et al. 2007; Fryd et al. 2011; Demuzere et al. 2014; Sussams et al. 2015). The EU's Adapting to Climate Change White Paper emphasises the "crucial role in adaptation in providing essential resources for social and economic purposes under extreme climate conditions" (CEC, 2009, p. 9). Increasing vegetation cover, planting street trees and maintaining/expanding public parks reduces temperatures (Cavan et al. 2014; Di Leo et al. 2016; Feyisa et al. 2014; Tonosaki K, Kawai S 2014; Zölch et al. 2016). Further, the appropriate design and spatial distribution of greenspaces within cities can help to alter urban climates to improve human health and comfort (e.g. (Brown and Nicholls 2015; Klemm et al. 2015)). The use of green walls and roofs can also reduce energy use in buildings (e.g. (Coma et al. 2017)). Similarly, natural flood management and ecosystem based approaches of providing space for water, renaturalising rivers and reducing surface run-off through the presence of permeable surfaces and vegetated features (including walls and roofs) can manage flood risks, impacts and vulnerability (e.g. (Gill et al. 2007; Munang et al. 2013)). Access to UGI in times of environmental stresses and shock can provide safety nets for people and can, therefore, be an important adaptation mechanism, both to climate change (Potschin et al. 2016) and land degradation.

Most examples of UGI implementation as a climate change adaptation strategy have centered on its role in water management for flood risk reduction. The importance for land degradation is either not stated, or not prioritized. In Beira, Mozambique, the government is using UGI to mitigate against increased flood risks predicted to occur under climate change and urbanisation, which will be done by improving the natural water capacity of the Chiveve River. As part of the UGI approach, mangrove habitats have been restored and future phases include developing new multi-functional urban green spaces along the river (World Bank 2016). The retention of green spaces within the city will have the added benefit of halting further degradation in those areas. Elsewhere, planning mechanisms promote the retention and expansion of green areas within cities to ensure ecosystem service delivery, which directly halts land degradation, but are largely viewed and justified in the context of climate change adaptation and mitigation. For instance, the Landscape Programme in Berlin includes five plans, one of which covers adapting to climate change through the recognition of the role of UGI (Green Surge 2016). Major climate related challenges facing Durban, South Africa, include sea level rise, urban heat island, water runoff and conservation (Roberts and O'Donoghue 2013). Now considered a global leader in climate adaptation planning (Roberts 2010), Durban's Climate Change Adaptation plan includes the retention and maintenance of natural ecosystems in particular those which are important for mitigating flooding, coastal erosion, water pollution, wetland siltation and climate change (eThekwini Municipal Council 2014).

4.9.2 Perennial Grains and Soil Organic Carbon

The severe ecological perturbation that is inherent in the conversion of native perennial vegetation to annual crops, and the subsequent high frequency of perturbation required to maintain annual crops, results in at least four forms of soil degradation that will be exacerbated by the effects of climate change (Crews et al. 2016). First, soil erosion is a very serious consequence of annual cropping with median losses exceeding rates of formation by 1-2 orders of magnitude in conventionally plowed agroecosystems, and while erosion is reduced with conservation tillage, median losses still exceed formation by several fold (Montgomery 2007). More severe storm intensity associated with climate change is expected to cause even greater losses to wind and water erosion (Nearing et al. 2004b). Secondly, the periods of time in which live roots are reduced or altogether absent from soils in annual cropping systems allow for substantial losses of nitrogen from fertilised croplands, averaging 50% globally (Ladha et al. 2005). This low retention of nitrogen is also expected to worsen with more intense weather events (Bowles et al. 2018). A third impact of annual cropping is the degradation of soil structure caused by tillage, which can reduce infiltration of precipitation, and increase surface runoff. It is predicted that the percentage of precipitation that infiltrates into agricultural soils will decrease further under climate change scenarios (Basche and DeLonge 2017; Wuest et al. 2006). The fourth form of soil degradation that results from annual cropping is the reduction of soil organic matter (SOM), a topic of particular relevance to climate change mitigation and adaptation.

Undegraded cropland soils can theoretically hold far more SOM (which is ~58% carbon) than they currently do (Soussana et al. 2006). We know this deficiency because, with few exceptions, comparisons between cropland soils and those of proximate mature native ecosystems commonly show a 40-75% decline in soil carbon attributable to agricultural practices. What happens when native ecosystems are converted to agriculture that induces such significant losses of SOM? Wind and water erosion commonly results in preferential removal of light organic matter fractions that can accumulate on or near the soil surface (Lal 2003). In addition to the effects of erosion, the fundamental practices of growing annual food and fiber crops alters both inputs and outputs of organic matter from most agroecosystems resulting in net reductions in soil carbon equilibria (Soussana et al. 2006; McLauchlan 2006; Crews et al. 2016). Native vegetation of almost all terrestrial ecosystems is dominated by perennial plants, and the belowground carbon allocation of these perennials is a key variable in determining formation rates of stable soil organic carbon (SOC) (Jastrow et al. 2007; Schmidt et al. 2011). When perennial vegetation is replaced by annual crops, inputs of root-associated carbon (roots, exudates, mycorrhizae) decline substantially. For example, perennial grassland species allocate around 67% of productivity to roots, whereas annual crops allocate between 13-30% (Saugier 2001; Johnson et al. 2006).

At the same time inputs of SOC are reduced in annual cropping systems, losses are increased because of tillage, compared to native perennial vegetation. Tillage breaks apart soil aggregates, which, among other functions, are thought to inhibit soil bacteria, fungi and other microbes from consuming and decomposing soil organic matter (Grandy and Neff 2008). Aggregates reduce microbial access to organic matter by restricting physical access to mineral-stabilized organic compounds as well as reducing oxygen availability (Cotrufo et al. 2015; Lehmann and Kleber 2015). When soil aggregates are broken open with tillage in the conversion of native ecosystems to agriculture, microbial consumption of SOC and subsequent respiration of CO_2 increase dramatically, reducing soil carbon stocks (Grandy and Robertson 2006; Grandy and Neff 2008).

Many management approaches are being evaluated to reduce soil degradation in general, especially by increasing mineral-protected forms of SOC in the world's croplands (Paustian et al. 2016). The menu of approaches being investigated focus either on increasing belowground carbon inputs, usually through increases in total crop productivity, or by decreasing microbial activity, usually through reduced soil disturbance (Crews and Rumsey 2017). However, the basic biogeochemistry of terrestrial ecosystems managed for production of annual crops presents serious challenges to achieving the standing stocks of SOC accumulated by native ecosystems that preceded agriculture. A novel new approach that is just starting to receive significant attention is the development of perennial cereal, legume and oilseed crops (Glover et al. 2010; Baker 2017).

There are two basic strategies that plant breeders and geneticists are using to develop new perennial grain crop species. The first involves making wide hybrid crosses between existing elite lines of annual crops, such as wheat, sorghum and rice, with related wild perennial species in order to introgress perennialism into the genome of the annual (Cox et al. 2018; Huang et al. 2018; Hayes et al. 2018). The other approach is *de novo* domestication of wild perennial species that have crop-like traits of interest (DeHaan et al. 2016; DeHaan and Van Tassel 2014). New perennial crop species undergoing *de novo* domestication include intermediate wheatgrass, a relative of wheat that produces grain also known as Kernza (DeHaan et al. 2018; Cattani and Asselin 2018) and *Silphium integrifolium*, an oilseed crop in the sunflower family (Van Tassel et al. 2017). Other perennial grain crops receiving attention include pigeon pea, barley, buckwheat and maize (Batello et al. 2014; Chen et al. 2018c) and a number of legume species (Schlautman et al. 2018). In most cases, the seed yields of perennial grain crops under development are well below those of elite modern grain varieties. In the time that it takes intensive breeding efforts to close the yield and other trait gaps between annual and perennial grains, perennial proto-crops may be used for purposes other than grain, including forage production (Ryan et al. 2018). Perennial rice stands out as a high-yielding exception, as its yields matched those of elite local varieties in the Yunnan Province for six growing seasons over three years (Huang et al. 2018).

In a perennial agroecosystem, the biogeochemical controls on SOC accumulation shift dramatically, and begin to resemble the controls that govern native ecosystems (Crews et al. 2016). When erosion is reduced or halted, and crop allocation to roots increases by 100-200%, and when soil aggregates are not disturbed thus reducing microbial respiration, SOC levels are expected to increase (Crews and Rumsey 2017). Deep roots growing year-round are also effective at increasing nitrogen retention (Culman et al. 2013; Jungers et al. 2019). Substantial increases in SOC have been measured where croplands that had historically been planted to annual grains were converted to perennial grasses, such as in the Conservation Reserve Program (CRP) of the US, or in plantings of second generation perennial biofuel crops. Two studies have assessed carbon accumulation in soils when croplands were converted to the perennial grain Kernza. In one, researchers found no differences in soil labile (permanganate-oxidizable) C after 4 years of cropping to perennial Kernza versus annual wheat in a sandy textured soil. Given that coarse textured soils do not offer the same physicochemical protection against microbial attack as many finer textured soils, these results are not surprising, but these results do underscore how variable rates of carbon accumulation can be (Jastrow et al. 2007). In the second study, researchers assessed the carbon balance of a Kernza field in Kansas USA over 4.5 years using eddy covariance observations (de Oliveira et al. 2018). They found the net C accumulation rate of about 1500 g C m^{-2} yr^{-1} in the first year of the study corresponding to the biomass of Kernza increasing, to about 300 g C m^{-2} yr^{-1}in the final year where CO_2 respiration losses from the decomposition of roots and soil organic matter approached new carbon inputs from photosynthesis. Based on measurements of soil carbon accumulation in restored grasslands in this part of US, the net carbon accumulation in stable organic matter under a perennial grain crop might be expected to sequester 30-50 g C m^{-2} yr^{-1}(Post and Kwon 2000) until a new equilibrium is reached. Sugar cane, a highly productive perennial, has been shown to accumulate a mean of 187 g C m^{-2} yr^{-1}in Brazil (La Scala Júnior et al. 2012).

Reduced soil erosion, increased nitrogen retention, greater water uptake efficiency and enhanced carbon sequestration represent improved ecosystem functions made possible in part by deep and extensive root systems of perennial crops (Figure 4.8).

Figure 4.8 Comparison of root systems between the newly domesticated intermediate wheatgrass (left) and annual wheat (right). Photo and copyright: Jim Richardson

When compared to annual grains like wheat, single species stands of deep rooted perennial grains such as Kernza are expected to reduce soil erosion, increase nitrogen retention, achieve greater water uptake efficiency and enhance carbon sequestration (Crews et al. 2018) (Figure 4.8). An even higher degree of ecosystem services can at least theoretically be achieved by strategically combining different functional groups of crops such as a cereal and a nitrogen-fixing legume (Soussana and Lemaire 2014). Not only is there evidence from plant diversity experiments that communities with higher species richness sustain higher concentrations of soil organic carbon (Hungate et al. 2017; Sprunger and Robertson 2018; Chen et al. 2018b; Yang et al. 2019), but other valuable ecosystem services such as pest suppression, lower greenhouse gas emissions, and greater nutrient retention may be enhanced (Schnitzer et al. 2011; Culman et al. 2013).

Similar to perennial forage crops such as alfalfa, perennial grain crops are expected to have a definite productive life span, probably in the range of 3-10 years. A key area of research on perennial grains cropping systems is to minimise losses of soil organic carbon during conversion of one stand of perennial grains to another. Recent work demonstrates that no-till conversion of a mature perennial grassland to another perennial crop will experience several years of high net CO_2 emissions as decomposition of copious crop residues exceeds ecosystem uptake of carbon by the new crop (Abraha et al. 2018). Most if not all of this lost carbon will be recaptured in the replacement crop. It is not known whether mineral-stabilised carbon that is protected in soil aggregates is vulnerable to loss in perennial crop succession.

Perennial grains hold promises of agricultural practices which can significantly reduce soil erosion and nutrient leakage while sequestering carbon. When cultivated in mixes with N-fixing species (legumes) such polycultures also reduce the need for external inputs of nitrogen - a large source of GHG from conventional agriculture.

4.9.3 Reversing land degradation through reforestation

4.9.3.1 South Korea Case Study on Reforestation Success

In the first half of the 20th century, forests in the Republic of South Korea were severely degraded and deforested during foreign occupations and the Korean War. Unsustainable harvest for timber and fuel wood resulted in severely degraded landscapes, heavy soil erosion and large areas denuded of vegetation cover. Recognising that South Korea's economic health would depend on a healthy environment, South Korea established a national forest service (1967) and embarked on the first phase of a 10-year reforestation program in 1973 (Forest Development Program), which was followed by subsequent reforestation programs that ended in 1987, after 2.4 Mha of forests were restored, see Figure 4.9.

As a consequence of reforestation, forest volume increased from 11.3 m^3 ha^{-1} in 1973 to 125.6 m^3 ha^{-1} in 2010 and 150.2 m^3 ha^{-1} in 2016 (Korea Forest Service 2017). Increases in forest volume had significant co-benefits such as increasing water yield by 43% and reducing soil losses by 87% from 1971 to 2010 (Kim et al. 2017).

The forest carbon density in South Korea has increased from 5–7 Mg C ha^{-1} in the period 1955–1973 to more than 30 Mg C ha^{-1} in the late 1990s (Choi et al. 2002). Estimates of C uptake rates in the late 1990s were 12 Tg C yr^{-1} (Choi et al. 2002). For the period 1954 to 2012 C uptake was 8.3 Tg C yr^{-1} (Lee et al. 2014), lower than other estimates because reforestation programs did not start until 1973. NEP in South Korea was 10.55 ± 1.09 Tg C yr^{-1} in the 1980s, 10.47 ± 7.28 Tg C yr^{-1} in the 1990s, and 6.32 ± 5.02 Tg C yr^{-1} in the 2000s, showing a gradual decline as average forest age increased (Cui et al. 2014). The estimated past and projected future increase in the carbon content of South Korea's forest area during 1992-2034 was 11.8 Tg C yr^{-1} (Kim et al. 2016).

Figure 4.9 Example of severely degraded hills in South Korea and stages of forest restoration. The top two photos are taken in the early 1970s, before and after restoration, the third photo about 5 years after restoration and the bottom photo was taken about 20 years after restoration. Many examples of such restoration success exist throughout South Korea (Source: Korea Forest Service).

During the period of forest restoration, South Korea also promoted inter-agency cooperation and coordination, especially between the energy and forest sectors, to replace firewood with fossil fuels, and by reducing demand for firewood helped forest recovery (Bae et al. 2012). As experience with forest restoration programs has increased, emphasis has shifted from fuelwood plantations, often with exotic species and hybrid varieties to planting more native species and encouraging natural regeneration (Kim and Zsuffa 1994; Lee et al. 2015). Avoiding monocultures in reforestation programs can reduce susceptibility to pests (Kim and Zsuffa 1994). Other important factors in the success of the reforestation program were that private landowners were heavily involved in initial efforts (both corporate entities and smallholders) and that the reforestation program was made part of the national economic development program (Lamb 2014).

The net present value and the benefit-cost ratio of the reforestation program were USD 54.3 billion and 5.84 billion in 2010, respectively. The breakeven point of the reforestation investment appeared within two decades. Substantial benefits of the reforestation program included disaster risk reduction and carbon sequestration (Lee et al. 2018a).

In summary, the reforestation program was a comprehensive technical and social initiative that restored forest ecosystems, enhanced the economic performance of rural regions, contributed to disaster risk reduction, and enhanced carbon sequestration (Kim et al. 2017; Lee et al. 2018a; UNDP 2017).

The success of the reforestation program in South Korea and the associated significant carbon sink indicate a high mitigation potential that might be contributed by a potential future reforestation program in the Democratic People's Republic of Korea (North Korea) (Lee et al. 2018b).

4.9.3.2 China Case Study on Reforestation Success

The dramatic decline in the quantity and quality of natural forests in China resulted in land degradation, such as soil erosion, floods, droughts, carbon emission, and damage to wildlife habitat (Liu and Diamond 2008). In response to failures of previous forestry and land policies, the severe droughts in 1997, and the massive floods in 1998, the central government decided to implement a series of land degradation control policies, including the National Forest Protection Program (NFPP), Grain for Green or the Conversion of Cropland to Forests and Grasslands Program (GFGP) (Liu et al. 2008; Yin 2009; Tengberg et al. 2016; Zhang et al. 2000). The NFPP aimed to completely ban logging of natural forests in the upper reaches of the Yangtze and Yellow rivers as well as in Hainan Province by 2000 and to substantially reduce logging in other places (Xu et al. 2006). In 2011, NFPP was renewed for the 10-year second phase, which also added another 11 counties around Danjiangkou Reservoir in Hubei and Henan Provinces, the water source for the middle route of the South-to-North Water Diversion Project (Liu et al. 2013). Furthermore, the NFPP afforested 31 Mha by 2010 through aerial seeding, artificial planting, and mountain closure (i.e., prohibition of human activities such as fuelwood collection and lifestock grazing) (Xu et al. 2006). China banned commercial logging in all natural forests by the end of 2016, which imposed logging bans and harvesting reductions in 68.2 Mha of forest land – including 56.4 Mha of natural forest (approximately 53% of China's total natural forests).

GFGP became the most ambitious of China's ecological restoration efforts with over USD 45 billion devoted to its implementation since 1990 (Kolinjivadi and Sunderland 2012) The program involves the conversion of farmland on slopes of 15-25° or greater to forest or grassland (Bennett 2008). The pilot program started in three provinces –Sichuan, Shaanxi, and Gansu – in 1999 (Liu and Diamond 2008). After initial success, it was extended to 17 provinces by 2000 and finally to all provinces by 2002, including the headwaters of the Yangtze and Yellow rivers (Liu et al. 2008).

NFPP and GFGP have dramatically improved China's land conditions and ecosystem services, and thus have mitigated the unprecedented land degradation in China (Liu et al. 2013; Liu et al 2002; Long et al. 2006; Xu et al. 2006). NFPP protected 107 Mha forest area and increased forest area by 10 Mha between 2000 and 2010. For the second phase (2011–2020), the NFPP plans to increase forest cover by a further 5.2 Mha, capture 416 million tons of carbon, provide 648,500 forestry jobs, further reduce land degradation, and enhance biodiversity (Liu et al. 2013). During 2000–2007, sediment concentration in the Yellow River had declined by 38%. In the Yellow River basin, it was estimated that surface runoff would be reduced by 450 million m^3 from 2000 to 2020, which is equivalent to 0.76% of the total surface water resources (Jia et al. 2006). GFGP had cumulatively increased vegetative cover by 25 Mha, with 8.8 Mha of cropland being converted to forest and grassland, 14.3 Mha barren land being afforested, and 2.0 million ha of forest regeneration from mountain closure. Forest cover within the GFGP region has increased 2% during the first 8 years (Liu et al. 2008). In Guizhou Province, GFGP plots had 35–53% less loss of phosphorus than non-GFGP plots (Liu et al. 2002). In Wuqi County of Shaanxi Province, the Chaigou Watershed had 48% and 55% higher soil moisture and moisture-holding capacity in GFGP plots than in non-GFGP plots, respectively (Liu et al. 2002). According to reports on China's first national ecosystem assessment (2000–2010), for carbon sequestration and soil retention, coefficients for the GTGP targeting forest restoration and NFPP are positive and statistically significant. For sand fixation, GTGP targeting grassland restoration is positive and statistically significant. Remote sensing observations confirm vegetation cover increases and bare soil decline in China over the period 2001 to 2015 (Qiu et al. 2017) (Qiu et al. 2017). But where afforestation is sustained by drip irrigation from groundwater, questions about plantation sustainability arise (Chen et al. 2018a). Moreover, greater gains in biodiversity could be achieved by promoting mixed forests over monocultures (Hua et al. 2016).

NFPP-related activities received a total commitment of 93.7 billion yuan (about USD 14 billion with today's exchange rate) between 1998 and 2009. Most of the money was used to offset economic losses of forest enterprises caused by the transformation from logging to tree plantations and forest management (Liu et al. 2008). By 2009, the cumulative total investment through the NFPP and GFGP exceeded USD 50 billion and directly involved more than 120 million farmers in 32 million households in the GFGP alone (Liu et al. 2013). All programs reduce or reverse land degradation and improve human well-being. Thus, a coupled human and natural systems perspective (Liu et al. 2008) would be helpful to understand the complexity of policies and their impacts, and to establish long-term management mechanisms to improve the livelihood of participants in these programs and other land management policies in both China and many other parts of the world.

4.9.4 Degradation and management of peat soils

Globally, peatlands cover 3-4 % of the Earth's land area (~430 Mha) (Xu et al. 2018a; Wu et al. 2017b) and store 26-44% of estimated global soil organic carbon (Moore 2002). They are most abundant in high northern latitudes, covering large areas in North America, Russia and Europe. At lower latitudes, the largest areas of tropical peatlands are located in Indonesia, the Congo Basin and the Amazon Basin in the form of peat swamp forests (Gumbricht et al. 2017; Xu et al. 2018a). It is estimated that while 80-85% of the global peatland areas is still largely in a natural state, they are such carbon-dense ecosystems that degraded peatlands (0.3% of the terrestrial land) are responsible for a disproportional 5% of global anthropogenic carbon dioxide (CO_2) emissions, that is an annual addition of 0.9-3 Gt of CO_2 to the atmosphere (Dommain et al. 2012; IPCC 2014c).

Peatland degradation is not well quantified globally, but regionally peatland degradation can involve a large percentage of the areas. Land-use change and degradation in tropical peatlands have primarily been quantified in Southeast Asia, where drainage and conversion to plantation crops is the dominant transition (Miettinen et al. 2016). Degradation of peat swamps in Peru is also a growing concern and one pilot survey showed that over 70% of the peat swamps were degraded in one region that was surveyed (Hergoualc'h et al. 2017a). Around 65,000km^2 or 10% of the European peatland area has been lost and 44% of the remaining European peatlands are degraded (Joosten, H., Tanneberger 2017). Large areas of fens have been entirely 'lost' or greatly reduced in thickness due to peat wastage (Lamers et al. 2015).

The main drivers of the acceleration of peatland degradation in the twentieth century were associated with drainage for agriculture, peat extraction and afforestation related activities (burning, over-grazing, fertilisation) with a variable scale and severity of impact depending on existing resources in the various countries (O'Driscoll et al. 2018; Abu et al. 2017; Dommain et al. 2018; Lamers et al. 2015). New drivers include urban development, wind farm construction (Smith et al. 2012), hydro-electric development, tar sands mining and recreational (Joosten, H., Tanneberger 2017). Anthropogenic pressures are now affecting peatlands in previously geographically isolated areas with consequences for global environmental concerns and impacts on local livelihoods (Dargie et al. 2017; Lawson et al. 2015; Butler et al. 2009).

Drained and managed peatlands are GHG emissions hotspots (Swails et al. 2018; Hergoualc'h et al. 2017b; Roman-Cuesta et al. 2016; Hergoualc'h et al. 2017a). In most cases, lowering of the water table leads to direct and indirect CO_2 and N_2O emissions to the atmosphere with rates dependent on a range of factors, including the groundwater level and the water content of surface peat layers, nutrient content, temperature, and vegetation communities. The exception is nutrient limited boreal peatlands (Minkkinen et al. 2018; Ojanen et al. 2014). Drainage also increases erosion and dissolved organic C loss, removing stored carbon into streams as dissolved and particulate organic carbon, which ultimately returns to the atmosphere (Moore et al. 2013; Evans et al. 2016).

In tropical peatlands, oil palm is the most widespread plantation crop and on average it emits around 40 t CO_2 ha^{-1} yr^{-1}; Acacia plantations for pulpwood are the second most widespread plantation crop and emit around 73 t CO_2 ha^{-1} yr^{-1} (Drösler et al. 2013). Other land uses typically emit less than 37 t CO_2 ha^{-1} yr^{-1}. Total emissions from peatland drainage in the region are estimated to be between 0.07 and 1.1 Gt CO_2 yr^{-1} (Houghton and Nassikas 2017; Frolking et al. 2011). Land-use change also affects the fluxes of N_2O and CH_4. Undisturbed tropical peatlands emit about 0.8 Mt CH_4 yr^{-1} and 0.002 Mt N_2O yr^{-1}, while disturbed peatlands emit 0.1 Mt CH_4 $yr^{-1}$and 0.2 Mt N_2O–N yr^{-1} (Frolking et al. 2011). These N_2O emissions are probably low as new findings show that emissions from fertilised oil palm can exceed 20 kg N_2O–N ha^{-1} yr^{-1} (Oktarita et al. 2017).

In the temperate and boreal zones, peatland drainage often leads to emissions on the order of 0.9 to 9.5 t CO_2 ha^{-1} y^{-1} in forestry plantations and 21 to 29 t CO_2 ha^{-1} y^{-1} in grasslands and croplands. Nutrient poor sites often continue to be CO_2 sinks for long periods (e.g. 50 y) following drainage and in some cases sinks for atmospheric CH_4, even when drainage ditch emissions are considered (Minkkinen et al. 2018; Ojanen et al. 2014). Undisturbed boreal and temperate peatlands emit about 030 Mt CH_4 yr^{-1} and 0.02 Mt N_2O-N yr^{-1}, while disturbed peatlands emit 0.1 Mt CH_4 $yr^{-1}$and 0.2 Mt yr^{-1} N_2O (Frolking et al. 2011).

Fire emissions from tropical peatlands are only a serious issue in Southeast Asia, where they are responsible for 634 (66–4070) Mt CO_2 yr^{-1} (van der Werf et al. 2017). Much of the variability is linked with the El Niño Southern Oscillation, which produces drought conditions in this region. Anomalously active fire seasons have also been observed in non-drought years and this has been attributed to the increasing effect of high temperatures that dry vegetation out during short dry spells in otherwise normal rainfall years (Fernandes et al. 2017; Gaveau et al. 2014). Fires have significant societal impacts; for example, the 2015 fires caused over 100,000 additional deaths across Indonesia, Malaysia and Singapore and this event was more than twice as deadly as the 2006 El Niño event (Koplitz et al. 2016).

Peatland degradation in other parts of the world differs from Asia. In Africa large peat deposits like those found in the Cuvette Centrale in the Congo Basin or in the Okavango inland delta, the principle threat is changing rainfall regimes due to climate variability and change (Weinzierl et al. 2016; Dargie et al. 2017). Expansion of agriculture is not yet a major factor in these regions. In the Western Amazon, extraction of non-timber forest products like the fruits of *Mauritia flexuosa* (moriche palm) and Suri worms are major sources of degradation that lead to losses of carbon stocks (Hergoualc'h et al. 2017a).

The effects of peatland degradation on livelihoods have not been systematically characterised. In places where plantation crops are driving the conversion of peat swamps, the financial benefits can be considerable. One study in Indonesia found that the net present value of an oil palm plantation is between USD 3,835 and 9,630 per ha to land owners (Butler et al. 2009). High financial returns are creating the incentives for the expansion of smallholder production in peatlands. Smallholder plantations extend over 22% of the peatlands in insular Southeast Asia compared to 27% for industrial plantations (Miettinen et al. 2016). In places where income is generated from extraction of marketable products, ecosystem degradation probably has a negative effect on livelihoods. For example, the sale of fruits of *M. flexuosa* in some parts of the western Amazon constitutes as much as 80% of the winter income of many rural households, but information on trade values and value chains of *M. flexuosa* is still sparse (Sousa et al. 2018; Virapongse et al. 2017).

There is little experience with peatland restoration in the tropics. Experience from northern latitudes suggests that extensive damage and changes in hydrological conditions mean that restoration in many cases is unachievable (Andersen et al. 2017). In the case of Southeast Asia, where peatlands form as raised bogs, drainage leads to collapse of the dome and this collapse cannot be reversed by rewetting. Nevertheless, efforts are underway to develop solutions or at least partial solutions in Southeast Asia, for example, by the Indonesian Peatland Restoration Agency. The first step is to restore the hydrological regime in drained peatlands and experiences with canal blocking and re-flooding of the peat. These efforts have been only partially successful (Ritzema et al. 2014). Market incentives with certification through the Roundtable on Sustainable Palm Oil have also not been particularly successful as many concessions seek certification only after significant environmental degradation has been accomplished (Carlson et al. 2017). Certification had no discernible effect on forest loss or fire detection in peatlands in Indonesia. To date there is no documentation of restoration methods or successes in many other parts of the tropics, but in situations where degradation does not involve drainage, ecological restoration may be possible. In South America, for example, there is growing interest in restoration of palm swamps, and as experiences are gained it will be important to document success factors to inform successive efforts (Virapongse et al. 2017).

In higher latitudes where degraded peatlands have been drained, the most effective option to reduce losses from these large organic carbon stocks is change hydrological conditions and increase soil moisture and surface wetness (Regina et al. 2015). Long-term GHG monitoring in boreal sites has demonstrated that rewetting and restoration noticeably reduce emissions compared to degraded drained sites and can restored the carbon sink function when vegetation is re-established (Wilson et al. 2016; IPCC 2014a; Nugent et al. 2018) although restored ecosystems may not yet be as resilient as their undisturbed counterparts (Wilson et al. 2016). Several studies have demonstrated the co-benefits of rewetting specific degraded peatlands for biodiversity, carbon sequestration, (Parry et al. 2014; Ramchunder et al. 2012; Renou-Wilson et al. 2018) and other ecosystem services such as improvement of water storage and quality (Martin-Ortega et al. 2014) with beneficial consequences for human well-being (Bonn et al. 2016; Parry et al. 2014).

4.9.5 Biochar

Biochar is organic matter that is carbonised by heating in an oxygen-limited environment, and used as a soil amendment. The properties of biochar vary widely, dependent on the feedstock and the conditions of production. Biochar could make a significant contribution to mitigating both land degradation and climate change, simultaneously.

4.9.5.1 Role of biochar in climate change mitigation

Biochar is relatively resistant to decomposition compared with fresh organic matter or compost, so represents a long-term C store (*very high confidence*). Biochars produced at higher temperature (> 450°C) and from woody material have greater stability than those produced at lower temperature (300-450°C), and from manures (*very high confidence*) (Singh et al. 2012; Wang et al. 2016b). Biochar stability is influenced by soil properties: biochar carbon can be further stabilised by interaction with clay minerals and native soil organic matter (*medium evidence*) (Fang et al. 2015). Biochar stability is estimated to range from decades to thousands of years, for different biochars in different applications (Singh et al., 2015; Wang et al., 2016). Biochar stability decreases as ambient temperature increases (*limited evidence*) (Fang et al. 2017).

Biochar can enhance soil carbon stocks through "negative priming", in which rhizodeposits are stabilised through sorption of labile C on biochar, and formation of biochar-organo-mineral complexes (Weng et al. 2015, 2017, 2018; Wang et al. 2016b). Conversely, some studies show increased turnover of native soil carbon ("positive priming") due to enhanced soil microbial activity induced by biochar. In clayey soils, positive priming is minor and short-lived compared to negative priming effects, which dominate in the medium to long-term (Singh and Cowie 2014; Wang et al. 2016b). Negative priming has been observed particularly in loamy grassland soil (Ventura et al.

2015) and clay-dominated soils, whereas positive priming is reported in sandy soils (Wang et al. 2016b) and those with low C content (Ding et al. 2018).

Biochar can provide additional climate change mitigation by decreasing nitrous oxide (N_2O) emissions from soil, due in part to decreased substrate availability for denitrifying organisms, related to the molar H/C ratio of the biochar (Cayuela et al. 2015). However, this impact varies widely: meta-analyses found an average decrease in N_2O emissions from soil of 30-54%, (Cayuela et al. 2015) (Moore 2002; Borchard et al. 2019), although another study found no significant reduction in field conditions when weighted by the inverse of the number of observations per site (Verhoeven et al. 2017). Biochar has been observed to reduce methane emissions from flooded soils, such as rice paddies, though, as for N_2O, results vary between studies and increases have also been observed (He et al. 2017; KAMMANN et al. 2017). Biochar has also been found to reduces methane uptake by dryland soils, though the effect is small in absolute terms (Jeffery et al. 2016).

Additional climate benefits of biochar can arise through reduced N fertiliser requirements, due to reduced losses of N through leaching and/or volatilization (Singh, Hatton, Balwant, & Cowie, 2010) and enhanced biological nitrogen fixation (Van Zwieten et al. 2015); increased yields of crop, forage, vegetable and tree species (Biederman and Stanley Harpole 2013), particularly in sandy soils and acidic tropical soils (Simon et al. 2017) ; avoided GHG emissions from manure that would otherwise be stockpiled, crop residues that would be burned or processing residues that would be landfilled; and reduced GHG emissions from compost when biochar is added (Agyarko-Mintah et al. 2017; Wu et al. 2017a).

Climate benefits of biochar could be substantially reduced through reduction in albedo if biochar is surface-applied at high rates to light-colored soils (Genesio et al. 2012; Bozzi et al. 2015; Woolf et al. 2010), or if black carbon dust is released (Genesio et al. 2016). Pelletizing or granulating biochar, and applying below the soil surface or incorporating into the soil, minimises the release of black carbon dust and reduces the effect on albedo (Woolf et al. 2010).

Biochar is a potential "negative emissions" technology: the thermochemical conversion of biomass to biochar slows mineralisation of the biomass, delivering long term C storage; gases released during pyrolysis can be combusted for heat or power, displacing fossil energy sources, and could be captured and sequestered if linked with infrastructure for carbon capture and storage (Smith 2016). Studies of the life cycle climate change impacts of biochar systems generally show emissions reduction in the range 0.4 -1.2 t CO_2e t^{-1} (dry) feedstock (Cowie et al. 2015). Use of biomass for biochar can deliver greater benefits than use for bioenergy, if applied in a context where it delivers agronomic benefits and/or reduces non-CO_2 GHG emissions (Ji et al. 2018; Woolf et al. 2010, 2018; Xu et al. 2019). A global analysis of technical potential, in which biomass supply constraints were applied to protect against food insecurity, loss of habitat and land degradation, estimated technical potential abatement of 3.7 - 6.6 Gt CO_2e yr^{-1} (including 2.6-4.6 GtCO_2e yr^{-1} carbon stabilization), with theoretical potential to reduce total emissions over the course of a century by 240 – 475 Gt CO_2e (Woolf et al. 2010). Fuss et al. 2018 propose a range of 0.5-2 GtCO_2e as the sustainable potential for negative emissions through biochar. Mitigation potential of biochar is reviewed in Chapter 2.

4.9.5.2 Role of biochar in management of land degradation

Biochars generally have high porosity, high surface area and surface-active properties that lead to high absorptive and adsorptive capacity, especially after interaction in soil (Joseph et al. 2010). As a result of these properties, biochar could contribute to avoiding, reducing and reversing land degradation through the following documented benefits:

- Improved nutrient use efficiency due to reduced leaching of nitrate and ammonium (e.g. (Haider et al. 2017) and increased availability of phosphorus (P) in soils with high P fixation capacity (Liu et al. 2018c), potentially reducing N and P fertiliser requirements.

- Management of heavy metals and organic pollutants: through reduced bioavailability of toxic elements (O'Connor et al., 2018; Peng ; Deng, ; Peng, & Yue, 2018), by reducing availability, through immobilization due to increased pH and redox effects (Rizwan et al. 2016) and adsorption on biochar surfaces (Zhang et al. 2013) thus providing a means of remediating contaminated soils, and enabling their utilisation for food production.
- Stimulation of beneficial soil organisms, including earthworms and mycorrhizal fungi (Thies et al. 2015).
- Improved porosity and water holding capacity (Quin et al. 2014), particularly in sandy soils (Omondi et al. 2016), enhancing microbial function during drought (Paetsch et al. 2018).
- Amelioration of soil acidification, through application of biochars with high pH and acid neutralising capacity (Chan et al. 2008)(Van Zwieten et al. 2010).

Biochar systems can deliver a range of other co-benefits including destruction of pathogens and weed propagules, avoidance of landfill, improved handling and transport of wastes such as sewage sludge, management of biomass residues such as environmental weeds and urban greenwaste, reduction of odors and management of nutrients from intensive livestock facilities, reduction in environmental N pollution and protection of waterways. As a compost additive, biochar has been found to reduce leaching and volatilisation of nutrients, increasing nutrient retention, through absorption and adsorption processes (Joseph et al. 2018).

While many studies report positive responses, some studies have found negative or zero impacts on soil properties or plant response (e.g. Kuppusamy, Thavamani, Megharaj, Venkateswarlu, & Naidu, 2016). The risk that biochar may enhance PAH in soil or sediments has been raised (Quilliam et al. 2013; Ojeda et al. 2016), but bioavailability of PAH in biochar has been shown to be very low (Hilber et al. 2017) Pyrolysis of biomass leads to losses of volatile nutrients, especially N. While availability of N and P in biochar is lower in biochar than in fresh biomass (Xu et al. 2016) the impact of biochar on plant uptake is determined by the interactions between biochar, soil minerals and activity of microorganisms (e.g. (Vanek and Lehmann 2015); (Nguyen et al. 2017). To avoid negative responses, it is important to select biochar formulations to address known soil constraints, and to apply biochar prior to planting (Nguyen et al., 2017). Nutrient enrichment improves the performance of biochar from low nutrient feedstocks (Joseph et al. 2013). While there are many reports of biochar reducing disease or pest incidence, there are also reports of nil or negative effects (Bonanomi et al. 2015). Biochar may induce systemic disease resistance (e.g., Elad et al. 2011)), though (Viger et al. 2015) reported down-regulation of plant defence genes, suggesting increased susceptibility to insect and pathogen attack. Disease suppression where biochar is applied is associated with increased microbial diversity and metabolic potential of the rhizosphere microbiome (Kolton et al. 2017). Differences in properties related to feedstock (Bonanomi et al. 2018) and differential response to biochar dose, with lower rates more effective (Frenkel et al. 2017) in contributing to variable disease responses.

Constraints to biochar adoption are high cost and limited availability due to limited large-scale production; limited amount of unutilised biomass; and competition for land for growing biomass. While early biochar research tended to use high rates of application (10 t ha^{-1} or more) subsequent studies have shown that biochar can be effective at lower rates especially when combined with chemical or organic fertilisers (Joseph et al. 2013). Biochar can be produced at many scales and levels of engineering sophistication, from simple cone kilns and cookstoves to large industrial scale units processing several tonnes of biomass per hour (Lehmann and Stephen 2015). Substantial technological development has occurred recently, though large-scale deployment is limited to date.

Governance of biochar is required to manage climate, human health and contamination risks associated with biochar production in poorly-designed or operated facilities that release methane or particulates (Downie et al. 2012)(Buss et al. 2015), to ensure quality control of biochar products, and to ensure biomass is sourced sustainably and is uncontaminated. Measures could include labelling standards, sustainability certification schemes and regulation of biochar production and use. Governance mechanisms should be tailored to context, commensurate with risks of adverse outcomes.

In summary, application of biochar to soil can improve soil chemical, physical and biological attributes, enhancing productivity and resilience to climate change, while also delivering climate change mitigation through carbon sequestration and reduction in GHG emissions (*medium agreement, robust evidence*). However, responses to biochar depend on biochar properties, in turn dependent on feedstock and biochar production conditions, and the soil and crop to which it is applied. Negative or nil results have been recorded. Agronomic and methane reduction benefits appear greatest in tropical regions, where acidic soils predominate and suboptimal rates of lime and fertiliser are common, while carbon stabilisation is greater in temperate regions. Biochar is most effective when applied in low volumes to the most responsive soils and when properties are matched to the specific soil constraints and plant needs. Biochar is thus a practice that has potential to address land degradation and climate change simultaneously, while also supporting sustainable development. The potential of biochar is limited by the availability of biomass for its production. Biochar production and use requires regulation and standardisation to manage risks (*strong agreement*).

4.9.6 Management of land degradation induced by tropical cyclones

Tropical cyclones are normal disturbances that natural ecosystems have been affected by and recovered from for millennia. Climate models mostly predict decreasing frequency of tropical cyclones, but dramatically increasing intensity of the strongest storms as well as increasing rainfall rates (Bacmeister et al. 2018; Walsh et al. 2016b). Large amplitude fluctuations in the frequency and intensity complicate both the detection and attribution of tropical cyclones to climate change (Lin and Emanuel 2016b). Yet, the intensity of high-intensity cyclones have increased and are expected to increase further due to global climate change (Knutson et al. 2010; Bender et al. 2010; Vecchi et al. 2008; Bhatia et al. 2018; Tu et al. 2018; Sobel et al. 2016) (*medium agreement, robust evidence*). Tropical cyclone paths are also shifting towards the poles increasing the area subject to tropical cyclones (Sharmila and Walsh 2018; Lin and Emanuel 2016b). Climate change alone will affect the hydrology of individual wetland ecosystems mostly through changes in precipitation and temperature regimes with great global variability (Erwin 2009). Over the last seven decades, the speed at which tropical cyclones move has decreased significantly as expected from theory, exacerbating the damage on local communities from increasing rainfall amounts and high wind speed (Kossin 2018). Tropical cyclones will accelerate changes in coastal forest structure and composition. The heterogeneity of land degradation at coasts that are affected by tropical cyclones can be further enhanced by the interaction of its components (for example, rainfall, wind speed, and direction) with topographic and biological factors (for example, species susceptibility) (Luke et al. 2016).

Small Island Developing States (SIDS) are particularly affected by land degradation induced by tropical cyclones, recent examples are Matthew (2016) in the Caribbean, and Pam (2015) and Winston (2016) in the Pacific (Klöck and Nunn 2019; Handmer and Nalau 2019). Even if the Pacific Ocean has experienced cyclones of unprecedented intensity in the recent years, their geomorphological effects may not be unprecedented (Terry and Lau 2018).

Cyclone impacts on coastal areas is not restricted to SIDS, but a problem for all low-lying coastal areas (Petzold and Magnan 2019). The Sundarban, one of the world's largest coastal wetlands, covers about one million hectares between Bangladesh and India. Large areas of the Sundarban mangroves have been converted into paddy fields over the past two centuries and more recently into shrimp farms (Ghosh et al. 2015). In 2009 the cyclone Aila caused incremental stresses on the socioeconomic conditions of the Sundarban coastal communities through rendering huge areas of land unproductive for a long time (Abdullah et al. 2016). The impact of Aila was wide spread throughout the Sundarbans mangroves showing changes between pre- and post-cyclonic period of 20-50% in the enhanced vegetation index (Dutta et al. 2015). Although the magnitude of the effects of the Sundarban mangroves derived from climate change is not yet defined (Payo et al. 2016; Loucks et al. 2010; Gopal and Chauhan 2006; Ghosh et al. 2015; Chaudhuri et al. 2015). There is *high agreement* that the joint effect of climate change and land degradation will be very negative for the area, strongly affecting the environmental services provided by these forests, including the extinction of large mammal species (Loucks et al. 2010). This changes in vegetation are mainly due to inundation and erosion (Payo et al. 2016).

The tropical cyclone Nargis hit unexpectedly the Ayeyarwady River delta (Myanmar) in 2008 with unprecedented and catastrophic damages to livelihoods, destruction of forests and erosion of fields (Fritz et al. 2009) as well as eroding the shoreline 148 m compared with the long-term average (1974-2015) of 0.62 m yr^{-1}. This is an example of the disastrous effects that changing cyclone paths can have on areas previously not affected by cyclones (Fritz et al. 2010).

4.9.6.1 Management of coastal wetlands

Tropical cyclones mainly, but not exclusively, affect coastal regions, threatening maintenance of the associated ecosystems, mangroves, wetlands, seagrasses, etc. This areas not only provide food, water and shelter for fish, birds and other wildlife, but also provide important ecosystem services such as water quality improvement, flood abatement and carbon sequestration (Meng et al. 2017).

Despite its importance coastal wetlands are listed amongst the most heavily damaged of natural ecosystems worldwide. Starting in the 1990s, wetland restoration and re-creation became a “hotspot” in the ecological research fields (Zedler 2000). The coastal wetland restoration and preservation is an extremely cost-effective strategy for society, for example the preservation of coastal wetlands in the USA provide storm protection services with the cost of 23.2 billion yr^{-1} USD (Costanza et al. 2008).

There is a *high agreement* with *medium evidence* that the success of wetland restoration depends mainly on the flow of the water through the system and the degree to which re-flooding occurs, the disturbance regimes, and the control of invasive species (Burlakova et al. 2009; López-Rosas et al. 2013). The implementation of the Ecological Mangrove Rehabilitation (EMR) protocol (López-Portillo et al. 2017) that includes monitoring and reporting tasks, has been proven to deliver successful rehabilitation of wetland ecosystem services.

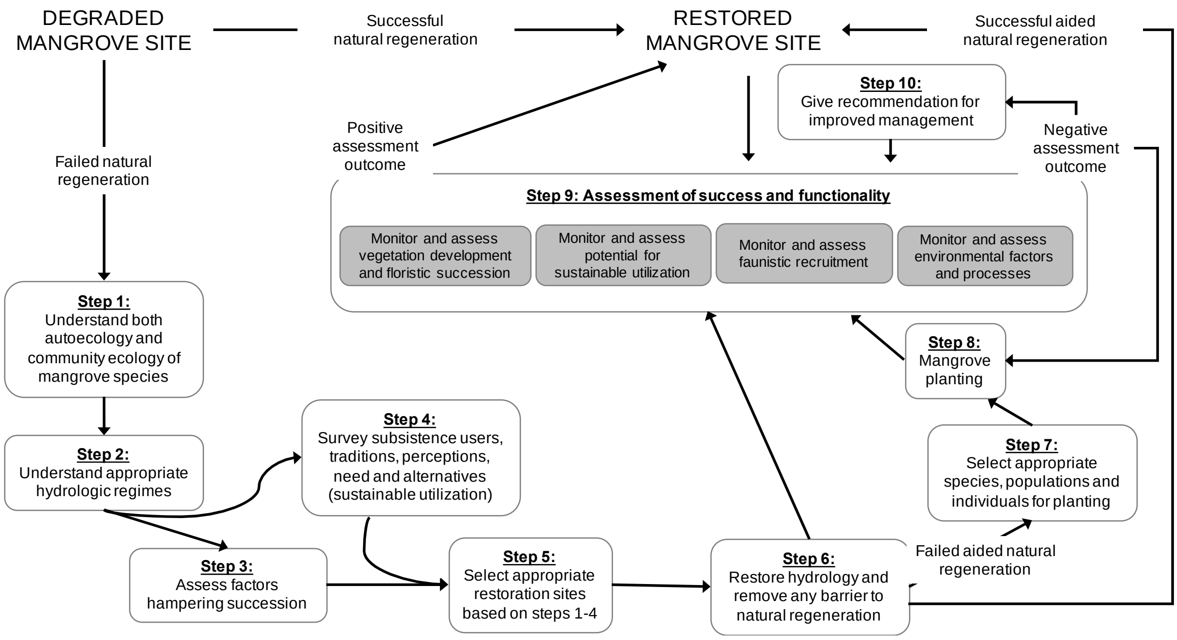

Figure 4.10 Decision tree showing recommended steps and tasks to restore a mangrove wetland based on original site conditions (Modified from Bosire et al. (2008)

4.9.7 Saltwater intrusion

Current environmental changes, including climate change, have caused sea levels to rise worldwide, particularly in tropical and subtropical regions (Fasullo and Nerem 2018). Combined with scarcity of water in river channels, such rises have been instrumental in the intrusion of highly saline seawater inland, posing a threat to coastal areas and an emerging challenge to land managers and policy makers. Assessing the extent of salinisation due to sea water intrusion at a global scale nevertheless remains challenging. Wicke et al. (2011) suggest that across the world, approximately 1.1 Gha of land is affected by salt, with 14% of this categorised as forest, wetland or some other form of protected area. Seawater intrusion is generally caused by: i) increased tidal activity, storm surges, cyclones and sea storms due to changing climate, ii) heavy groundwater extraction or land use changes as a result of changes in precipitation, and droughts/floods, iii) coastal erosion as a result of destruction of mangrove forests and wetlands iv) construction of vast irrigation canals and drainage networks leading to low river discharge in the deltaic region; and v) sea level rise contaminating nearby freshwater aquifers as a result of subsurface intrusion (Uddameri et al. 2014).

The Indus delta, located in the south-eastern coast of Pakistan near Karachi in the North Arabian sea, is one of the six largest estuaries in the world spanning an area of 600,000 ha. The Indus delta is a clear example of seawater intrusion and land degradation due to local as well as up-country climatic and environmental conditions (Rasul et al. 2012). Salinisation and waterlogging in the up-country areas including provinces of Punjab and Sindh is, however, caused by the irrigation network and over-irrigation (Qureshi 2011).

Such degradation takes the form of high soil salinity, inundation and waterlogging, erosion and freshwater contamination. The inter-annual variability of precipitation with flooding conditions in some years and drought conditions in others has caused variable river flows and sediment runoff below Kotri barrage (about 200 km upstream of the Indus delta). This has affected hydrological processes in the lower reaches of the river and the delta, contributing to the degradation (Rasul et al. 2012).

Over 480,000 ha of fertile land is now affected by sea water intrusion, wherein eight coastal subdivisions of the districts of Badin and Thatta are mostly affected (Chandio et al. 2011). A very high intrusion rate of 0.179±0.0315 km yr^{-1}, based on the analysis of satellite data, was observed in the Indus delta during the past 10 years (2004–2015) (Kalhoro et al. 2016). The area of agricultural crops under cultivation has been declining with economic losses of millions of USD (IUCN 2003). Crop yields have reduced due to soil salinity, in some places failing entirely. Soil salinity varies seasonally, depending largely on the river discharge: during the wet season (August 2014), salinity (0.18 mg L^{-1}) reached 24 km upstream while during the dry season (May 2013), it reached 84 km upstream (Kalhoro et al. 2016). The freshwater aquifers have also been contaminated with sea water rendering them unfit for drinking or irrigation purposes. Lack of clean drinking water and sanitation causes widespread diseases, of which diarrhoea is most common (IUCN 2003).

Lake Urmia in northwest Iran, the second largest saltwater lake in the world and the habitat for endemic Iranian brine shrimp, *Artemia urmiana*, has also been affected by salty water intrusion. During a 17-year period between 1998 and 2014, human disruption including agriculture and years of dam building affected the natural flow of freshwater as well as salty sea water in the surrounding area of Lake Urmia. Water quality has also been adversely affected, with salinity fluctuating over time, but in recent years reaching a maximum of 340 g L^{-1} (similar to levels in the Dead Sea). This has rendered the underground water unfit for drinking and agricultural purposes and risky to human health and livelihoods. Adverse impacts of global climate change as well as direct human impacts have caused changes in land use, overuse of underground water resources and construction of dams over rivers which resulted in the drying-up of the lake in large part. This condition created sand, dust and salt storms in the region which affected many sectors including agriculture, water resources, rangelands, forests and health, and generally presented desertification conditions around the lake (Karbassi et al. 2010; Marjani and Jamali 2014; Shadkam et al. 2016).

Rapid irrigation expansion in the basin has, however, indirectly contributed to inflow reduction. Annual inflow to Lake Urmia has dropped by 48% in recent years. About three fifths of this change was caused by climate change and two fifths by water resource development and agriculture (Karbassi et al. 2010; Marjani and Jamali 2014; Shadkam et al. 2016).

In the drylands of Mexico, intensive production of irrigated wheat and cotton using groundwater (Halvorson et al. 2003) resulted in sea water intrusion into the aquifers of La Costa de Hermosillo, a coastal agricultural valley at the center of Sonora Desert in Northwestern Mexico. Production of these crops in 1954 was on 64,000 ha of cultivated area, increasing to 132,516 ha in 1970, but decreasing to 66,044 ha in 2009 as a result of saline intrusion from the Gulf of California (Romo-Leon et al. 2014). In 2003, only 15% of the cultivated area was under production, with around 80,000 ha abandoned due to soil salinisation whereas in 2009, around 40,000 ha was abandoned (Halvorson et al. 2003; Romo-Leon et al. 2014). Salinisation of agricultural soils could be exacerbated by climate change, as Northwestern Mexico is projected to be warmer and drier under climate change scenarios (IPCC 2013a).

In other countries, intrusion of seawater is exacerbated by destruction of mangrove forests. Mangroves are important coastal ecosystems that provide spawning bed for fish, timber for building, livelihoods to dependent communities, act as barriers against coastal erosion, storm surges, tropical cyclones and tsunamis (Kalhoro et al. 2017) and are among the most carbon-rich stocks on Earth (Atwood et al. 2017). They nevertheless face a variety of threats: climatic (storm surges, tidal activities, high temperatures) and human (coastal developments, pollution, deforestation, conversion to aquaculture, rice culture, oil palm plantation), leading to declines in their areas. In Pakistan, using remote sensing (RS), the mangrove forest cover in the Indus delta decreased from 260,000 ha in 1980s to 160,000 ha in 1990 (Chandio et al. 2011). Based on remotely sensed data, a sharp decline in the mangrove area was also found in the arid coastal region of Hormozgan province in southern Iran during 1972, 1987 and 1997 (Etemadi et al. 2016). Myanmar has the highest rate (about 1% yr^{-1}) of mangrove deforestation in the world (Atwood et al. 2017). Regarding global loss of carbon stored in the mangrove due to deforestation, four countries exhibited high levels of loss: Indonesia (3,410 Gg

CO_2 yr^{-1}), Malaysia (1,288 GgCO_2 yr^{-1}), US (206 Gg CO_2 yr^{-1}) and Brazil (186 GgCO_2 yr^{-1}). Only in Bangladesh and Guinea Bissau there was no decline in the mangrove area from 2000 to 2012 (Atwood et al. 2017).

Frequency and intensity of average tropical cyclones will continue to increase (Knutson et al. 2015) and global sea level will continue to rise. The IPCC (2013) projected with *medium confidence* that sea level in the Asia Pacific region will rise from 0.4 to 0.6 m, depending on the emission pathway, by the end of this century. Adaptation measures are urgently required to protect the world's coastal areas from further degradation due to saline intrusion. A viable policy framework is needed to ensure the environmental flows to deltas in order to repulse the intruding seawater.

4.9.8 Avoiding coastal maladaptation

Coastal degradation—for example, beach erosion, coastal squeeze, and coastal biodiversity loss—as a result of rising sea levels is a major concern for low lying coasts and small islands (*high confidence*). The contribution of climate change to increased coastal degradation has been well documented in AR5 (Nurse et al. 2014; Wong et al. 2014) and is further discussed in Section 4.4.1.3. as well as in the IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC). However, coastal degradation can also be indirectly induced by climate change as the result of adaptation measures that involve changes to the coastal environment, for example, coastal protection measures against increased flooding and erosion due to sea level rise and storm surges transforming the natural coast to a 'stabilised' coastline (Cooper and Pile 2014; French 2001). Every kind of adaptation response option is context-dependent, and, in fact, sea walls play an important role for adaptation in many places. Nonetheless, there are observed cases where the construction of sea walls can be considered 'maladaptation' (Barnett and O'Neill 2010; Magnan et al. 2016) by leading to increased coastal degradation, such as in the case of small islands, where due to limitations of space coastal retreat is less of an option than in continental coastal zones. There is emerging literature on the implementation of alternative coastal protection measures and mechanisms on small islands to avoid coastal degradation induced by sea walls (e.g., Mycoo and Chadwick 2012; Sovacool 2012).

In many cases, increased rates of coastal erosion due to the construction of sea walls are the result of the negligence of local coastal morphological dynamics and natural variability as well as the interplay of environmental and anthropogenic drivers of coastal change (*medium evidence*, *high agreement*). Sea walls in response to coastal erosion may be ill-suited for extreme wave heights under cyclone impacts and can lead to coastal degradation by keeping overflowing sea water from flowing back into the sea, and therefore affect the coastal vegetation through saltwater intrusion, as observed in Tuvalu (Government of Tuvalu 2006; Wairiu 2017). Similarly, in Kiribati, poor construction of sea walls has resulted in increased erosion and inundation of reclaimed land (Donner 2012; Donner and Webber 2014). In the Comoros and Tuvalu, sea walls have been constructed from climate change adaptation funds and 'often by international development organizations seeking to leave tangible evidence of their investments' (Marino and Lazrus 2015, p. 344). In these cases, they have even increased coastal erosion, due to poor planning and the negligence of other causes of coastal degradation, such as sand mining (Marino and Lazrus 2015; Betzold and Mohamed 2017; Ratter et al. 2016). On the Bahamas, the installation of sea walls as a response to coastal erosion in areas with high wave action has led to the contrary effect and even increased sand loss in those areas (Sealey 2006). The reduction of natural buffer zones—i.e., beaches and dunes—due to vertical structures, such as sea walls, increased the impacts of tropical cyclones on Reunion Island (Duvat et al. 2016). Such a process of 'coastal squeeze' (Pontee 2013) also results in the reduction of intertidal habitat zones, such as wetlands and marshes (Linham and Nicholls 2010). Coastal degradation resulting from the construction of sea walls, however, is not only observed in Small Island Developing States (SIDS), as described above, but also on islands in the Global North, for example, the North Atlantic (Muir et al. 2014; Young et al. 2014; Cooper and Pile 2014; Bush 2004).

The adverse effects of coastal protection measures may be avoided by the consideration of local social-ecological dynamics, including the critical studying of diverse drivers of ongoing shoreline changes, and the according implementation of locally adequate coastal protection options (French 2001; Duvat 2013). Critical elements for avoiding maladaptation include profound knowledge of local tidal regimes, availability of relative sea level rise scenarios and projections for extreme water levels. Moreover, the downdrift effects of sea walls need to be considered, since undefended coasts may be exposed to increased erosion (Linham and Nicholls 2010). In some cases, it may be possible to keep intact and restore natural buffer zones as an alternative to the construction of hard engineering solutions. Otherwise, changes in land-use, building codes, or even coastal realignment can be an option in order to protect and avoid the loss of the buffer function of beaches (Duvat et al. 2016; Cooper and Pile 2014). Examples of Barbados show that combinations of hard and soft coastal protection approaches can be sustainable and reduce the risk of coastal ecosystem degradation while keeping the desired level of protection for coastal users (Mycoo and Chadwick 2012). Nature-based solutions and approaches such as ‘building with nature’ (Slobbe et al. 2013) may allow for more sustainable coastal protection mechanisms and avoid coastal degradation. Examples from the Maldives, several Pacific islands and the North Atlantic show the importance of the involvement of local communities in coastal adaptation projects, considering local skills, capacities, as well as demographic and socio-political dynamics, in order to ensure the proper monitoring and maintenance of coastal adaptation measures (Sovacool 2012; Muir et al. 2014; Young et al. 2014; Buggy and McNamara 2016; Petzold 2016).

4.10 Knowledge gaps and key uncertainties

The co-benefits of improved land management, such as mitigation of climate change, increased climate resilience of agriculture, and impacts on rural areas/societies are well-known in theory but there is a lack of a coherent and systematic global inventory of such integrated efforts. Both successes and failures are important to document systematically.

Efforts to reduce climate change through land-demanding mitigation actions aimed at removing atmospheric carbon, such as afforestation, reforestation, bioenergy crops, intensification of land management and plantation forestry can adversely affect land conditions and lead to degradation. However, they may also lead to avoidance, reduction and reversal of degradation. Regionally differentiated, socially and ecologically appropriate sustainable land management strategies need to be identified, implemented, monitored and the results communicated widely to ensure climate effective outcomes.

Impacts of new technologies on land degradation and their social and economic ramifications need more research.

Improved quantification of the global extent, severity and rates of land degradation by combining remote sensing with a systematic use of ancillary data is a priority. The current attempts need a better scientific underpinning and appropriate funding.

Land degradation is defined using multiple criteria but the definition does not provide thresholds or the magnitude of acceptable change. In practice, human interactions with land will result in a variety of changes, some may contribute positively to one criterion while adversely affecting another. Research is required on the magnitude of impacts and the resulting trade-offs. Given the urgent need to remove carbon from the atmosphere and to reduce climate change impacts, it is important to reach agreement on what level of reduction in one criterion (biological productivity, ecological integrity) may be acceptable for a given increase in another criterion (ecological integrity, biological productivity)?

Attribution of land degradation to the underlying drivers is a challenge because a complex web of causality rather than simple cause-effect relationships. Also, diverging views on land degradation in relation to other challenges is hampering such efforts.

A more systematic treatment of the views and experiences of land users would be useful in land degradation studies.

Much research has tried to understand how social and ecological systems are affected by a particular stressor, for example drought, heat, or waterlogging. But less research has tried to understand how such systems are affected by several simultaneous stressors – which of course is more realistic in the context of climate change (Mittler 2006).

More realistic modelling of carbon dynamics, including better appreciation of belowground biota, would help us to better quantify the role of soils and soil management for soil carbon sequestration.

Frequently Asked Questions

FAQ 4.1 How do climate change and land degradation interact with land use?

Climate change, land degradation, and land use are linked in a complex web of causality. One important impact of climate change (e.g. flood and drought) on land degradation is that increasing global temperatures intensify the hydrological cycle resulting in more intense rainfall, which is an important driver of soil erosion. This means that sustainable land management (SLM) becomes even more important with climate change. Land-use change in the form of clearing of forest for rangeland and cropland (e.g., for provision of bio-fuels), and cultivation of peat soils, is a major source of greenhouse gas emission from both biomass and soils. Many SLM practices (e.g., agroforestry, shifting perennial crops, restoration, etc.) increase carbon content of soil and vegetation cover and hence provide both local and immediate adaptation benefits combined with global mitigation benefits in the long term, while providing many social and economic co-benefits. Avoiding, reducing and reversing land degradation has a large potential to mitigate climate change and help communities to adapt to climate change.

FAQ 4.2 How does climate change affect land-related ecosystem services and biodiversity?

Climate change will affect land-related ecosystem services (e.g. pollination, resilience to extreme climate events, water yield, soil conservation, carbon storage, etc.) and biodiversity, both directly and indirectly. The direct impacts range from subtle reductions or enhancements of specific services, such as biological productivity, resulting from changes in temperature, temperature variability or rainfall, to complete disruption and elimination of services. Disruptions of ecosystem services can occur where climate change causes transitions from one biome to another, e.g., forest to grassland as a result of changes in water balance or natural disturbance regimes. Climate change will result in range shifts and, in some cases, extinction of species. Climate change can also alter the mix of land-related ecosystem services, such as groundwater recharge, purification of water, and flood protection. While the net impacts are specific to ecosystem types, ecosystem services and time, there is an asymmetry of risk such that overall impacts of climate change are expected to reduce ecosystem services. Indirect impacts of climate change on land-related ecosystem services include those that result from changes in human behavior, including potential large-scale human migrations or the implementation of afforestation, reforestation or other changes in land management, which can have positive or negative outcomes on ecosystem services.

Table of Contents

Executive summary

The current food system (production, transport, processing, packaging, storage, retail, consumption, loss and waste) feeds the great majority of world population and supports the livelihoods of ca. 200 million people. Since 1961, food supply per capita has increased more than 30%, accompanied by greater use of nitrogen fertilisers (increase of about 800%) and water resources for irrigation (increase of more than 100%). However, an estimated 821 million people are currently undernourished, 151 million children under 5 are stunted, 613 million women and girls aged 15 to 49 suffer from iron deficiency, and 2 billion adults are overweight or obese. The food system is under pressure from non-climate stressors (e.g., population and income growth, demand for animal-sourced products), and from climate change. These climate and non-climate stresses are impacting the four pillars of food security (availability, access, utilisation, and stability). {5.1.1, 5.1.2}

Observed climate change is already affecting food security through increasing temperatures, changing precipitation patterns, and greater frequency of some extreme events *(high confidence)*. Increasing temperatures are affecting agricultural productivity in higher latitudes, raising yields of some crops (maize, cotton, wheat, sugar beets), while yields of others (maize, wheat, barley) are declining in lower-latitude regions. Warming compounded by drying has caused yield declines in parts of Southern Europe. Based on indigenous and local knowledge, climate change is affecting food security in drylands, particularly those in Africa, and high mountain regions of Asia and South America. {5.2.2}

Food security will be increasingly affected by projected future climate change *(high confidence)*. Across SSPs 1, 2, and 3, global crop and economic models projected a 1-29% cereal price increase in 2050 due to climate change (RCP 6.0), which would impact consumers globally through higher food prices; regional effects will vary *(high confidence)*. Low-income consumers are particularly at risk, with models projecting increases of 1-183 million additional people at risk of hunger across the SSPs compared to a no climate change scenario *(high confidence)*. While increased CO_2 is projected to be beneficial for crop productivity at lower temperature increases, it is projected to lower nutritional quality *(high confidence)* (e.g., wheat grown at 546-586 ppm CO_2 has 5.9–12.7% less protein, 3.7–6.5% less zinc, and 5.2–7.5% less iron). Distributions of pests and diseases will change, affecting production negatively in many regions *(high confidence)*. Given increasing extreme events and interconnectedness, risks of food system disruptions are growing *(high confidence)*. {5.2.3, 5.2.4}

Vulnerability of pastoral systems to climate change is very high (*high confidence*). Pastoralism is practiced in more than 75% of countries by between 200 and 500 million people, including nomadic communities, transhumant herders, and agro-pastoralists. Impacts in pastoral systems include lower pasture and animal productivity, damaged reproductive function, and biodiversity loss. Pastoral system vulnerability is exacerbated by non-climate factors (land tenure, sedentarisation, changes in traditional institutions, invasive species, lack of markets, and conflicts). {5.2.2}

Fruit and vegetable production, a key component of healthy diets, is also vulnerable to climate change *(medium evidence, high agreement)*. Declines in yields and crop suitability are projected under higher temperatures, especially in tropical and semi-tropical regions. Heat stress reduces fruit set and speeds up development of annual vegetables, resulting in yield losses, impaired product quality, and increasing food loss and waste. Longer growing seasons enable a greater number of plantings to be cultivated and can contribute to greater annual yields. However, some fruits and vegetables need a period of cold accumulation to produce a viable harvest, and warmer winters may constitute a risk. {5.2.2}

Food security and climate change have strong gender and equity dimensions (*high confidence*). Worldwide, women play a key role in food security, although regional differences exist. Climate change impacts vary among diverse social groups depending on age, ethnicity, gender, wealth, and class. Climate extremes have immediate and long-term impacts on livelihoods of poor and vulnerable communities, contributing to greater risks of food insecurity that can be a stress multiplier for internal and external migration *(medium confidence).* {5.2.6} Empowering women and rights-based approaches to decision-making can create synergies among household food security, adaptation, and mitigation. {5.6.4}

Many practices can be optimised and scaled up to advance adaptation throughout the food system *(high confidence)*. Supply-side options include increased soil organic matter and erosion control, improved cropland, livestock, and grazing land management, and genetic improvements for tolerance to heat and drought. Diversification in the food system (e.g., implementation of integrated production systems, broad-based genetic resources, and heterogeneous diets) is a key strategy to reduce risks (*medium confidence*). Demand-side adaptation, such as adoption of healthy and sustainable diets, in conjunction with reduction in food loss and waste, can contribute to adaptation through reduction in additional land area needed for food production and associated food system vulnerabilities. Indigenous and local knowledge can contribute to enhancing food system resilience *(high confidence)*. {5.3, 5.6.3 Cross-Chapter Box 6}.

Ca. 25-30% of total GHG emissions are attributable to the food system. These are from agriculture and land use, storage, transport, packaging, processing, retail, and consumption *(medium confidence)*. This estimate includes emissions of 10–12% from crop and livestock activities within the farm gate and 8-10% from land use and land use change including deforestation and peatland degradation *(high confidence)*; 5–10% is from supply chain activities *(medium confidence)*. This estimate includes GHG emissions from food loss and waste. Within the food system, during the period 2007-2016, the major sources of emissions from the supply side were agricultural production, with crop and livestock activities within the farm gate generating respectively 142 ± 43 Tg CH_4 yr^{-1} *(high confidence)* and 8.3 ± 2.3 Tg N_2O yr^{-1} *(high confidence)*, and CO_2 emissions linked to relevant land use change dynamics such as deforestation and peatland degradation, generating 4.8 ± 2.4 Gt CO_2 yr^{-1}. Using 100-year GWP values (no climate feedback) from the IPCC AR5, this implies that total GHG emissions from agriculture were 6.2 ± 1.9 Gt CO_2eq yr^{-1}, increasing to 11.0 ± 3.1 Gt CO_2eq yr^{-1} including relevant land use. Without intervention, these are likely to increase by about 30%–40% by 2050, due to increasing demand based on population and income growth and dietary change *(high confidence)*. {5.4}

Supply-side practices can contribute to climate change mitigation by reducing crop and livestock emissions, sequestering carbon in soils and biomass, and by decreasing emissions intensity within sustainable production systems *(high confidence)*. Total mitigation potential of crop and livestock activities is estimated as 1.5–4.0 GtCO_2-eq yr^{-1} by 2030 at prices ranging from 20-100 USD/tCO_2eq *(high confidence)*. Options with large potential for GHG mitigation in cropping systems include soil carbon sequestration (at decreasing rates over time), reductions in N_2O emissions from fertilisers, reductions in CH_4 emissions from paddy rice, and bridging of yield gaps. Options with large potential for mitigation in livestock systems include better grazing land management, with increased net primary production and soil carbon stocks, improved manure management, and higher-quality feed. Reductions in GHG emissions intensity (emissions per unit product) from livestock can support reductions in absolute emissions, provided appropriate governance to limit total production is implemented at the same time (*medium confidence*). {5.5.1}

Consumption of healthy and sustainable diets presents major opportunities for reducing GHG emissions from food systems and improving health outcomes *(high confidence)*. Examples of healthy and sustainable diets are high in coarse grains, pulses, fruits and vegetables, and nuts and seeds; low in energy-intensive animal-sourced and discretionary foods (such as sugary beverages); and with a carbohydrate threshold. Total mitigation potential of dietary changes is estimated as 1.8-3.4 GtCO_2eq yr^{-1} by 2050 at prices ranging from 20-100 USD/tCO_2 *(medium confidence)*. This estimate includes reductions in emissions from livestock and soil carbon sequestration on spared land, but co-benefits with health are not taken into account. Mitigation potential of dietary change may be higher, but achievement of this potential at broad scales depends on consumer choices and dietary preferences that are guided by social, cultural, environmental, and traditional factors, as well as income growth. Meat analogues such as imitation meat (from plant products), cultured meat, and insects may help in the transition to more healthy and sustainable diets, although their carbon footprints and acceptability are uncertain. {5.5.2, 5.6.5}

Reduction of food loss and waste could lower GHG emissions and improve food security *(medium confidence)*. Combined food loss and waste amount to a third of global food production *(high confidence)*. During 2010-2016, global food loss and waste equalled 8–10% of total GHG emissions from food systems *(medium confidence)*; and cost about USD 1 trillion per year (2012 prices) *(low confidence)*. Technical options for reduction of food loss and waste include improved harvesting techniques, on-farm storage, infrastructure, and packaging. Causes of food loss (e.g., lack of refrigeration) and waste (e.g., behaviour) differ substantially in developed and developing countries, as well as across regions *(robust evidence, medium agreement)*. {5.5.2}

Agriculture and the food system are key to global climate change responses. Combining supply-side actions such as efficient production, transport, and processing with demand-side interventions such as modification of food choices, and reduction of food loss and waste, reduces GHG emissions and enhances food system resilience (*high confidence*). Such combined measures can enable the implementation of large-scale land-based adaptation and mitigation strategies without threatening food security from increased competition for land for food production and higher food prices. Without combined food system measures in farm management, supply chains, and demand, adverse effects would include increased number of malnourished people and impacts on smallholder farmers (*medium evidence, high agreement*). Just transitions are needed to address these effects. {5.5, 5.6, 5.7}

For adaptation and mitigation throughout the food system, enabling conditions need to be created through policies, markets, institutions, and governance *(high confidence)*. For adaptation, resilience to increasing extreme events can be accomplished through risk sharing and transfer mechanisms such as insurance markets and index-based weather insurance *(high confidence)*. Public health policies to improve nutrition – such as school procurement, health insurance incentives, and awareness-raising campaigns – can potentially change demand, reduce health-care costs, and contribute to lower GHG emissions *(limited evidence, high agreement)*. Without inclusion of comprehensive food system responses in broader climate change policies, the mitigation and adaptation potentials assessed in this chapter will not be realised and food security will be jeopardised (*high confidence*). {5.7}

5.1 Framing and context

The current food system (production, transport, processing, packaging, storage, retail, consumption, loss and waste) feeds the great majority of world population and supports the livelihoods of ca. 200 million people. Agriculture as an economic activity generates between 1% and 60% of national GDP in many countries, with a world average of about 4% in 2017 (World Bank 2019). Since 1961, food supply per capita has increased more than 30%, accompanied by greater use of nitrogen fertiliser (increase of about 800%) and water resources for irrigation (increase of more than 100%).

The rapid growth in agricultural productivity since the 1960s has underpinned the development of the current global food system that is both a major driver of climate change, and increasingly vulnerable to it (from production, transport, and market activities). Given the current food system, the FAO estimates that there is a need to produce about 50% more food by 2050 in order to feed the increasing world population (FAO 2018a). This would engender significant increases in GHG emissions and other environmental impacts, including loss of biodiversity. FAO (2018a) projects that by 2050 cropland area will increase 90-325 Mha, between 6-21% more than the 1,567 Mha cropland area of 2010, depending on climate change scenario and development pathway (the lowest increase arises from reduced food loss and waste and adoption of more sustainable diets).

Climate change has direct impacts on food systems, food security, and, through the need to mitigate, potentially increases the competition for resources needed for agriculture. Responding to climate change through deployment of land-based technologies for negative emissions based on biomass production would increasingly put pressure on food production and food security through potential competition for land.

Using a food system approach, this chapter addresses how climate change affects food security, including nutrition, the options for the food system to adapt and mitigate, synergies and trade-offs among these options, and enabling conditions for their adoption. The chapter assesses the role of incremental and transformational adaptation, and the potential for combinations of supply-side measures such as sustainable intensification (increasing productivity per hectare) and demand-side measures (e.g., dietary change and waste reduction) to contribute to climate change mitigation.

5.1.1 Food security and insecurity, the food system, and climate change

The *food system* encompasses all the activities and actors in the production, transport, manufacturing, retailing, consumption, and waste of food, and their impacts on nutrition, health and well-being, and the environment (Figure 5.1).

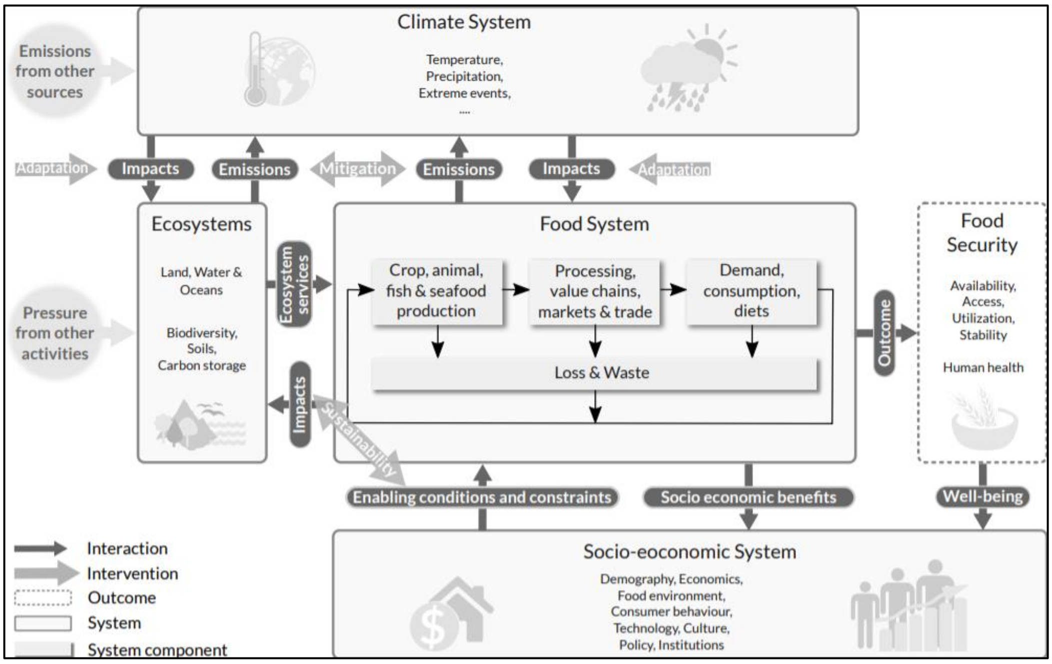

Figure 5.1 Interlinkages between the climate system, food system, ecosystem (land, water and oceans), and socio-economic system. These systems operate at multiple scales, both global and regional. Food security is an outcome of the food system leading to human well-being, which is also indirectly linked with climate and ecosystems through the socio-economic system. Response options for sustainable (S) practices, mainly in terms of climate change mitigation (M) and adaptation (A) are represented by grey arrows. Adapation measures can help to reduce negative impacts of climate change on the food system and ecosystems. Mitigation measures can reduce greenhouse gas emissions coming from the food system and ecosystems.

5.1.1.1 Food security as an outcome of the food system

The activities and the actors in the food system leads to outcomes such as food security and generate impacts on the environment. As part of the environmental impacts, food systems are a considerable contributor to greenhouse gas emissions, and thus climate change (Section 5.4). In turn climate change has complex interactions with food systems, leading to food insecurity through impacts on food availability, access, utilisation and stability (Table 5.1; Section 5.2).

We take a *food systems lens* in the Special Report on Climate Change and Land (SRCCL) to recognise that demand for and supply of food are interlinked and need to be jointly assessed in order to identify the challenges of mitigation and adaptation to climate change. Outcomes cannot be disaggregated solely to, for example, agricultural production, because the demand for food shapes what is grown, where it is grown, and how much is grown. Thus, greenhouse gas emissions from agriculture result, in large part, from ‘pull’ from the demand side. Mitigation and adaptation involve modifying production, supply chain, and demand practices (through for example dietary choices, market incentives, and trade relationships), so as to evolve a more sustainable and healthy food system.

According to FAO (2001a), *food security* is a situation that exists when all people, at all times, have physical, social, and economic access to sufficient, safe, and nutritious food that meets their dietary needs and food preferences for an active and healthy life. “All people at all times” implies the need for equitable and stable food distribution, but it is increasingly recognised that it also covers the need for inter-generational equity, and therefore “sustainability” in food production. “Safe and nutritious food …for a healthy life” implies that food insecurity can occur if the diet is not nutritious, including when there is consumption of an excess of calories, or if food is not safe, meaning free from harmful substances.

A prime impact of food insecurity is *malnourishment* (literally "bad nourishment") leading to *malnutrition*, which refers to deficiencies, excesses, or imbalances in a person's intake of energy and/or nutrients. As defined by FAO et al. (2018), undernourishment occurs when an individual's habitual food consumption is insufficient to provide the amount of dietary energy required to maintain a normal, active, healthy life. In addition to undernourishment in the sense of insufficient calories ("hunger"), undernourishment occurs in terms of nutritional deficiencies in vitamins (e.g., Vitamin A) and minerals (e.g., iron, zinc, iodine), so-called "hidden hunger". Hidden hunger tends to be present in countries with high levels of undernourishment (Muthayya et al. 2013), but micronutrient deficiency can occur in societies with low prevalence of undernourishment. For example, in many parts of the world teenage girls suffer from iron deficiency (Whitfield et al. 2015) and calcium deficiency is common in Western-style diets (Aslam and Varani 2016). Food security is related to nutrition, and conversely food insecurity is related to malnutrition. Not all malnourishment arises from food insecurity, as households may have access to healthy diets but choose to eat unhealthily, or it may arise from illness. However, in many parts of the world, poverty is linked to poor diets (FAO et al. 2018). This may be through lack of resources to produce or access food in general, or healthy food, in particular, as healthier diets are more expensive than diets rich in calories but poor in nutrition (*high confidence)* (see meta-analysis by Darmon and Drewnowski 2015). The relationship between poverty and poor diets may also be linked to unhealthy "food environments," with retail outlets in a locality only providing access to foods of low-nutritional quality (Gamba et al. 2015) – such areas are sometimes termed "food deserts" (Battersby 2012).

Whilst conceptually the definition of food security is clear, it is not straightforward to measure in a simple way that encompasses all its aspects. Although there are a range of methods to assess food insecurity, they all have some shortcomings. For example, the UN FAO has developed the Food Insecurity Experience Scale (FIES), a survey-based tool to measure the severity of overall households' inability to access food. While it provides reliable estimates of the prevalence of food insecurity in a population, it does not reveal whether actual diets are adequate or not with respect to all aspects of nutrition (see Section 5.1.2.1).

5.1.1.2 Effects of climate change on food security

Climate change is projected to negatively impact the four pillars of food security – availability, access, utilisation and stability – and their interactions (FAO et al. 2018) *(high confidence)*. This chapter assesses recent work since AR5 that has strengthened understanding of how climate change affects each of these pillars across the full range of food system activities (Table 5.1, Section 5.2).

While most studies continue to focus on availability via impacts on food production, more studies are addressing related issues of access (e.g., impacts on food prices), utilisation (e.g., impacts on nutritional quality), and stability (e.g., impacts of increasing extreme events) as they are affected by a changing climate (Bailey et al. 2015). Low-income producers and consumers are likely to be most affected because of a lack of resources to invest in adaptation and diversification measures (UNCCD 2017; Bailey et al. 2015).

Table 5.1 Relationships between food security, the food system, and climate change and guide to chapter.

Food security pillar	**Examples of observed and projected climate change impacts**	**Sections**	**Examples of adaptation and mitigation**	**Section**
Availability *Production*	Reduced yields in crop and livestock systems	5.2.2.1, 5.2.2.2	Development of adaptation practices	5.3

of food and its readiness for use through storage, processing, distribution, sale and/or exchange	Reduced yields from lack of pollinators; pests and diseases	5.2.2.3, 5.2.2.4	Adoption of new technologies, new and neglected varieties	5.3.2.3, 5.3.3.1,
	Reduced food quality affecting availability (e.g., food spoilage and loss from mycotoxins)	5.2.4.1, 5.5.2.5	Enhanced resilience by integrated practices, better food storage	5.3.2.3, 5.3.3.4, 5.6.4
	Disruptions to food storage and transport networks from change in climate, including extremes	5.2.5.1, 5.3.3.4, 5.8.1, Box 5.5	Reduction of demand on by reducing waste, modifying diets	5.3.4, 5.5.2, 5.7
			Closing of crop yield and livestock productivity gaps	5.6.4.4, 5.7
			Risk management, including marketing mechanisms, financial insurance	5.3.2, 5.7
Access: *Ability to obtain food, including effects of price*	Yield reductions, changes in farmer livelihoods, limitations on ability to purchase food	5.2.2.1, 5.2.2.2	Integrated agricultural practices to build resilient livelihoods	5.6.4
	Price rise and spike effects on low-income consumers, in particular women and children, due to lack of resources to purchase food	5.1.3, 5.2.3.1, 5.2.5.1, Box 5.1	Increased supply chain efficiency (e.g., reducing loss and waste)	5.3.3, 5.3.4
	Effects of increased extreme events on food supplies, disruption of agricultural trade and transportation infrastructure	5.8.1	More climate-resilient food systems, shortened supply chains, dietary change, market change	5.7
Utilisation *Achievement of food potential through nutrition, cooking, health*	Impacts on food safety due to increased prevalence of microorganisms and toxins	5.2.4.1	Improved storage and cold chains	5.3.3, 5.3.4
	Decline in nutritional quality resulting from increasing atmospheric CO_2	5.2.4.2	Adaptive crop and livestock varieties, healthy diets, better sanitation	5.3.4, 5.5.2, 5.7
	Increased exposure to diarrheal and other infectious diseases due to increased risk of flooding	5.2.4.1		
Stability *Continuous availability and access to food without disruption*	Greater instability of supply due to increased frequency and severity of extreme events; food price rises and spikes; instability of agricultural incomes	5.2.5, 5.8.1	Resilience via integrated systems and practices, diversified local agriculture, infrastructure investments, modifying markets and trade, reducing food loss and waste	5.6.4, 5.7, 5.8.1
	Widespread crop failure contributing to migration and conflict	5.8.2	Crop insurance for farmers to cope with extreme events	5.3.2.2, 5.7
			Capacity building to develop resilient systems	5.3.6, 5.7.4

Combined *Systemic impacts from interactions of all four pillars*	Increasing undernourishment as food system is impacted by climate change	5.1	Increased food system productivity and efficiency (e.g., supply side mitigation, reducing waste, dietary change)	5.5.1, 5.7
	Increasing obesity and ill health through narrow focus on adapting limited number commodity crops	5.1	Increased production of healthy food and reduced consumption of energy-intensive products	5.5.2, 5.7
	Increasing environmental degradation and GHG emissions	Cross-Chapter Box 6	Development of climate smart food systems by reducing GHG emissions, building resilience, adapting to climate change	5.3.3, 5.7
	Increasing food insecurity due to competition for land and natural resources (e.g., for land-based mitigation)	5.6.1	Governance and institutional responses (including food aid) that take into consideration gender and equity	5.2.5, 5.7

5.1.2 Status of the food system, food insecurity, and malnourishment

5.1.2.1 Trends in the global food system

Food is predominantly produced on land, with, on average, 83% of the 697 kg of food consumed per person per year, 93% of the 2884 kcal per day, and 80% of the 81 g of protein eaten per day coming from terrestrial production in 2013 (FAOSTAT 2018)[1]. With increases in crop yields and production (Figure 5.2), the absolute supply of food has been increasing over the last five decades. Growth in production of animal-sourced food is driving crop utilisation for livestock feed (FAOSTAT 2018; Pradhan et al. 2013a). Global trade of crop and animal-sourced food has increased by around 5 times between 1961 and 2013 (FAOSTAT 2018). During this period, global food availability has increased from 2200 kcal/cap/day to 2884 kcal/cap/day, making a transition from a food deficit to a food surplus situation (FAOSTAT 2018; Hiç et al. 2016).

The availability of cereals, animal products, oil crops, and fruits and vegetables has mainly grown (FAOSTAT 2018), reflecting shifts towards more affluent diets. This, in general, has resulted in a decrease in prevalence of underweight and an increase in prevalence of overweight and obesity among adults (Abarca-Gómez et al. 2017). During the period 1961-2016, anthropogenic greenhouse gas emissions associated with agricultural production has grown from 3.1 Gt CO_2-eq yr^{-1} to 5.8 Gt CO_2-eq yr^{-1} (Section 5.4.2, Chapter 2). The increase in emissions is mainly from the livestock sector (from enteric fermentation and manure left on pasture), use of synthetic fertiliser, and rice cultivation (FAOSTAT 2018).

[1] FOOTNOTE: Does not take into account terrestrial production of feed.

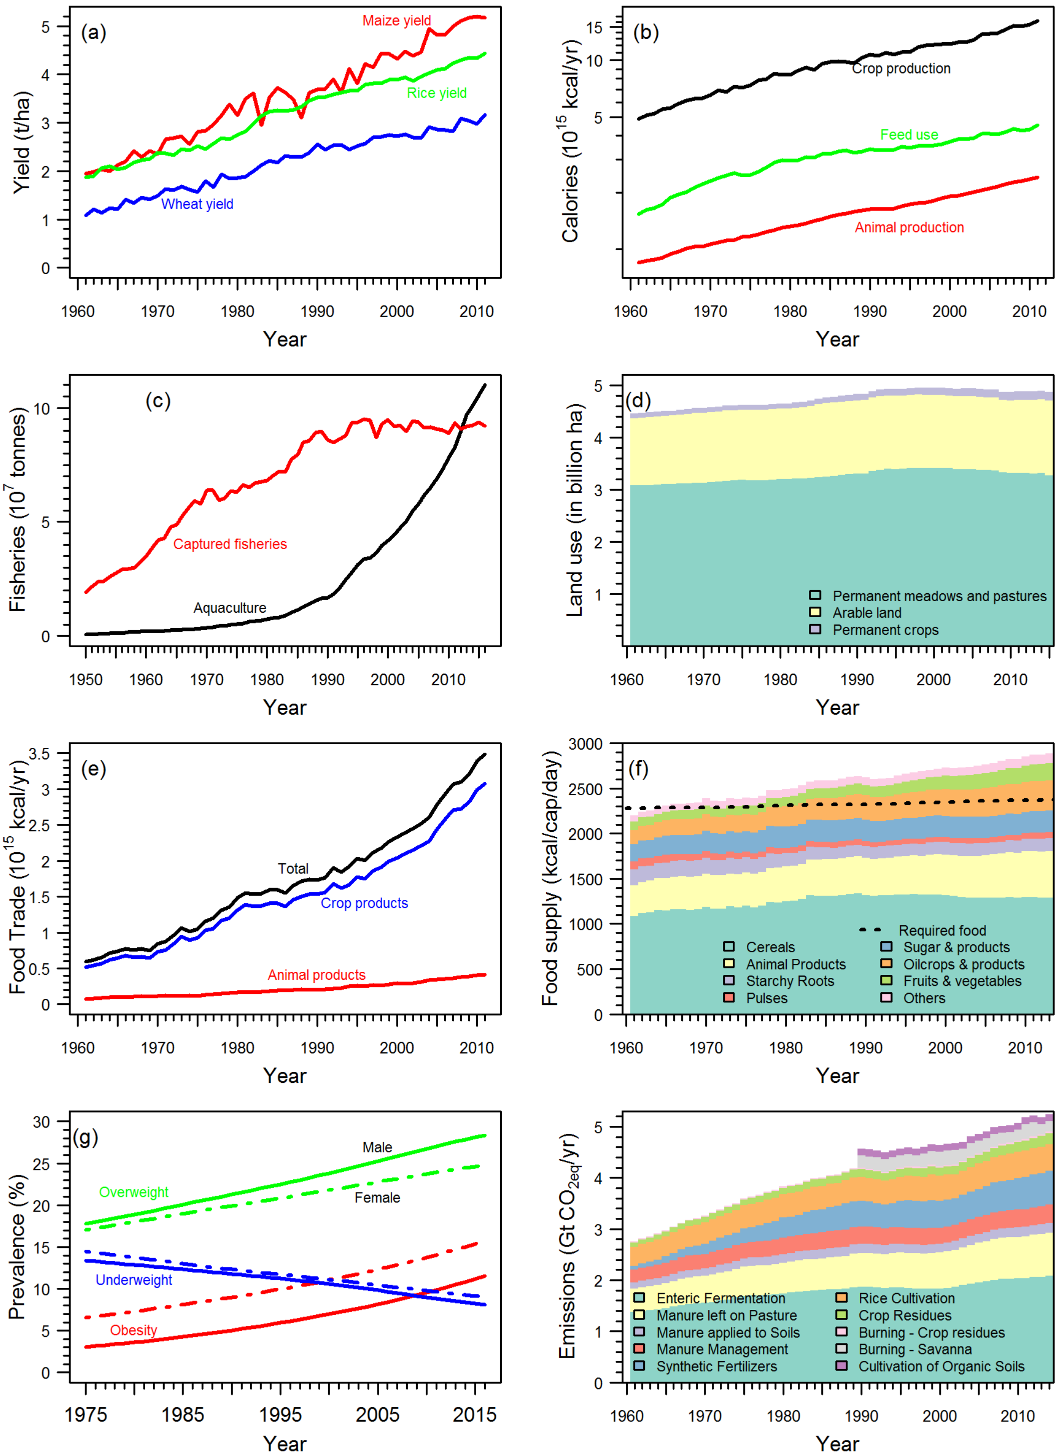

Figure 5.2 Global trends in (a) yields of maize, rice, and wheat (FAOSTAT 2018) – the top three crops grown in the world; (b) production of crop and animal calories and use of crop calories as livestock feed (FAOSTAT 2018); (c) production from marine and aquaculture fisheries (FishStat 2019); (d) land used for agriculture (FAOSTAT 2018); (e) food trade in calories (FAOSTAT 2018); (f) food supply and required food (i.e., based on human energy requirements for medium physical activities) from 1961–2012 (FAOSTAT 2018; Hiç et al. 2016); (g) prevalence of overweight, obesity and underweight from 1975–2015 (Abarca-Gómez et al. 2017); and (h) GHG emissions for the agriculture sector, excluding land use change (FAOSTAT 2018). For figures (b) and (e), data provided in mass units were converted into calories using nutritive factors (FAO 2001b). Data on emissions due to burning of savanna and cultivation of organic soils is provided only after 1990 (FAOSTAT 2018).

5.1.2.2 Food insecurity status and trends

In addressing food security the dual aspects of malnutrition – under-nutrition and micro-nutrient deficiency, as well as over-consumption, overweight, and obesity – need to be considered (Figure 5.2g and Table 5.2). The UN agencies' *State of Food Security and Nutrition* 2018 report (FAO et al. 2018) and the Global Nutrition Report 2017 (Development Initiatives 2017) summarise the global data. The *State of Food Security* report's estimate for undernourished people on a global basis is 821 million, up from 815 million the previous year and 784 million the year before that. Previous to 2014/2015 the prevalence of hunger had been declining over the last three decades. The proportion of young children (under 5) who are stunted (low height-for-age), has been gradually declining, and was 22% in 2017 compared to 31% in 2012 (150.8 million, down from 165.2 million in 2012). In 2017, 50.5 million children (7.5%) under 5 were wasted (low weight for height). Since 2014, undernutrition has worsened, particularly in parts of sub-Saharan Africa, South-Eastern Asia and Western Asia, and recently Latin America. Deteriorations have been observed most notably in situations of conflict and conflict combined with droughts or floods (FAO et al. 2018).

Regarding micronutrient deficiencies known as 'hidden hunger', reporting suggests a prevalence of one in three people globally (FAO 2013a; von Grebmer et al. 2014; Tulchinsky 2010) (Table 5.2). In the last decades, hidden hunger (measured through proxies targeting iron, vitamin A, and zinc deficiencies) worsened in Africa, while it mainly improved in Asia and Pacific (Ruel-Bergeron et al. 2015). In 2016, 613 million women and girls aged 15 to 49 suffered from iron deficiency (Development Initiatives 2018); in 2013, 28.5% of the global population suffered from iodine deficiency; and in 2005, 33.3% of children under five and 15.3% of pregnant women suffered from vitamin A deficiency, and 17.3% of the global population suffered from zinc deficiency (HLPE 2017).

Table 5.2 Global prevalence of various forms of malnutrition

	HLPE 2017 (UN)	SOFI 2017 (FAO)	GNR 2017	SOFI 2018 (FAO)	GNR2018
Overweight but not obese[a]	1.3 billion		1.93 billion		1.34 billion (38,9%)[c]
Overweight under five	41 million	41 million	41 million	38 million	38 million
Obesity[b]	600 million	600 million (13%)	641 million	672 million	678 million (13,1%)[c]
Undernourishment	800 million	815 million	815 million	821 million	
Stunting under five	155 million	155 million	155 million[d]	151 million	151 million[d] (22%)
Wasting under five	52 million	52 million (8%)	52 million[d]	50 million	51 million[d] (7%)
MND (iron)	19.2% of pregnant women[e]	33% women of reproductive age	613 million women and girls aged 15 to 49[f]	613 million (32.8%) women and girls aged 15 to 49[f]	613 million (32.8%) women and girls aged 15 to 49[f]

HLPE: High Level Panel of Experts of the committee of world food security; *SOFI*: The State of Food Security and Nutrition in the World; *GNR*: Global Nutrition Report; *MND*: Micro nutrient deficiency (Iron deficiency for year 2016, uses anemia as a proxy (percentage of pregnant women whose haemoglobin level is less than 110 grams per litre at sea level and percentage of non-pregnant women whose haemoglobin level is less than 120 grams per litre at sea level).

[c]Prevalence of overweight/obesity among adults (age ≥18) in year 2016. Data from NCD Risc data source.

[d]UNICEF WHO Joint Malnutrition;

[e]In 2011

[f]Anaemia prevalence in girls and women aged 15 to 49

Globally, as the availability of inexpensive calories from commodity crops increases, so does per capita consumption of calorie-dense foods (Ng et al. 2014; NCD-RisC 2016a; Abarca-Gómez et al. 2017; Doak and Popkin 2017). As a result, in every region of the world, the prevalence of obesity (body mass index >30 kg/m^2) and overweight (body mass index range between normality [18.5-24.9] and obesity) is increasing. There are now more obese adults in the world than underweight adults (Ng et al. 2014; NCD-RisC 2016a; Abarca-Gómez et al. 2017; Doak and Popkin 2017). In 2016, around two billion adults were overweight, including 678 million suffering from obesity (NCD-RisC 2016a; Abarca-Gómez et al. 2017). The prevalence of overweight and obesity has been observed in all age groups.

Around 41 million children under five years and 340 million children and adolescents aged 5–19 years were suffering from overweight or obesity in 2016 (NCD-RisC 2016a; FAO et al. 2017; WHO 2015). In many high-income countries, the rising trends in children and adolescents suffering from overweight and obesity have stagnated at high levels; however, these have accelerated in parts of Asia and have very slightly reduced in European and Central Asian lower and middle-income countries (Abarca-Gómez et al. 2017; Doak and Popkin 2017; Christmann et al. 2009).

There are associations between obesity and non-communicable diseases such as diabetes, dementia, inflammatory diseases (Saltiel and Olefsky 2017), cardio-vascular disease (Ortega et al. 2016) and some cancers, e.g., of the colon, kidney, and liver (Moley and Colditz 2016). There is a growing recognition of the rapid rise in overweight and obesity on a global basis and its associated health burden created through the non-communicable diseases (NCD-RisC 2016a; HLPE 2017).

Analyses reported in FAO et al. (2018) highlight the link between food insecurity, as measured by the FIES scale, and malnourishment (*medium agreement, robust evidence*). This varies by malnourishment measure as well as country (FAO et al. 2018). For example, there is *limited evidence* (*low agreement* but multiple studies) that food insecurity and childhood wasting (i.e., or low weight for height) are closely related, but it is very likely (*high agreement, robust evidence*) that childhood stunting and food insecurity are related (FAO et al. 2018). With respect to adult obesity there is *robust evidence, with medium agreement*, that food insecurity, arising from poverty reducing access to nutritious diets, is related to the prevalence of obesity, especially in high-income countries and adult females. An additional meta-analysis (for studies in Europe and North America) also finds a negative relationship between income and obesity, with some support for an effect of obesity causing low income (as well as vice versa) (Kim and von dem Knesebeck 2018).

As discussed in Section 5.1.1.1, different methods of assessing food insecurity can provide differential pictures. Of particular note is the spatial distribution of food insecurity, especially in higher-income countries. FAO et al. (2018) reports FIES estimates of severe food insecurity in Africa, Asia and Latin America of 29.8%, 6.9% and 9.8% of the population, respectivity, but of 1.4% of the population (i.e., about 20 million in total; pro rata <5 million for US, <1 million for UK) in Europe and North America. However, in the United States, USDA estimates 40 million people were exposed to varying degrees of food insecurity, from mild to severe (overall prevalence about 12%) (Coleman-Jensen et al. 2018). In the UK, estimates from 2017 and 2018 indicate about 4 million adults are moderately to severely food insecure (prevalence 8%) (End Hunger UK 2018; Bates et al. 2017). The UK food bank charity, the Trussell Trust, over a year in 2017/18, distributed 1,332,952 three-day emergency food parcels to people referred to the charity as being in food crisis. Furthermore, a 2003 study in the UK (Schenker 2003) estimated that 40% of adults, and 15% of children, admitted to hospitals were malnourished, and that 70% of undernourishment in the UK was unreported.

In total, more than half the world's population are underweight or overweight (NCD-RisC 2017a), so their diets do not provide the conditions for 'an active and healthy life'. This will be more compromised under the impacts of climate change by changing the availability, access, utilisation, and stability of diets of sufficient nutritional quality as shown in Table 5.2 and discussed in detail below (see Section 5.2).

5.1.3 Climate change, gender, and equity

Throughout, the chapter considers many dimensions of gender and equity in regard to climate change and the food system (Box 5.1). Climate change impacts differ among diverse social groups depending on factors such as age, ethnicity, ability/disability, sexual orientation, gender, wealth, and class (*high confidence*) (Vincent and Cull 2014; Kaijser and Kronsell 2014). Poverty, along with socio-economic and political marginalisation, cumulatively put women, children and the elderly in a disadvantaged position in coping with the adverse impacts of the changing climate (UNDP 2013; Skoufias et al. 2011). The contextual vulnerability of women is higher due to their differentiated relative power, roles, and responsibilities at the household and community levels (Bryan and Behrman 2013; Nelson et al. 2002). They often have a higher reliance on subsistence agriculture, which will be severely impacted by climate change (Aipira et al. 2017).

Through impacts on food prices (section 5.2.3.1) poor people's food security is particularly threatened. Decreased yields can impact nutrient intake of the poor by decreasing supplies of highly nutritious crops and by promoting adaptive behaviours that may substitute crops that are resilient but less nutritious (Thompson et al. 2012; Lobell and Burke 2010). In Guatemala, food prices and poverty have been correlated with lower micronutrient intakes (Iannotti et al. 2012). In the developed world, poverty is more typically associated with calorically-dense but nutrient-poor diets, obesity, overweight, and other related diseases (Darmon and Drewnowski 2015).

Rural areas are especially affected by climate change (Dasgupta et al. 2014), through impacts on agriculture-related livelihoods and rural income (Mendelsohn et al. 2007) and through impacts on employment. Jessoe et al. (2018) using a 28-year panel on individual employment in rural Mexico, found that years with a high occurrence of heat lead to a reduction in local employment by up to 1.4% with a medium emissions scenario, particularly for wage work and non-farm labour, with impacts on food access. Without employment opportunities in areas where extreme poverty is prevalent, people may be forced to migrate, exacerbating potential for ensuing conflicts (FAO 2018a).

Finally, climate change can affect human health in other ways that interact with food utilisation. In many parts of the world where agriculture relies still on manual labour, projections are that heat stress will reduce the hours people can work, and increase their risk (Dunne et al. 2013). For example, Takakura et al (2017) estimates that under RCP8.5, the global economic loss from people working shorter hours to mitigate heat loss may be 2.4–4% of GDP. Furthermore, as discussed by (Watts et al. 2018); people's nutritional status interacts with other stressors and affects their susceptibility to ill health (the "utilisation pillar" of food security): so food-insecure people are more likely to be adversely affected by extreme heat, for example.

In the case of food price hikes, those more vulnerable are more affected (Uraguchi 2010), especially in urban areas (Ruel et al. 2010), where livelihood impacts are particularly severe for the individuals and groups that have scarce resources or are socially isolated (Revi et al. 2014; Gasper et al. 2011) (*high confidence*). These people often lack power and access to resources, adequate urban services and functioning infrastructure. As climate events become more frequent and intense, this can increase the scale and depth of urban poverty (Rosenzweig et al. 2018b). Urban floods and droughts may result in water contamination increasing the incidence of diarrhoeal illness in poor children (Bartlett 2008). In the near destruction of New Orleans by Hurricane Katrina, about 40,000 jobs were lost (Rosemberg 2010).

Box 5.1 Gender, food security, and climate change

Differentiated impacts, vulnerability, risk perception, behaviours and coping strategies for climate change related to food security derive from cultural (gendered) norms, that is, the behaviours, tasks, and responsibilities a society defines as "male" or "female", and the differential gendered access to resources (Paris and Rola-Rubzen 2018; Aberman and Tirado 2014; Lebel et al. 2014; Bee 2016). In many rural areas women often grow most of the crops for domestic consumption and are primarily responsible for storing, processing, and preparing food; handling livestock; gathering food, fodder and fuelwood; managing domestic water supply; and providing most of the labour for post-harvest activities (FAO 2011a). They are mostly impacted through increased hardship, implications for household roles, and subsequent organisational responsibilities (Boetto and McKinnon 2013; Jost et al. 2016). Water scarcity can particularly affect women because they need to spend more time and energy to collect water, where they may be more exposed to physical and sexual violence (Sommer et al. 2015; Aipira et al. 2017). They may be forced to use unsafe water in the household increasing risk of water-borne diseases (Parikh 2009). Climate change also has differentiated gendered impacts on livestock-holders food security (McKune et al. 2015; Ongoro and Ogara 2012; Fratkin et al. 2004) (See Supplementary Material Table SM5.1).

Gender dimensions of the four pillars

Worldwide, women play a key role in food security (World Bank 2015) and the four pillars of food security have strong gender dimensions (Thompson 2018). In terms of food availability, women tend to have less access to productive resources, including land, and thus less capacity to produce food (Cross-chapter box 11: Gender in Chapter 7).

In terms of food access, gendered norms in how food is divided at mealtimes may lead to smaller food portions for women and girls. Women's intra-household inequity limits their ability to purchase food; limitations also include lack of women's mobility impacting trips to the market and lack of decision-making within the household (Ongoro and Ogara 2012; Mason et al. 2017; Riley and Dodson 2014).

In terms of food utilisation, men, women, children and the elderly have different nutritional needs (e.g., during pregnancy or breast-feeding).

In terms of stability, women are more likely to be disproportionately affected by price spikes (Vellakkal et al. 2015; Arndt et al. 2016; Hossain and Green 2011; Darnton-Hill and Cogill 2010; Cohen and Garrett 2010; Kumar and Quisumbing 2013) because when food is scarce women reduce food consumption relative to other family members, although these norms vary according to age, ethnicity, culture, region, and social position, as well as by location in rural or urban areas (Arora-Jonsson 2011; Goh 2012; Niehof 2016; Ongoro and Ogara 2012).

Integrating gender into adaptation

Women have their own capabilities to adapt to climate change. In the Pacific Islands, women hold critical knowledge on where or how to find clean water; which crops to grow in a flood or a drought season; how to preserve and store food and seeds ahead of approaching storms, floods or droughts;

and how to carry their families through the recovery months. They also play a pivotal role in managing household finances and investing their savings in education, health, livelihoods, and other activities that assist their families to adapt and respond to climate effects (Aipira et al. 2017). Decreasing women's capacity to adapt to the impacts of climate change also decreases that of the household (Bryan and Behrman 2013).

However, gender norms and power inequalities also shape the ability of men, women, boys, girls and the elderly to adapt to climate risks (Rossi and Lambrou 2008). For example, women pastoralists in the Samburu district of Kenya cannot make decisions affecting their lives, limiting their adaptive capacity (Ongoro and Ogara 2012).

Participation in decision-making and politics, division of labour, resource access and control, and knowledge and skills (Nelson and Stathers 2009) are some of the barriers to adaptation. Women's adaptive capacity is also diminished because their work often goes unrecognised (Rao 2005; Nelson and Stathers 2009). Many of women's activities are not defined as "economically active employment" in national accounts (FAO 2011a). This non-economic status of women's activities implies that they are not included in wider discussions of priorities or interventions for climate change. Their perspectives and needs are not met; and thus, interventions, information, technologies, and tools promoted are potentially not relevant, and even can increase discrimination (Alston 2009; Edvardsson Björnberg and Hansson 2013; Huynh and Resurreccion 2014).

Where gender-sensitive policies to climate change may exist, effective implementation in practice of gender equality and empowerment may not be achieved on the ground due to lack of technical capacity, financial resources and evaluation criteria, as shown in the Pacific Islands (Aipira et al. 2017). Thus, corresponding institutional frameworks that are well-resourced, coordinated, and informed are required, along with adequate technical capacity within government agencies, NGOs and project teams, to strength collaboration and promote knowledge sharing (Aipira et al. 2017).

Women's empowerment: Synergies among adaptation, mitigation, and food security

Empowered and valued women in their societies increases their capacity to improve food security under climate change, make substantial contributions to their own well-being, to that of their families and of their communities (Langer et al. 2015; Ajani et al. 2013; Alston 2014) (*high confidence*). Women's empowerment includes economic, social and institutional arrangements and may include targeting men in integrated agriculture programs to change gender norms and improve nutrition (Kerr et al. 2016). Empowerment through collective action and groups-based approaches in the near-term has the potential to equalise relationships on the local, national and global scale (Ringler et al. 2014). Empowered women are crucial to creating effective synergies among adaptation, mitigation, and food security.

In Western Kenya, widows in their new role as main livelihood providers invested in sustainable innovations like rainwater harvesting systems and agroforestry (this can serve as both adaptation and mitigation), and worked together in formalised groups of collective action (Gabrielsson and Ramasar 2013) to ensure food and water security. In Nepal, women's empowerment had beneficial outcomes in maternal and children nutrition, reducing the negative effect of low production diversity (Malapit et al. 2015). Integrated nutrition and agricultural programs have increased women's decision-making power and control over home gardens in Burkina Faso (van den Bold et al. 2015) with positive impacts on food security.

5.1.4 Food systems in AR5, SR15, and the Paris Agreement

Food, and its relationship to the environment and climate change, has grown in prominence since the Rio Declaration in 1992, where food production is Chapter 14 of Agenda 21, to the Paris Agreement of 2015, which includes the need to ensure food security under the threat of climate change on its first page. This growing prominence of food is reflected in recent IPCC reports, including its Fifth Assessment Report (IPCC 2014a) and the Special Report on Global Warming of 1.5°C (SR15) (IPCC 2018a).

5.1.4.1 Food systems in AR5 and SR15

The IPCC Working Group (WG) II AR5 chapter on Food Security and Food Production Systems broke new ground by expanding its focus beyond the effects of climate change primarily on agricultural production (crops, livestock and aquaculture) to include a food systems approach as well as directing attention to undernourished people (Porter et al. 2014). However, it focused primarily on food production systems due to the prevalence of studies on that topic (Porter et al. 2017). It highlighted that a range of potential adaptation options exist across all food system activities, not just in food production, and that benefits from potential innovations in food processing, packaging, transport, storage, and trade were insufficiently researched at that time.

The IPCC WG III AR5 chapter on Agriculture, Forestry and Other Land Use (AFOLU) assessed mitigation potential considering not only the supply, but also the demand side of land uses, by consideration of changes in diets; it also included food loss and waste (Smith et al. 2014). AR5 focused on crop and livestock activities within the farm gate and land use and land use change dynamics associated with agriculture. It did not take a full food system approach to emissions estimates that includes processing, transport, storage, and retail.

The IPCC WG II AR5 Rural Areas chapter (Revi et al. 2014) found that farm households in developing countries are vulnerable to climate change due to socio-economic characteristics and non-climate stressors, as well as climate risks (Dasgupta et al. 2014). They also found that a wide range of on-farm and off-farm climate change adaptation measures are already being implemented and that the local social and cultural context played a prominent role in the success or failure of different adaptation strategies for food security, such as trade, irrigation or diversification. The IPCC WG II AR5 Urban Areas chapter found that food security of people living in cities was severely affected by climate change through reduced supplies, including urban-produced food, and impacts on infrastructure, as well as a lack of access to food. Poor urban dwellers are more vulnerable to rapid changes of food prices due to climate change.

Many climate change response options in IPCC WG II and WG III AR5 (IPCC 2014b) address incremental adaptation or mitigation responses separately rather than being inclusive of more systemic or transformational changes in multiple food systems that are large-scale, in depth, and rapid, requiring social, technological, organisational and system responses (Rosenzweig and Solecki 2018; Mapfumo et al. 2017; Termeer et al. 2017). In many cases, transformational change will require integration of resilience and mitigation across all parts of the food system including production, supply chains, social aspects, and dietary choices. Further, these transformational changes in the food system need to encompass linkages to ameliorative responses to land degradation (see Chapter 4), desertification (see Chapter 3), and declines in quality and quantity of water resources throughout the food-energy-water nexus (Chapter 2; Section 5.7).

The IPCC Special Report on Global Warming of 1.5°C found that climate-related risks to food security are projected to increase with global warming of 1.5°C and increase further with 2°C (IPCC 2018a).

5.1.4.2 Food systems and the Paris Agreement

To reach the temperature goal put forward in the Paris Agreement of limiting warming to well below 2°C, and pursuing efforts to limit warming to 1.5°C, representatives from 196 countries signed the United Nations Framework Convention on Climate Change (UNFCCC) Paris Agreement (UNFCCC 2015) in December 2015. The Agreement put forward a temperature target of limiting warming to well below 2°C, and pursuing efforts to limit warming to 1.5°C. Under the Paris Agreement, Parties are expected to put forward their best efforts through nationally determined contributions (NDCs) and to strengthen these efforts in the years ahead. Article 2 of the Agreement makes clear the agreement is within “the context of sustainable development” and states actions should be "in a manner that does not threaten food production” to ensure food security.

Many countries have included food systems in their mitigation and adaptation plans as found in their NDCs for the Paris Agreement (Rosenzweig et al. 2018a). Richards et al. (2015) analysed 160 Party submissions and found that 103 include agricultural mitigation; of the 113 Parties that include adaptation in their NDCs, almost all (102) include agriculture among their adaptation priorities. There is much attention to conventional agricultural practices that can be climate-smart and sustainable (e.g., crop and livestock management), but less to the enabling services that can facilitate uptake (e.g., climate information services, insurance, credit). Considerable finance is needed for agricultural adaptation and mitigation by least developed countries – in the order of USD 3 billion annually for adaptation and USD 2 billion annually for mitigation, which may be an underestimate due to a small sample size (Richards et al. 2015). On the mitigation side, none of the largest agricultural emitters included sector-specific contributions from the agriculture sector in their NDCs, but most included agriculture in their economy-wide targets (Richards et al. 2018).

Carbon dioxide removal (CDR). A key aspect regarding the implementation of measures to achieve the Paris Agreement goals involves measures related to carbon dioxide removal (CDR) through bioenergy (Sections 5.5 and 5.6). To reach the temperature target put forward of limiting warming to well below 2°C, and pursuing efforts to limit warming to 1.5°C, large investments and abrupt changes in land use will be required to advance bioenergy with carbon capture and sequestration (BECCS), afforestation and reforestation (AR), and biochar technologies. Existing scenarios estimate the global area required for BECCS alone to help limit warming to 1.5°C in the range of 109-990 Mha, most commonly around 380-700 Mha.

Most scenarios assume very rapid deployment between 2030 and 2050, reaching rates of expansion in land use in 1.5°C scenarios exceeding 20 M ha yr^{-1}, which are unprecedented for crops and forestry reported in the FAO database from 1961. Achieving the 1.5 °C target would thus result in major competing demands for land between climate change mitigation and food production, with cascading impacts on food security.

This chapter assesses how the potential conflict for land could be alleviated by sustainable intensification to produce food with a lower land footprint (Section 5.6, Cross-Chapter Box 6: Agricultural intensification). To accomplish this, farmers would need to produce the same amount of food with lower land requirement, which depends on technology, skills, finance, and markets. Achieving this would also rely on demand-side changes including dietary choices that enable reduction of the land footprint for food production while still meeting dietary needs. Transitions required for such transformative changes in food systems are addressed in Section 5.7.

5.1.4.3 Charting the future of food security

This chapter utilises the common framework of the Representative Concentration Pathways (RCPs) and the Shared Socio-economic Pathways (SSPs) (Popp et al. 2017; Riahi et al. 2017; Doelman et al. 2018) to assess the impacts of future GHG emissions, mitigation measures, and adaptation on food security (See Cross-Chapter Box 1: Scenarios in Chapter 1, Section 5.2 and 5.6).

New work utilising these scenario approaches has shown that the food system externalises costs onto human health and the environment (Springmann et al. 2018a; Swinburn et al. 2019; Willett et al. 2019), leading to calls for transforming the food system to deliver better human and sustainability outcomes (Willett et al. 2019; IAP 2018; Development Initiatives 2018; Lozano et al. 2018). Such a transformation could be an important lever to address the complex interactions between climate change and food security. Through acting on mitigation and adaptation in regard to both food demand and food supply we assess the potential for improvements to both human health and the Sustainable Development Goals (Section 5.6).

This chapter builds on the food systems and scenario approaches followed by AR5 and its focus on climate change and food security, but new work since AR5 has extended beyond production to how climate change interacts with the whole food system. The analysis of climate change and food insecurity has expanded beyond undernutrition to include the overconsumption of unhealthy mass-produced food high in sugar and fat, which also threatens health in different but highly damaging ways and the role of dietary choices and consumption in greenhouse gas emissions. It focused on land-based food systems, though highlighting in places the contributions of freshwater and marine production.

The chapter assesses new work on the observed and projected effects of CO_2 concentrations on the nutritional quality of crops (Section 5.2.4.2) and emphasises the role of extreme climate events (Section 5.2.5.1), social aspects including gender and equity (Box 5.1. and Cross-chapter Box 11: Gender in Chapter 7), and dietary choices (Section 5.4.6, 5.5.2). Other topics with considerable new literature include impacts on smallholder farming systems (Section 5.2.2.6), food loss and waste (Section **Error! Reference source not found.**), and urban and peri-urban agriculture (Section 5.6.5). he chapter explores the potential competing demands for land that mitigation measures to achieve temperature targets may engender, with cascading impacts on food production, food security, and farming systems (Section 5.6), and the enabling conditions for achieving the mitigation and adaptation in equitable and sustainable ways (Section 5.7). Section 5.8 presents challenges to future food security, including food price spikes, migration, and conflict.

5.2 Impacts of climate change on food systems

There are many routes by which climate change can impact food security and thus human health (Watts et al. 2018; Fanzo et al. 2017). One major route is via climate change affecting the amount of food, both from direct impacts on yields (Section 5.2.2.1) and indirect effects through climate change's impacts on water availability and quality, pests and diseases (Section 5.2.2.3), and pollination services (Section 5.2.2.4). Another route is via changing CO_2 in the atmosphere, affecting biomass and nutritional quality (Section 5.2.4.2). Food safety risks during transport and storage can also be exacerbated by changing climate (Section 5.2.4.1).

Further, the direct impacts of changing weather can affect human health through the agricultural workforce's exposure to extreme temperatures (Section 5.2.5.1). Through changing metabolic demands and physiological stress for people exposed to extreme temperatures, there is also the potential for interactions with food availability: people may require more food to cope, whilst at the same time being impaired from producing it (Watts et al. 2018). All these factors have the potential to alter both physical health as well as cultural health, through changing the amount, safety and quality of food available for individuals within their cultural context.

This section assesses recent literature on climate change impacts on the four pillars of food security: availability (Section 5.2.2), access (Section 5.2.3), utilisation (Section 5.2.4), and stability (Section 5.2.5). It considers impacts on the food system from climate changes that are already taking place and how impacts are projected to occur in the future. See Supplementary Material Section SM5.2 for discussion of detection and attribution and improvement in projection methods.

5.2.1 Climate drivers important to food security

Climate drivers relevant to food security and food systems include temperature-related, precipitation-related, and integrated metrics that combine these and other variables. These are projected to affect many aspects of the food security pillars (FAO 2018b) (see Supplementary Material Table SM5.2 and Chapter 6 for assessment of observed and projected climate impacts). Climate drivers relevant to food production and availability may be categorised as modal climate changes (e.g., shifts in climate envelopes causing shifts in cropping varieties planted), seasonal changes (e.g., warming trends extending growing seasons), extreme events (e.g., high temperatures affecting critical growth periods, flooding/droughts), and atmospheric conditions (e.g., CO_2 concentrations, short-lived climate pollutants (SLCPs), and dust). Water resources for food production will be affected through changing rates of precipitation and evaporation, ground water levels, and dissolved oxygen content (Cruz-Blanco et al. 2015; Sepulcre-Canto et al. 2014; Huntington et al. 2017; Schmidtko et al. 2017). Potential changes in major modes of climate variability can also have widespread impacts such as occurred during late 2015 to early 2016 when a strong El Niño contributed to regional shifts in precipitation in the Sahel region. Significant drought across Ethiopia resulted in widespread crop failure and more than 10 million people in Ethiopia required food aid (U.S. Department of State 2016; Huntington et al. 2017) (see Figure 5.3).

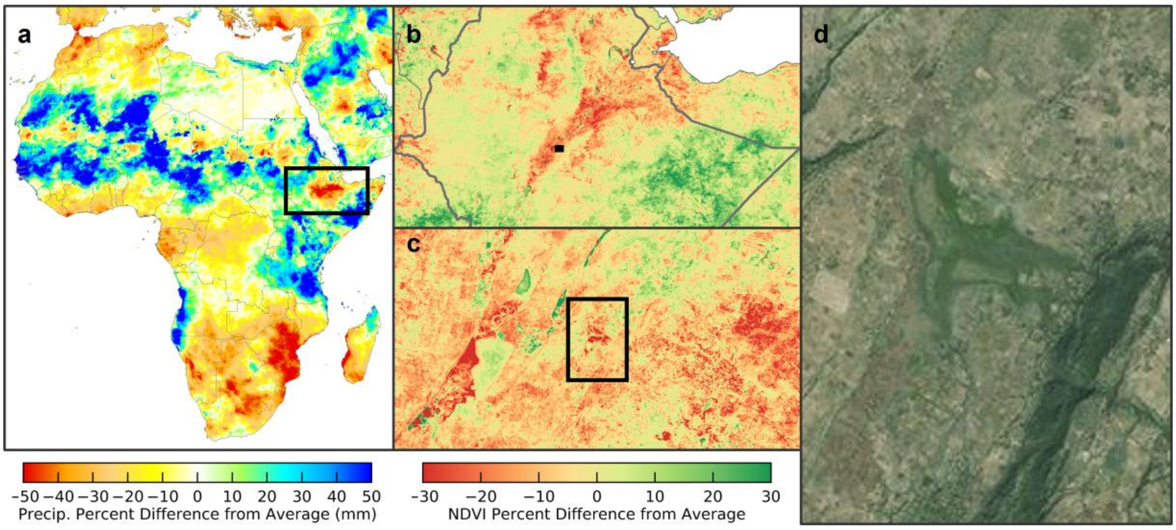

Figure 5.3 Precipitation anomaly and vegetation response in Eastern Africa. (a) Sep 2015–Feb 2016 Climate Hazards Group Infrared Precipitation with Station (CHIRPS) precipitation anomaly over Africa relative to the 1981–2010 average shows that large areas of Ethiopia received less than half of normal precipitation. Consequently, widespread impacts to agricultural productivity, especially within pastoral regions, were present across Ethiopia as evidenced by (d) reduced greenness in remote sensing images. (b) MODIS NDVI anomalies for Sep 2015–Feb 2016 relative to 2000–2015 average are shown for the inset box in (a). (c) Landsat NDVI anomalies for Sep 2015–Feb 2016 relative to 2000–2015 average are shown for the inset box in (b) (Huntington et al. 2017).

Other variables that affect agricultural production, processing, and/or transport are solar radiation, wind, humidity, and (in coastal areas) salinisation and storm surge (Mutahara et al. 2016; Myers et al. 2017). Extreme climate events resulting in inland and coastal flooding, can affect the ability of people to obtain and prepare food (Rao et al. 2016; FAO et al. 2018). For direct effects of atmospheric CO_2 concentrations on crop nutrient status see Section 5.2.4.2.

5.2.1.1 Short-lived climate pollutants

The important role of short-lived climate pollutants such as ozone and black carbon is increasingly emphasised since they affect agricultural production through direct effects on crops and indirect effects on climate (Emberson et al. 2018; Lal et al. 2017; Burney and Ramanathan 2014; Ghude et al. 2014) (see Chapters 2 and 4). Ozone causes damage to plants through damages to cellular metabolism that influence leaf-level physiology to whole-canopy and root-system processes and feedbacks; these impacts affect leaf-level photosynthesis senescence and carbon assimilation, as well as whole-canopy water and nutrient acquisition and ultimately crop growth and yield (Emberson et al. 2018). Using atmospheric chemistry and a global integrated assessment model, Chuwah et al. (2015) found that without a large decrease in air pollutant emissions, high ozone concentration could lead to an increase in crop damage of up to 20% in agricultural regions in 2050 compared to projections in which changes in ozone are not accounted for. Higher temperatures are associated with higher ozone concentrations; C3 crops are sensitive to ozone (e.g., soybeans, wheat, rice, oats, green beans, peppers, and some types of cottons) and C4 crops are moderately sensitive (Backlund et al. 2008).

Methane increases surface ozone which augments warming-induced losses and some quantitative analyses now include climate, long-lived (CO_2) and mulitple short-lived pollutants (CH_4, O_3) simultaneously (Shindell et al. 2017; Shindell 2016). Reduction of tropospheric ozone and black carbon can avoid premature deaths from outdoor air pollution and increases annual crop yields (Shindell et al. 2012). These actions plus methane reduction can influence climate on shorter time scales than those of carbon dioxide–reduction measures. Implementing them substantially reduces the risks of crossing the 2°C threshold and contributes to achievement of the SDGs (Haines et al. 2017; Shindell et al. 2017).

5.2.2 Climate change impacts on food availability

Climate change impacts food availability through its effect on the production of food and its storage, processing, distribution, and exchange.

5.2.2.1 Impacts on crop production

Observed impacts. Since AR5, there have been further studies that document impacts of climate change on crop production and related variables (See Supplementary Material Table SM5.3). There have been also a few studies that demonstrate a strengthening relationship between observed climate variables and crop yields that indicate future expected warming will have severe impacts on crop production (Mavromatis 2015; Innes et al. 2015). At the global scale, Iizumi et al. (2018) used a counterfactual analysis and found that climate change between 1981-2010 has decreased global mean yields of maize, wheat, and soybeans by 4.1, 1.8 and 4.5%, respectively, relative to preindustrial climate, even when CO_2 fertilisation and agronomic adjustments are considered. Uncertainties (90% probability interval) in the yield impacts are -8.5 to +.5% for maize, -7.5 to +4.3% for wheat, and -8.4 to -0.5% for soybeans. For rice, no significant impacts were detected. This study suggests that climate change has modulated recent yields on the global scale and led to production losses, and that adaptations to date have not been sufficient to offset the negative impacts of climate change, particularly at lower latitudes.

Dryland settlements are perceived as vulnerable to climate change with regard to food security, particularly in developing countries; such areas are known to have low capacities to cope effectively with decreasing crop yields (Shah et al. 2008; Nellemann et al. 2009). This is of concern because drylands constitute over 40% of the earth's land area, and are home to 2.5 billion people (FAO et al. 2011).

Australia. In Australia, declines in rainfall and rising daily maximum temperatures based on simulations of 50 sites caused water-limited yield potential to decline by 27% from 1990 to 2015, even though elevated atmospheric CO_2 concentrations had a positive effect (Hochman et al. 2017). In New South Wales, high-temperature episodes during the reproduction stage of crop growth were found to have negative effects on wheat yields, with combinations of low rainfall and high temperatures being the most detrimental (Innes et al. 2015).

Asia. There are numerous studies demonstrating that climate change is affecting agriculture and food security in Asia. Several studies with remote sensing and statistical data have examined rice areas in northeastern China, the northernmost region of rice cultivation, and found expansion over various time periods beginning in the 1980s, with most of the increase occurring after 2000 (Liu et al. 2014; Wang et al. 2014; Zhang et al. 2017). Rice yield increases have also been found over a similar period (Wang et al. 2014). Multiple factors, such as structural adjustment, scientific and technological progress, and government policies, along with regional warming (1.43°C in the past century) (Fenghua et al. 2006) have been put forward as contributing to the observed expanded rice areas and yield in the region. Shi et al. (2013) indicate that there is a partial match between climate change patterns and shifts in extent and location of the rice-cropping area (2000-2010).

There have also been documented changes in winter wheat phenology in Northwest China (He 2015). Consistent with this finding, dates of sowing and emergence of spring and winter wheat were delayed, dates of anthesis and maturity was advanced, and length of reproductive growth period was prolonged from 1981-2011 in a study looking at these crops across China (Liu et al. 2018b). Another study looking in Norwest China demonstrated that there have been changes in the phenology and productivity of spring cotton (Huang and Ji 2015). A study looking at wheat growth and yield in different climate zones of China from 1981-2009 found that impacts were positive in Northern China and negative in Southern China (Tao et al. 2014). Temperature increased across the zones while precipitation changes were not consistent (Tao et al. 2014).

Crop yield studies focusing on India have found that warming has reduced wheat yields by 5.2% from 1981 to 2009, despite adaptation (Gupta et al. 2017); that maximum daytime temperatures have risen along with some night-time temperatures (Jha and Tripathi 2017).

Agriculture in Pakistan has also been affected by climate change. From 1980 to 2014, spring maize growing periods have shifted an average of 4.6 days per decade earlier, while sowing of autumn maize has been delayed 3.0 days per decade (Abbas et al. 2017). A similar study with sunflower showed that increases in mean temperature from 1980 to 2016 were highly correlated with shifts in sowing, emergence, anthesis, and maturity for fall and spring crops (Tariq et al. 2018).

Mountain people in the Hindu-Kush Himalayan region encompassing parts of Pakistan, India, Nepal, and China, are particularly vulnerable to food insecurity related to climate change because of poor infrastructure, limited access to global markets, physical isolation, low productivity, and hazard exposure, including Glacial Lake Outburst Floods (GLOFs) (Rasul et al. 2019; Rasul 2010; Tiwari and Joshi 2012; Huddleston et al. 2003; Ward et al. 2013; FAO 2008; Nautiyal et al. 2007; Din et al. 2014). Surveys have been conducted to determine how climate-related changes have affected food security (Hussain et al. 2016; Shrestha and Nepal 2016) with results showing that the region is experiencing an increase in extremes, with farmers facing more frequent floods as well as prolonged droughts with ensuing negative impacts on agricultural yields and increases in food insecurity (Hussain et al. 2016; Manzoor et al. 2013).

South America. In another mountainous region, the Andes, inhabitants are also beginning to experience changes in the timing, severity, and patterns of the annual weather cycle. Data collected through participatory workshops, semi-structured interviews with agronomists, and qualitative fieldwork from 2012 to 2014 suggest that in Colomi, Bolivia climate change is affecting crop yields and causing farmers to alter the timing of planting, their soil management strategies, and the use and spatial distribution of crop varieties (Saxena et al. 2016). In Argentina, there has also been in increase in yield variability of maize and soybeans (Iizumi and Ramankutty 2016). These changes have had important implications for the agriculture, human health, and biodiversity of the region (Saxena et al. 2016).

Africa. In recent years, yields of staple crops such as maize, wheat, sorghum, and fruit crops, such as mangoes, have decreased across Africa, widening food insecurity gaps (Ketiem et al. 2017). In Nigeria, there have been reports of climate change having impacts on the livelihoods of arable crop farmers (Abiona et al. 2016; Ifeanyi-obi et al. 2016; Onyeneke 2018). The Sahel region of Cameroon has experienced an increasing level of malnutrition, partly due to the impact of climate change since harsh climatic conditions leading to extreme drought have a negative influence on agriculture (Chabejong 2016).

Utilising farmer interviews in Abia State, Nigeria, researchers found that virtually all responders agreed that the climate was changing in their area (Ifeanyi-obi et al. 2016). With regard to management responses, a survey of farmers from Anambra State, Nigeria showed that farmers are adapting to climate change by utilising such techniques as mixed cropping systems, crop rotation, fertiliser application (Onyeneke et al. 2018). In Ebonyi State, Nigeria, Eze (2017) interviewed 160 women cassava farmers and found the major climate change risks in production to be severity of high temperature stress, variability in relative humidity, and flood frequency.

Europe. The impacts of climate change are varied across the continent. Moore and Lobell (2015) showed that climate trends are affecting European crop yields, with long-term temperature and precipitation trends since 1989 reducing continent-wide wheat and barley yields by 2.5% and 3.8%, respectively, and having slightly increased maize and sugar beet yields. Though these aggregate affects appear small, the impacts are not evenly distributed. In cooler regions such as the United Kingdom and Ireland, the effect of increased warming has been ameliorated by an increase in rainfall. Warmer regions, such as Southern Europe, have suffered more from the warming; in Italy this effect has been amplified by a drying, leading to yield declines of 5% or greater.

Another study examining the impacts of recent climate trends on cereals in Greece showed that crops are clearly responding to changes in climate – and demonstrated via statistical analysis that significant impacts on wheat and barley production are expected at the end of the twenty-first century (Mavromatis 2015). In the Czech Republic, a study documented positive long-term impacts of recent warming on yields of fruiting vegetables (cucumbers and tomatoes) (from 4.9 to 12% per 1°C increase in local temperature) but decreases in yield stability of traditionally grown root vegetables in the warmest areas of the country (Potopová et al. 2017). A study in Hungary also indicated the increasingly negative impacts of temperature on crops and indicated that a warming climate is at least partially responsible for the stagnation or reduction in crop yields since the mid-1980s in Eastern Europe (Pinke and Lövei 2017).

In summary, climate change is already affecting some aspects of food security *(high confidence)*. Recent studies in both large-scale and smallholder farming systems document declines in crop productivity related to rising temperatures and changes in precipitation. Evidence for climate change impacts (e.g., declines and stagnation in yields, changes in sowing and harvest dates, increased infestation of pests and diseases, and declining viability of some crop varieties) is emerging from detection and attribution studies and indigenous and local knowledge in Australia, Europe, Asia, Africa, North America, and South America (*medium evidence, robust agreement*).

Projected impacts. Climate change effects have been studied on a global scale following a variety of methodologies that have recently been compared (Lobell and Asseng 2017; Zhao et al. 2017a; Liu et al. 2016). Approaches to study global and local changes include global gridded crop model simulations (e.g., (Deryng et al. 2014)), point-based crop model simulations (e.g., (Asseng et al. 2015)), analysis of point-based observations in the field (e.g., (Zhao et al. 2016)), and temperature-yield regression models (e.g., (Auffhammer and Schlenker 2014)). For an evaluation of model skills see e.g., used in AgMIP see Müller et al. (2017b).

Results from Zhao et al. (2017a) across different methods consistently showed negative temperature impacts on crop yield at the global scale, generally underpinned by similar impacts at country and site scales. A limitation of Zhao et al. (2017a) is that it is based on the assumption that yield responses to temperature increase are linear, while yield response differs depending on growing season temperature level. Iizumi et al. (2017) showed that the projected global mean yields of maize and soybean at the end of this century do decrease monotonically with warming, whereas those of rice and wheat increase with warming and level off at a warming of about 3°C (2091–2100 relative to 1850–1900).

Empirical statistical models have been applied widely to different cropping systems, at multiple scales. Analyses using statistical models for maize and wheat tested with global climate model scenarios found that the RCP4.5 scenario reduced the size of average yield impacts, risk of major slowdowns, and exposure to critical heat extremes compared to RCP8.5 in the latter decades of the 21st century (Tebaldi and Lobell 2018). Impacts on crops grown in the tropics are projected to be more negative than in mid- to high-latitudes as stated in AR5 and confirmed by recent studies (e.g., (Levis et al. 2018)). These projected negative effects in the tropics are especially pronounced under conditions of explicit nitrogen stress (Figure 5.4) (Rosenzweig et al. 2014).

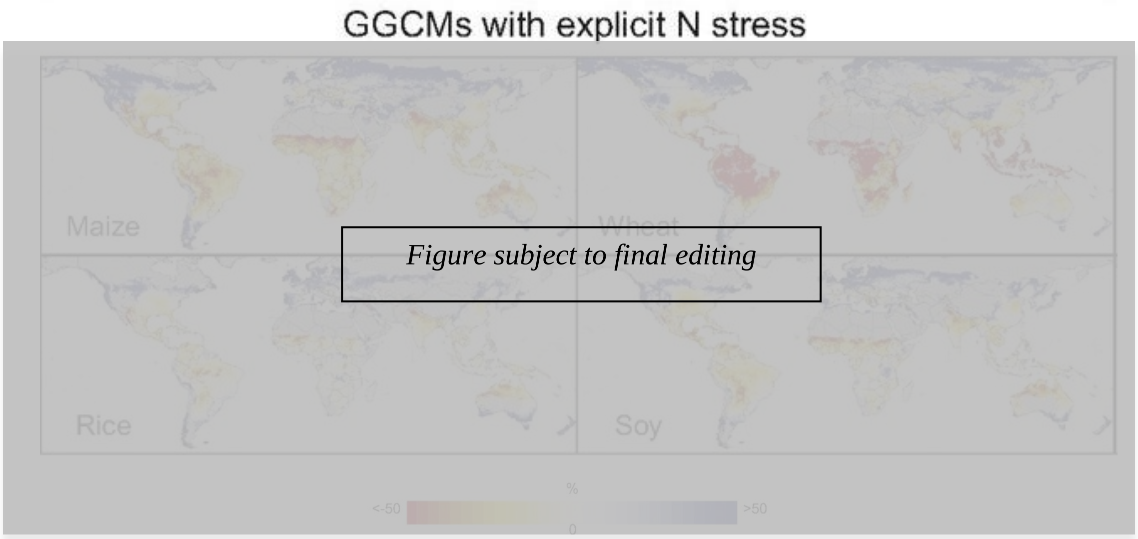

Figure 5.4 Median yield changes (%) for RCP8.5 (2070–2099 in comparison to 1980–2010 baseline) with CO_2 effects and explicit nitrogen stress over five GCMs x four Global Gridded Crop Models (GGCMs) for rainfed maize, wheat, rice, and soy (20 ensemble members from EPIC, GEPIC, pDSSAT, and PEGASUS; except for rice which has 15). Gray areas indicate historical areas with little to no yield capacity. All models use a 0.5° grid, but there are differences in grid cells simulated to represent agricultural land. While some models simulated all land areas, others simulated only potential suitable cropland area according to evolving climatic conditions; others utilised historical harvested areas in 2000 according to various data sources (Rosenzweig et al. 2014).

Reyer et al. (2017b) examined biophysical impacts in five world regions under different warming scenarios - 1, 1.5, 2, and 4 °C warming. For the Middle East and Northern Africa region a significant correlation between crop yield decrease and temperature increase was found, regardless of whether the effects of CO_2 fertilisation or adaptation measures are taken into account (Waha et al. 2017). For Latin America and the Caribbean the relationship between temperature and crop yield changes was only significant when the effect of CO_2 fertilisation is considered (Reyer et al. 2017a).

A review of recent scientific literature found that projected yield loss for West Africa depends on the degree of wetter or drier conditions and elevated CO_2 concentrations (Sultan and Gaetani 2016). Faye et al. (2018b) in a crop modelling study with RCPs 4.5 and 8.5 found that climate change could have limited effects on peanut yield in Senegal due to the effect of elevated CO_2 concentrations.

Crop productivity changes for 1.5°C and 2.0°C. The IPCC Special Report on Global Warming of 1.5°C found that climate-related risks to food security are projected to increase with global warming of 1.5°C and increase further with 2°C (IPCC 2018b). These findings are based among others on Schleussner et al. (2018); Rosenzweig et al. (2018a); Betts et al. (2018), Parkes et al. (2018) and Faye et al. (2018a). The importance of assumptions about CO_2 fertilisation was found to be significant by Ren et al. (2018) and Tebaldi and Lobell (2018)

AgMIP coordinated global and regional assessment (CGRA) results confirm that at the global scale, there are mixed results of positive and negative changes in simulated wheat and maize yields, with declines in some breadbasket regions, at both 1.5°C and 2.0°C (Rosenzweig et al. 2018a). In conjunction with price changes from the global economics models, productivity declines in the Punjab, Pakistan resulted in an increase in vulnerable households and poverty rate (Rosenzweig et al. 2018a).

Crop suitability. Another method of assessing the effects of climate change on crop yields that combined observations of current maximum-attainable yield with climate analogues also found strong reductions in attainable yields across a large fraction of current cropland by 2050 (Pugh et al. 2016).

However, the study found the projected total land area in 2050, including regions not currently used for crops, climatically suitable for a high attainable yield similar to today. This indicates that large shifts in land-use patterns and crop choice will likely be necessary to sustain production growth and keep pace with current trajectories of demand.

Fruits and vegetables. Understanding the full range of climate impacts on fruits and vegetables is important for projecting future food security, especially related to dietary diversity and healthy diets. However, studies for vegetables are very limited (Bisbis et al. 2018). Of the 174 studies considered in a recent review only 14 described results of field or greenhouse experiments studying impacts of increased temperatures on yields of different root and leafy vegetables, tomatoes and legumes (Scheelbeek et al. 2018). Bisbis et al. (2018) found similar effects for vegetables as have been found for grain crops, that is, the effect of increased CO_2 on vegetables is mostly beneficial for production, but may alter internal product quality, or result in photosynthetic down-regulation. Heat stress reduces fruit set of fruiting vegetables, and speeds up development of annual vegetables, shortening their time for photoassimilation. Yield losses and impaired product quality result, thereby increasing food loss and waste. On the other hand, a longer growing season due to warmer temperatures enables a greater number of plantings and can contribute to greater annual yields. However, some vegetables, such as cauliflower and asparagus, need a period of cold accumulation to produce a harvest and warmer winters may not provide those requirements.

For vegetables growing in higher baseline temperatures (>20°C), mean yield declines caused by 4°C warming were 31.5%; for vegetables growing in cooler environments (</= 20°C), yield declines caused by 4°C were much less, on the order of ~5% (Scheelbeek et al. 2018). Rippke et al. (2016) found that 30–60% of the common bean growing area and 20–40% of the banana growing areas in Africa will lose viability in 2078–2098 with a global temperature increase of 2.6°C and 4°C respectively. Tripathi et al. (2016) found fruits and vegetable production to be highly vulnerable to climate change at their reproductive stages and also due to potential for greater disease pressure.

In summary, studies assessed find that climate change will increasingly be detrimental to crop productivity as levels of warming progress *(high confidence)*. Impacts will vary depending on CO_2 concentrations, fertility levels, and region. Productivity of major commodity crops as well as crops such as millet and sorghum yields will be affected. Studies on fruits and vegetables find similar effects to those projected for grain crops in regard to temperature and CO_2 effects. Total land area climatically suitable for high attainable yield, including regions not currently used for crops, will be similar in 2050 to today.

5.2.2.2 Impacts on livestock production systems

Livestock systems are impacted by climate change mainly through increasing temperatures and precipitation variation, as well as atmospheric carbon dioxide (CO_2) concentration and a combination of these factors. Temperature affects most of the critical factors of livestock production, such as water availability, animal production and reproduction, and animal health (mostly through heat stress) (Figure 5.5). Livestock diseases are mostly affected by increases in temperature and precipitation variation (Rojas-Downing et al. 2017). Impacts of climate change on livestock productivity, particularly of mixed and extensive systems, are strongly linked to impacts on rangelands and pastures, which include the effects of increasing CO_2 on their biomass and nutritional quality. This is critical considering the very large areas concerned and the number of vulnerable people affected (Steinfeld 2010; Morton 2007). Pasture quality and quantity are mainly affected through increases in temperature and CO_2, and precipitation variation.

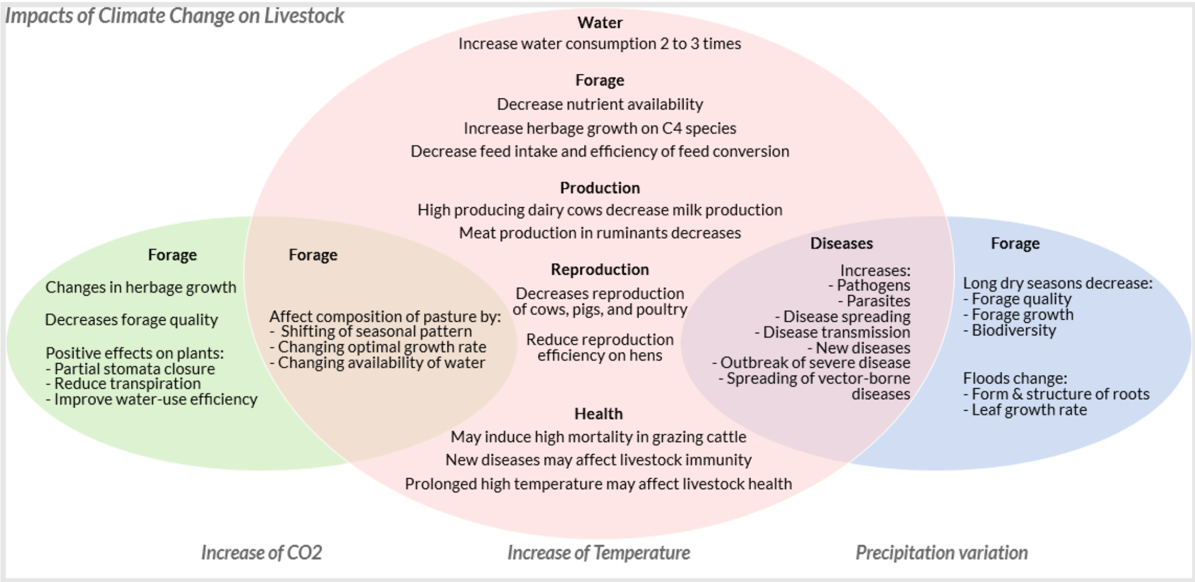

Figure 5.5 Impacts of climate change on livestock, based on (Rojas-Downing et al. 2017)

Among livestock systems, pastoral systems are particularly vulnerable to climate change (Dasgupta et al. 2014) (see Section 5.2.2.6 for impacts on smallholder systems that combine livestock and crops). Industrial systems will suffer most from indirect impacts leading to rises in the costs of water, feeding, housing, transport and the destruction of infrastructure due to extreme events, as well as an increasing volatility of the price of feedstuff which increases the level of uncertainty in production (Rivera-Ferre et al. 2016b; Lopez-i-Gelats 2014). Mixed systems and industrial or landless livestock systems could encounter several risk factors mainly due to the variability of grain availability and cost, and low adaptability of animal genotypes (Nardone et al. 2010).

Considering the diverse typologies of animal production, from grazing to industrial, Rivera-Ferre et al. (2016b) distinguished impacts of climate change on livestock between those related to extreme events and those related to more gradual changes in the average of climate-related variables. Considering vulnerabilities, they grouped the impacts as those impacting the animal directly, such as heat and cold stress, water stress, physical damage during extremes; and others impacting their environment, such as modification in the geographical distribution of vector-borne diseases, location, quality and quantity of feed and water and destruction of livestock farming infrastructures.

With severe negative impacts due to drought and high frequency of extreme events, the average gain of productivity might be cancelled by the volatility induced by increasing variability in the weather. For instance, semiarid and arid pasture will likely have reduced livestock productivity, while nutritional quality will be affected by CO_2 fertilisation (Schmidhuber and Tubiello 2007).

Observed impacts. Pastoralism is practiced in more than 75% of countries by between 200 and 500 million people, including nomadic communities, transhumant herders, and agro-pastoralists (McGahey et al. 2014). Observed impacts in pastoral systems reported in the literature include decreasing rangelands, decreasing mobility, decreasing livestock number, poor animal health, overgrazing, land degradation, decreasing productivity, decreasing access to water and feed, and increasing conflicts for the access to pasture land (López-i-Gelats et al. 2016; Batima et al. 2008; Njiru 2012; Fjelde and von Uexkull 2012; Raleigh and Kniveton 2012; Egeru 2016) (*high confidence*).

Pastoral systems in different regions have been affected differently. For instance, in China changes in precipitation were a more important factor in nomadic migration than temperature (Pei and Zhang 2014). There is some evidence that recent years have already seen an increase in grassland fires in parts of China and tropical Asia (IPCC 2012). In Mongolia, grassland productivity has declined by 20-30% over the latter half of the 20th centrury, and ewe average weight reduced by 4 kg on an annual basis, or about 8% since 1980 (Batima et al. 2008). Substantial decline in cattle herd sizes can be due to increased mortality and forced off-take (Megersa et al. 2014). Important but less studied is the impact of the interaction of grazing patterns with climate change on grassland composition. (Spence et al. 2014) showed that climate change effects on Mongolia mountain steppe could be contingent on land use.

Conflicts due to resource scarcity (as well as other socio-political factors (Benjaminsen et al. 2012)) aggravated by climate change has differentiated impact on women. In Turkana, female-headed households have lower access to decision-making on resource use and allocation, investment and planning (Omolo 2011), increasing their vulnerability (Section 5.1.3, Gender Box in Chapter 7).

Non-climate drivers add vulnerability of pastoral systems to climate change (McKune and Silva 2013). For instance, during environmental disasters, livestock holders have been shown to be more vulnerable to food insecurity than their crop-producing counterparts because of limited economic access to food and unfavorable market exchange rates (Nori et al. 2005). Sami reindeers in Finland showed reduced freedom of action in response to climate change due to loss of habitat, increased predation, and presence of economic and legal constraints) (Tyler et al. 2007; Pape and Löffler 2012). In Tibet, emergency aid has provided shelters and privatised communally owned rangeland, which have increased the vulnerability of pastoralists to climate change (Yeh et al. 2014; Næss 2013).

Projected impacts. The impacts of climate change on global rangelands and livestock have received comparatively less attention than the impacts on crop production. Projected impacts on grazing systems include changes in herbage growth (due to changes in atmospheric CO_2 concentrations and rainfall and temperature regimes) and changes in the composition of pastures and in herbage quality, as well as direct impacts on livestock (Herrero et al. 2016b). Droughts and high temperatures in grasslands can also be a predisposing factor for fire occurrence (IPCC 2012).

Net primary productivity, soil organic carbon, and length of growing period. There are large uncertainties related to grasslands and grazing lands (Erb et al. 2016), especially in regard to net primary productivity (NPP) (Fetzel et al. 2017; Chen et al. 2018). Boone et al. (2017) estimated that the mean global annual net primary production (NPP) in rangelands may decline by 10 g C m^{-2} yr^{-1} in 2050 under RCP 8.5, but herbaceous NPP is likely to increase slightly (i.e., average of 3 g C m^{-2} yr^{-1}) (Figure 5.6). Results of a similar magnitude were obtained by Havlík et al. (2015), using EPIC and LPJmL on a global basis (Rojas-Downing et al. 2017). According to Rojas-Downing et al. (2017), an increase of 2°C is estimate to negatively impact pasture and livestock production in arid and semiarid regions and positively impact humid temperate regions.

Boone et al. (2017) identified significant regional heterogeneity in responses, with large increases in annual productivity projected in northern regions (e.g., a 21% increase in productivity in the US and Canada) and large declines in western Africa (-46% in sub-Saharan western Africa) and Australia (-17%). Regarding the length of growing period (LGP, average number of growing days per year) (Herrero et al. 2016b) projected reductions in the lower latitudes due to changes in rainfall patterns and increases in temperatures, which indicate increasing limitations of water. They identified 35°C as a critical threshold for rangeland vegetation and heat tolerance in some livestock species.

Figure 5.6 Ensemble simulation results for projected annual net primary productivity of rangelands as simulated in 2000 (top) and their change in 2050 (bottom) under emissions scenario RCP 8.5, with plant responses enhanced by CO_2 fertilisation. Results from RCP 4.5 and 8.5, with and without positive effects of atmospheric CO_2 on plant production, differed considerably in magnitude but had similar spatial patterns, and so results from RCP 8.5 with increasing production are portrayed spatially here and in other figures. Scale bar labels and the stretch applied to colors are based on the spatial mean value plus or minus two standard deviations (Boone et al. 2017).

Rangeland composition. According to Boone et al. (2017), the composition of rangelands is projected to change as well (see Chapter 3). Bare ground cover is projected to increase, averaging 2.4% across rangelands, with increases projected for the eastern Great Plains, eastern Australia, parts of southern Africa, and the southern Tibetan Plateau. Herbaceous cover declines are projected in the Tibetan Plateau, the eastern Great Plains, and scattered parts of the Southern Hemisphere. Shrub cover is projected to decline in eastern Australia, parts of southern Africa, the Middle East, the Tibetan Plateau, and the eastern Great Plains. Shrub cover could also increase in much of the Arctic and some parts of Africa. In mesic and semi-arid savannahs south of the Sahara, both shrub and tree cover are projected to increase, albeit at lower productivity and standing biomass. Rangelands in western and southwestern parts of the Isfahan province in Iran were found to be more vulnerable to future drying–warming conditions (Saki et al. 2018; Jaberalansar et al. 2017).

Soil degradation and expanding woody cover suggest that climate-vegetation-soil feedbacks catalysing shifts toward less productive, possibly stable states (Ravi et al. 2010) may threaten mesic and semi-arid savannahs south of the Sahara (see Chapter 3 and 4). This will also change their suitability for grazing different animal species; switches from cattle, which mainly consume herbaceous plants, to goats or camels are likely to occur as increases in shrubland occur.

Direct and indirect effects on livestock. Direct impacts of climate change in mixed and extensive production systems are linked to increased water and temperature stress on the animals potentially leading to animal morbidity, mortality and distress sales. Most livestock species have comfort zones between 10^{o}C–30^{o}C, and at temperatures above this animals reduce their feed intake 3–5% per additional degree of temperature (NRC 1981). In addition to reducing animal production, higher temperatures negatively affect fertility (HLPE 2012).

Indirect impacts to mixed and extensive systems are mostly related to the impacts on the feed base, whether pastures or crops, leading to increased variability and sometimes reductions in availability and quality of the feed for the animals (Rivera-Ferre et al. 2016b). Reduced forage quality can increase CH_4 emissions per unit of gross energy consumed. Increased risk of animal diseases is also an important impact to all production systems (Bett et al. 2017). These depend on the geographical region, land use type, disease characteristics, and animal susceptibility (Thornton et al. 2009). Also important is the interaction of grazing intensity with climate change. Pfeiffer et al. (2019) estimated that in a scenario of mean annual precipitation below 500 mm increasing grazing intensity reduced rangeland productivity and increased annual grass abundance.

Pastoral systems. In Kenya, some 1.8 million extra cattle could be lost by 2030 because of increased drought frequency, the value of the lost animals and production foregone amounting to USD 630 million (Herrero et al. 2010). Martin et al. (2014) assessed impacts of changing precipitation regimes to identify limits of tolerance beyond which pastoral livelihoods could not be secured and found that reduced mean annual precipitation had always negative effects as opposed to increased rainfall variability. Similarly, Martin et al. (2016) found that drought effects on pastoralists in High Atlas in Morocco depended on income needs and mobility options (see Section 5.2.2.6 for additional information about impacts on smallholder farmers).

In summary, observed impacts in pastoral systems include changes in pasture productivity, lower animal growth rates and productivity, damaged reproductive functions, increased pests and diseases, and loss of biodiversity (*high confidence*). Livestock systems are projected to be adversely affected by rising temperatures, depending on the extent of changes in pasture and feed quality, spread of diseases, and water resource availability (*high confidence*). Impacts will differ for different livestock systems and for different regions (*high confidence*). Vulnerability of pastoral systems to climate change is very high (*high confidence*), and mixed systems and industrial or landless livestock systems could encounter several risk factors mainly due to variability of grain availability and cost, and low adaptability of animal genotypes. Pastoral system vulnerability is exacerbated by non-climate factors (land tenure issues, sedentarisation programs, changes in traditional institutions, invasive species, lack of markets, and conflicts) (*high confidence*).

5.2.2.3 Impacts on pests and diseases

Climate change is changing the dynamics of pests and diseases of both crops and livestock. The nature and magnitude of future changes is likely to depend on local agro-ecological and management context. This is because of the many biological and ecological mechanisms by which climate change can affect the distribution, population size, and impacts of pests and diseases on food production (Canto et al. 2009; Gale et al. 2009; Thomson et al. 2010; Pangga et al. 2011; Juroszek and von Tiedemann 2013; Bett et al. 2017).

These mechanisms include changes in host susceptibility due to CO_2 concentration effects on crop composition and climate stresses; changes in the biology of pests and diseases or their vectors (e.g., more generational cycles, changes in selection pressure driving evolution); mismatches in timing between pests or vectors and their 'natural enemies'; changes in survival or persistence of pests or disease pathogens (e.g., changes in crop architecture driven by CO_2 fertilisation and increased temperature, providing a more favourable environment for persistence of pathogens like fungi), and changes in pest distributions as their "climate envelopes" shift. Such processes may affect pathogens, and their vectors, as well as plant, invertebrate and vertebrate pests. (Latham et al. 2015) .

Furthermore, changes in diseases and their management, as well as changing habitat suitability for pests and diseases in the matrix surrounding agricultural fields, have the ability to reduce or exacerbate impacts (Bebber 2015). For example, changes in water storage and irrigation to adapt to rainfall variation have the potential to enhance disease vector populations and disease occurrence (Bett et al. 2017).

There is *robust evidence* that pests and diseases have already responded to climate change (Bebber et al. 2014), and many studies have now built predictive models based on current incidence of pests, diseases or vectors that indicate how they may respond in future (e.g., (Caminade et al. 2015; Kim et al. 2015; Kim and Cho 2016; Samy and Peterson 2016; Yan et al. 2017)). Warren et al. (2018) estimate that about 50% of insects, which are often pests or disease vectors, will change ranges by about 50% by 2100 under current GHG emissions trajectories. These changes will lead to crop losses due to changes in insect pests (Deutsch et al. 2018) and weed pressure (Ziska et al. 2018), and thus affect pest and disease management at the farm level (Waryszak et al. 2018). For example, Samy and Peterson (2016) modelled Blue-tongue virus (BTV), which is spread by biting *Culicodes* midges, finding that the distribution of BTV is likely to be extended, particularly in central Africa, the US, and western Russia.

There is some evidence (*medium confidence*) that exposure will, on average, increase (Bebber and Gurr 2015; Yan et al. 2017), although there are a few examples where changing stresses may limit the range of a vector. There is also a general expectation that perturbations may increase the likelihood of pest and disease outbreaks by disturbing processes that may currently be at some quasi-equilibrium (Canto et al. 2009; Thomson et al. 2010; Pangga et al. 2011). However, in some places, and for some diseases, risks may decrease as well as increase (e.g., drying out may reduce the ability of fungi to survive) (Kim et al. 2015; Skelsey and Newton 2015), or Tsetse fly's range may decrease (Terblanche et al. 2008; Thornton et al. 2009) .

Pests, diseases, and vectors for both crop and livestock diseases are likely to be altered by climate change (*high confidence*). Such changes are likely to depend on specifics of the local context, including management, but perturbed agroecosystems are more likely, on theoretical grounds, to be subject to pest and disease outbreaks (*low confidence*). Whilst specific changes in pest and disease pressure will vary with geography, farming system, pest/pathogen – increasing in some situations decreasing in others – there is robust evidence, with *high agreement*, that pest and disease pressures are likely to change; such uncertainty requires robust strategies for pest and disease mitigation.

5.2.2.4 Impacts on pollinators

Pollinators play a key role on food security globally (Garibaldi et al. 2016). Pollinator-dependent crops contribute up to 35% of global crop production volume and are important contributors to healthy human diets and nutrition (IPBES 2016). On a global basis, some 1500 crops require pollination (typically by insects, birds and bats) (Klein et al. 2007). Their importance to nutritional security is therefore perhaps under-rated by valuation methodologies, which, nonetheless, include estimates of the global value of pollination services at over USD 225 billion (2010 prices) (Hanley et al. 2015). As with other ecosystem processes affected by climate change (e.g., changes in pests and diseases), how complex systems respond is highly context-dependent. Thus, predicting the effects of climate on pollination services is difficult (Tylianakis et al. 2008; Schweiger et al. 2010) and uncertain, although there is *limited evidence* that impacts are occurring already (Section 5.2.2.4), and *medium evidence* that there will be an effect.

Pollination services arise from a mutualistic interaction between an animal and a plant – which can be disrupted by climate's impacts on one or the other or both (Memmott et al. 2007). Disruption can occur through changes in species' ranges or by changes in timing of growth stages (Settele et al.

2016). For example, if plant development responds to different cues (e.g., day length) from insects (e.g., temperature), the emergence of insects may not match the flowering times of the plants, causing a reduction in pollination. Climate change will affect pollinator ranges depending on species, life-history, dispersal ability and location. Warren et al. (2018) estimate that under a 3.2ºC warming scenario, the existing range of about 49% of insects will be reduced by half by 2100, suggesting either significant range changes (if dispersal occurs) or extinctions (if it does not). However, in principle, ecosystem changes caused by invasions, in some cases, could compensate for the decoupling generated between native pollinators and pollinated species (Schweiger et al. 2010).

Other impacts include changes in distribution and virulence of pathogens affecting pollinators, such as the fungus *Nosema cerana*, which can develop at a higher temperature range than the less-virulent *Nosema apis*; increased mortality of pollinators due to higher frequency of extreme weather events; food shortage for pollinators due to reduction of flowering length and intensity; and aggravation of other threats, such as habitat loss and fragmentation (González-Varo et al. 2013; Goulson et al. 2015; Le Conte and Navajas 2008; Menzel et al. 2006; Walther et al. 2009; IPBES, 2016). The increase in atmospheric CO_2 is also reducing the protein content of pollen, with potential impact on pollination population biology (Ziska et al. 2016).

In summary, as with other complex agroecosystem processes affected by climate change (e.g., changes in pests and diseases), how pollination services respond will be highly context-dependent. Thus, predicting the effects of climate on pollination services is difficult and uncertain, although there is *medium evidence* that there will be an effect.

5.2.2.5 Impacts on aquaculture

This report focuses on land-based aquaculture; for assessment of impacts on marine fisheries both natural and farmed see the IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC, forthcoming).

Aquaculture will be affected by both direct and indirect climate change drivers, both in the short and the long-term. Barange et al. (2018) provides some examples of short-term loss of production or infrastructure due to extreme events such as floods, increased risk of diseases, toxic algae and parasites; and decreased productivity due to suboptimal farming conditions; and long-term impacts may include scarcity of wild seed, limited access to freshwater for farming due to reduced precipitation, limited access to feeds from marine and terrestrial sources, decreased productivity due to suboptimal farming conditions, eutrophication and other perturbations.

FAO (2014a) assessed the vulnerability of aquaculture stakeholders to non-climate change drivers which add to climate change hazards. Vulnerability arises from discrimination in access to inputs and decision-making; conflicts; infrastructure damage; and dependence on global markets and international pressures. Other non-climate drivers identified by McClanahan et al. (2015), which add vulnerability to fisheries for food security include: declining fishery resources; a North–South divide in investment; changing consumption patterns; increasing reliance on fishery resources for coastal communities; and inescapable poverty traps creating by low net resource productivity and few alternatives. In areas where vulnerability to climate change is heightened, increased exposure to climate change variables and impacts is likely to exacerbate current inequalities in the societies concerned, penalising further already disadvantaged groups such as migrant fishers (e.g. Lake Chad) or women (e.g. employees in Chile's processing industry) (FAO 2014a).

In many countries the projected declines co-occur across both marine fisheries and agricultural crops (Blanchard et al. 2017), both of which will impact the aquaculture and livestock sectors (See Supplementary Material Figure SM5.1). Countries with low Human Development Index, trade opportunities and aquaculture technologies are likely to face greater challenges. These cross-sectoral impacts point to the need for a more holistic account of the inter-connected vulnerabilities of food systems to climate and global change.

5.2.2.6 Impacts on smallholder farming systems

New work has developed farming system approaches that take into account both biophysical and economic processes affected by climate change and multiple activities. Farm households in the developing world often rely on a complex mix of crops, livestock, aquaculture, and non-agricultural activities for their livelihoods (Rosenzweig and Hillel 2015; Antle et al. 2015). Across the world, smallholder farmers are considered to be disproportionately vulnerable to climate change because changes in temperature, rainfall and the frequency or intensity of extreme weather events directly affect their crop and animal productivity as well as their household's food security, income and well-being (Vignola et al. 2015; Harvey et al. 2014b). For example, smallholder farmers in the Philippines, whose survival and livelihood largely depend on the environment, constantly face risks and bear the impacts of the changing climate (Peria et al. 2016).

Smallholder farming systems have been recognised as highly vulnerable to climate change (Morton, 2007) because they are highly dependent on agriculture and livestock for their livelihood (Dasgupta et al. 2014) (*high confidence*). In Zimbawe, farmers were found vulnerable due to their marginal location, low levels of technology, and lack of other essential farming resources. Farmers observed high frequency and severity of drought, excessive precipitation, drying up of rivers, dams and wells, and changes in timing and pattern of seasons as evidence of climate change, and indicated that prolonged wet, hot, and dry weather conditions resulted in crop damage, death of livestock, soil erosion, bush fires, poor plant germination, pests, lower incomes, and deterioration of infrastructure (Mutekwa 2009).

In Madagascar, Harvey et al. (2014b) conducted surveyed 600 small farmers and found that chronic food insecurity, physical isolation and lack of access to formal safety nets increased Malagasy farmers' vulnerability to any shocks to their agricultural system, particularly extreme events. In Chitwan, Nepal, occurrence of extreme events and increased variability in temperature has increased the vulnerability of crops to biotic and abiotic stresses and altered the timing of agricultural operations; thereby affecting crop production (Paudel et al. 2014). In Lesotho, a study on subsistence farming found that food crops were the most vulnerable to weather, followed by soil and livestock. Climate variables of major concern were hail, drought and dry spells which reduced crop yields. In the Peruvean Altiplan, Sietz et al. (2012) evaluate smallholders' vulnerability to weather extremes with regard to food security and found the relevance of resource scarcity (livestock, land area), diversification of activities (lack of alternative income, education deprivation) and income restrictions (harvest failure risk) in shaping vulnerability of smallholders. See Section 5.2.2.6 for observed impacts on smallholder pastoral systems.

Projected impacts. By including regional economic models, integrated methods take into account the potential for yield declines to raise prices and thus livelihoods (up to a certain point) in some climate change scenarios. Regional economic models of farming systems can be used to examine the potential for switching to other crops and livestock, as well as the role that non-farm income can play in adaptation (Valdivia et al. 2015; Antle et al. 2015). On the other hand, lost income for smallholders from climate change-related declines, for example in coffee production, can decrease their food security (Hannah et al. 2017).

Farming system methods developed by AgMIP have been used in regional integrated assessments in Sub-Saharan Africa (Kihara et al. 2015), West Africa (Adiku et al. 2015); East Africa (Rao et al. 2015), South Africa (Beletse et al. 2015), Zimbabwe (Masikati et al. 2015), South Asia (McDermid et al. 2015), Pakistan (Ahmad et al. 2015), the Indo-Gangetic Basin (Subash et al. 2015), Tamil Nadu

(Ponnusamy et al. 2015) and Sri Lanka (Zubair et al. 2015). The assessments found that climate change adds pressure to smallholder farmers across Sub-Saharan Africa and South Asia, with winners and losers within each area studied. Temperatures are expected to increase in all locations, and rainfall decreases are projected for the western portion of West Africa and Southern Africa, while increases in rainfall are projected for eastern West Africa and all study regions of South Asia. The studies project that climate change will lead to yield decreases in most study regions except South India and areas in central Kenya, as detrimental temperature effects overcome the positive effects of CO_2. These studies use AgMIP representative agricultural pathways (RAPs) as a way to involve stakeholders in regional planning and climate resilience (Valdivia et al. 2015). RAPs are consistent with and complement the RCP/SSP approaches for use in agricultural model intercomparisons, improvement, and impact assessments

New methods have been developed for improving analysis of climate change impacts and adaptation options for the livestock component of smallholder farming systems in Zimbabwe (Descheemaeker et al. 2018). These methods utilised disaggregated climate scenarios, as well as differentiating farms with larger stocking rates compared to less densely stocked farms. By disaggregating climate scenarios, impacts, and smallholder farmer attributes, such assessments can more effectively inform decision-making towards climate change adaptation.

In Central Asia, a study using the bio-economic farm model (BEFM) found large differences in projected climate change impact ranging from positive income gains in large-scale commercial farms in contrast to negative impacts in small-scale farms (Bobojonov and Aw-Hassan 2014). Negative impacts may be exacerbated if irrigation water availability declines due to climate change and increased water demand in upstream regions. In Iran, changes in rainfall and water endowments are projected to significantly impact crop yield and water requirements, as well as income and welfare of farm families (Karimi et al. 2018).

Climate change impacts on food, feed and cash crops other than cereals, often grown in smallholder systems or family farms are less often studied, although impacts can be substantial. For example, areas suitable for growing coffee are expected to decrease by 21% in Ethiopia with global warming of 2.4°C (Moat et al. 2017) and more than 90% in Nicaragua (Läderach et al. 2017) with 2.2°C local temperature increase.

Climate change can modify the relationship between crops and livestock in the landscape, affecting mixed crop-livestock systems in many places. Where crop production will become marginal, livestock may provide an alternative to cropping. Such transitions could occur in up to 3% of the total area of Africa, largely as a result of increases in the probability of season failure in the drier mixed crop–livestock systems of the continent (Thornton et al. 2014).

In Mexico, subsistence agriculture is expected to be the most vulnerable to climate change, due to its intermittent production and reliance on maize and beans (Monterroso et al. 2014). Overall, a decrease in suitability and yield is expected in Mexico and Central America for beans, coffee, maize, plantain and rice (Donatti et al. 2018). Municipalities with a high proportional area under subsistence crops in Central America tend to have less resources to promote innovation and action for adaptation (Bouroncle et al. 2017). .

In summary, smallholder farmers are especially vulnerable to climate change because their livelihoods often depend primarily on agriculture. Further, smallholder farmers often suffer from chronic food insecurity (*high confidence*). Climate change is projected to exacerbate risks of pests and diseases and extreme weather events in smallholder farming systems.

5.2.3 Climate change impacts on access

Access to food involves the ability to obtain food, including the ability to purchase food at affordable prices.

5.2.3.1 Impacts on prices and risk of hunger

A protocol-based analysis based on AgMIP methods tested a combination of RCPs and SSPs to provide a range of projections for prices, risk of hunger, and land use change (Figure 5.7 and Supplementary Material Table SM5.4.) (Hasegawa et al. 2018). Previous studies have found that decreased agricultural productivity will depress agricultural supply, leading to price increases. Despite different economic models with various representations of the global food system (Valin et al. 2014; Robinson et al. 2014; Nelson et al. 2013; Schmitz et al. 2014), as well as having represented the SSPs in different ways (i.e., technological change, land-use policies, sustainable diets, etc. (Stehfest et al. 2019; Hasegawa et al. 2018)), the ensemble of participating models projected a 1-29% cereal price increase in 2050 across SSPs 1, 2, and 3 due to climate change (RCP 6.0), which would impact consumers globally through higher food prices; regional effects will vary. The median cereal price increase was 7%, given current projections of demand. In all cases (across SSPs and global economic models), prices are projected to increase for rice and coarse grains, with only one instance of a price decline (-1%) observed for wheat in SSP1, with price increases projected in all other cases. Animal-sourced foods (ASFs) are also projected to see price increases (1%), but the range of projected price changes are about half those of cereals, highlighting that the climate impacts on ASFs is indirect through the cost and availability of feed, and that there is significant scope for feed substitution within the livestock sector.

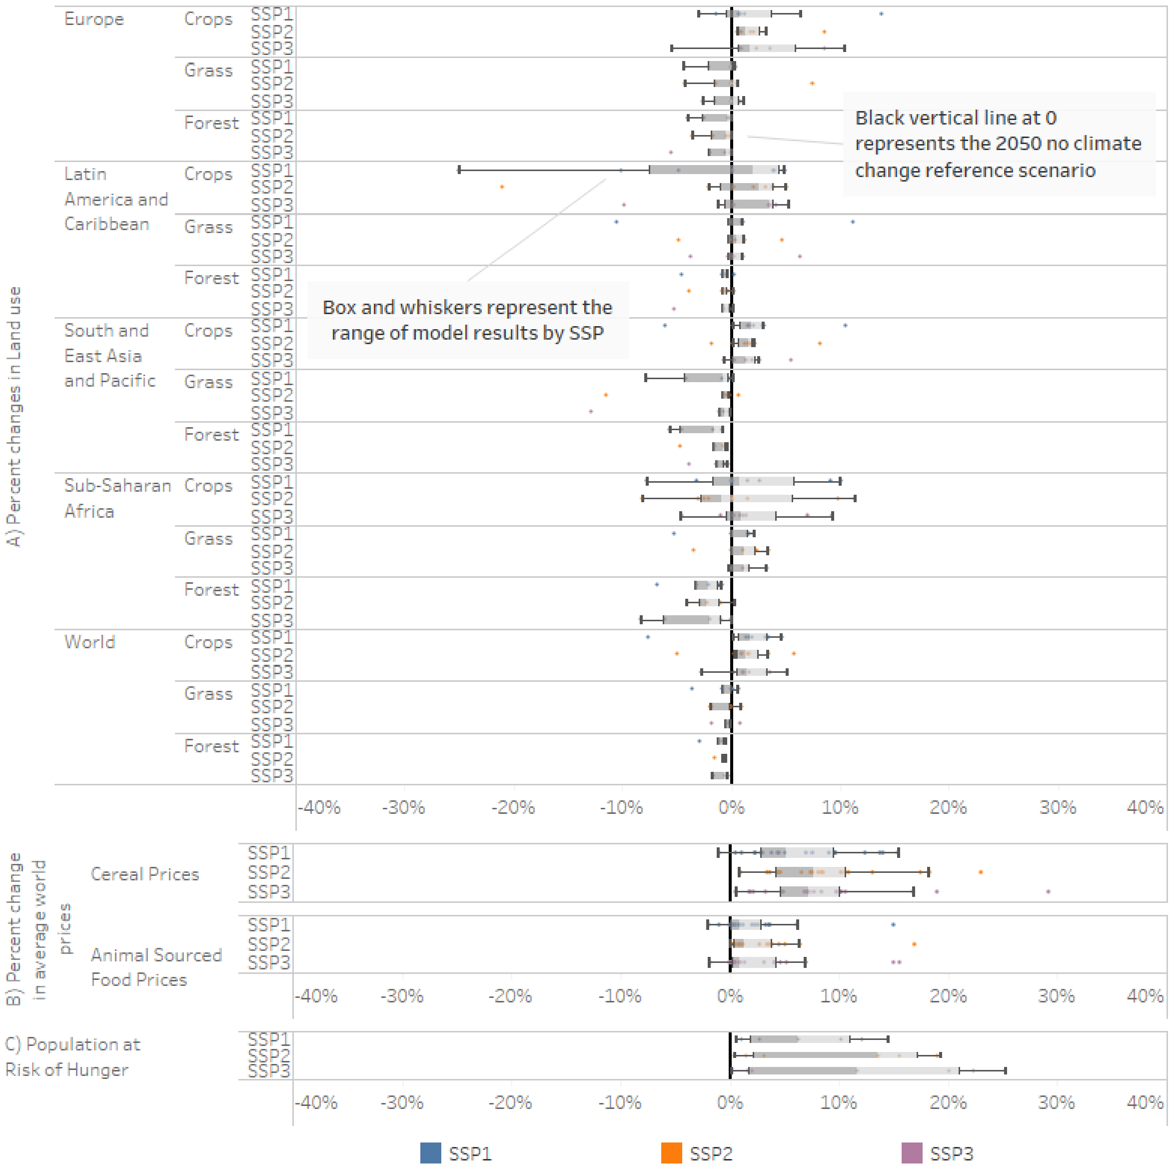

Figure 5.7. Implications of climate change by 2050 on land-use, selected agricultural commodity prices, and the population at risk of hunger based on AgMIP Global Economic Model analysis. (A) Projected % change in land-use by 2050 by land type (cropland, grassland, and forest) and SSP. (B) Projected % changes in average world prices by 2050 for cereals (rice, wheat, and coarse grains) and animal sourced foods (ruminant meat, monogastric, and dairy) by SSP. (C) Percentage change by 2050 in the global population at risk of hunger by SSP.

Declining food availability caused by climate change is likely to lead to increasing food cost impacting consumers globally through higher prices and reduced purchasing power, with low-income consumers particularly at risk from higher food prices (Nelson et al. 2010; Springmann et al. 2016a; Nelson et al. 2018). Higher prices depress consumer demand, which in turn will not only reduce energy intake (calories) globally (Hasegawa et al. 2015; Nelson et al. 2010; Springmann et al. 2016a; Hasegawa et al. 2018), but will also likely lead to less healthy diets with lower availability of key micronutrients (Nelson et al. 2018) and increase diet-related mortality in lower and middle-income countries (Springmann et al. 2016a). These changes will slow progress towards the eradication of malnutrition in all its forms.

The extent that reduced energy intake leads to a heightened risk of hunger varies by global economic model. However, all models project an increase in the risk of hunger, with the median projection of an increase in the population at risk of insufficient energy intake by 6, 14, and 12 % in 2050 for SSPs 1, 2 and 3 respectively compared to a no climate change reference scenario. This median percentage increase would be the equivalent of 8, 24, and 80 million (full range 1-183 million) additional people at risk of hunger due to climate change (Hasegawa et al. 2018).

5.2.3.2 Impacts on land use

Climate change is likely to lead to changes in land use globally (Nelson et al. 2014; Schmitz et al. 2014; Wiebe et al. 2015). Hasegawa et al. (2018) found that declining agricultural productivity broadly leads to the need for additional cropland, with 7 of 8 models projecting increasing cropland and the median increase by 2050 projected across all models of 2 % compared to a no climate change reference (Figure 5.7). Not all regions will respond to climate impacts equally, with more uncertainty on regional land-use change across the model ensemble than the global totals might suggest. For example, the median land-use change for Latin America is an increase of cropland by 3 %, but the range across the model ensemble is significant, with 3 models projecting declines in cropland (-25 –-1 %) compared to the 5 models projecting cropland increase (0 – 5 %). For further discussion on land use change and food security see Section 5.6.

5.2.4 Climate change impacts on food utilisation

Food utilisation involves nutrient composition of food, its preparation, and overall state of health. Food safety and quality affects food utilisation.

5.2.4.1 Impacts on food safety and human health

Climate change can influence food safety through changing the population dynamics of contaminating organisms due to, for example, changes in temperature and precipitation patterns, and also humidity, increased frequency and intensity of extreme weather events, and changes in contaminant transport pathways. Changes in food and farming systems, e.g., intensification to maintain supply under climate change, may also increase vulnerabilities as the climate changes (Tirado et al. 2010). Climate-related changes in the biology of contaminating organisms include changing the activity of mycotoxin-producing fungi, changing the activity of micro-organisms in aquatic food chains that cause disease (e.g., dinoflagellates, bacteria like *Vibrio*), and increasingly heavy rainfall and floods causing contamination of pastures with enteric microbes (like *Salmonella*) that can enter the human food chain. Degradation and spoilage of products in storage and transport can also be affected by changing humidity and temperature outside of cold chains, notably from microbial decay but also from potential changes in the population dynamics of stored product pests (e.g., mites, beetles, moths) (Moses et al. 2015).

Mycotoxin-producing fungi occur in specific conditions of temperature and humidity, so climate change will affect their range, increasing risks in some areas (such as mid-temperate latitudes) and reducing them in others (e.g., the tropics) (Paterson and Lima 2010). There is *robust evidence* from process-based models of particular species (*Aspergillus*/Aflatoxin B1, *Fusarium*/deoxynivalenol) with projections of future climate that show that aflatoxin contamination of maize in southern Europe will increase significantly (Battilani et al. 2016), and deoxynivalenol contamination of wheat in north-west Europe will increase by up to 3 times (van der Fels-Klerx et al. 2012b,a). Whilst the downscaled climate models make any specific projection for a given geography uncertain (Van der Fels-Klerx et al. 2013), experimental evidence on the small scale suggests that the combination of rising CO_2 levels, affecting physiological processes in photosynthetic organisms, and temperature changes, can be significantly greater than temperature alone (Medina et al. 2014). Risks related to aflatoxins are likely to change, but detailed projections are difficult because they depend on local conditions (Vaughan et al. 2016).

Foodborne pathogens in the terrestrial environment typically come from enteric contamination (from humans or animals), and can be spread by wind (blowing contaminated soil) or flooding – the incidence of both of which are likely to increase with climate change (Hellberg and Chu 2016). Furthermore, water stored for irrigation, which may be increased in some regions as an adaptation strategy, can become an important route for the spread of pathogens (as well as other pollutants); contaminated water and diarrheal diseases are acute threats to food security (Bond et al. 2018). Whilst there is little direct evidence (in terms of modelled projections) the results of a range of reviews, as well as expert groups, suggest that risks from foodborne pathogens are likely to increase through multiple mechanisms (Tirado et al. 2010; van der Spiegel et al. 2012; Liu et al. 2013; Kirezieva et al. 2015; Hellberg and Chu 2016).

An additional route to climate change impacts on human health can arise from the changing biology of plants altering human exposure levels. This may include climate changing how crops sequester heavy metals (Rajkumar et al. 2013), or how they respond to changing pest pressure (e.g., cassava produces hydrogen cyanide as a defence against herbivore attack).

All of these factors will lead to regional differences regarding food safety impacts (Paterson and Lima 2011). For instance, in Europe it is expected that most important food safety-related impacts will be mycotoxins formed on plant products in the field or during storage; residues of pesticides in plant products affected by changes in pest pressure; trace elements and/or heavy metals in plant products depending on changes in abundance and availability in soils; polycyclic aromatic hydrocarbons in foods following changes in long-range atmospheric transport and deposition; and presence of pathogenic bacteria in foods following more frequent extreme weather, such as flooding and heat waves (Miraglia et al. 2009).

In summary, there is *medium evidence,* with *high agreement* that food utilisation via changes in food safety (and potentially food access from food loss) will be impacted by climate change, mostly by increasing risks, but there is *low confidence,* exactly how they may change for any given place.

5.2.4.2 Impacts on food quality

There are two main routes by which food quality may change. First, the direct effects of climate change on plant and animal biology, such as through changing temperatures changing the basic metabolism of plants. Secondly, by increasing carbon dioxide's effect on biology through CO_2 fertilisation.

Direct effects on plant and animal biology. Climate affects a range of biological processes, including the metabolic rate in plants and ectothermic animals. Changing these processes can change growth rates, and therefore yields, but can also cause organisms to change relative investments in growth vs reproduction, and therefore change the nutrients assimilated. This may decrease protein and mineral nutrient concentrations, as well as alter lipid composition (DaMatta et al. 2010). For example, apples in Japan have been exposed to higher temperatures over 3–4 decades and have responded by blooming earlier. This has led to changes in acidity, firmness, and water content, reducing quality (Sugiura et al. 2013). In other fruit, such as grapes, warming-induced changes in sugar composition affect both colour and aroma (Mira de Orduña 2010). Changing heat stress in poultry can affect yield as well as meat quality (by altering fat deposition and chemical constituents), shell quality of eggs, and immune systems (Lara and Rostagno 2013).

Effects of rising CO_2 concentrations. Climate change is being driven by rising concentrations of carbon dioxide and other greenhouse gases in the atmosphere. As plants use CO_2 in photosynthesis to form sugar, rising CO_2 levels, all things being equal, enhances the process unless limited by water or nitrogen availability. This is known as "CO_2 fertilisation". Furthermore, increasing CO_2 allows the stomata to be open for a shorter period for gas exchange, reducing water loss through transpiration. These two factors affect the metabolism of plants, and, as with changing temperatures, affects plant growth rates, yields and their nutritional quality. Studies of these effects include meta-analyses, modelling, and small-scale experiments (Franzaring et al. 2013; Mishra and Agrawal 2014; Myers et al. 2014; Ishigooka et al. 2017; Zhu et al. 2018; Loladze 2014; Yu et al. 2014)

In regard to nutrient quality, a meta-analysis from seven Free-Air Carbon dioxide Enrichment (FACE), (with elevated atmospheric CO_2 concentration of 546–586 ppm) experiments (Myers et al. 2014), found that wheat grains had 9.3% lower zinc (CI5.9–12.7%), 5.1% lower iron (CI 3.7–6.5%) and 6.3% lower protein (CI 5.2–7.5%), and rice grains had 7.8% lower protein content (CI 6.8–8.9%). Changes in nutrient concentration in field pea, soybean and C4 crops such as sorghum and maize were small or insignificant. Zhu et al. (2018) report a meta-analysis of FACE trials on a range of rice cultivars. They show that protein declines by an average of 10% under elevated CO_2, iron and zinc decline by 8% and 5% respectively. Furthermore, a range of vitamins show large declines across all rice cultivars, including B1 (-17%), B2 (-17%), B5 (-13%) and B9 (-30%), whereas Vitamin E increased. As rice underpins the diets of many of the world's poorest people in low-income countries, especially in Asia, Zhu et al. (2018) estimate that these changes under high CO_2 may affect the nutrient status of about 600 million people.

Decreases in protein concentration with elevated CO_2 are related to reduced nitrogen concentration possibly caused by nitrogen uptake not keeping up with biomass growth, an effect called 'carbohydrate dilution' or 'growth dilution', and by inhibition of photorespiration which can provide much of the energy used for assimilating nitrate into proteins (Bahrami et al. 2017). Other mechanisms have also been postulated (Feng et al. 2015; Bloom et al. 2014; Taub and Wang 2008). Together, the impacts on protein availability may take as many as 150 million people into protein deficiency by 2050 (Medek et al. 2017). Legume and vegetable yields increased with elevated CO_2 concentration of 250 ppm above ambient by 22% (CI 11.6–32.5%), with a stronger effect on leafy vegetables than on legumes and no impact for changes in iron, vitamin C or flavonoid concentration (Scheelbeek et al. 2018).

Increasing concentrations of atmospheric CO_2 lower the content of zinc and other nutrients in important food crops. Dietary deficiencies of zinc and iron are a substantial global public health problem (Myers et al. 2014). An estimated two billion people suffer these deficiencies (FAO 2013a), causing a loss of 63 million life-years annually (Myers et al. 2014). Most of these people depend on C3 grain legumes as their primary dietary source of zinc and iron. Zinc deficiency is currently responsible for large burdens of disease globally, and the populations who are at highest risk of zinc deficiency receive most of their dietary zinc from crops (Myers et al. 2015). The total number of people estimated to be placed at new risk of zinc deficiency by 2050 is 138 million. The people likely to be most affected live in Africa and South Asia, with nearly 48 million residing in India alone. Differences between cultivars of a single crop suggest that breeding for decreased sensitivity to atmospheric CO_2 concentration could partly address these new challenges to global health (Myers et al. 2014).

In summary, while increased CO_2 is projected to be beneficial for crop productivity at lower temperature increases, it is projected to lower nutritional quality (e.g., less protein, zinc, and iron) *(high confidence)*.

5.2.5 Climate change impacts on food stability

Food stability is related to people's ability to access and use food in a steady way, so that there not intervening periods of hunger. Increasing extreme events associated with climate change can disrupt food stability. (See Section 5.8.1 for assessment of food price spikes.)

5.2.5.1 Impacts of extreme events

FAO et al. (2018) conducted an analysis of prevalence of undernourishment (PoU) and found that in 2017, the average of the prevalence of undernourishment (PoU) was 15.4% for all countries exposed to climate extremes (See Supplementary Material Figure SM5.2). At the same time, the PoU was 20% for countries that additionally show high vulnerability of agriculture production/yields to climate variability, or 22.4% for countries with high PoU vulnerability to severe drought. When there is both high vulnerability of agriculture production/yields and high PoU sensitivity to severe drought, the PoU is 9.8 points higher (25.2%). These vulnerabilities were found to be higher when countries had a high dependence on agriculture as measured by the number of people employed in the sector. Bangkok experienced severe flooding in 2011-2012 with large-scale disruption of the national food supply chains since they were centrally organised in the capital city (Allen et al. 2017).

The IPCC projects that frequency, duration, and intensity of some extreme events will increase in the coming decades (IPCC 2018a, 2012). To test these effects on food security, Tigchelaar et al. (2018) showed rising instability in global grain trade and international grain prices, affecting especially the about 800 million people living in extreme poverty who are most vulnerable to food price spikes (see Section 5.8.1). They used global datasets of maize production and climate variability combined with future temperature projections to quantify how yield variability will change in the world's major maize-producing and -exporting countries under 2°C and 4°C of global warming.

Tesfaye et al. (2017) projected that the extent of heat-stressed areas in South Asia could increase by up to 12% in 2030 and 21% in 2050 relative to the baseline (1950–2000). Another recent study found that drier regions are projected to dry earlier, more severely and to a greater extent than humid regions, with the population of sub-Saharan Africa most vulnerable (Lickley and Solomon 2018).

5.2.5.2 Food aid

Food aid plays an important role in providing food security and saving lives after climate disasters. In 2015, 14.5 million people were assisted through disaster-risk reduction, climate change and/or resilience building activities (WFP 2018). However, there is no agreement on how to better use emergency food aid, since it can come with unintended consequences for individuals, groups, regions, and countries (Barrett 2006). These may include negative dependency of food recipients (Lentz et al. 2005) or price increases, among others.

Some authors state that tied food aid provided as "in kind" by the donor country hampers local food production (Clay 2006), although others found no evidence of this (Ferrière and Suwa-Eisenmann 2015). Untied cash aid can be used to buy food locally or in neighbouring countries, which is cheaper and can contribute to improving the livelihoods of local farmers (Clay 2006).

Ahlgren et al. (2014) found that food aid dependence of Marshall Islands due to climate change impacts can result in poor health outcomes due to the poor nutritional quality of food aid, which may result in future increases of chronic diseases. In this regard, Mary et al. (2018) showed that nutrition-sensitive aid can reduce the prevalence of undernourishment.

In summary, based on AR5 and SR15 assessments that the likelihood that extreme weather will increase, (e.g., increases in heatwaves, droughts, inland and coastal flooding due to sea level rise depending on region) in both frequency and magnitude, decreases in food stability and thus increases in food insecurity will likely rise as well *(medium evidence, high agreement)*.

5.3 Adaptation options, challenges, and opportunities

This section assesses the large body of literature on food system adaptation to climate change, including increasing extreme events, within a framework of autonomous, incremental, and transformational adaptation. It focuses primarily on regional and local considerations and adaptation options for both the supply side (production, storage, transport, processing, and trade) and the demand side (consumption and diets) of the food system. Agroecological, social, and cultural contexts are considered throughout. Finally, the section assesses the role of institutional measures at global, regional (multiple countries), national, and local scales and capacity-building.

5.3.1 Challenges and opportunities

By formulating effective adaptation strategies, it is possible to reduce or even avoid some of the negative impacts of climate change on food security (See Section 5.2). However, if unabated climate change continues, limits to adaptation will be reached (SR15). In the food system, adaptation actions involve any activities designed to reduce vulnerability and enhance resilience of the system to climate change. In some areas, expanded climate envelopes will alter agro-ecological zones, with opportunity for expansion towards higher latitudes and altitudes, soil and water resources permitting (Rosenzweig and Hillel 2015).

More extreme climatic events are projected to lead to more agro-meteorological disasters with associated economic and social losses. There are many options for adapting the food system to extreme events reported in IPCC (2012), highlighting measures that reduce exposure and vulnerability and increase resilience, even though risks cannot fully be eliminated (IPCC 2012). Adaptation responses to extreme events aim to minimise damages, modify threats, prevent adverse impacts, or share losses, thus making the system more resilient (Harvey et al. 2014a).

With current and projected climate change (higher temperature, changes in precipitation, flooding and extremes events), achieving adaptation will require both technological (e.g., recovering and improving orphan crops, new cultivars from breeding or biotechnology) and non-technological (e.g., market, land management, diet change) solutions. Climate interacts with other factors such as market supplies over longer distances and policy drivers (Mbow et al. 2008; Howden et al. 2007), as well as local agricultural productivity to determine access to food locally.

Given the site-specific nature of climate change impacts on food system components together with wide variation in agroecosystems types and management, and socio-economic conditions, it is widely understood that adaptation strategies are linked to environmental and cultural contexts at the regional and local levels (*high confidence*). Developing systemic resilience that integrates climate drivers with social and economic drivers would reduce the impact on food security, particularly in developing countries. For example, in Africa, improving food security requires evolving food systems to be highly climate resilient, while supporting the need for increasing yield to feed the growing population (Mbow et al. 2014b) (Box 5.2).

Adaptation involves producing more food where needed, moderating demand, reducing waste, and improving governance (Godfray and Garnett 2014) (see Section 5.6 for the significant synergies between adaptation and mitigation through specific practices, actions and strategies.).

Box 5.2 Sustainable solutions for food systems and climate change in Africa

Climate change, land use change, and food security are important aspects of sustainability policies in Africa. According to the McKinsey Global Institute (2010), Africa has around 60% of the global uncultivated arable land; thus the continent has a high potential for transformative change in food production. With short and long-term climate change impacts combined with local poverty conditions, land degradation and poor farming practices, Africa cannot grow enough food to feed its rapidly growing population. Sustainable improvement of productivity is essential, even as the impacts of climate change on food security in Africa are projected to be plural and severe.

Sustainable Land Management (SLM) of farming systems is important to address climate change while dealing with these daunting food security needs and the necessity to improve access to nutritious food to maintain healthy and active lives in Africa (AGRA 2017). SLM has functions beyond the production of food, such as delivery of water, protection against disease (especially zoonotic diseases), the delivery of energy, fibre and building materials.

Commodity-based systems—driven by external markets—are increasing in Africa (cotton, cocoa, coffee, oil palm, groundnuts) with important impacts on the use of land and climate. Land degradation, decreasing water resources, loss of biodiversity, excessive use of synthetic fertilisers and pesticides are some of the environmental challenges that influence preparedness to adapt to climate change (Pretty and Bharucha 2015).

A balanced strategy on African agriculture can be based on SLM and multifunctional land use approaches combining food production, cash crops, ecosystem services, biodiversity conservation, and ecosystem services delivery, and indigenous and local knowledge.

Thus, sustainable food systems in Africa entail multiple dimensions as shown in Figure 5.7.

Figure 5.7 Factors influencing sustainable food systems in Africa

With rapid urbanisation, it is important to used combined land goals (e.g., zero-carbon energy, smart irrigation systems, and climate-resilient agriculture) to minimise the negative side effects of climate change while securing quality food for a growing population.

Building resilience into productivity and production can be based on simultaneous attention to the following five overarching issues:

1) Closing yield gaps through adapted cultivars, sustainable land management, that combine production and preservation of ecosystems essential functions such as sustainable

intensification approaches based on conservation agriculture and community-based adaptation with functioning support services and market access (Mbow et al. 2014a).

2) Identifying Sustainable Land Management practices (agroecology, agroforestry, etc.) addressing different ecosystem services (food production, biodiversity, reduction of GHG emissions, soil carbon sequestration) for improved land-based climate change adaptation and mitigation (Sanz et al. 2017; Francis 2016).

3) Paying attention to the food-energy-water nexus, especially water use and reutilisation efficiency but also management of rain water (Albrecht et al. 2018).

4) Implementing institutional designs focused on youth, women through new economic models that help access credit and loans to support policies that balance cash and food crops.

5) Build on and use of local knowledge, culture and traditions while seeking innovations for food waste reduction and transformation of agricultural products.

These aspects suppose both incremental and transformational adaptation that may stem from better infrastructure (storage and food processing), adoption of harvest and post-harvest technologies that minimise food waste, and development of new opportunities for farmers to respond to environmental, economic and social shocks that affect their livelihoods (Morton 2017).

Agriculture in Africa offers a unique opportunity for merging adaption to and mitigation of climate change with sustainable production to ensure food security (CCAFS 2012; FAO 2012). Initiatives throughout the food system on both the supply and demand sides can lead to positive outcomes.

5.3.2 Adaptation framing and key concepts

5.3.2.1 Autonomous, incremental, and transformational adaptation

Framing of adaptation in this section categorises and assesses adaptation measures as autonomous, incremental, and transformational (See Glossary and Table 5.3). Adaptation responses can be reactive or anticipatory.

Autonomous. Autonomous adaptation in food systems does not constitute a conscious response to climatic stimuli but is triggered by changes in agroecosystems, markets, or welfare changes. It is also referred to as spontaneous adaptation (IPCC 2007). Examples of autonomous adaptation of rural populations have been documented in the Sahel (IRD 2017). In India, farmers are changing sowing and harvesting timing, cultivating short duration varieties, inter-cropping, changing cropping patterns, investing in irrigation, and establishing agroforestry. These are considered as passive responses or autonomous adaptation, because they do not acknowledge that these steps are taken in response to perceived climatic changes (Tripathi and Mishra 2017).

Incremental. Incremental adaptation maintains the essence and integrity of a system or process at a given scale (Park et al. 2012). Incremental adaptation focuses on improvements to existing resources and management practices. The central aim of incremental adaptation is to maintain the essence and integrity of a system or process at a given scale (IPCC 2014a).

Transformational. Transformational adaptation changes the fundamental attributes of a socio-ecological system either in anticipation of or in response to climate change and its impacts (IPCC 2014a). Transformational adaptation seeks alternative livelihoods and land use strategies needed to develop new farming systems (Termeer et al. 2016). For example, limitations in incremental adaptation among smallholder rice farmers in Northwest Costa Rica led to a shift from rice to sugarcane production due to decreasing market access and water scarcity (Warner et al. 2015). Migration from the Oldman River Basin has been described as a transformational adaption to climate change in the Canadian agriculture sector (Hadarits et al. 2017). If high-end scenarios of climate change eventuate, the food security of farmers and consumers will depend on how transformational change in food systems is managed. An integrated framework of adaptive transition – management of socio-technical transitions and adaptation to socio-ecological changes – may help build transformational adaptive capacity (Mockshell and Kamanda 2018; Pant et al. 2015). Rippke et al. (2016) has suggested overlapping phases of adaptation needed to support transformational change in Africa.

Table 5.3 Synthesis of food security related adaptation options to address various climate risks (IPCC 2014b; Vermeulen et al. 2013, 2018; Burnham and Ma 2016; Bhatta and Aggarwal 2016)

Key climate drivers and risks	**Incremental adaptation**	**Transformational adaptation**	**Enabling conditions**
Extreme events and short-term climate variability Stress on water resources, drought stress, dry spells, heat extremes, flooding, shorter rainy seasons, pests	- Change in variety, water management, water harvesting, supplemental irrigation during dry spells, - Planting dates, pest control, feed banks, - Transhumance, Other sources of revenue (e.g. charcoal, wild fruits, wood, temporary work) - Soil management, composting,	- Early Warning Systems - Use of planning and prediction at seasonal to intra-seasonal climate risk to transition to a food safer condition. - Abandonment of monoculture, diversification - Crop and livestock insurance - Alternate cropping, intercropping -Erosion control	- Establishment of climate services - Integrated water management policies, integrated land and water governance - Seed banks, seed sovereignty and seed distribution policies - Capacity building and extension programs
Warming trend, drying trend Reduced crop productivity due to persistent heat, long drought cycles, deforestation and land degradation with strong adverse effects on food production and nutrition quality, increased pest and disease damage	- Strategies to reduce effects of recurring food challenges - Sustainable intensification, agroforestry, conservation agriculture, SLM - Adoption of existing drought-tolerant crop and livestock species - Counter season crop production, - Livestock fattening - New ecosystem-based adaptation (e.g. bee keeping, woodlots)	- Climate services for new agricultural programs, e.g., sustainable irrigation districts) - New technology, e.g., new farming systems, new crops and livestock breeds - Switches between cropping and transhumant livelihoods, replacement of pasture or forest to irrigated/rainfed crops - Shifting to small ruminants or drought resistant livestock or fish	- Climate information in local development policies. - Stallholders' access to credit and production resources, - National food security program based on increased productivity, diversification, transformation and trade - Strengthening (budget, capacities, expertise) of local and national institutions to support agriculture and

	- Farmers management of natural resources - Labor redistribution (e.g., mining, development projects, urban migration) - Adjustments to markets and trade pathways already in place	farming Food storage infrastructures, food transformation - Changes in cropping area, land rehabilitation (enclosures, afforestation) perennial farming - New markets and trade pathways	livestock breeding - Devolution to local communities, women empowerment, market opportunities - Incentives for establishing new markets and trade pathways

5.3.2.2 *Risk management*

Climate risks affect all pillars of food security, particularly stability because extreme events lead to strong variation to food access. The notion of risk is widely treated in IPCC reports (IPCC 2014c) (see also Chapter 7 in this report). With food systems, many risks co-occur or reinforce each other and this can limit effective adaptation planning as they require a comprehensive and dynamic policy approach covering a range of drivers and scales. For example, from the understanding by farmers of change in risk profiles to the establishment of efficient markets that facilitate response strategies will require more than systemic reviews of risk factors (Howden et al. 2007).

Integration of Climate Change Adaptation (CCA) and Disaster Risk Reduction (DRR) helps to minimise the overlap and duplication of projects and programs (Nalau et al. 2016). Recently, countries started integrating the concept of DRR and CCA. For instance, The Philippines has introduced legislation calling for CCA and DRR integration as current policy instruments were largely unsuccessful in combining agencies and experts across the two areas (Leon and Pittock 2016).

Studies reveal that the amplitude of interannual growing-season temperature variability is in general larger than that of long-term temperature change in many locations. Responding better to seasonal climate-induced food supply shocks therefore increases society's capability to adapt to climate change. Given these backgrounds, seasonal crop forecasting and early response recommendations, based on seasonal climate forecasts, are emerging to strengthen existing operational systems for agricultural monitoring and forecasting (FAO 2016a; Ceglar et al. 2018; Iizumi et al. 2018).

While adaptation and mitigation measures are intended to reduce the risk from climate change impacts in food systems, they can also be sources of risk themselves (e.g. investment risk, political risk) (IPCC 2014b). Climate-related hazards are a necessary element of risks related to climate impacts but may have little or nothing to do with risks related to some climate policies/responses

Adoption of agroecological practices could provide resilience for future shocks, spread farmer risk and mitigate the impact of droughts (Niles et al. 2018) (See Section 5.3.2.3). Traditionally, risk management is performed through multifunctional landscape approaches in which resource utilisation is planned across wide areas and local agreements on resource access. Multifunctionality permits vulnerable communities to access various resources at various times and under various risk conditions (Minang et al. 2015).

In many countries, governmental compensation for crop-failure and financial losses are used to protect against risk of severe yield reductions. Both public and private sector groups develop insurance markets and improve and disseminate index-based weather insurance programs.

Catastrophe bonds, microfinance, disaster contingency funds, and cash transfers are other available mechanisms for risk management.

In summary, risk management can be accomplished through agro-ecological landscape approaches and risk sharing and transfer mechanisms such as development of insurance markets and improve index-based weather insurance programs *(high confidence)*.

5.3.2.3 Role of agroecology and diversification

Agro-ecological systems are integrated land-use systems that maintain species diversity in a range of productive niches. Diversified cropping systems and practicing traditional agro-ecosystems of crop production where a wide range of crop varieties are grown in various spatial and temporal arrangements, are less vulnerable to catastrophic loss (Zhu et al. 2011). The use of local genetic diversity, soil organic matter enhancement, multiple-cropping or poly-culture systems, and home gardening, agro-ecological approaches can build resilience against extreme climate events (Altieri and Koohafkan 2008). However, Nie et al. (2016) argued that while integrated crop-livestock systems present some opportunities such as control of weeds, pests and diseases, and environmental benefits, there are some challenges, including yield reduction, difficulty in pasture-cropping, grazing, and groundcover maintenance in high rainfall zones, and development of persistent weeds and pests. Adaptation measures based on agroecology entail enhancement of agrobiodiversity; improvement of ecological processes and delivery of ecosystem services. They also entail strengthening of local communities and recognition of the role and value of indigenous and local knowledge. Such practices can enhance the sustainability and resilience of agricultural systems by buffering climate extremes, reducing degradation of soils, and reversing unsustainable use of resources; outbreak of pests and diseases and consequently increase yield without damaging biodiversity. Increasing and conserving biological diversity such as soil microorganisms can promote high crop yields and sustain the environment (Schmitz et al 2015; Bhattacharyya et al 2016; Garibaldi et al 2017).

Diversification of many components of the food system is a key element for increasing performance and efficiency that may translate into increased resilience and reduced risks (integrated land management systems, agrobiodiversity, indigenous and local knowledge, local food systems, dietary diversity, the sustainable use of indigenous fruits, neglected and underutilised crops as a food source) *(medium confidence)* (Makate et al. 2016; Lin 2011; Awodoyin et al. 2015).

The more diverse the food systems are, the more resilient they are in enhancing food security in the face of biotic and abiotic stresses. Diverse production systems are important for providing regulatory ecosystem services such as nutrient cycling, carbon sequestration, soil erosion control, reduction of GHG emissions and control of hydrological processes (Chivenge et al. 2015). Further options for adapting to change in both mean climate and extreme events are livelihood diversification (Michael 2017; Ford et al. 2015), and production diversity (Sibhatu et al. 2015).

Crop diversification, maintaining local genetic diversity, animal integration, soil organic matter management, water conservation, and harvesting the role of microbial assemblages. These types of farm management significantly affect communities in soil, plant structure, and crop growth in terms of number, type, and abundance of species (Morrison-Whittle et al. 2017). Complementary strategies towards sustainable agriculture (ecological intensification, strengthening existing diverse farming systems and investment in ecological infrastructure) also address important drivers of pollinator decline (IPBES 2016).

Evidence also shows that, together with other factors, on-farm agricultural diversity can translate into dietary diversity at the farm level and beyond (Pimbert and Lemke 2018; Kumar et al. 2015; Sibhatu et al. 2015). Dietary diversity is important but not enough as an adaptation option, but results in positive health outcomes by increasing the variety of healthy products in people's diets and reducing exposure to unhealthy environments.

Locally developed seeds and the concept of seed sovereignty can both help protect local agrobiodiversity and can often be more climate resilient than generic commercial varieties (Wattnem 2016; Coomes et al., 2015; van Niekerk and Wynberg 2017; Vasconcelos et al. 2013). Seed exchange networks and banks protect local agrobiodiversity and landraces, and can provide crucial lifelines when crop harvests fail (Coomes et al. 2015; van Niekerk and Wynberg 2017; Vasconcelos et al. 2013).

Related to locally developed seeds, neglected and underutilised species (NUS) can play a key role in increasing dietary diversity (*high confidence*) (Baldermann et al. 2016; van der Merwe et al. 2016; Kahane et al. 2013; Muhanji et al. 2011) (see Box 5.3). These species can also improve nutritional and economic security of excluded social groups, such as tribals (Nandal and Bhardwaj 2014; Ghosh-Jerath et al. 2015), indigent (Kucich and Wicht 2016) or rural populations (Ngadze et al. 2017).

Box 5.3 Climate change and indigenous food systems in the Hindu-Kush Himalayan Region

Diversification of production systems through promotion of Neglected and Underutilised Species (NUS; also known as understudied, neglected, orphan, lost or disadvantaged crops) offers adaptation opportunities to climate change, particularly in mountains. Neglected and Underutilised Species (NUS) have a potential to improve food security and at the same time help protect and conserve traditional knowledge and biodiversity. Scaling-up NUS requires training farmers and other stakeholders on ways to adopt adequate crop management, quality seed, select varieties, farming systems, soil management, development of new products, and market opportunities (Padulosi et al. 2013). Farmers in the Rasuwa district, in the mid-hills of Nepal, prefer to cultivate local bean, barley, millet and local maize, rather than commodity crops because they are more tolerant to water stress and extremely cold conditions (Adhikari et al. 2017). Farmers in the high-altitude cold climate of Nepal prefer local barley with its short growing period because of a shorter growing window. Buckwheat is commonly grown in the Hindu-Kush Himalayan (HKH) region mainly because it grows fast and suppresses weeds. In Pakistan, quinoa (*Chenopodium quinoa*) grew and produced well under saline and marginal soil where other crops would not grow (Adhikari et al. 2017).

At the same time, in many parts of the HKH region, a substantial proportion of the population is facing malnutrition. Various factors are responsible for this, and lack of diversity in food and nutrition resulting from production and consumption of few crops is one of them. In the past, food baskets in this region consisted of many different edible plant species, many of which are now neglected and underutilised. This is because almost all the efforts of the Green Revolution after 1960 focused on major crops. Four crops viz. rice, wheat, maize and potato account for about 60% of global plant-derived energy supply (Padulosi et al. 2013).

While the Green Revolution technologies substantially increased the yield of few crops and allowed countries to reduce hunger, they also resulted in inappropriate and excessive use of agrochemicals, inefficient water use, loss of beneficial biodiversity, water and soil pollution and significantly reduced crop and varietal diversity. With farming systems moving away from subsistence-based to commercial farming, farmers are also reluctant to grow these local crops because of low return, poor market value and lack of knowledge about their nutritional environmental value.

However, transition from traditional diets based on local foods to a commercial crop-based diet with high fats, salt, sugar and processed foods, increased the incidence of non-communicable diseases, such as diabetes, obesity, heart diseases and certain types of cancer (Abarca-Gómez et al. 2017; NCD-

RisC 2016b, 2017b). This 'hidden hunger' – enough calories, but insufficient vitamins - is increasingly evident in mountainous communities including the HKH region.

Internationally, there is rising interest nowadays on NUS, not only because they present tremendous opportunities for fighting poverty, hunger and malnutrition, but also because of their role in mitigating climate risk in agricultural production systems. NUS play an important role in mountain agro-ecosystems because mountain agriculture is generally low-input agriculture, for which many NUS are well adapted.

In the HKH region, mountains are agro-ecologically suitable for cultivation of traditional food crops, such as barley, millet, sorghum, buckwheat, bean, grams, taro, yam and a vast range of wild fruits, vegetables and medicinal plants. In one study carried out in two villages of mid-hills in Nepal, Khanal et al. (2015) reported 52 indigenous crop species belonging to 27 families with their various uses. Farming communities continue to grow various indigenous crops, albeit in marginal land, because of their value on traditional food and associated culture. Nepal Agricultural Research Council (NARC) has identified a list of indigenous crops based on their nutritional, medicinal, cultural and other values.

Many indigenous crops supply essential micronutrients to the human body, and need to be conserved in mountain food systems. Farmers in HKH region are cultivating and maintaining various indigenous crops such as amaranthus, barley, black gram, horse gram, olarum, yam, rayo, sesame, niger, etc. because of their nutritional value. Most of these indigenous crops are comparable with commercial cereals in terms of dietary energy and protein content, but are also rich in micronutrients. For example, pearl millet has higher content of calcium, iron, zinc, fiboflavin and folic acid than rice or maize (Adhikari et al. 2017).

NUS can provide both climate resilience and more options for dietary diversity to the farming communities of mountain ecosystems. Some of these indigenous crops have high medical importance. For example, mountain people in the HKH region have been using *jammun* (i.e., *Syzygium cumini*) to treat diabetes. In the Gilgit-Baltistan province of Pakistan, realising the importance of sea-buckthorn for nutritional and medicinal purposes, local communities have expanded its cultivation to larger areas. Many of these crops can be cultivated in marginal and/or fallow land which otherwise remains fallow. Most of these species are drought resistant and can be easily grown in rainfed conditions in non-irrigated land.

Dietary diversity has also been correlated (*medium evidence, medium agreement*) to agricultural diversity in small-holder and subsistence farms (Ayenew et al. 2018; Jones et al. 2014; Jones 2017; Pimbert and Lemke 2018), including both crops and animals, and has been proposed as a strategy to reduce micronutrient malnutrition in developing countries (Tontisirin et al. 2002). In this regard, the capacity of subsistence farming to supply essential nutrients in reasonable balance to the people dependent on them has been considered as a means of overcoming their nutrient limitations in sound agronomic and sustainable ways (Graham et al. 2007).

Ecosystem-based adaptation (EbA). EbA is a set of nature-based methods addressing climate change adaptation and food security by strengthening and conserving natural functions, goods and services that benefit to people. EbA approaches to address food security provide co-benefits such as contributions to health and improved diet, sustainable land management, economic revenue and water security. EbA practices can reduce greenhouse gas emissions and increase carbon storage (USAID 2017).

For example, agroforestry systems can contribute to improving food productivity while enhancing biodiversity conservation, ecological balance and restoration under changing climate conditions

(Mbow et al. 2014a; Paudela et al. 2017; Newaj et al. 2016; Altieri et al. 2015). Agroforestry systems have been shown to reduce erosion through their canopy cover and their contribution to the micro-climate and erosion control (Sida et al. 2018). Adoption of conservation farming practices such as removing weeds from and dredging irrigation canals, draining and levelling land, and using organic fertilisation were among the popular conservation practices in small-scale paddy rice farming community of northern Iran (Ashoori and Sadegh 2016).

Adaptation potential of ecologically-intensive systems includes also forests and rivers ecosystems, where improved resources management such as soil conservation, water cycling and agro-biodiversity support the function of food production affected by severe climate change (Muthee et al. 2017). The use of non-crop plant resources in agro-ecosystems (permaculture, perennial polyculture) can improve ecosystem conservation and may lead to increased crop productivity (Balzan et al. 2016; Crews et al. 2018; Toensmeier 2016).

In summary, increasing the resilience of the food system through agroecology and diversification is an effective way to achieve climate change adaptation (*robust evidence, high agreement)*. Diversification in the food system is a key adaptation strategy to reduce risks (e.g., implementation of integrated production systems at landscape scales, broad-based genetic resources, and heterogeneous diets) (*medium confidence*).

5.3.2.4 Role of cultural values

Food production and consumption are strongy influenced by cultures and beliefs. Culture, values and norms are primary factors in most climate change and food system policies. The benefits of integrating cultural beliefs and indigenous and local knowledge (ILK) into formal climate change mitigation and adaptation strategies can add value to the development of sustainable climate change that are rich in local aspirations, and planned with and for local people (Nyong et al. 2007).

Cultural dimensions are important in understanding how societies establish food production systems and respond to climate change, since they help to explain differences in responses across populations to the same environmental risks (Adger et al. 2013). There is an inherent adaptability of indigenous people who are particularly connected to land use, developed for many centuries to produce specific solutions to particular climate change challenges. Acknowledging that indigenous cultures across the world are supporting many string strategies and beliefs that offer sustainable systems with pragmatic solutions will help move forward the food and climate sustainability policies. For instance, in the Sahel, the local populations have developed and implemented various adaptation strategies that sustain their resilience despite many threats (Nyong et al. 2007). There is an increased consideration of these local knowledge and cultural values and norms in the design and implementation of modern mitigation and adaptation strategies.

There are some entrenched cultural beliefs and values that may be barriers to climate change adaptation. For instance, culture has been shown to be a major barrier to adaptation for the Fulbe ethnic group of Burkina Faso (Nielsen and Reenberg 2010). Thus, it is important to understand how beliefs, values, practices and habits interact with the behaviour of individuals and collectivities that have to confront climate change (Heyd and Thomas 2008). Granderson (2014) suggests that making sense of climate change and its responses at the community level demands attention to the cultural and political processes that shape how risk is conceived, prioritised and managed. For a discussion of gender issues related to climate change, see Section 5.2.

Culturally sensitive risk analysis can deliver a better understanding of what climate change means for society (O'Brien and Wolf 2010; Persson et al. 2015) and thus, how to better adapt. Murphy et al. (2016) stated that culture and beliefs play an important role in adaptive capacity but that they are not static. In the work done by Elum et al. (2017) in South Africa about farmers perception of climate change, they concluded that perceptions and beliefs often have negative effects on adaptation options.

Culture is a key issue in food systems and the relation of people with nature. Food is an intrinsically cultural process: food production shapes landscapes, which are in turn linked to cultural heritages and identities (Koohafkan and Altieri 2011; Fuller and Qingwen 2013), and food consumption has a strong cultural dimension. The loss of subsistence practices in modern cultures and its related indigenous and local knowledge, has resulted in a loss of valuable adaptive capacities (Hernández-Morcillo et al. 2014). This is so because these systems are often characterised by livelihood strategies linked to the management of natural resources that that have been evolved to reduce overall vulnerability to climate shocks ('adaptive strategies') and to manage their impacts ex-post ('coping strategies') (Morton 2007; López-i-Gelats et al. 2016).

5.3.3 Supply-side adaptation

Supply-side adaptation takes place in the production (of crops, livestock, and aquaculture), storage, transport, processing, and trade of food.

5.3.3.1 Crop production

There are many current agricultural management practices that can be optimised and scaled up to advance adaptation. Among the often-studied adaptation options include increased soil organic matter, improved cropland management, increased food productivity, prevention and reversal of soil erosion (see Chapter 6 for evaluation of these practices in regard to desertification and land degradation). Many analyses have demonstrated the effectiveness of soil management and changing sowing date, crop type or variety (Waongo et al. 2015; Bodin et al. 2016; Teixeira et al. 2017; Waha et al. 2013; Zimmermann et al. 2017; Chalise and Naranpanawa 2016; Moniruzzaman 2015; Sanz et al. 2017). Biophysical adaptation options also include pest and disease management (Lamichhane et al. 2015) and water management (Palmer et al. 2015; Korbeľová and Kohnová 2017).

In Africa, Scheba (2017) found that conservation agriculture techniques were embedded in an agriculture setting based on local traditional knowledge, including crop rotation, no or minimum tillage, mulching, and cover crops. Cover cropping and no-tillage also improved soil health in a highly commercialised arid irrigated system in California's San Joaquin Valley, US (Mitchell et al. 2017). Biofertilisers can enhance rice yields (Kantachote et al. 2016), and Amanullah and Khalid (2016) found that manure and biofertiliser improve maize productivity under semi-arid conditions.

Adaptation also involves use of current genetic resources as well as breeding programs for both crops and livestock. More drought, flood and heat-resistant crop varieties (Atlin et al. 2017; Mickelbart et al. 2015; Singh et al. 2017) and improved nutrient and water use efficiency, including overabundance as well as water quality (such as salinity) (Bond et al. 2018) are aspects to factor in to the design of adaptation measures. Both availability and adoption of these varieties is a possible path of adaptation and can be facilitated by new outreach policy and capacity building.

Water management is another key area for adaptation. Increasing water availability and reliability of water for agricultural production using different techniques of water harvesting, storage, and its judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas have been presented by Rao et al. (2017) and Rivera-Ferre et al. (2016a). In addition, improved drainage systems (Thiel et al. 2015), and Alternate Wetting and Drying (AWD) techniques for rice cultivation (Howell et al. 2015; Rahman and Bulbul 2015) have been proposed. Efficient irrigation systems have been also analysed and proposed by (Jägermeyr et al. 2016) Naresh et al (2017) (Gunarathna et al.

2017; Chartzoulakis and Bertaki 2015). Recent innovation includes using farming system with low usage of water such as drip-irrigation or hydroponic systems mostly in urban farming.

5.3.3.2 Livestock production systems

Considering the benefits of higher temperature in temperate climate and the increase of pasture with incremental warming in some humid and temperate grasslands, as well as potential negative effects, can be useful in planning adaptation strategies to future climate change. Rivera-Ferre et al. (2016b) characterize adaptation for different livestock systems as managerial, technical, behavioural and policy-related options. Managerial included production adjustments (e.g., intensification, integration with crops, shifting from grazing to browsing species, multispecies herds, mobility, soil and nutrient management, water management, pasture management, corralling, feed and food storage, farm diversification or cooling systems); and changes in labor allocation (diversifying livelihoods, shifting to irrigated farming, labor flexibility). Technological options included breeding strategies and information technology research. Behavioral options are linked to cultural patterns and included encouraging social collaboration and reciprocity, e.g., livestock loans, communal planning, food exchanges. and information sharing. Policy options are discussed in Section 5.7 and Chapter 7.

5.3.3.3 Aquaculture, fisheries, and agriculture interactions

Options may include livelihood diversification within and across sectors of fisheries, aquaculture and agriculture. Thus, adaptation options need to provide management approaches and policies that build the livelihood asset base, reducing vulnerability to multiple stressors with a multi-sector perspective (Badjeck et al. 2010). In Bangladesh fishing pressure on post-larval prawns has increased as displaced farmers have shifted to fishing following salt-water intrusion of agricultural land (Ahmed et al. 2013). In West Africa, strategies to cope with sudden shifts in fisheries are wider-reaching and have included turning to seafood import (Gephart et al. 2017) or terrestrial food production including farming and bush-meat hunting on land (Brashares et al. 2004). Proposed actions for adaptation include effective governance, improved management and conservation, efforts to maximise societal and environmental benefits from trade, increased equitability of distribution and innovation in food production, and the continued development of low-input and low-impact aquaculture (FAO 2018c).

Particular adaptation strategies proposed by FAO (2014a) include diverse and flexible livelihood strategies, such as introduction of fish ponds in areas susceptible to intermittent flood/drought periods; flood-friendly small-scale homestead bamboo pens with trap doors allowing seasonal floods to occur without loss of stocked fish; cage fish aquaculture development using plankton feed in reservoirs created by dam building; supporting the transition to different species, polyculture and integrated systems, allowing for diversified and more resilient systems; promotion of rice–fish farming systems reducing overall water needs and providing integrated pest management; and supporting transitions to alternative livelihoods.

Risk reduction initiatives include innovative weather-based insurance schemes being tested for applicability in aquaculture and fisheries and climate risk assessments introduced for integrated coastal zone management. For aquaculture’s contribution to building resilient food systems, Troell et al. (2014) found that aquaculture could potentially enhance resilience through improved resource use efficiencies and increased diversification of farmed species, locales of production, and feeding strategies. Yet, given its high reliance on terrestrial crops and wild fish for feeds, its dependence on freshwater and land for culture sites and its environmental impacts reduce this potential. For instance, the increase in aquaculture worldwide may enhance land competition for feed crops, increasing price levels and volatility and worsening food insecurity among the most vulnerable populations.

5.3.3.4 Transport and storage

Fewer studies have been done on adaptation of food system transport and storage compared to the many studies on adaptation to climate in food production.

Transport. One transport example is found in Bangkok. Between mid-November 2011 and early January 2012, Bangkok, the capital city of Thailand, faced its most dramatic flood in approximately 70 years with most transport networks cut-off or destroyed. This caused large-scale disruption of the national food supply chains since they were centrally organised in the capital city (Allen et al. 2017). From this experience, the construction and management of 'climate-proof' rural roads and transport networks is argued as one the most important adaptation strategies for climate change and food security in Thailand (Rattanachot et al. 2015).

Similarly in Africa, it has been shown that enhanced transportation networks combined with other measures could reduce the impact of climate change on food and nutrition security (Brown et al. 2017b). This suggests that strengthening infrastructure and logistics for transport would significantly enhance resilience to climate change while improving food and nutrition security in developing counties.

Storage. Storage refers to both structures and technologies for storing seed as well as produce. Predominant storage methods used in Uganda are single-layer woven polypropylene bags (popularly called "kavera" locally), chemical insecticides and granaries. Evidence from Omotilewa et al. (2018) showed that the introduction of new storage technology called Purdue Improved Crop Storage (PICS) could contribute to climate change adaptation. PICS is a chemical-free airtight triple-layered technology consisting of two high-density polyethylene inner liners and one outer layer of woven polypropylene bag. Its adoption has increased the number of households planting hybrid maize varieties that are more susceptible to insect pests in storage than traditional lower-yielding varieties. Such innovations could help to protect crops more safely and for longer periods from postharvest insect pests that are projected to increase as result of climate change, thus contributing to food security. In the Indo-Gangetic Plains many different storage structures based on ILK provide reliable and low-cost options made of local materials. For example, elevated grain stores protect from floods, but also provide for air circulation to prevent rot and to control insects and other vermin (Rivera-Ferre et al. 2013).

5.3.3.5 Trade and processing

Adaptation measures are also being considered in trade, processing, and packaging, other components of the food system. These will enable availability, stability, and safety of food under changing climate conditions.

Trade. Brooks & Matthews (2015) found that food trade increases the availability of food by enabling products to flow from surplus to deficit areas, raises incomes and favors access to food, improves utilisation by increasing the diversity of national diets while pooling production risks across individual markets to maintain stability.

Processing. Growth of spoilage bacteria of red meat and poultry during storage due to increasing temperature has been demonstrated by European Food Safety Authority (EFSA Panel on Biological Hazards 2016). In a recent experiment conducted on the optimisation of processing conditions of Chinese traditional smoke-cured bacon (Larou), Liu et al. (2018a) showed that the use of new natural coating solution composed of lysozyme, sodium alginate, and chitosan during storage period resulted in 99.69% rate of reducing deterioration after 30-day storage. Also, the use of High Hydrostatic Pressure (HHP) technology to inactivate pathogenic, spoilage microorganisms and enzymes with little or no effects on the nutritional and sensory quality of foods have been described by Wang et al.

(2016) and Ali et al. (2018) as new advances in processing and packaging fruits, vegetables, meats, seafood, dairy, and egg products.

In summary, there are many practices that can be optimised and scaled up to advance supply-side adaptation. On-farm adaptation options include increased soil organic matter and erosion control in cropland, improved livestock and grazing land management, and transition to different species, polyculture and integrated systems in aquaculture. Crop and livestock genetic improvements include tolerance to heat, drought, and pests and diseases. Food transport, storage, trade, and processing will likely play increasingly important roles in adapting to climate change-induced food insecurity.

5.3.4 Demand-side adaptation

Adaptation in the demand side of the food system involves consumption practices, diets, and reducing food loss and waste. Recent studies showed that supply-side adaptation measures alone will not be sufficient to sustainably achieve food security under climate change (Springmann et al. 2018b; Swinburn et al. 2019; Bajželj et al. 2014). As noted by Godfray (2015), people with higher income demand more varied diets, and typically ones that are richer in meat and other food types that require more resources to produce. Therefore, both supply-side (production, processing, transport, trade, etc.) and demand-side solutions (changing diets, food loss and waste reduction, etc.) can be effective in adapting to climate change (Creutzig et al. 2016) (see Section **Error! Reference source not found.** or food loss and waste).

The implications of dietary choice can have severe consequences for land. For example, Alexander et al. 2016, found that if every country were to adopt the UK's 2011 average diet and meat consumption, 95% of global habitable land area would be needed for agriculture – up from 50% of land currently used. For the average US diet, 178% of global land would be needed (relative to 2011) (Alexander et al. 2016); and for "business as usual" dietary trends and existing rates of improvement in yields, 55% more land would be needed above baseline (2009) (Bajželj et al. 2014). Changing dietary habits has been suggested as an effective food route to affect land use (Beheshti et al. 2017) and promote adaptation to climate change through food demand.

Most literature has focused on demand-side options that analyse the effects on climate change mitigation by dietary changes. Little focus has been brought on demand-side adaptation measures to adjust the demand to the food challenges related to drivers such as market, climate change, inputs limitations (e.g., fossil fuels, nitrogen, phosphorus), food access, and quality. Adding to that, the high cost of nutritious foods contributes to a higher risk of overweight and obesity (FAO 2018d). Adaptation measures relate also to the implications of easy access to inexpensive, high-calorie, low-nutrition foods which have been shown to lead to malnutrition (Section 5.1). Therefore, adaptation related to diet may be weighed against the negative side-effects on health of current food choices.

Reduction in the demand for animal-based food products and increasing proportions of plant-based foods in diets, particularly pulses and nuts; and replacing red meat with other more-efficient protein sources are demand-side adaptation measures (Machovina et al. 2015) (see also Section 5.5.2). For example, replacing beef in the US diet with poultry can meet caloric and protein demands of about 120 to 140 million additional people consuming the average American diet (Shepon et al. 2016). Similar suggestions are made for adopting the benefits of moving to plant-based protein, such as beans (Harwatt et al. 2017).

The main reason why reducing meat consumption is an adaptation measure is because it reduces pressure on land and water and thus our vulnerability to climate change and inputs limitations (Vanham et al. 2013). For animal feed, ruminants can have positive ecological effects (species diversity, soil carbon) if they are fed extensively on existing grasslands. Similarly, reducing waste at all points along the entire food chain is a significant opportunity for improving demand-side adaptation measures (Godfray 2015).

It is important to highlight the opportunities for improving the feed-to-meat conversion considered as a form of food loss. However, the unique capacity of ruminants to produce high-quality food from low-quality forage, in particular from landscapes that cannot be cropped and from cellulosic biomass that humans cannot digest could be seen as an effective way to improve the feed:meat ratio (Cawthorn and Hoffman 2015).

In summary, there is potential for demand-side adaptation, such as adoption of diets low in animal-sourced products, in conjunction with reduction in food loss and waste to contribute to reduction in food demand, land sparing, and thus need for adaptation.

5.3.5 Institutional measures

To facilitate the scaling up of adaptation throughout the food system, institutional measures are needed at global, regional, national, and local levels (See Section 5.7). Institutional aspects including policies and laws depend on scale and context. International institutions (financial and policies) are driving many aspects of global food systems (e.g., UN agencies, international private sector agribusinesses and retailers). Many others operate at local level and strongly influence livelihoods and markets of smallholder farmers. Hence, differentiation in the roles of the organisations, their missions and outcomes related to food and climate change action need to be clearly mapped and understood.

Awareness about the institutional context within which adaptation planning decisions are made is essential for the usability of climate change projection (Lorenz 2017) (Chapter 7 SRCCL). In the planning and operational process of food production, handling and consumption, the environment benefits and climate change goals can be mainstreamed under sustainable management approaches that favor alternative solutions for inputs, energy consumption, transformation and diet. For instance, land use planning would guide current and future decision making and planners in exploring uncertainty to increase the resilience of communities (Berke & Stevens 2016). One of the important policy implications for enhanced food security are the trade-offs between agricultural production and environmental concerns, including the asserted need for global land use expansion, biodiversity and ecological restoration (See Section 5.6) (Meyfroidt 2017).

There are a number of adaptation options in agriculture in the form of policy, planning, governance and institutions (Lorenz 2017). For example, early spatial planning action is crucial to guide decision-making processes and foster resilience in highly uncertain future climate change (Brunner and Grêt-Regamey, 2016). Institutions may develop new capacities to empower value chain actors take climate change into account as they develop quality products, promote adoption of improved diet for healthier lifestyles, aid the improvement of livelihoods of communities, and further socioeconomic development (Sehmi et al. 2016). Other adaptation policies include property rights and land tenure security as legal and institutional reforms to ensure transparency and access to land that could stimulate adaptation to climate change Antwi-Agyei et al. (2015).

5.3.5.1 Global initiatives

Climate change poses serious wide-ranging risks, requiring a broader approach in fighting the phenomenon. The United Nations Framework Convention on Climate Change (UNFCCC) and its annual Conferences of the Parties (COPs) has been instrumental in ensuring international cooperation in the field of tackling the impacts of climate change in a broader framework (Clémençon 2016). The National Adaptation Plan (NAP) program under the UNFCCC, was established to: identify vulnerable regions; assess the impacts of climate change on food security; and prioritise adaptation measures for implementation to increase resilience. The National Adaptation Programs of Action (NAPAs) was also established to support least-developed countries (LDCs) address their particular challenges in adaptation, to enhance food security among other priorities. The Paris Agreement (UNFCCC 2015) is a major victory for small island states and vulnerable nations that face climate change-related impacts of floods and droughts resulting in food security challenges. Adaptation and mitigation targets set by the parties through their nationally determined commitments (NDCs) are reviewed internationally to ensure consistency and progress towards actions (Falkner 2016).

The Food and Agriculture Organization of the United Nations (FAO) also plays a significant role in designing and coordinating national policies to increase adaptation and food security. The five key strategic objectives of FAO (Help eliminate hunger, food insecurity and malnutrition; Make agriculture, forestry and fisheries more productive and sustainable; Reduce rural poverty; Enable inclusive and efficient agricultural and food systems; and increase the resilience of livelihoods to climate threats) (FAO 2018e), all relate to building resilience and increasing global adaptation to climate variability.

In support of the Paris Agreement, FAO launched a global policy, "Tracking Adaptation" with the aim of monitoring the adaptation processes and outcomes of the parties to increase food security, and make available technical information for evaluation by stakeholders. In response to the estimated world population of 9.7 billion by 2050, FAO adopted the Climate Smart Agriculture (CSA) approach to increase global food security without compromising environmental quality (See Section 5.6). FAO supports governments at the national level to plan CSA programs and to seek climate finance to fund their adaptation programs.

The Global Commission on Adaptation, co-managed by World Resources Institute (WRI) and the Global Center on Adaptation, seeks to accelerate adaptation action by elevating the political visibility of adaptation and focusing on concrete solutions (Global Commission on Adaptation 2019). The Commission works to demonstrate that adaptation is a cornerstone of better development, and can help improve lives, reduce poverty, protect the environment, and enhance resilience around the world. The Commission is led by Ban Ki-moon, 8th Secretary-General of the United Nations, Bill Gates, co-chair of the Bill & Melinda Gates Foundation, and Kristalina Georgieva, CEO, World Bank. It is convened by 17 countries and guided by 28 commissioners. A global network of research partners and advisors provide scientific, economic, and policy analysis.

5.3.5.2 National policies

The successful development of food systems under climate change conditions requires a national-level management that involves the cooperation of a number of institutions and governance entities to enable more sustainable and beneficial production and consumption practices.

For example, Nepal has developed a novel multi-level institutional partnership, under the Local Adaptation Plan of Action (LAPA), which is an institutional innovation that aims to better integrate local adaptation planning processes and institutions into national adaptation processes. That includes collaboration with farmers and other non-governmental organisations (Chhetri et al. 2012). By combining conventional technological innovation process with the tacit knowledge of farmers, this new alliance has been instrumental in the innovation of location-specific technologies thereby facilitating the adoption of technologies in a more efficient manner.

National Adaptation Planning of Indonesia was officially launched in 2014 and was an important basis for ministries and local governments to mainstream climate change adaptation into their respective sectoral and local development plans Kawanishi et al. (2016). Crop land use policy to switch from crops that are highly impacted by climate change to those that are less vulnerable were suggested for improving climate change adaptation policy processes and outcomes in Nepal (Chalise and Naranpanawa 2016). Enhancement of representation, democratic and inclusive governance, as well as equity and fairness for improving climate change adaptation policy processes and outcomes in Nepal were also suggested as intuitional measure by Ojha et al. (2015). Further, food, nutrition, and health policy adaptation options such as social safety nets and social protection have been implemented in India, Pakistan, Middle East and North Africa (Devereux 2015; Mumtaz and Whiteford 2017; Narayanan and Gerber 2017).

Financial incentives policies at the national scale used as adaptation options include taxes and subsidies; index-based weather insurance schemes; and catastrophe bonds (Zilberman et al. 2018; Linnerooth-Bayer and Hochrainer-Stigler 2015; Ruiter et al. 2017; Campillo et al. 2017). Microfinance, disaster contingency funds, and cash transfers are other mechanisms (Ozaki 2016; Kabir et al. 2016).

5.3.5.3 Community-based adaptation

Community-based adaptation (CBA) builds on social organisational capacities and resources to addressing food security and climate change. CBA represents bottom-up approaches and localised adaptation measures where social dynamics serve as the power to respond to the impacts of climate change (Ayers and Forsyth 2009). It identifies, assists, and implements development activities that strengthen the capacity of local people to adapt to living in a riskier and less predictable climate, while ensuring their food security.

Klenk et al. (2017) found that mobilisation of local knowledge can inform adaptation decision-making and may facilitate greater flexibility in government-funded research. As an example, rural innovation in terrace agriculture developed on the basis of a local coping mechanism and adopted by peasant farmers in Latin America may serve as an adaptation option to climate change (Bocco and Napoletano, 2017). Clemens et al. (2015) indicated that learning alliances provided social learning and knowledge-sharing in Vietnam through an open dialogue platform that provided incentives and horizontal exchange of ideas.

Community-based adaptation generates strategies through participatory processes, involving local stakeholders and development and disaster risk–reduction practitioners. Fostering collaboration and community stewardship is central to the success of CBA (Scott et al. 2017). Preparedness behaviours that are encouraged include social connectedness, education, training, and messaging; CBA also can encompass beliefs that might improve household preparedness to climate disaster risk (Thomas et al. 2015). Reliance on social networks, social groups connectivities, or moral economies reflect the importance of collaboration within communities (Reuter 2018; Schramski et al. 2017).

Yet, community-based adaptation also needs to consider methods that engage with the drivers of vulnerability as part of community-based approaches, particularly questions of power, culture, identity and practice (Ensor et al. 2018). The goal is to avoid maladaptation or exacerbation of existing inequalities within the communities (Buggy and McNamara 2016). For example, in the Pacific Islands, elements considered in a CBA plan included people’s development aspirations; immediate economic, social and environmental benefits; dynamics of village governance, social rules and protocols; and traditional forms of knowledge that could inform sustainable solutions (Remling and Veitayaki 2016).

With these considerations, community-based adaptation can help to link local adaptation with international development and climate change policies (Forsyth 2013). In developing CBA programs, barriers exist that may hinder implementation. These include poor coordination within and between organisations implementing adaptation options, poor skills, poor knowledge about climate change, and inadequate communication among stakeholders (Spires et al. 2014). A rights-based approach has been suggested to address issues of equality, transparency, accountability and empowerment in adaptation to climate change (Ensor et al. 2015).

In summary, institutional measures, including risk management, policies, and planning at global, national, and local scales can support adaptation. Advance planning and focus on institutions can aid in guiding decision-making processes and foster resilience. There is evidence that institutional measures can support the scaling up of adaptation and thus there is reason to believe that systemic resilience is achievable.

5.3.6 Tools and finance

5.3.6.1 Early Warning Systems

Many countries and regions in the world have adopted early warning systems (EWS) to cope with climate variability and change as it helps to reduce interruptions and improve response times before and after extreme weather events (Ibrahim and Kruczkiewicz 2016). The Early Warning and Early Action (EW/EA) framework has been implemented in West Africa (Red Cross 2011) and Mozambique (DKNC 2012). Bangladesh has constructed cyclone shelters where cyclone warnings are disseminated and responses organised (Mallick et al. 2013). In Benin, a Standard Operating Procedure is used to issue early warnings through the UNDP Climate Information and Early Warning Systems Project (UNDP 2016).

However, there are some barriers to building effective early warning systems in Africa, such as lack of reliable data and distribution systems, lack of credibility, and limited relationships with media and government agencies (UNDP 2016). Mainstreaming early warning systems in adaptation planning could present a significant opportunity for climate disaster risk reduction (Zia and Wagner 2015). Enenkel et al. (2015) suggested that the use of smartphone applications that concentrate on food and nutrition security could help with more frequent and effective monitoring of food prices, availability of fertilisers and drought-resistant seeds, and could help to turn data streams into useful information for decision support and resilience building.

GIS and remote sensing technology are used for monitoring and risk quantification for broad-spectrum stresses such as drought, heat, cold, salinity, flooding, and pests (Skakun et al. 2017; Senay et al. 2015; Hossain et al. 2015; Brown 2016), while site-specific applications, such as drones, for nutrient management, precision fertilisers, and residue management can help devise context-specific adaptations (Campbell et al. 2016; Baker et al. 2016). Systematic monitoring and remote sensing options, as argued by Aghakouchak et al. (2015), showed that satellite observations provide opportunities to improve early drought warning. Waldner et al. (2015) found that cropland mapping allows strategic food and nutrition security monitoring and climate modelling.

Access to a wide range of adaptation technologies for precipitation change is important, such as rainwater harvesting, wastewater treatment, stormwater management and bioswales, water demand reduction, water-use efficiency, water recycling and reuse, aquifer recharge, inter-basin water transfer, desalination, and surface-water storage (ADB 2014).

5.3.6.2 Financial resources

Financial instruments such as micro-insurance, index-based insurance, provision of post-disaster finances for recovery and pre-disaster payment are fundamental means to reduce lower and medium level risks (Linnerooth-Bayer and Hochrainer-Stigler 2014). Fenton & Paavola, 2015; Dowla, 2018). Hammill et al. (2010) found that microfinance services (MFS) are especially helpful for the poor. MFS can provide poor people with the means to diversify, accumulate and manage the assets needed to become less susceptible to shocks and stresses. As a result, MFS plays an important role in vulnerability reduction and climate change adaptation among some of the poor. The provision of small-scale financial products to low-income and otherwise disadvantaged groups by financial institutions can serve as adaptation to climate change. Access to finance in the context of climate change adaptation that focuses on poor households and women in particular is bringing encouraging results (Agrawala and Carraro 2010).

In summary, effective adaptation strategies can reduce the negative impacts of climate change. Food security under changing climate conditions depends on adaptation throughout the entire food system – production, supply chain, and consumption/demand, as well as reduction of food loss and waste. Adaptation can be autonomous, incremental, or transformative, and can reduce vulnerability and enhance resilience. Local food systems are embedded in culture, beliefs and values, and indigenous and local knowledge can contribute to enhancing food system resilience to climate change *(high confidence)*. Institutional and capacity-building measures are needed to scale up adaptation measures across local, national, regional, and global scales.

5.4 Impacts of food systems on climate change

5.4.1 Greenhouse gas emissions from food systems

This chapter assesses the contributions of the entire food system to greenhouse gas (GHG) emissions. Food systems emissions include CO_2 and non-CO_2 gases, specifically those generated from: i) crop and livestock activities within the farm gate (Table 5.4, category 'Agriculture'); ii) land use and land use change dynamics associated with agriculture (Table 5.4, category 'Land Use'); and iii) food processing, retail and consumption patterns, including upstream and downstream processes such as manufacture of chemical fertilisers and fuel (Table 5.4, category 'Beyond Farm Gate'). The first two categories comprise emissions reported by countries in the AFOLU (Agriculture, Forestry, and Other Land Use) sectors of national GHG inventories; the latter comprises emissions reported in other sectors of the inventory, as appropriate, for instance, industrial processes, energy use, and food loss and waste.

The first two components (agriculture and land use) identified above are well quantified and supported by an ample body of literature (Smith et al. 2014). During the period 2007-2016, global agricultural non-CO_2 emissions from crop and livestock activities within the farm gate were 6.2 ± 1.9 Gt CO_2-eq yr^{-1} during 2007-2016, with methane (142 ± 43 Mt CH_4 yr^{-1}, or 4.1 ± 1.2 Gt CO_2-eq yr^{-1}) contributing in CO2eq about twice as much as nitrous oxide (8.3 ± 2.3 Mt N_2O yr^{-1}, or 2.1 ± 0.6 Gt CO_2-eq yr^{-1}) to this total (see Table 2.2 in Chapter 2). Emissions from land use associated with agriculture in some regions, such as from deforestation and peatland degradation (both processes involved in preparing land for agricultural use), added globally during the same period another 4.8 ± 2.4 Gt CO_2-eq yr^{-1} (see Chapter 2). These estimates are associated with uncertainties of about 30% (agriculture) and 50% (land use), as per IPCC AR5 (Smith et al. 2014).

Agriculture activities within the farm gate and associated land use dynamics are therefore responsible for about 11.0 ± 3.1 Gt CO_2-eq yr^{-1}, or some 20% of total anthropogenic emissions (Table 5.4), consistent with post-AR5 findings (e.g., Tubiello et al. (2015)). In terms of individual gases, the contributions of agriculture to total emissions by gas are significantly larger. For instance, over the period 2010-2016, methane gas emissions within the farm gate represented about half of the total CH_4 emitted by all sectors, while nitrous dioxide gas emissions within the farm gate represented about three-quarters of the total N_2O emitted by all sectors (Tubiello 2019). In terms of carbon, CO_2

emissions from deforestation and peatland degradation linked to agriculture contributed about 10% of the CO_2 emitted by all sectors in 2017 (Le Quéré et al. 2018).

Food systems emissions beyond the farm gate, such as those upstream from manufacturing of fertilisers, or downstream such as food processing, transport and retail, and food consumption, generally add to emissions from agriculture and land use, but their estimation is very uncertain due to lack of sufficient studies. The IPCC AR5 (Fischedick et al. 2014) provided some information on these other food system components, noting that emissions beyond the farm gate in developed countries may equal those within the farm gate, and cited one study estimating world total food system emissions to be up to 30% of total anthropogenic emissions (Garnett 2011). More recently, Poore and Nemecek (2018), by looking at a database of farms and using a combination of modelling approaches across relevant processes, estimated a total contribution of food systems around 26% of total anthropogenic emissions. Total emissions from food systems may thus account for 25-30% of total GHG emissions (*medium confidence*).

Based on the available literature, a break-down of individual contributions of food systems emissions is show in Table 5.4, between those from agriculture within the farm gate (10-12%) (*high confidence*); emissions from land use and land use change dynamics such as deforestation and peatland degradation, which are associated with agriculture in many regions (8-10%) (*high confidence*); and those from food supply chain activities past the farm gate, such as storage, processing, transport, and retail (5-10%) *(limited evidence, medium agreement).* Note that the corresponding lower range of emissions past the farm gate, i.e., 2.5 Gt CO_2-eq yr^{-1} (Table 5.4), is consistent with recent estimates made by Poore and Nemecek (2018). Contributions from food loss and waste are implicitly included in these estimates of total emissions from food systems (See Section 5.5.2.5). They may account for 8–10% of total GHG emissions from agriculture and land use (FAO 2013b) (*low confidence*).

Table 5.4 GHG emissions (Gt CO_2eq yr^{-1}) from the food system and their contribution (%) to total anthopogenic emissions. Mean of 2007-2016 period.

Food system component	Emissions (Gt CO_2eq yr^{-1})	Share in mean total emissions (%)
Agriculture	6.2 ± 1.9 [a]	10-12%
Land use	4.8 ± 2.4 [a]	8-10%
Beyond farm gate	3.8 ± 1.3 [b]	5-10%
Food system (Total)	14.8 ± 3.4	25-30%

Notes: Food system emissions are estimated by combining emissions data from a) FAOSTAT (2018) and US EPA (See also Chapter 2) and b) Garnett (2011) and Poore and Nemecek (2018). Percentage shares were computed by using a total emissions value for the period 2007-2016 of nearly 51 Gt CO_2-eq yr^{-1} (See Chapter 2). GWP values used are those , and by using GWP values of the IPCC AR5 with no climate feedback (GWP-CH4=28; GWP-N2O=265)..

5.4.2 Greenhouse gas emissions from croplands and soils

Since AR5, a few studies have quantified separate contributions of crops and soils on the one hand, and livestock on the other, to the total emissions from agriculture and associated land use. For instance, Carlson et al. (2017) estimated emissions from cropland to be in the range of 2–3 $GtCO_2$-eq

yr^{-1}, including methane emissions from rice, CO_2 emissions from peatland cultivation, and N_2O emissions from fertiliser applications. Data from FAOSTAT (2018), recomputed to use AR5 GWP values, indicated that cropland emissions from these categories were 3.6 ± 1.2 Gt CO_2-eq yr^{-1} over the period 2010–2016; two-thirds of this were related to peatland degradation, followed by N_2O emissions from synthetic fertilisers and methane emissions from paddy rice fields (Tubiello 2019). These figures are a subset of the total emissions from agriculture and land use reported in Table 5.4. Asia, especially India, China and Indonesia accounted for roughly 50% of global emissions from croplands. Figure 5.8 shows the spatial distribution of emissions from cropland according to Carlson et al. (2017), not including emissions related to deforestation or changes in soil carbon.

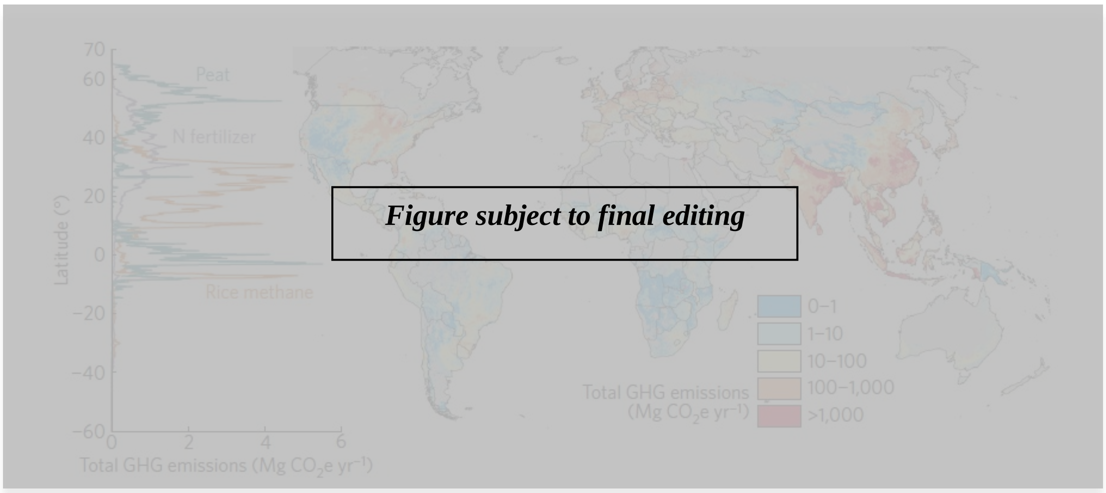

Figure 5.8 Cropland GHGs consist of CH_4 from rice cultivation, CO_2, N_2O, and CH_4 from peatland draining, and N_2O from N fertiliser application. Total emissions from each grid cell are concentrated in Asia, and are distinct from patterns of production intensity (Carlson et al. 2017).

5.4.3 Greenhouse gas emissions from livestock

Emissions from livestock include non-CO_2 gases from enteric fermentation from ruminant animals and from anaerobic fermentation in manure management processes, as well as non-CO_2 gases from manure deposited on pastures (Smith et al. 2014). Estimates after the AR5 include those from Herrero et al. (2016), who quantified non-CO_2 emissions from livestock to be in the range of 2.0–3.6 $GtCO_2$-eq yr^{-1}, with enteric fermentation from ruminants being the main contributor. FAOSTAT (2018) estimates of these emissions, renormalized to AR5 GWP values, were 4.1 ± 1.2 Gt CO_2-eq yr^{-1} over the period 2010–2016.

These estimates of livestock emissions are for those generated within the farm gate. Adding emissions from relevant land use change, energy use, and transportation processes, FAO (2014a) and Gerber et al. (2013) estimated livestock emissions of up to 5.3 ±1.6 $GtCO_2$-eq yr^{-1} circa the year 2010 (data from original papers, but scaled to SAR global warming potential (GWP) values for methane, for comparability with previous results).

All estimates agree that cattle are the main source of global livestock emissions (65–77%). Livestock in low and middle-income countries contribute 70% of the emissions from ruminants and 53% from monogastric livestock (animals without ruminant digestion processes such as sheep, goats, pigs, and poultry), and these are expected to increase as demand for livestock products increases in these countries (Figure 5.9). In contrast to the increasing trend in absolute GHG emissions, GHG emissions intensities, defined as GHG emissions per unit produced, have declined globally and are about 60% lower today than in the 1960s. This is largely due to improved meat and milk productivity of cattle breeds (FAOSTAT 2018; Davis et al. 2015).

Still, products like red meat remain the most inefficient in terms of emissions per kg of protein produced in comparison to milk, pork, eggs and all crop products (IPCC 2014b). Yet, the functional unit used in these measurements is higly relevant and may produce different results (Salou et al. 2017). For instance, metrics based on products tend to rate intensive livestock systems as efficient, while metrics based on area or resources used tend to rate extensive system as efficient (Garnett 2011). In ruminant dairy systems, less intensified farms show higher emissions if expressed by product, and lower emissions if expressed by Utilizable Agricultural Land (Gutiérrez-Peña et al. 2019; Salvador et al. 2017; Salou et al. 2017).

Furthermore, if other variables are used in the analysis of GHG emissions of different ruminant production systems, such as human-edible grains used to feed animals instead of crop waste and pastures of marginal lands, or C sequestration in pasture systems in degraded lands, then the GHG emissions of extensive systems are reduced. Reductions of 26 and 43% have been shown in small ruminants, such as sheep and goats (Gutiérrez-Peña et al. 2019; Salvador et al. 2017; Batalla et al. 2015; Petersen et al. 2013). In this regard, depending on what the main challenge is in different regions (e.g., undernourishment, overconsumption, natural resources degradation), different metrics could be used as reference. Other metrics that consider nutrient density have been proposed because they provide potential for addressing both mitigation and health targets (Doran-Browne et al. 2015).

Uncertainty in worldwide livestock population numbers remain the main source of variation in total emissions of the livestock sector, while at the animal level, feed intake, diet regime, and nutritional composition are the main sources of variation through their impacts on enteric fermentation and manure N excretion.

Increases in economies of scale linked to increased efficiencies and decreased emission intensities may lead to more emissions, rather than less, an observed dynamic referred to by economists as a ‘rebound effect.’ This is because increased efficiency allows production processes to be performed using fewer resources and often at lower cost. This in turn influences consumer behaviour and product use, increasing demand and leading to increased production. In this way, the expected gains from new technologies that increase the efficiency of resource use may be reduced (i.e., increase in the total production of livestock despite increased efficiency of production due to increased demand for meat sold at lower prices). Thus, in order for the livestock sector to provide a contribution to GHG mitigation, reduction in emissions intensities need to be accompanied by appropriate governance and incentive mechanisms to avoid rebound effects, such as limits on total production.

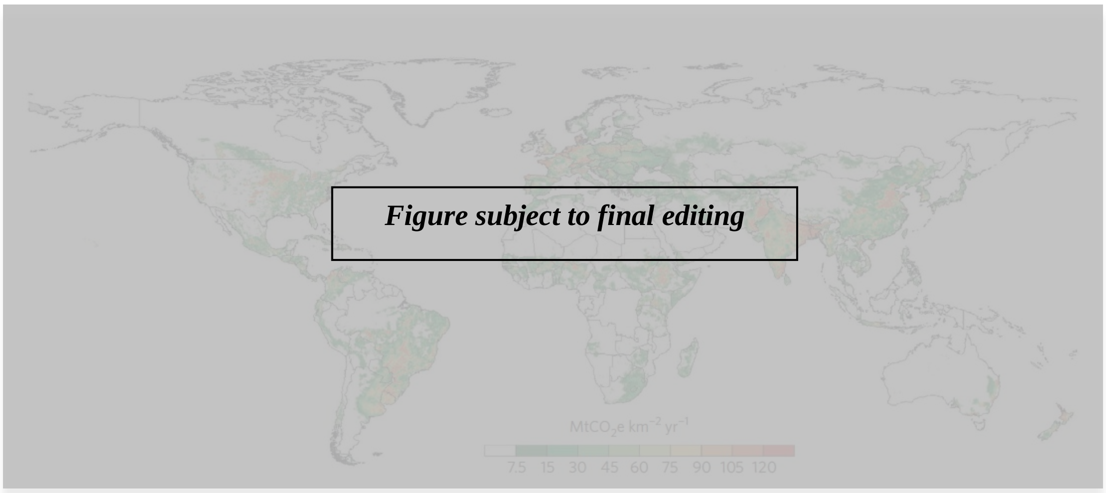

Figure 5.9 Global GHG emissions from livestock for 1995-2005 (Herrero et al. 2016a)

Variation in estimates of N_2O emissions are due to differing a) climate regimes, b) soil types, and c) N transformation pathways (Charles et al. 2017; Fitton et al. 2017). It was recently suggested that

N_2O soil emissions linked to livestock through manure applications could be 20%-40% lower than previously estimated in some regions, for instance in Sub-Saharan Africa and Eastern Europe (Gerber et al. 2016) and from smallholder systems in East Africa (Pelster et al. 2017). Herrero et al. (2016a) estimated global livestock enteric methane to range from 1.6–2.7 Gt CO_2-eq, depending on assumptions of body weight and animal diet.

5.4.4 Greenhouse gas emissions from aquaculture

Emissions from aquaculture and fisheries may represent some 10% of total agriculture emissions, or about 0.58 Gt CO_2-eq yr-1 (Barange et al. 2018), with two-thirds being non-CO_2 emissions from aquaculture (Hu et al. 2013; Yang et al. 2015) and the rest due to fuel use in fishing vessels. They were not included in Table 5.4 under agriculture emissions, as these estimates are not included in national GHG inventories and global numbers are small as well as uncertain.

Methodologies to measure aquaculture emissions are still being developed (Vasanth et al. 2016). N_2O emissions from aquaculture are partly linked to fertiliser use for feed as well as aquatic plant growth, and depend on the temperature of water as well as on fish production (Paudel et al. 2015). Hu et al. (2012) estimated the global N_2O emissions from aquaculture in 2009 to be 0.028 Gt CO_2-eq yr^{-1}, but could increase to 0.114 Gt CO_2-eq yr^{-1} (that is 5.72% of anthropogenic N_2O–N emissions) by 2030 for an estimated 7.10% annual growth rate of the aquaculture industry. Numbers estimated by Williams and Crutzen (2010) were around 0.036 Gt CO_2-eq yr^{-1}, and suggested that this may rise to more than 0.179 Gt CO_2-eq yr^{-1} within 20 years for an estimated annual growth of 8.7%. (Barange et al. 2018) assessed the contribution of aquaculture to climate change as 0.38 Gt CO_2-eq yr^{-1} in 2010, around 7% of those from agriculture.

CO_2 emissions coming from the processing and transport of feed for fish raised in aquaculture, and also the emissions associated with the manufacturing of floating cultivation devices (e.g., rafts or floating fish-farms), connecting or mooring devices, artificial fishing banks or reefs, and feeding devices (as well as their energy consumption) may be considered within the emissions from the food system. Indeed, most of the GHG emissions from aquaculture are associated with the production of raw feed materials and secondarily, with the transport of raw materials to mills and finished feed to farms (Barange et al. 2018).

5.4.5 Greenhouse gas emissions from inputs, processing, storage, and transport

Apart from emissions from agricultural activities within the farm gate, food systems also generate emissions from the pre- and post-production stages in the form of input manufacturing (fertilisers, pesticides, feed production) and processing, storage, refrigeration, retail, waste disposal, food service, and transport. The total contribution of these combined activities outside the farm gate is not well documented. Based on information reported in the AR5 (Fischedick et al. 2014), we estimated their total contribution to be roughly 15% of total anthropogenic emissions (Table 5.4). There is no post-AR5 assessment at the global level in terms of absolute emissions. Rather, several studies have recently investigated how the combined emissions within and outside the farm gate are embedded in food products and thus associated with specific dietary choices (see next section). Below important components of food systems emissions beyond the farm gate are discussed based on recent literature.

Refrigerated trucks, trailers, shipping containers, warehouses, and retail displays that are vital parts of food supply chains all require energy and are direct sources of GHG emissions. Upstream emissions in terms of feed and fertiliser manufacture and downstream emissions (transport, refrigeration) in intensive livestock production (dairy, beef, pork) can account for up to 24–32% of total livestock emissions, with the higher fractions corresponding to commodities produced by monogastric animals

(Weiss and Leip 2012). The proportion of upstream/downstream emissions fall significantly for less-intensive and more-localised production systems (Mottet et al. 2017a).

Transport and processing. Recent globalisation of agriculture has promoted industrial agriculture and encouraged value-added processing and more distant transport of agricultural commodities, all leading to increased GHG emissions. Although greenhouse gas-intensive, food transportation plays an important role in food chains: it delivers food from producers to consumers at various distances, particularly to feed people in food-shortage zones from food-surplus zones. (See Section **Error! eference source not found.** for assessment of local food production.)

To some extent, processing is necessary in order to make food supplies more stable, safe, long-lived, and in some cases, nutritious (FAO 2007). Agricultural production within the farm gate may contribute 80–86% of total food-related emissions in many countries, with emissions from other processes such as processing and transport being small (Vermeulen et al. 2012). However, in net food-importing countries where consumption of processed food is common, emissions from other parts of the food life cycle generated in other locations are much higher (Green et al. 2015).

A study conducted by Wakeland et al. (2012) in the US found that the transportation-related carbon footprint varies from a few percent to more than half of the total carbon footprint associated with food production, distribution, and storage. Most of the GHGs emitted from food processing are a result of the use of electricity, natural gas, coal, diesel, gasoline or other energy sources. Cookers, boilers, and furnaces emit carbon dioxide, and wastewater emits methane and nitrous oxide. The most energy-intensive processing is wet milling of maize, which requires 15% of total US food industry energy (Bernstein et al. 2008); processing of sugar and oils also requires large amounts of energy.

5.4.6 Greenhouse gas emissions associated with different diets

There is now an extensive literature on the relationship between food products and emissions, although the focus of the studies has been on high-income countries. Godfray et al. (2018) updated Nelson et al. (2016), a previous systematic review of the literature on environmental impacts associated with food, and concluded that higher consumption of animal-based foods was associated with higher estimated environmental impacts, whereas increased consumption of plant-based foods was associated with estimated lower environmental impact. Assessment of individual foods within these broader categories showed that meat – sometimes specified as ruminant meat (mainly beef) – was consistently identified as the single food with the greatest impact on the environment, most often in terms of GHG emissions and/or land use per unit commodity. Similar hierarchies, linked to well-known energy losses along trophic chains, from roots to beef were found in another recent review focussing exclusively on GHG emissions (Clune et al. 2017), and one on life-cycle assessments (Poore and Nemecek 2018). Poore and Nemecek (2018) amassed an extensive database that specifies both the hierarchy of emissions intensities and the variance with the production context (i.e., by country and farming system).

The emissions intensities of red meat mean that its production has a disproportionate impact on total emissions (Godfray et al. 2018). For example, in the US 4% of food sold (by weight) is beef, which accounts for 36% of food-related emissions (Heller and Keoleian 2015). Food-related emissions are therefore very sensitive to the amount and type of meat consumed. However, 100 g of beef has twice as much protein as the equivalent in cooked weight of beans, for example, and 2.5 times more iron. One can ingest only about 2.5 kg of food per day and not all food items are as dense in nutrition.

There is therefore *robust evidence with high agreement* that the mixture of foods eaten can have a highly significant impact on per capita carbon emissions, driven particularly through the amount of (especially grain-fed) livestock and products.

Given the rising costs of malnutrition in all its forms, a legitimate question is often asked: would a diet that promotes health through good nutrition also be one that mitigates GHG emissions? Whilst sustainable diets need not necessarily provide more nutrition, there is certainly significant overlap between those that are healthier (e.g., via eating more plant-based material and less livestock-based material), and eating the appropriate level of calories. In their systematic review, Nelson et al. (2016) conclude that, in general, a dietary pattern that is higher in plant-based foods, such as vegetables, fruits, whole grains, legumes, nuts, and seeds, and lower in animal-based foods is more health-promoting and is associated with lesser environmental impact (GHG emissions and energy, land, and water use) than is the current average “meat-based” diet.

Recent FAO projections of food and agriculture to 2050 under alternative scenarios characterised by different degrees of sustainability, provide global-scale evidence that rebalancing diets is key to increasing the overall sustainability of food and agricultural systems world-wide. A 15% reduction of animal products in the diets of high-income countries by 2050 would contribute to containing the need to expand agricultural output due to upward global demographic trends. Not only would GHG emissions and the pressure on land and water be significantly reduced but the potential for low-income countries to increase the intake of animal-based food, with beneficial nutritional outcomes, could be enhanced (FAO 2018a). Given that higher-income countries typically have higher emissions per capita, results are particularly applicable in such places.

However, Springmann et al. (2018a) found that there are locally applicable upper bounds to the footprint of diets around the world, and for lower-income countries undergoing a nutrition transition, adopting “Westernised” consumption patterns (over consumption, large amounts of livestock produce, sugar and fat), even if in culturally applicable local contexts, would increase emissions. The global mitigation potential of healthy but low-emissions diets is discussed in detail in Section **Error! eference source not found.**.

In summary, food system emissions are growing globally due to increasing population, income, and demand for animal-sourced products (*high confidence*). Diets are changing on average toward greater consumption of animal-based foods, vegetable oils and sugar/sweeteners (*high confidence*) (see also Chapter 2), with GHG emissions increasing due to greater amounts of animal-based products in diets (*robust evidence, medium agreement*).

5.5 Mitigation options, challenges, and opportunities

The IPCC AR5 WG III concluded that mitigation in agriculture, forestry, and land use (AFOLU) is key to limit climate change in the 21st century, in terms of mitigation of non-CO_2 GHGs, which are predominately emitted in AFOLU, as well as in terms of land-based carbon sequestration. Wollenberg et al. (2016) highlighted the need to include agricultural emissions explicitly in national mitigation targets and plans, as a necessary strategy to meet the 2°C goal of the Paris Agreement. This chapter expands on these key findings to document how mitigation in the entire food system, from farm ate to consumer, can contribute to reaching the stated global mitigation goals, but in a context of improved food security and nutrition. To put the range of mitigation potential of food systems in context, it is worth noting that emissions from crop and livestock are expected to increase by 30-40% from present to 2050, under business-as-usual scenarios that include efficiency improvements as well as dietary changes linked to increased income per capita (FAO 2018a; Tubiello et al. 2014). Using current emissions estimates in this chapter and Chapter 2, these increases translate into projected GHG emissions from agriculture of 8-9 Gt CO_2eq yr^{-1} by 2050 (*medium confidence*).

The AR5 ranked mitigation measures from simple mechanisms such as improved crop and livestock management (Smith et al. 2014) to more complex carbon dioxide reduction interventions, such as afforestation, soil carbon storage and biomass energy projects with carbon capture and storage (BECCS). The AR5 WGIII AFOLU chapter (Smith et al. 2014) identified two primary categories of mitigation pathways from the food system:

Supply side: Emissions from agricultural soils, land use change, land management, and crop and livestock practices can be reduced and terrestrial carbon stocks can be increased by increased production efficiencies and carbon sequestration in soils and biomass, while emissions from energy use at all stages of the food system can be reduced through improvements in energy efficiency and fossil fuel substitution with carbon-free sources including biomass.

Demand side: GHG emissions could be mitigated by changes in diet, reduction in food loss and waste, and changes in wood consumption for cooking.

In this chapter, supply-side mitigation practices include land use change and carbon sequestration in soils and biomass in both crop and livestock systems. Cropping systems practices include improved land and fertiliser management, land restoration, biochar applications, breeding for larger root systems, and bridging yield gaps (Dooley and Stabinsky 2018). Options for mitigation in livestock systems include better manure management, improved grazing land management, and better feeding practices for animals. Agroforestry also is a supply-side mitigation practice. Improving efficiency in supply chains is a supply-side mitigation measure.

Demand-side mitigation practices include dietary changes that lead to reduction of GHG emissions from production and changes in land use that sequester carbon. Reduction of food loss and waste can contribute to mitigation of GHGs on both the supply and demand sides. See Section 5.7 and Chapter 7 for the enabling conditions needed to ensure that these food system measures would deliver their potential mitigation outcomes.

5.5.1 Supply-side mitigation options

The IPCC AR5 identified options for GHG mitigation in agriculture including cropland management, restoration of organic soils, grazing land management and livestock, with a total mitigation potential of 1.5–4.0 $GtCO_2$-eq yr^{-1} by 2030 (compared to baseline emissions in the same year), at carbon prices from 20 to 100 USD/tCO_2-eq (Smith et al. 2014). Reductions in GHG emissions intensity (emissions per unit product) from livestock and animal products can also be a means to achieve reductions in absolute emissions in specific contexts and with appropriate governance (*medium confidence*). Agroforestry mitigation practices include rotational woodlots, long-term fallow, and integrated land use.

Emissions from food systems can be reduced significantly by the implementation of practices that reduce carbon dioxide, methane, and nitrous oxide emissions from agricultural activities related to the production of crops, livestock, and aquaculture. These include implementation of more sustainable and efficient crop and livestock production practices aimed at reducing the amount of land needed per output (reductions in GHG emissions intensity from livestock and animal production can support reductions in absolute emissions if total production is constrained), bridging yield gaps, implementing better feeding practices for animals and fish in aquaculture, and better manure management (FAO 2019a). Practices that promote soil improvements and carbon sequestration can also play an important role. In the South America region, reduction of deforestation, restoration of degraded pasture areas, and adoption of agroforestry and no-till agricultural techniques play a major role in the nation's voluntary commitments to reduce GHG emissions in the country's mitigation activities (Box 5.4).

The importance of supply-side mitigation options is that these can be directly applied by food system actors (farmers, processors, retailers, etc.) and can contribute to improved livelihoods and income generation. Recognising and empowering farming system actors with the right incentives and governance systems will be crucial to increasing the adoption rates of effective mitigation practices and to build convincing cases for enabling GHG mitigation (Section 5.7 and Chapter 7).

Box 5.4 Towards sustainable intensification in South America region

Reconciling the increasing global food demand with limited land resources and low environmental impact is a major global challenge (FAO 2018a; Godfray and Garnett 2014; Yao et al. 2017). South America has been a significant contributor of the world's agricultural production growth in the last three decades (OECD and FAO 2015), driven partly by increased export opportunities for specific commodities, mainly soybeans and meat (poultry, beef and pork).

Agricultural expansion, however, has driven profound landscape transformations in the region, particularly between the 1970s and early 2000s, contributing to increased deforestation rates and associated GHG emissions. High rates of native vegetation conversion were found in Argentina, Bolivia, Brazil, Colombia, Ecuador, Paraguay and Peru (FAO 2016b; Graesser et al. 2015), threatening ecologically important biomes, such as the Amazon, the savannas (Cerrado, Chacos and Lannos), the Atlantic Rainforest, the Caatinga, and the Yungas. The Amazon biome is a particularly sensitive biome as it provides crucial ecosystem services including biodiversity, hydrological processes (through evapotranspiration, cloud formation, and precipitation), and biogeochemical cycles (including carbon) (Bogaerts et al. 2017; Fearnside 2015; Beuchle et al. 2015; Grecchi et al. 2014; Celentano et al. 2017; Soares-Filho et al. 2014; Nogueira et al. 2018). Further, deforestation associated with commodity exports has not led to inclusive socioeconomic development, but rather has exacerbated social inequality and created more challenging living conditions for lower-income people (Celentano et al. 2017); nor has it avoided increased hunger of local populations in the last few years (FAO 2018b).

In the mid-2000s, governments, food industries, NGOs, and international programs joined forces to put in place important initiatives to respond to the growing concerns about the environmental impacts of agricultural expansion in the region (Negra et al. 2014; Finer et al. 2018). Brazil led regional action by launching the Interministerial Plan of Action for Prevention and Control of Deforestation of the Legal Amazon[2] (PPCDAm), associated with development of a real-time deforestation warning system. Further, Brazil built capacity to respond to alerts by coordinated efforts of ministries, the federal police, the army and public prosecution (Negra et al. 2014; Finer et al. 2018).

Other countries in the region have also launched similar strategies, including a zero-deforestation plan in Paraguay in 2004 (Gasparri and de Waroux 2015), and no-deforestation zones in Argentina in 2007 (Garcia Collazo et al. 2013). Peru also developed the National System of Monitoring and Control, led by the National Forest Service and Wildlife Authority (SERFOR), to provide information and coordinate response to deforestation events, and Colombia started producing quarterly warning reports on active fronts of deforestation in the country (Finer et al. 2018).

Engagement of the food industry and NGOs, particularly through the Soy Moratorium (from 2006) and Beef Moratorium (from 2009) also contributed effectively to keep deforestation at low historical rates in the regions where they were implemented (Nepstad et al. 2014; Gibbs et al. 2015). In 2012, Brazil also created the national land registry system (SICAR), a georeferenced database, which allows monitoring of farms' environmental liability in order to grant access to rural credit. Besides the

[2] FOOTNOTE: The Legal Amazon is a Brazilian region of 501.6 Mha (ca. 59% of the Brazilian territory) that contains all the Amazon but also 40% of the Cerrado and 40% of the Pantanal biomes, with a total population of 25.47 million inhabitants.

governmental schemes, funding agencies and the Amazon Fund provide financial resources to assist smallholder farmers to comply with environmental regulations (Jung et al. 2017).

Nevertheless, Azevedo et al. (2017) argue that the full potential of these financial incentives has not been achieved, due to weak enforcement mechanisms and limited supporting public policies. Agricultural expansion and intensification have complex interactions with deforestation. While mechanisms have been implemented in the region to protect native forests and ecosystems, control of deforestation rates require stronger governance of natural resources (Ceddia et al. 2013; Oliveira and Hecht 2016), including monitoring programs to evaluate fully the results of land use policies in the region.

Public and private sector actions resulted in a reduction of the Brazilian legal Amazon deforestation rate from 2.78 Mha yr^{-1} in 2004, to about 0.75 Mha yr^{-1} (ca. 0.15%) in 2009 (INPE 2015), oscillating from 0.46 Mha and 0.79 Mha (2016) since then (INPE 2018; Boucher and Chi 2018). The governmental forest protection scheme was also expanded to other biomes. As a result, the Brazilian Cerrado deforestation was effectively reduced from 2.9 Mha yr^{-1} in 2004 to an average of 0.71 Mha yr^{-1} in 2016-2017 (INPE 2018).

Overall, deforestation rates in South America have declined significantly, with current deforestation rates being about half of rates in the early 2000s (FAOSTAT 2018). However, inconsistent conservation policies across countries (Gibbs et al. 2015) and recent hiccups (Curtis et al. 2018) indicate that deforestation control still requires stronger reinforcement mechanisms (Tollefson 2018). Further, there are important spill-over effects that need coordinated international governance. Curtis et al. (2018) and Dou et al. (2018) point out that, although the Amazon deforestation rate decreased in Brazil, it has increased in other regions, particularly in Southern Asia, and in other countries in South America, resulting in nearly constant deforestation rates worldwide.

Despite the reduced expansion rates into forest land, agricultural production continues to rise steadily in South America, relying on increasing productivity and substitution of extensive pastureland by crops. The average soybean and maize productivity in the region increased from 1.8 and 2.0 t ha^{-1} in 1990 to 3.0 and 5.0 t ha^{-1}, respectively, in 2015 (FAOSTAT 2018). Yet, higher crop productivity was not enough to meet growing demand for cereals and oilseeds and cultivation continued to expand, mainly on grasslands (Richards 2015). The reconciliation of this expansion with higher demand for meat and dairy products was carried out through the intensification of livestock systems (Martha et al. 2012). Nevertheless, direct and indirect deforestation still occurs, and recently deforestation rates have increased (INPE 2018), albeit they remain far smaller than observed in the 2000-2010 period.

The effort towards sustainable intensification has also been incorporated in agricultural policies. In Brazil, for instance, the reduction of deforestation, the restoration of degraded pasture areas, the adoption of integrated agroforestry systems[3] and no-till agricultural techniques play a major role in the nation's voluntary commitments to reduce GHG emissions in the country's NAMAs (Mozzer 2011) and NDCs (Silva Oliveira et al. 2017; Rochedo et al. 2018). Such commitment under the UNFCCC is operationalised through the Low Carbon Agriculture Plan (ABC)[4], which is based on low interest credit for investment in sustainable agricultural technologies (Mozzer 2011). Direct pasture restoration and integrated systems reduce area requirements (Strassburg et al. 2014), and increase organic matter (Gil et al. 2015; Bungenstab 2012; Maia et al. 2009), contributing to overall life cycle

[3] FOOTNOTE: Integrated agroforestry systems are agricultural systems that strategically integrate two or more components among crops, livestock and forestry. The activities can be in consortium, succession or rotation in order to achieve overall synergy.

[4] FOOTNOTE: ABC - *Agricultura de Baixo Carbono* in Portuguese.

emissions reduction (Cardoso et al. 2016; de Oliveira Silva et al. 2016). Also, increased adoption of supplementation and feedlots, often based on agro-industrial co-products and agricultural crop residues are central to improve productivity and increase climate resilience of livestock systems (Mottet et al. 2017a; van Zanten et al. 2018).

Despite providing clear environmental and socio-economic co-benefits, including improved resource productivity, socio-environmental sustainability and higher economic competitiveness, implementation of the Brazilian Low Carbon Agriculture Plan is behind schedule (Köberle et al. 2016). Structural inefficiencies related to the allocation and distribution of resources need to be addressed to put the plan on track to meet its emissions reduction targets. Monitoring and verification are fundamental tools to guarantee the successful implementation of the plan.

Overall, historical data and projections show that South America is one of the regions of the world with the highest potential to increase crop and livestock production in the coming decades in a sustainable manner (Cohn et al. 2014), increasing food supply to more densely populated regions in Asia, Middle East and Europe. However, a great and coordinated effort is required from governments, industry, traders, scientists and the international community to improve planning, monitoring and innovation to guarantee sustainable intensification of its agricultural systems, contribution to GHG mitigation, and conservation of the surrounding environment (Negra et al. 2014; Curtis et al. 2018; Lambin et al. 2018).

5.5.1.1 Greenhouse gas mitigation in croplands and soils

The mitigation potential of agricultural soils, cropland and grazing land management has been the subject of much research and was thoroughly summarised in the AR5 (Smith et al. 2014) (See also Chapter 2 Section 2.5.1 and Chapter 6 Section 6.3.1). Key mitigation pathways are related to practices reducing nitrous oxide emissions from fertiliser applications, reducing methane emissions from paddy rice, reducing both gases through livestock manure management and applications, and sequestering carbon or reducing its losses, with practices for improving grassland and cropland management identified as the largest mitigation opportunities. Better monitoring reporting and verification (MRV) systems are currently needed for reducing uncertainties and better quantifying the actual mitigation outcomes of these activities.

New work since AR5 has focused on identifying pathways for the reductions of GHG emissions from agriculture to help meet Paris Agreement goals (Paustian et al. 2016; Wollenberg et al. 2016). Altieri and Nicholls (2017) have characterised mitigation potentials from traditional agriculture. Zomer et al. (2017) have updated previous estimates of global carbon sequestration potential in cropland soils. Mayer et al. (2018) converted soil carbon sequestration potential through agricultural land management into avoided temperature reductions. Fujisaki et al. (2018) identify drivers to increase soil organic carbon in tropical soils. For discussion of integrated practices such as sustainable intensification, conservation agriculture and agroecology, see Section 5.6.4.

Paustian et al. (2016) developed a decision-tree for facilitating implementation of mitigation practices on cropland and described the features of key practices. They observed that most individual mitigation practices will have a small effect per unit of land, and hence they need to be combined and applied at large scales for their impact to be significant. Examples included aggregation of cropland practices (e.g., organic amendments, improved crop rotations and nutrient management and reduced tillage) and grazing land practices (e.g., grazing management, nutrient and fire management and species introduction) that could increase net soil C stocks while reducing emissions of N_2O and CH_4. However, it is well-known that the portion of projected mitigation from soil C stock increase (about 90% of the total technical potential) is impermanent, i.e., it would be effective for only 20–30 years due to saturation of the soil capacity to sequester carbon, whereas non-CO_2 emission reductions could continue indefinitely. “Technical potential” is the maximum amount of GHG mitigation achievable through technology diffusion.

Biochar application and management towards enhanced root systems are mitigation options that have been highlighted in recent literature (Dooley and Stabinsky 2018; Hawken 2017; Paustian et al. 2016; Woolf et al. 2010; Lenton 2010).

5.5.1.2 Greenhouse gas mitigation in livestock systems

The technical options for mitigating GHG emissions in the livestock sector have been the subject of recent reviews (Mottet et al., 2017b; Hristov et al. 2013a,b; Smithers 2015; Herrero et al. 2016a; Rivera-Ferre et al. 2016b) (Figure 5.11). They can be classified as either targeting reductions in enteric methane; reductions in nitrous oxide through manure management; sequestering carbon in pastures; implementation of best animal husbandry and management practices, which would have an effect on most GHG; and land use practices that also help sequester carbon. Excluding land use practices, these options have a technical mitigation potential ranging 0.2-2.4 $GtCO_2$-eq yr^{-1} (Herrero et al. 2016a; FAO 2007). See also Chapters 2 and 6 in this report.

The opportunities for carbon sequestration in grasslands and rangelands may be significant (Conant 2010), for instance, through changes in grazing intensity or manure recycling aimed at maintaining grassland productivity (Hirata et al. 2013). Recent studies have questioned the economic potential of such practices, i.e., whether they could implement at scale for economic gain (Garnett et al. 2017; Herrero et al. 2016a; Henderson et al. 2015). For instance, Henderson et al. (2015) found economic potentials below 200 $MtCO_2$-eq yr^{-1}. Carbon sequestration can occur in situations where grasslands are highly degraded (Garnett 2016). Carbon sequestration linked to livestock management could thus be considered as a co-benefit of well-managed grasslands, as well as a mitigation practice.

Different production systems will require different strategies, including the assessment of impacts on food security, and this has been the subject of significant research (e.g., Rivera-Ferre et al. 2016b). Livestock systems are heterogeneous in terms of their agro-ecological orientation (arid, humid or temperate/highland locations), livestock species (cattle, sheep, goats, pigs, poultry and others), structure (grazing only, mixed-crop-livestock systems, industrial systems, feedlots and others), level of intensification, and resource endowment (Robinson 2011).

The implementation of strategies presented in **Error! Reference source not found.** builds on this ifferentiation, providing more depth compared to the previous AR5 analysis. Manure management strategies are more applicable in confined systems, where manure can be easily collected, such as in pigs and poultry systems or in smallholder mixed crop–livestock systems. More intensive systems, with strong market orientation, such as dairy in the US, can implement a range of sophisticated practices like feed additives and vaccines, while many market-oriented dairy systems in tropical regions can improve feed digestibility by improving forage quality and adding larger quantities of concentrate to the rations. Many of these strategies can be implemented as packages in different systems, thus maximising the synergies between different options (Mottet et al. 2017b).

See the Supplementary Material Section SM5.5 for detailed description of livestock mitigation strategies; synergies and trade-offs with other mitigation and adaptation options are discussed in Section 5.6.

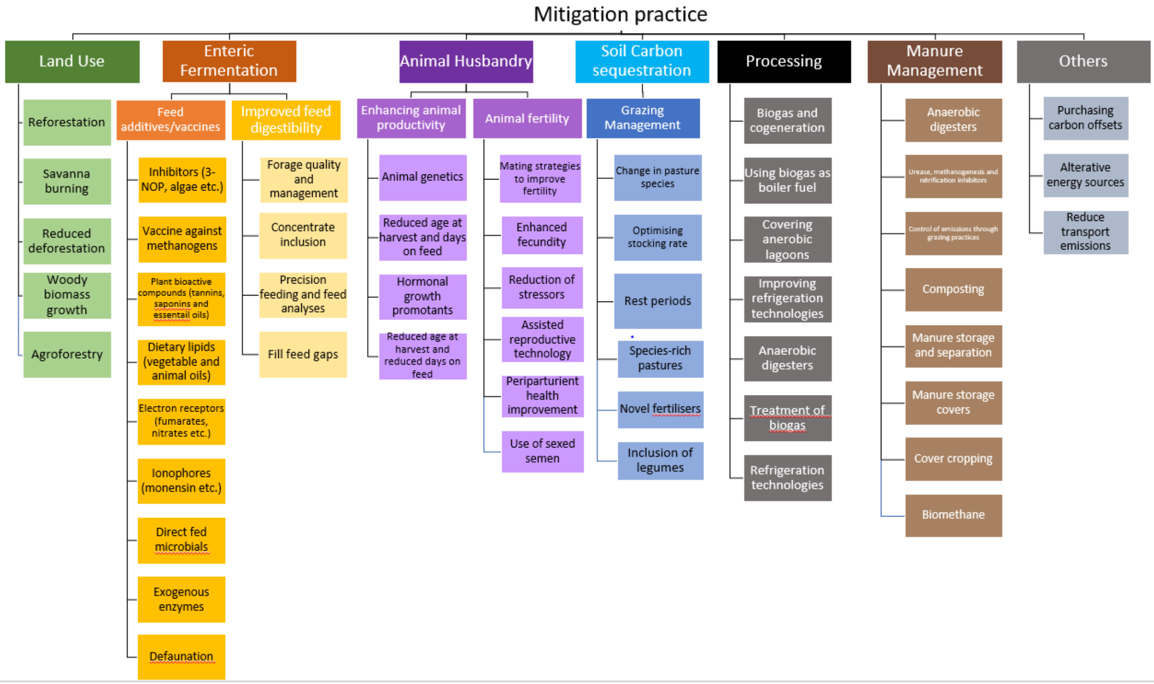

Figure 5.10 Technical supply-side mitigation practices in the livestock sector (adapted from Hristov et al. 2013b; Herrero et al. 2016b; Smith et al. 2014)

5.5.1.3 Greenhouse gas mitigation in agroforestry

Agroforestry can curb GHG emissions of CO_2, CH_4, and N_2O in agricultural systems in both developed and developing countries (See Glossary for definition) (see Chapter 2, Section 2.5.1 and Figure 2.24). Soil carbon sequestration, together with biological N fixation, improved land health and underlying ecosystem services may be enhanced through agricultural lands management practices used by large-scale and smallholder farmers, such as incorporation of trees within farms or in hedges (manure addition, green manures, cover crops, etc.), whilst promoting greater soil organic matter and nutrients (and thus soil organic carbon) content and improve soil structure (Mbow et al. 2014b) (Table 5.5). The tree cover increases the microbial activity of the soil and increases the productivity of the grass under cover. CO_2 emissions are furthermore lessened indirectly, through lower rates of erosion due to better soil structure and more plant cover in diversified farming systems than in monocultures. There is great potential for increasing above ground and soil C stocks, reducing soil erosion and degradation, and mitigating GHG emissions.

These practices can improve food security through increases in productivity and stability since they contribute to increased soil quality and water-holding capacity. Agroforestry provides economic, ecological, and social stability through diversification of species and products. On the other hand, trade-offs are possible when cropland is taken out of production mainly as a mitigation strategy.

Table 5.5 Carbon sequestration potential for agroforestry (Mbow et al. 2014b)

Source	**Carbon sequestration (tCO_2 km^{-2} yr^{-1}) (range)**	**C stock (tCO_2 km^{-2}) (range)**	**Max rotation period (years)**
Dominant parklands	183 (73–293)	12,257 (2,091–25,983)	50
Rotational woodlots[a]	1,431 (807–2,128)	6,789 (4,257–9,358)	5

Tree planting-windrows-home gardens	220.2 (146–293)	6,973 (-)	25
Long term fallows, regrowth of woodlands in abandoned farms[b]	822 (80–2,128)	5,761 (-)	25
Integrated land use	1,145 (367–2,458)	28,589 (4,404–83,676)	50
Soil carbon	330 (91–587)	33,286 (4,771–110,100)	-

[a] May be classified as forestry on forest land, depending on the spatial and temporal characteristics of these activities.
[b] This is potentially not agro-forestry, but forestry following abandonment of agricultural land.

Meta-analyses have been done on carbon budgets in agroforestry systems (Zomer et al. 2016; Chatterjee et al. 2018). In a review of 42 studies, (Ramachandran Nair et al. 2009) estimated C sequestration potentials of differing agroforestry systems. These include sequestration rates in ranging from 954 (semi-arid); to 1,431 (temperate); 2,238 (sub-humid) and 3,670 tCO_2 km^{-2} yr^{-1} (humid). The global technical potential for agroforestry is 0.1–5.7 Gt CO2e yr-1 (Griscom et al. 2017; Zomer et al. 2016; Dickie et al. 2014) (see Chapter 2, Section 2.5.1). Agroforestry-based carbon sequestration can be used to offset N_2O and CO_2 emissions from soils and increase methane sink strength compared to annual cropping systems (Rosenstock et al. 2014).

Agroforestry systems with perennial crops, such as coffee and cacao, may be more important carbon sinks than those that combine trees with annual crops. Brandt et al. (2018) showed that farms in semi-arid region (300–600 mm precipitation) were increasing in tree cover due to natural regeneration and that the increased application of agroforestry systems were supporting production and reducing GHG emissions.

5.5.1.4 Integrated approaches to crop and livestock mitigation

Livestock mitigation in a circular economy. Novel technologies for increasing the integration of components in the food system are being devised to reduce GHG emissions. These include strategies that help decoupling livestock from land use. Work by van Zanten et al. (2018) shows that 7–23 g of animal protein per capita per day could be produced without livestock competing for vital arable land. This would imply a contraction of in the land area utilised by the livestock sector, but also a more efficient use of resources, and would lead to land sparing and overall emissions reductions.

Pikaar et al. (2018) demonstrated the technical feasibility of producing microbial protein as a feedstuff from sewage that could replace use of feed crops such as soybean. The technical potential of this novel practice could replace 10–19% of the feed protein required, and would reduce cropland demand and associated emissions by 6-7%. These practices are, however, not economically feasible nor easily upscalable in most systems. Nonetheless, significant progress in Japan and South Korea in the reduction and use of food waste to increase efficiencies in livestock food chains has been achieved, indicating a possible pathway to progress elsewhere (FAO 2017; zu Ermgassen et al. 2016). Better understanding of biomass and food and feed wastes, value chains, and identification of mechanisms for reducing the transport and processing costs of these materials is required to facilitate larger-scale implementation.

Waste streams into energy. Waste streams from manure and food waste can be used for energy generation and thus reduction in overall GHG emissions in terms of recovered methane (for instance through anaerobic digestion) production (De Clercq et al. 2016) or for the production of microbial protein (Pikaar et al. 2018). Second-generation biorefineries, once the underlying technology is improved, may enable the generation of hydro-carbon from agricultural residues, grass, and woody biomass in ways that do not compete with food and can generate, along with biofuel, high-value products such as plastics (Nguyen et al. 2017). Second-generation energy biomass from residues may constitute a complementary income source for farmers that can increase their incentive to produce. Technologies include CHP (combined heat and power) or gas turbines, and fuel types such as bio-diesel, bio-pyrolysis (i.e., high temperature chemical transformation of organic material in the absence of oxygen), torrefaction of biomass, production of cellulosic bio-ethanol and of bio-alcohols produced by other means than fermentation, and the production of methane by anaerobic fermentation. (Nguyen et al. 2017).

Technology for reducing fossil fuel inputs. Besides biomass and bioenergy, other forms of renewable energy substitution for fossil fuels (e.g., wind, solar, geothermal, hydro) are already being applied on farms and throughout the supply chain. Energy efficiency measures are being developed for refrigeration, conservation tillage, precision farming (e.g., fertiliser and chemical application and precision irrigation.

Novel technologies. Measures that can reduce livestock emissions given continued research and development include methane and nitrification inhibitors, methane vaccines, targeted breeding of lower-emitting animals, and genetically modified grasses with higher sugar content. New strategies to reduce methanogenesis include supplementing animal diets with antimethanogenic agents (e.g., 3-NOP, algae, chemical inhibitors such as chloroform) or supplementing with electron acceptors (e.g., nitrate) or dietary lipids. These could potentially contribute, once economically feasible at scale, to significant reductions of methane emissions from ruminant livestock. A well-tested compound is 3-nitrooxypropanol (3-NOP), which was shown to decrease methane by up to 40% when incorporated in diets for ruminants (Hristov et al. 2015).

Whilst these strategies may become very effective at reducing methane, they can be expensive and also impact on animal performance and/or welfare (Llonch et al. 2017). The use of novel fertilisers and/or plant species that secrete biological nitrification inhibitors also have the potential to significantly reduce N_2O emissions from agricultural soils (Subbarao et al. 2009; Rose et al. 2018).

Economic mitigation potentials of crop and livestock sectors. Despite the large technical mitigation potential of the agriculture sector in terms of crop and livestock activities, its economic potential is relatively small in the short term (2030) and at modest carbon prices (less than USD 20 tC^{-1}). For crop and soil management practices, it is estimated that 1.0–1.5 $GtCO_2$-eq yr^{-1} could be a feasible mitigation target at a carbon price of USD 20/tonne of carbon (Frank et al. 2018, 2017; Griscom et al. 2016; Smith et al. 2013; Wollenberg et al. 2016). For the livestock sector, these estimates range from 0.12–0.25 $GtCO_2$-eq yr^{-1} at similar carbon prices (Herrero et al. 2016c; Henderson et al. 2017). But care in needed in comparing crop and livestock economic mitigation potentials due to differing assumptions.

Frank et al. (2018) recently estimated that the economic mitigation potential of non-CO_2 emissions from agriculture and livestock to 2030 could be up to four times higher than indicated in the AR5, if structural options such as switching livestock species from ruminants to monogastrics, or allowing for flexibility to relocate production to more efficient regions were implemented, at the same time as the technical options such as those described above. At higher carbon prices (i.e., at about USD 100tC^{-1}), they found a mitigation potential of supply-side measures of 2.6 $GtCO_2$-eq yr^{-1}.

In this scenario, technical options would account for 38% of the abatement, while another 38% would be obtained through structural changes, and a further 24% would be obtained through shifts in consumption caused by food price increases. Key to the achievement of this mitigation potential lay in the livestock sector, as reductions in livestock consumption, structural changes and implementation of technologies in the sector had some of the highest impacts. Regions with the highest mitigation potentials were Latin America, China and Sub-Saharan Africa. The large-scale implementability of such proposed sweeping changes in livestock types and production systems is likely very limited as well as constrained by long-established socio-economic, traditional and cultural habits, requiring significant incentives to generate change.

In summary, supply-side practices can contribute to climate change mitigation by reducing crop and livestock emissions, sequestering carbon in soils and biomass, and by decreasing emissions intensity within sustainable production systems *(high confidence)*. The AR5 estimated the total economic mitigation potential of crop and livestock activities as 1.5–4.0 $GtCO_2$-eq yr^{-1} by 2030 at prices ranging from 20-100 USD/tCO_2eq *(high confidence)*. Options with large potential for GHG mitigation in cropping systems include soil carbon sequestration (at decreasing rates over time), reductions in N_2O emissions from fertilisers, reductions in CH_4 emissions from paddy rice, and bridging of yield gaps. Options with large potential for mitigation in livestock systems include better grazing land management, with increased net primary production and soil carbon stocks, improved manure management, and higher-quality feed. Reductions in GHG emissions intensity (emissions per unit product) from livestock can support reductions in absolute emissions, provided appropriate governance structures to limit total production isare implemented at the same time *(medium confidence)*.

5.5.1.5 Greenhouse gas mitigation in aquaculture

Barange et al. (2018) provide a synthesis of effective options for GHG emissions reduction in aquaculture including reduction of emissions from production of feed material, replacement of fish-based feed ingredients with crop-based ingredients; reduction of emissions from feed mill energy use, improvement of feed conversion rates, improvement of input use efficiency, shift of energy supply (from high-carbon fossil fuels to low-carbon fossil fuels or renewables), and improvement of fish health. Conversion of 25% of total aquaculture area to integrated aquaculture-agriculture ponds (greening aquaculture) has the potential to sequester 95.4 millions tonnes carbon per year (Ahmed et al. 2017).

Proposed mitigation in aquaculture includes avoided deforestation. By halting annual mangrove deforestation in Indonesia, associated total emissions would be reduced 10-31% of estimated annual emissions from land use sector at present (Murdiyarso et al. 2015). Globally, 25% mangrove regeneration could sequester 0.54–0.65 millions tonnes carbon per year (Ahmed et al. 2017) of which 0.17-0.21 could be through integrated or organic shrimp culture (Ahmed et al. 2018).

5.5.1.6 Cellular agriculture

The technology for growing muscle tissue in culture from animal stem cells to produce meat, i.e., “cultured” or “synthetic” or “in vitro” or “hydroponic” meat could in theory be constructed with different characteristics and be produced faster and more efficiently than traditional meat (Kadim et al. 2015). Cultured meat (CM) is part of so-called cellular agriculture, which includes production of milk, egg white and leather from industrial cell cultivation (Stephens et al. 2018). CM is produced from muscle cells extracted from living animals, isolation of adult skeletal muscle stem cells (myosatellite cells), placement in a culture medium which allow their differentiation into myoblasts and then, through another medium, generation of myocytes which coalesce into myotubes and grow into strands in a stirred-tank bioreactor (Mattick et al. 2015). Current technology enables the creation of beef hamburgers, nuggets, steak chips or similar products from meat of other animals, including wild species, although production currently is far from being economically feasible. Nonetheless, by allowing bioengineering from the manipulation of the stem cells and nutritive culture, CM allows for reduction of harmful fatty acids, with advantages such as reduced GHG emissions, mostly indirectly through reduced land use (Bhat et al. 2015; Kumar et al. 2017b).

Tuomisto and de Mattos (2011) made optimistic technological assumptions, relying on cyanobacteria hydrolysate nutrient source, and produced the lowest estimates on energy and land use. Tuomisto and de Mattos (2011) conducted a lifecycle assessment that indicates that cultured meat could have less than 60% of energy use and 1% of land use of beef production and it would have lower GHG emissions than pork and poultry as well. Newer estimates (Alexander et al. 2017; Mattick et al. 2015) indicate a trade-off between industrial energy consumption and agricultural land requirements of conventional and cultured meat and possibly higher GWP than pork or poultry due to higher energy use. The change in proportion of CO_2 vs CH_4 could have important implications in climate change projections and, depending on decarbonisation of the energy sources and climate change targets, cultured meat may be even more detrimental than exclusive beef production (Lynch 2019).

Overall, as argued by Stephens et al. (2018), cultured meat is an "as-yet undefined ontological object" and, although marketing targets people who appreciate meat but are concerned with animal welfare and environmental impacts, its market is largely unknown (Bhat et al. 2015; Slade 2018). In this context it will face the competition of imitation meat (meat analogues from vegetal protein) and insect-derived products, which have been evaluated as more environmentally friendly (Alexander et al. 2017) and it may be considered as being an option for a limited resource world, rather than a mainstream solution. Besides, as commercial production process is still largely undefined, its actual contribution to climate change mitigation and food security is largely uncertain and challenges are not negligible. Finally, it is important to understand the systemic nature of these challenges and evaluate their social impacts on rural populations due to transforming animal agriculture into an industrialised activity and its possible rebound effects on food security, which are still understudied in the literature.

Studies are needed to improve quantification of mitigation options for supply chain activities.

5.5.2 Demand-side mitigation options

Although population growth is one of the drivers of global food demand and the resulting environmental burden, demand-side management of the food system could be one of the solutions to curb climate change. Avoiding food waste during consumption, reducing over-consumption, and changing dietary preferences can contribute significantly to provide healthy diets for all, as well as reduce the environmental footprint of the food system. The number of studies addressing this issue have increased in the last few years (see also Chapter 2). (See Section 5.6 for synergies and trade-offs with health and Section 5.7 for discussion of Just Transitions).

5.5.2.1 Mitigation potential of different diets

A systematic review found that higher consumption of animal-based foods was associated with higher estimated environmental impact, whereas increased consumption of plant-based foods was associated with an estimated lower environmental impact (Nelson et al. 2016). Assessment of individual foods within these broader categories showed that meat – especially ruminant meat (beef and lamb) – was consistently identified as the single food with the greatest impact on the environment, on a global basis, most often in terms of GHG emissions and/or land use.

Figure 5.12 shows the technical mitigation potentials of some scenarios of alternative diets examined in the literature. Stehfest et al. (2009) were among the first to examine these questions. They found that under the most extreme scenario, where no animal products are consumed at all, adequate food production in 2050 could be achieved on less land than is currently used, allowing considerable forest regeneration, and reducing land-based greenhouse gas emissions to one third of the reference "business-as-usual" case for 2050, a reduction of 7.8 Gt CO_2-eq yr^{-1}. Springmann et al. (2016b) recently estimated similar emissions reduction potential of 8 Gt CO_2-eq yr^{-1} from a vegan diet without animal-sourced foods. This defines the upper bound of the technical mitigation potential of demand side measures.

Herrero et al. (2016a) reviewed available options, with a specific focus on livestock products, assessing technical mitigation potential across a range of scenarios, including "No animal products", "No meat", "No ruminant meat", and "Healthy diet" (reduced meat consumption). With regard to 'credible low-meat diets,' where reduction in animal protein intake was compensated by higher intake of pulses, emissions reductions by 2050 could be in the 4.3–6.4 Gt CO_2-eq yr^{-1}, compared to a business-as-usual scenario. Of this technical potential, 1–2 $GtCO_2$-eq yr^{-1} come from reductions of mostly non-CO_2 GHG within the farm gate, while the remainder was linked to carbon sequestration on agricultural lands no longer needed for livestock production. When the transition to a low-meat diet reduces the agricultural area required, land is abandoned and the re-growing vegetation can take up carbon until a new equilibrium is reached. This is known as the land-sparing effect.

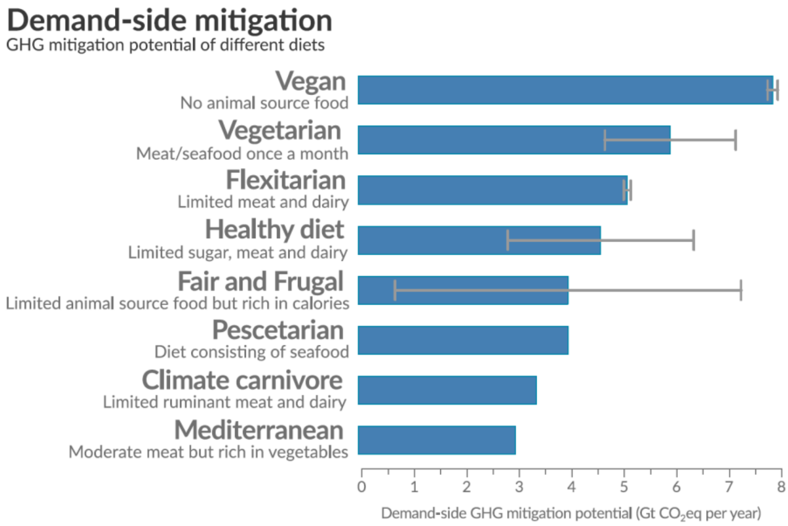

Figure 5.12 Technical mitigation potential of changing diets by 2050 according to a range of scenarios examined in the literature. Estimates are technical potential only, and include additional effects of carbon sequestration from land-sparing. Data without error bars are from one study only.

All diets need to provide a full complement of nutritional quality, including micronutrients (FAO et al. 2018)
Vegan: Completely plant-based (Springmann et al. 2016; Stehfest et al. 2009)
Vegetarian: Grains, vegetables, fruits, sugars, oils, eggs and dairy, and generally at most one serving per month of meat or seafood (Springmann et al. 2016; Tilman and Clark 2014; Stehfest et al. 2009)
Flexitarian: 75% of meat and dairy replaced by cereals and pulses; at least 500 g per day fruits and vegetables; at least 100 g per day of plant-based protein sources; modest amounts of animal-based proteins and limited amounts of red meat (one portion per week), refined sugar (less than 5% of total energy), vegetable oils high in saturated fat, and starchy foods with relatively high glycaemic index (Springmann et al. 2018; Hedenus et al. 2014)
Healthy diet: Based on global dietary guidelines for consumption of red meat, sugar, fruits and vegetables, and total energy intake (Springmann et al. 2018; Bajželj et al. 2014)
Fair and Frugal: Global daily per-capita calorie intake of 2800 kcal/cap/day (11.7 MJ/cap/day), paired with relatively low level of animal products (Smith et al. 2013)
Pescetarian: Vegetarian diet that includes seafood (Tilman and Clark 2014)
Climate carnivore: 75% of ruminant meat and dairy replaced by other meat (Hedenus et al. 2014)
Mediterranean: Vegetables, fruits, grains, sugars, oils, eggs, dairy, seafood, moderate amounts of poultry, pork, lamb and beef (Tilman and Clark 2014)

Other studies have found similar results for potential mitigation linked to diets. For instance, Smith et al. (2013) analysed a dietary change scenario that assumed a convergence towards a global daily per-capita calorie intake of 2800 kcal cap^{-1} day^{-1} (11.7 MJ cap^{-1} day^{-1}), paired with a relatively low level of animal product supply, estimated technical mitigation potential in the range 0.7–7.3 Gt CO_2-eq yr^{-1} for additional variants including low or high-yielding bioenergy, 4.6 Gt CO_2-eq yr^{-1} if spare land is afforested.

Bajželj et al. (2014) developed different scenarios of farm systems change, waste management, and dietary change on GHG emissions coupled to land use. Their dietary scenarios were based on target kilocalorie consumption levels and reductions in animal product consumption. Their scenarios were "Healthy Diet"; Healthy Diet with 2500 kcal cap^{-1} day^{-1} in 2050; corresponded to technical mitigation potentials in the range 5.8 and 6.4 Gt CO_2-eq yr^{-1}.

Hedenus et al. (2014) explored further dietary variants based on the type of livestock product. "Climate Carnivore", in which 75% of the baseline-consumption of ruminant meat and dairy was replaced by pork and poultry meat, and "Flexitarian", in which 75% of the baseline-consumption of meat and dairy was replaced by pulses and cereal products. Their estimates of technical mitigation potentials by 2050 ranged 3.4- 5.2 Gt CO_2-eq yr^{-1}, the high end achieved under the Flexitarian. Finally, Tilman and Clark (2014) used stylised diets as variants that included "Pescetarian", "Mediterranean", "Vegetarian", compared to a reference diet, and estimated technical mitigation potentials within the farm gate of 1.2-2.3 Gt CO_2-eq yr^{-1}, with additional mitigation from carbon sequestration on spared land ranging 1.8–2.4 Gt CO_2-eq yr^{-1}.

Studies have defined dietary mitigation potential as, for example, 20kg per person per week CO_2-eq for Mediterranean diet, vs 13kg per person per week CO_2-eq for vegan (Castañé and Antón 2017). Rosi et al. (2017) developed seven-day diets in Italy for about 150 people defined as omnivore 4.0 ± 1.0; ovo-lacto-veggie 2.6 ± 0.6; and vegan 2.3 ± 0.5 kg CO_2-eq per capita per day.

Importantly, many more studies that compute the economic and calorie costs of these scenarios are needed. Herrero et al. (2016a) estimated that once considerations of economic and calorie costs of their diet-based solutions were included, the technical range of 4.3-6.4 Gt CO_2-eq yr^{-1} in 2050 was reduced to 1.8-3.4 Gt CO_2-eq yr^{-1} when implementing a GHG tax ranging from 20-100 USD/tCO_2. While caloric costs where low below 20 USD/tCO_2, they ranged from 27-190 kcal cap^{-1} day^{-1} under the higher economic potential, thus indicating possible negative trade-offs with food security.

In summary, demand-side changes in food choices and consumption can help to achieve global GHG mitigation targets *(high confidence)*. Low-carbon diets on average tend to be healthier and have smaller land footprints. By 2050, technical mitigation potential of dietary changes range from 2.7–6.4 GtCO_2-eq yr^{-1} for assessed diets *(high confidence)*. At the same time, the economic potential of such solutions is lower, ranging from 1.8-3.4 Gt CO_2-eq yr^{-1} at prices of 20-100 USD/tCO_2, with caloric costs up to 190 kcal cap^{-1} day^{-1}. The feasibility of how to create economically viable transitions to more sustainable and healthy diets that also respect food security requirements needs to be addressed in future research.

5.5.2.2 Role of dietary preferences

Food preference is an inherently cultural dimension that can ease or hinder transformations to food systems that contribute to climate change mitigation. Consumer choice and dietary preferences are guided by social, cultural, environmental, and traditional factors as well as economic growth. The food consumed by a given group conveys cultural significance about social hierarchy, social systems and human-environment relationships (Herforth and Ahmed 2015).

As suggested by Springmann et al. (2018a), per capita dietary emissions will translate into different realised diets, according to regional contexts including cultural and gendered norms (e.g, among some groups, eating meat is perceived as more masculine (Ruby and Heine 2011). In some cases, women and men have different preferences in terms of food, with women reporting eating healthier food (Imamura et al. 2015; Kiefer et al. 2005; Fagerli and Wandel 1999): these studies found that men tend to eat more meat, while women eat more vegetables, fruits and dairy products (Kanter and Caballero 2012).

Food preferences can change over time, with the nutrition transition from traditional diets to high-meat, high-sugar, high-saturated fat diets being a clear example of significant changes occurring in a short period of time. Meat consumption per capita consistently responds to income with a saturating trend at high income levels (Sans and Combris 2015; Vranken et al. 2014). Some emerging economies have rapidly increased demand for beef, leading to pressure on natural resources (Bowles et al. 2019). In another example, by reducing beef consumption between 2005 and 2014, Americans avoided approximately 271 million metric tonnes of emissions (CO_2eq) (NRDC 2017). See Section **Error! eference source not found.** for quantitative analysis. Attending farmers markets or buying directly from local producers has been shown to change worldviews (Kerton and Sinclair 2010), and food habits towards healthier diets (Pascucci et al. 2011) can be advanced through active learning (Milestad et al. 2010).

Regarding the options to reduce meat intake in developed countries, research shows that there is an apparent sympathy of consumers for meat reduction due to environmental impacts (Dagevos and Voordouw 2013) which has not been exploited. Social factors that influence reducing meat consumption in New Zealand include the need for better education or information dispersal regarding perceived barriers to producing meat-reduced/less meals; ensuring there is sensory or aesthetic appeal; and placing emphasis on human health or nutritional benefits (Tucker 2018).

Different and complementary strategies can be used in parallel for different consumer's profiles to facilitate step-by-step changes in the amounts and the sources of protein consumed. In the Netherlands, a nationwide sample of 1083 consumers were used to study their dietary choices toward smaller portions of meat, smaller portions using meat raised in a more sustainable manner, smaller portions and eating more vegetable protein, and meatless meals with or without meat substitutes. Results showed that strategies to change meat eating frequencies and meat portion sizes appeared to overlap and that these strategies can be applied to address consumers in terms of their own preferences (de Boer et al. 2014).

5.5.2.3 Uncertainties in demand-side mitigation potential

Both reducing ruminant meat consumption and increasing its efficiency are often identified as main options to reduce greenhouse gases emissions (GHGE) and to lessen pressure on land (Westhoek et al. 2014) (See Section 5.6 for synergies and trade-offs with health and Section 5.7 for discussion of Just Transitions). However, analysing ruminant meat production is highly complex because of the extreme heterogeneity of production systems and due to the numerous products and services associated with ruminants (Gerber et al. 2015). See Supplementary Material Section SM5.5 for further discussion of uncertainties in estimates of livestock mitigation technical potential. Further, current market mechanisms are regarded as insufficient to decrease consumption or increase efficiency, and governmental intervention is often suggested to encourage mitigation in both the supply-side and demand-side of the food system (See Section 5.7) (Wirsenius et al. 2011; Henderson et al. 2018).

Minimising GHG emissions through mathematical programming with near-minimal acceptability constraints can be understood as a reference or technical potential for mitigation through diet shifts. In this context (Macdiarmid et al. 2012) found up to 36% reduction in emissions in UK with similar diet costs applying fixed lifecycle analyses (LCA) carbon footprints (i.e., no rebound effects considered). Westhoek et al. (2014) found 25-40 % in emissions by halving meat, dairy and eggs intake in EU, applying standard IPCC fixed emission intensity factors. Uncertainty about the consequences of on-the-ground implementation of policies towards low ruminant meat consumption in the food system and their externalities remain noteworthy.

Often, all emissions are allocated to only to human edible meat and the boundaries are set only within the farm gate (Henderson et al. 2018; Gerber et al. 2013). However, less than 50% of slaughtered cattle weight is human edible meat, and 1-10% of the mass is lost or incinerated, depending on specified risk materials legislation. The remaining mass provide inputs to multiple industries e.g. clothing, furniture, vehicle coating materials, biofuel, gelatine, soap, cosmetics, chemical and pharmaceutical industrial supplies, pet feed ingredients and fertilisers (Marti et al. 2011; Mogensen et al. 2016; Sousa et al. 2017). This makes ruminant meat production one of the most complex problems for LCA in the food system (Place and Mitloehner 2012; de Boer et al. 2011). There are only a few examples taking into account slaughter byproducts e.g., Mogensen et al. (2016).

5.5.2.4 Insect-based diets

Edible insects are, in general, rich in protein, fat, and energy and can be a significant source of vitamins and minerals (Rumpold and Schlüter 2015). Approximately 1,900 insect species are eaten worldwide, mainly in developing countries (van Huis 2013). The development of safe rearing and effective processing methods are mandatory for utilisation of insects in food and feed. Some insect species can be grown on organic side streams, reducing environmental contamination and transforming waste into high-protein feed. Insects are principally considered as meat substitutes, but worldwide meat substitute consumption is still very low, principally due to differences in food culture, and will require transition phases such as powdered forms (Megido et al. 2016; Smetana et al. 2015). Wider consumer acceptability will relate to pricing, perceived environmental benefits, and the development of tasty insect-derived protein products (van Huis et al. 2015; van Huis 2013). Clearly increasing share of insect-derived protein has the potential to reduce GHG emissions otherwise associated with livestock production. No study to date however has quantified such potential.

5.5.2.5 Food loss and waste, food security, and land use

Food loss and waste impacts food security by reducing global and local food availability, limiting food access due to increase in food price and decrease of producer income, and affecting future food production due to unstainable use of natural resources (HLPE 2014). Food loss is defined as the reduction of edible food during production, postharvest, and processing, whereas food discarded by consumers is considered as food waste (FAO 2011b). Combined food loss and waste amount to a third of global food production *(high confidence)*. During 2010-2016, global food loss and waste equalled 8–10% of total GHG emissions *(medium confidence);* and cost about USD 1 trillion per year (FAO 2014b) *(low confidence).*

A large share of produced food is lost in developing countries due to poor infrastructure, while a large share of produced food is wasted in developed countries (Godfray et al. 2010). Changing consumer behaviour to reduce per capita overconsumption offers substantial potential to improve food security by avoiding related health burdens (Alexander et al. 2017; Smith 2013) and reduce emissions associated with the extra food (Godfray et al. 2010). In 2007, around 20% of the food produced went to waste in Europe and North America, while around 30% of the food produced was lost in sub-Saharan Africa (FAO 2011b). During the last 50 years, the global food loss and waste increased from around 540 Mt in 1961 to 1630 Mt in 2011 (Porter et al. 2016).

In 2011, food loss and waste resulted in about 8–10% of the total anthropogenic greenhouse gas emissions of the entire food system. The mitigation potential of reduced food loss and waste from a full life-cycle perspective, i.e., considering both food supply chain activities and land use change, was estimated as 4.4 Gt CO_2-eq yr^{-1} (FAO 2015a, 2013b). At a global scale, loss and waste of milk, poultry meat, pig meat, sheep meat, and potatoes are associated with 3% of the global agricultural N_2O emissions (more than 200 Gg N_2O-N yr^{-1} or 0.06 Gt CO_2-eq yr^{-1}) in 2009 (Reay et al. 2012). For the United States, 35% of energy use, 34% of blue water use, 34% of GHG emissions, 31% of land use, and 35% of fertiliser use related to an individual's food-related resource consumption were accounted for as food waste and loss in 2010 (Birney et al. 2017).

Similar to food waste, overconsumption, defined as food consumption in excess of nutrient requirements, leads to GHG emissions (Alexander et al. 2017). In Australia for example, overconsumption accounts for about 33% GHGs associated with food (Hadjikakou 2017). In addition to GHG emissions, overconsumption also can lead to severe health conditions such as obesity or diabetes. Over-eating was found to be at least as large a contributor to food system losses (Alexander et al. 2017). Similarly, food system losses associated with consuming resource-intensive animal-based products instead of nutritionally-comparable plant-based alternatives are defined as 'opportunity food losses.' These were estimated to be 96, 90, 75, 50, and 40% for beef, pork, dairy, poultry, and eggs, respectively, in the US (Shepon et al. 2018).

Avoiding food loss and waste will contribute to reducing emissions from the agriculture sector. By 2050, agricultural GHG emissions associated with production of food that might be wasted may increase to 1.9–2.5 Gt CO_2-eq yr^{-1} (Hiç et al. 2016). When land use change for agriculture expansion is also considered, halving food loss and waste reduces the global need for cropland area by around 14% and GHG emissions from agriculture and land use change by 22–28% (4.5 Gt CO_2-eq yr^{-1}) compared to the baseline scenarios by 2050 (Bajželj et al. 2014). The GHG emissions mitigation potential of food loss and waste reduction would further increase when life cycle analysis accounts for emissions throughout food loss and waste through all food system activities.

Reducing food loss and waste to zero might not be feasible. Therefore, appropriate options for the prevention and management of food waste can be deployed to reduce food loss and waste and to minimise its environmental consequences. Papargyropoulou et al. (2014) proposed the 3Rs (i.e., reduction, recovery and recycle) options to prevent and manage food loss and waste. A wide range of approaches across the food supply chain is available to reduce food loss and waste, consisting of technical and non-technical solutions (Lipinski et al. 2013). However, technical solutions (e.g., improved harvesting techniques, on-farm storage, infrastructure, packaging to keep food fresher for longer, etc.) include additional costs (Rosegrant et al. 2015) and may have impacts on local environments (FAO 2018b). Additionally, all parts of food supply chains need to become efficient to achieve the full reduction potential of food loss and waste (Lipinski et al. 2013).

Together with technical solutions, approaches (i.e, non- technical solutions) to changes in behaviours and attitudes of a wide range of stakeholders across the food system will play an important role in reducing food loss and waste. Food loss and waste can be recovered by distributing food surplus to groups affected by food poverty or converting food waste to animal feed (Vandermeersch et al. 2014). Unavoidable food waste can also be recycled to produce energy based on biological, thermal and thermochemical technologies (Pham et al. 2015). Additionally, strategies for reducing food loss and waste also need to consider gender dynamics with participation of females throughout the food supply chain (FAO 2018f).

In summary, reduction of food loss and waste can be considered as a climate change mitigation measure that provides synergies with food security and land use (*robust evidence, medium agreement*,). Reducing food loss and waste reduces agricultural GHG emissions and the need for agricultural expansion for producing excess food. Technical options for reduction of food loss and waste include improved harvesting techniques, on-farm storage, infrastructure, and packaging. However, the beneficial effects of reducing food loss and waste will vary between producers and consumers, and across regions. Causes of food loss (e.g., lack of refrigeration) and waste (e.g., behaviour) differ substantially in developed and developing countries *(robust evidence, medium agreement)*. Additionally, food loss and waste cannot be avoided completely.

5.5.2.6 Shortening supply chains

Encouraging consumption of locally produced food and enhancing efficiency of food processing and transportation can in some cases minimise food loss, contribute to food security, and reduce GHG emissions associated with energy consumption and food loss. For example, Michalský and Hooda (2015), through a quantitative assessment of GHG emissions of selected fruits and vegetables in the UK, reported that increased local production offers considerable emissions savings. They also highlighted that when imports are necessary, importing from Europe instead of the Global South can contribute to considerable GHG emissions savings. Similar results were found by Audsley et al. (2010), with exceptions for some foods, such as tomatoes, peppers or sheep and goat meat. Similarly, a study in India shows that long and fragmented supply chains, which lead to disrupted price signals, unequal power relations perverse incentives and long transport time, could be a key barrier to reducing post-harvest losses (CIPHET 2007).

In other cases, environmental benefits associated with local food can be offset by inefficient production systems with high emission intensity and resource needs, e.g., water, due to local conditions. For example, vegetables produced in open fields can have much lower GHG emissions than locally produced vegetables from heated greenhouses (Theurl et al. 2014). Whether locally grown food has a lower carbon footprint depends on the on-farm emissions intensity as well as the transport emissions. In some cases, imported food may have a lower carbon footprint than locally grown food because some distant countries can produce food at much lower emissions intensity. For example, Avetisyan et al. (2014) reported that regional variation of emission intensities associated with production of ruminant products have large implications for emissions associated with local food. They showed that consumption of local livestock products can reduce emissions due to short supply chains in countries with low emission intensities; however, this might not be the case in countries with high emission intensities.

In addition to improving emission intensity, efficient distribution systems for local food are needed for lowering carbon footprints (Newman et al. 2013). Emissions associated with food transport depend on the mode of transport, for example, emissions are lower for rail rather than truck (Brodt et al. 2013). Tobarra et al. (2018) reported that emissions saving from local food may vary across seasons and regions of import. They highlighted that in Spain local production of fruits and vegetables can reduce emissions associated with imports from Africa but imports from France and Portugal can save emissions in comparison to production in Spain. Additionally, local production of seasonal products in Spain reduces emissions, while imports of out-of-season products can save emissions rather than producing them locally.

In summary, consuming locally grown foods can reduce GHG emissions, if they are grown efficiently *(high confidence)*. The emissions reduction potential varies by region and season. Whether food with shorter supply chains has a lower carbon footprint depends on both the on-farm emissions intensity as well as the transport emissions. In some cases, imported food may have a lower carbon footprint because some distant agricultural regions can produce food at lower emissions intensities.

5.6 Mitigation, Adaptation, Food Security, and Land Use – Synergies, Trade-Offs, and Co-Benefits

Food systems will need to adapt to changing climates and also to reduce their greenhouse gas (GHG) emissions and sequester carbon if Paris Agreement goals are to be met (Springmann et al. 2018a; van Vuuren et al. 2014). The synergies and trade-offs between the food system mitigation and adaptation options described in Sections 5.3 and 5.5 are of increasing importance in both scientific and policy communities because of the necessity to ensure food security, i.e., provision of nutritious food for the growing population, while responding to climate change (Rosenzweig and Hillel 2015) A special challenge involves interactions between land-based non-food system mitigation, such as negative emissions technologies, and food security. Response options for the food system have synergies and trade-offs between climate change mitigation and adaptation (Figure 5.13; Chapter 6).

Tirado et al. (2013) suggest an integrated approach to address the impacts of climate change to food security that considers a combination of nutrition-sensitive adaptation and mitigation measures, climate-resilient and nutrition-sensitive agricultural development, social protection, improved maternal and child care and health, nutrition-sensitive risk reduction and management, community development measures, nutrition-smart investments, increased policy coherence, and institutional and cross-sectoral collaboration. These measures are a meansto achieve both short-term and long-term benefits in poor and marginalised groups.

This section assesses the synergies and trade-offs for land-based atmospheric carbon dioxide removal measures, effects of mitigation measures on food prices, and links between dietary choices and human health. It then evaluates a range of integrated agricultural systems and practices that combine mitigation and adaptation measures, including the role of agricultural intensification. The roles of women's empowerment and urban agriculture are examined, as well as interactions between SDG2 (Zero Hunger) and SDG 13 (Climate Action).

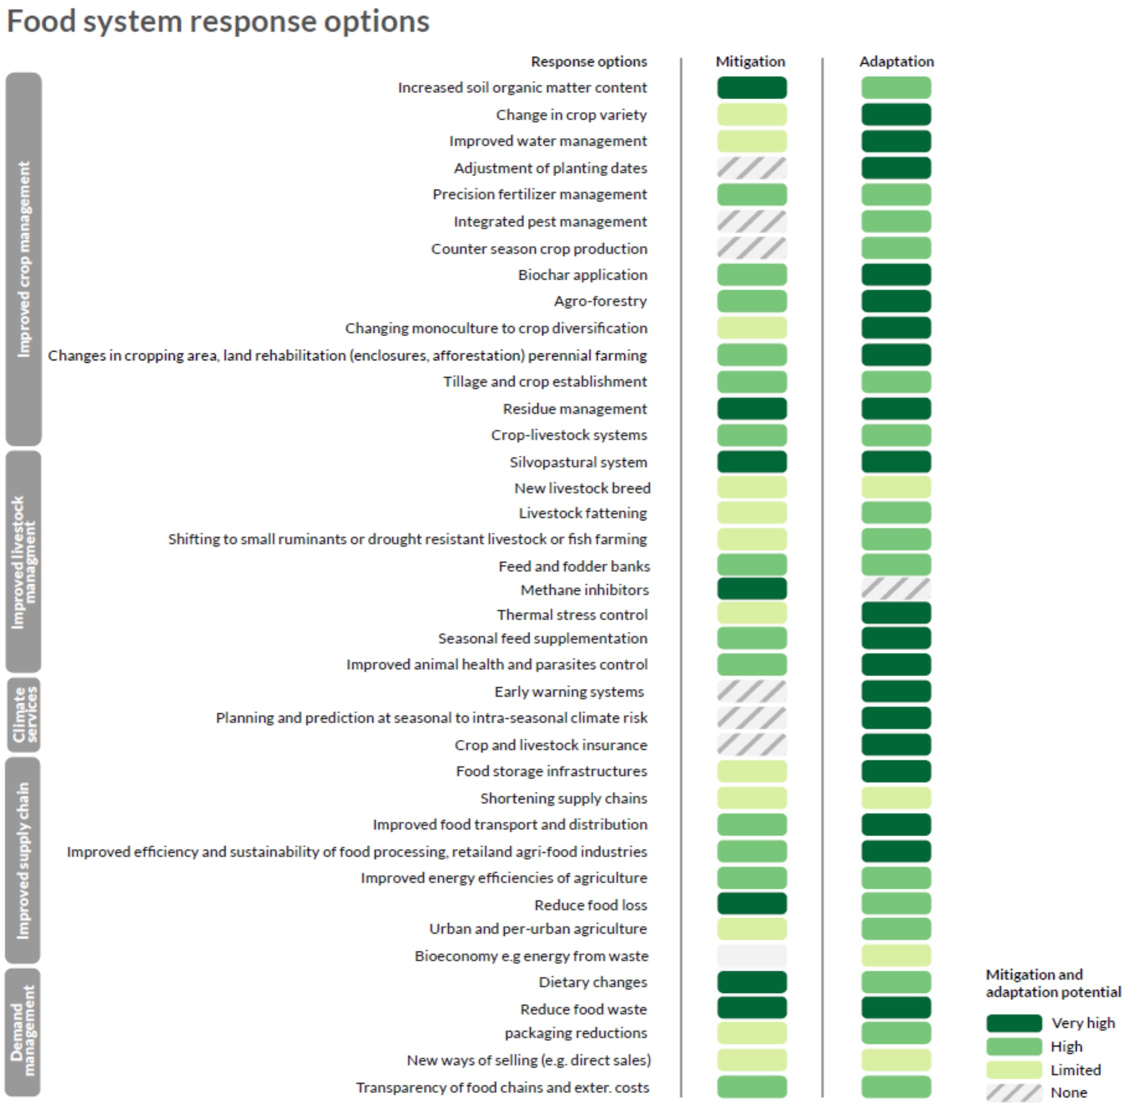

Figure 5.13 Response options related to food system and their potential impacts on mitigation and adaptation. Many response options offer significant potential for both mitigation and adaptation.

5.6.1 Land-based carbon dioxide removal (CDR) and bioenergy

Large-scale deployment of negative emission technologies (NETs) in emission scenarios has been identified as necessary for avoiding unacceptable climate change (IPCC 2018b). Among the available NETs, carbon dioxide removal (CDR) technologies are receiving increasing attention. Land-based CDRs include afforestation and reforestation (AR), sustainable forest management, biomass energy with carbon capture and storage (BECCS), and biochar (BC) production (Minx et al. 2018). Most of the literature on global land-based mitigation potential relies on CDRs, particularly on BECCS, as a major mitigation action (Kraxner et al. 2014; Larkin et al. 2018; Rogelj et al. 2018, 2015, 2011). BECCS is not yet deployable at a commercial scale, as it faces challenges similar to fossil fuel carbon capture and storage (CCS) (Fuss et al. 2016; Vaughan and Gough 2016; Nemet et al. 2018). Regardless, the effectiveness of large-scale BECCS to meet Paris Agreement goals has been questioned and other pathways to mitigation have been proposed (Anderson and Peters 2016; van Vuuren et al. 2017, 2018; Grubler et al. 2018; Vaughan and Gough 2016).

Atmospheric CO_2 removal by storage in vegetation depends on achieving net organic carbon accumulation in plant biomass over decadal time scales (Kemper 2015) and, after plant tissue decay, in soil organic matter (Del Grosso et al. 2019). AR, BECCS and BC differ in the use and storage of plant biomass. In BECCS, biomass carbon from plants is used in industrial processes (e.g., for electricity, hydrogen, ethanol, and biogas generation), releasing CO_2, which is then captured and geologically stored (Greenberg et al. 2017; Minx et al. 2018).

Afforestation and reforestation result in long-term carbon storage in above and belowground plant biomass on previously unforested areas, and is effective as a carbon sink during the AR establishment period, in contrast to thousands of years for geological C storage (Smith et al. 2016).

Biochar is produced from controlled thermal decomposition of biomass in absence of oxygen (pyrolysis), a process that also yields combustible oil and combustible gas in different proportions. Biochar is a very stable carbon form, with storage on centennial timescales (Lehmann et al. 2006) (See also Chapter 4). Incorporated in soils, some authors suggest it may lead to improved water-holding capacity, nutrient retention, and microbial processes (Lehmann et al. 2015). There is however considerable uncertainty about the benefits and risks of this practice (The Royal Society 2018).

Land-based CDRs require high biomass-producing crops. Since not all plant biomass is harvested (e.g., roots and harvesting losses), it can produce co-benefits related to soil carbon sequestration, crop productivity, crop quality, as well improvements in air quality, but the overall benefits strongly depend on the previous land use and soil management practices (Smith et al. 2016; Wood et al. 2018). In addition, CDR effectiveness varies widely depending on type of biomass, crop productivity, and emissions offset in the energy system. Importantly, its mitigation benefits can be easily lost due to land-use change interactions (Harper et al. 2018; Fuss et al. 2018; Daioglou et al. 2019).

Major common challenges of implementing these large-scale CDR solutions, as needed to stabilise global temperature "well-below" 2°C by the end of the century, are the large investments and the associated significant changes in land use required. Most of the existing scenarios estimate the global area required for BECCS alone in the range of 109-990 Mha (IPCC 2018a), most commonly around 380–700 Mha (Smith et al. 2016), reaching rates of net area expansion rates up to 23.7 M ha yr^{-1} (IPCC 2018b). The upper limit implies unprecedented rates of area expansion for crops and forestry observed historically, for instance as reported by FAO since 1961 (FAOSTAT 2018). By comparison, the sum of recent worldwide rates of expansion in harvested area of soybean and sugarcane has not exceeded 3.5 M ha yr^{-1} on average. Even at this rate, they have been the source of major concerns for their possible negative environmental and food security impacts (Boerema et al. 2016; Popp et al. 2014).

Most land area available for CDR is currently pasture, estimated at 3,300 Mha globally (FAOSTAT 2018). However, there is *low confidence* about how much low-productivity land is actually available for CDR (Lambin et al. 2013; Gibbs and Salmon 2015). There is also *low confidence* and *low agreement* if the transition to BECCS will take place directly on low-productivity grasslands (Johansson and Azar 2007), and uncertainty on the governance mechanisms required to avoid unwanted spill-over effects, for instance causing additional deforestation (Keles et al. 2018).

Further, grasslands and rangelands may often occur in marginal areas, in which case they may be exposed to climate risks, including periodic flooding. Grasslands and especially rangelands and savannahs tend to predominate in less-developed regions, often bordering areas of natural vegetation with little infrastructure available for transport and processing of large quantities of CDR-generated biomass (O'Mara 2012; Beringer et al. 2011; Haberl et al. 2010; Magdoff 2007).

CDR-driven reductions in available pastureland area is a scenario of constant or increasing global animal protein output as proposed by (Searchinger et al. 2018). However, despite the recent reduction in meat consumption in western countries, this will require productivity improvements (Cohn et al. 2014; Strassburg et al. 2014). It would also result in lower emission intensities and create conditions for increased soil carbon stocks (de Oliveira Silva et al. 2016; Searchinger et al. 2018; Soussana et al.

2019, 2013). At the same time, food security may be threatened if land-based mitigation displaced crops elsewhere, especially if to regions of lower productivity potential, higher climatic risk, and higher vulnerability.

There is *low agreement* about what are the more competitive regions of the world for CDRs. Smith et al. (2016) and Vaughan et al. (2018) identify as candidates relatively poor countries in Latin America, Africa and Asia (except China and India). Others indicate those regions may be more competitive for food production, placing Europe as a major BECCS exporter (Muratori et al. 2016). Economically feasible CDR investments are forecast to be directed to regions with high biomass production potential, demand for extra energy production, low leakage potential for deforestation and low competition for food production (Vaughan et al. 2018). Latin America and Africa, for instance, although having high biomass production potential, still have low domestic energy consumption (589 and 673 MTOE – 24.7 and 28.2 EJ, respectively), with about 30% of primary energy from renewable sources (reaching 50% in Brazil), mainly hydropower and traditional biomass.

There is *high confidence* that deployment of BECCS will require ambitious investments and policy interventions (Peters and Geden 2017) with strong regulation and governance of bioenergy production to ensure protection of forests, maintain food security and enhance climate benefits (Burns and Nicholson 2017; Vaughan et al. 2018; Muratori et al. 2016), and that such conditions may be challenging for developing countries. Increased value of bioenergy puts pressure on land, ecosystem services, and the prices of agricultural commodities, including food (*high confidence*).

There is *medium confidence* for the impact of CDR technologies on increased food prices and reduced food security, as these depend on several assumptions. Nevertheless, those impacts could be strong, with food prices doubling under certain scenario combinations (Popp et al. 2017). The impacts of land-mitigation policies on the reduction of dietary energy availability alone, i.e., without climate change impacts, is estimated at over 100 kcal.person^{-1} day^{-1} by 2050, with highest regional impacts in south Asia and sub-Saharan Africa (Hasegawa et al. 2018) (See Section 5.2). However, only limited pilot BECCS projects have been implemented to date (Lenzi et al. 2018). Integrated assessment models (IAMs) use theoretical data based on high-level studies and limited regional data from the few on-the-ground BECCS projects.

Furthermore, it has been suggested that several BECCS IAM scenarios rely on unrealistic assumptions regarding regional climate, soils and infrastructure suitability (Anderson and Peters 2016), as well as international bioenergy trade (Lamers et al. 2011). Current global IAMs usually consider major trends in production potential and projected demand, overlooking major challenges for the development of a reliable international market. Such a market will have to be created from scratch and overcome a series of constraints, including trade barriers, logistics, and supply chains, as well as social, ecological and economic impacts (Matzenberger et al. 2015).

In summary, there is *high agreement* that better assessment of BECCS mitigation potential would need to be based on increased regional, bottom-up studies of biomass potentials, socio-economic consequences (including on food security), and environmental impacts in order to develop more realistic estimates (IPCC 2018a).

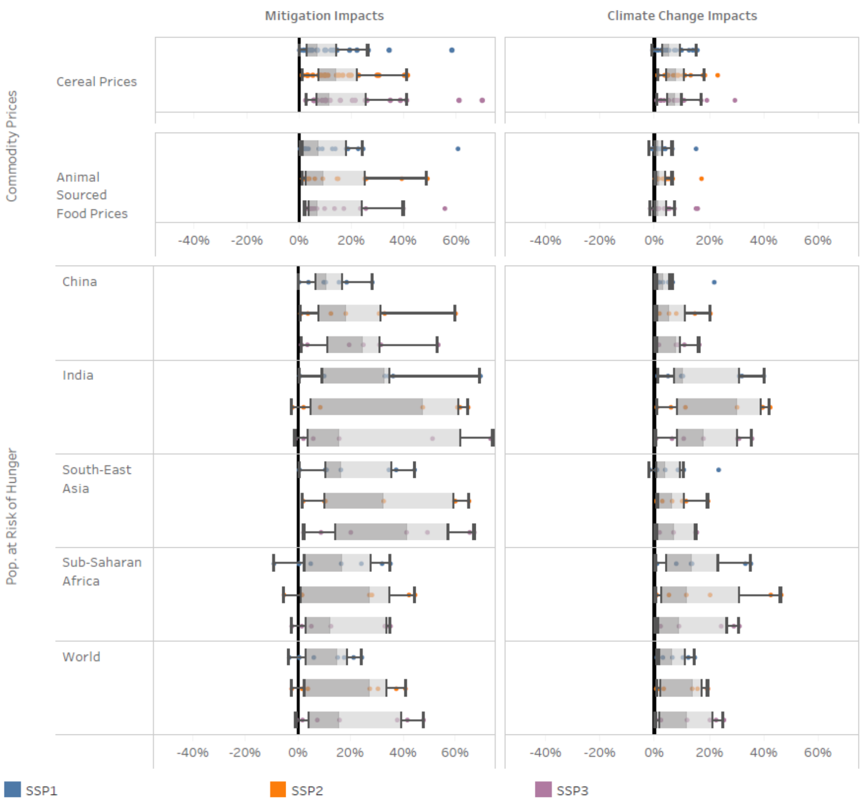
5.6.2 Mitigation, food prices, and food security

Food prices are the result of supply, demand and trade relations. Earlier studies (e.g., (Nelson et al. 2009)) showed that recent climate impacts that reduced crop productivity led to higher prices and increased trade of commodities between regions, with asymmetric impacts on producers and consumers. In terms of published scenario analyses, the most affected regions tend to be Sub-Saharan Africa and parts of Asia, but there is significant heterogeneity in results between countries. Relocation of production to less affected areas buffers these impacts to a certain extent, as well as potential for improvements in food production technologies (Hasegawa et al. 2018; van Meijl et al. 2017; Wiebe et al. 2015; Lotze-Campen et al. 2014; Valin et al. 2014; Robinson et al. 2014).

A newer, less studied impact of climate change on prices and their impacts on food security is the level of land-based mitigation necessary to stabilise global temperature. Hasegawa et al. (2018), using an ensemble of seven global economic models across a range of greenhouse gas emissions pathways and socioeconomic trajectories, suggested that the level of mitigation effort needed to reduce emissions can have a more significant impact on prices than the climate impacts themselves on reduced crop yields (Figure 5.14). This occurs because in the models, taxing GHG emissions leads to higher crop and livestock prices, while land-based mitigation leads to less land availability for food production, potentially lower food supply, and therefore food price increases.

Price increases in turn lead to reduced consumption, especially by vulnerable groups, or to shifts towards cheaper food, which are often less nutritious. This leads to significant increases in the number of malnourished people. Frank et al. (2017) and Fujimori et al. (2017) arrived at the same conclusions for the 1.5°C mitigation scenario using the IAM Globiom and ensembles of AgMIP global economic models. While the magnitude of the response differs between models, the results are consistent between them. In contrast, a study based on five global agro-economic models highlights that the global food prices may not increase much when the required land for bioenergy is accessible on the margin of current cropland, or the feedstock does not have a direct completion with agricultural land (Lotze-Campen et al. 2014).

These studies highlight the need for careful design of emissions mitigation policies in upcoming decades—for example, targeted schemes encouraging more productive and resilient agricultural production systems and the importance of incorporating complementary policies (such as safety-net programmes for poverty alleviation) that compensate or counteract the impacts of the climate change mitigation policies on vulnerable regions (Hasegawa et al. 2018). Fujimori et al. (2018) showed how an inclusive policy design can avoid adverse side-effects on food security through international aid, bioenergy taxes, or domestic reallocation of income. These strategies can shield impoverished and vulnerable people from the additional risk of hunger that would be caused by the economic effects of policies narrowly focussing on climate objectives only.



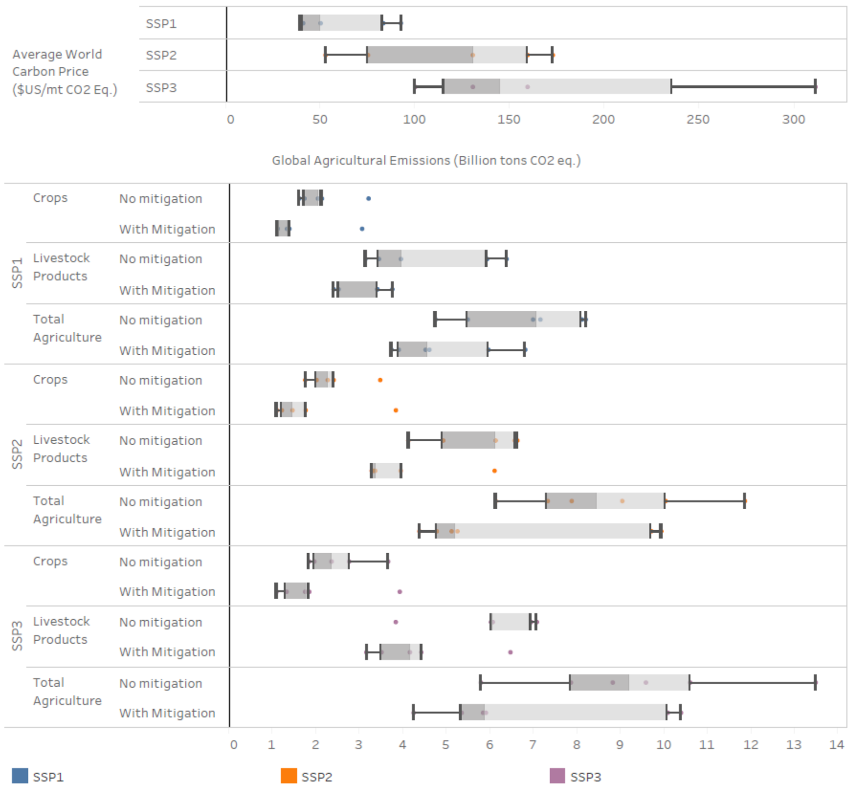


Figure 5.14 Regional impacts of climate change and mitigation on food price (top), population (pop) at risk of hunger or undernourishment (middle), greenhouse gas emissions (bottom) in 2050 under different socio-economic scenarios (SSP1, SSP2 and SSP33). Values indicate changes from no climate change and no climate change mitigation scenario. MAgPIE, a global land use allocation model, is excluded due to

inelastic food demand. The value of India includes that of Other Asia in MAGNET, a global general equilibrium model (Hasegawa et al. 2018)

In summary, food security will be threatened through increasing numbers of malnourished people if land-based mitigation raises prices, unless other policy mechanisms reduce its impact (*high confidence*). Inclusive policy design can avoid adverse side-effects on food security by shielding vulnerable people from the additional risk of hunger that would be caused by the economic effects of policies narrowly focusing on climate objectives (*medium confidence*).

5.6.3 Environmental and health effects of adopting healthy and sustainable diets

Two key questions arise from the potentially significant mitigation potential of dietary change: 1) Are 'low-GHG emission diets' likely to be beneficial for health? and 2) Would changing diets at scale provide substantial benefits? In short, what are the likely synergies and trade-offs between low-GHG emissions diets and food security, health, and climate change? See Supplementary Material Section SM5.6 for further discussion.

Are "low GHG emission diets" healthy? Consistent evidence indicates that, in general, a dietary pattern that is higher in plant-based foods, such as vegetables, fruits, whole grains, legumes, nuts, and seeds, and lower in animal-based foods, is more health-promoting and associated with lower environmental impact (GHG emissions and energy, land, and water use) than either the current global average diets (Swinburn et al. 2019; Willett et al. 2019; Springmann et al. 2016b), or the current average US diet (Nelson et al. 2016). Another study (Van Mierlo et al. 2017) showed that nutritionally-equivalent diets can substitute plant-based foods for meat and provide reductions in GHG emissions.

There are several studies that estimate health adequacy and sustainability and conclude that healthy sustainable diets are possible. These include global studies (e.g., (Willett et al. 2019; Swinburn et al. 2019)), as well as localised studies (e.g., (Van Dooren et al. 2014). For example, halving consumption of meat, dairy products and eggs in the European Union would achieve a 40% reduction in ammonia emissions, 25–40% reduction in non-CO_2 GHG emissions (primarily from agriculture) and 23% per capita less use of cropland for food production, with dietary changes lowering health risks (Westhoek et al. 2014). In China, diets were designed that could meet dietary guidelines while creating significant reductions in GHG emissions (between 5% and 28%, depending on scenario) (Song et al. 2017). Changing diets can also reduce non-dietary related health issues caused by emissions of air pollutants; for example, specific changes in diets were assessed for their potential to mitigate PM2.5 in China (Zhao et al. 2017b).

A range of studies are starting to estimate both health and environmental benefits from dietary shifts. For example, (Farchi et al. 2017) estimate health (colorectal cancer, cardio-vascular disease) and GHG reductions of "Mediterranean" diets, low in meat, in Italy, finding the potential to reduce deaths from colorectal cancer of 7-10% and CVD from 9-10%, and potential savings of up to 263 CO_2-eq.person^{-1}.yr^{-1}. In the US, Hallström et al. (2017) found that adoption of healthier diets (consistent with dietary guidelines, and reducing amounts of red and processed meats) could reduce relative risk of coronary heart disease, colorectal cancer, and type 2 diabetes by 20–45%, US health care costs by USD 77–93 billion per year, and direct GHG emissions by 222–826 kg CO_2-eq/capita yr^{-1} (69–84 kg from the health care system, 153–742 kg from the food system). Broadly similar conclusions were found for the Netherlands (Biesbroek et al. 2014); and the UK (Friel et al. 2009; Milner et al. 2015).

Whilst for any given disease, there are a range of factors, including diet, that can affect it, and evidence is stronger for some diseases than others, a recent review found that an overall trend toward increased cancer risk was associated with unhealthy dietary patterns, suggesting that diet-related choices could significantly affect the risk of cancer (Grosso et al. 2017). Tilman and Clark (2014) found significant benefits in terms of reductions in relative risk of key diseases: type 2 diabetes, cancer, coronary mortality and all causes of mortality (Figure 5.11).

5.6.3.1 Can dietary shifts provide significant benefits?

Many studies now indicate that dietary shifts can significantly reduce GHG emissions. For instance, several studies highlight that if current dietary trends are maintained, this could lead to emissions from agriculture of approximately 20 Gt CO_2-eq yr^{-1} by 2050, creating significant mitigation potential (Pradhan et al. 2013b; Bajželj et al. 2014; Hedenus et al. 2014; Bryngelsson et al. 2017). Additionally in the US, a shift in consumption towards a broadly healthier diet, combined with meeting the USDA and Environmental Protection Agency's 2030 food loss and waste reduction goals, could increase *per capita* food-related energy use by 12%, decrease blue water consumption by 4%, decrease green water use by 23%, decrease GHG emissions from food production by 11%, decrease GHG emissions from landfills by 20%, decrease land use by 32%, and increase fertiliser use by 12% (Birney et al. 2017). This study, however, does not account for all potential routes to emissions, ignoring, for example, fertiliser use in feed production. Similar studies have been conducted, for China (Li et al. 2016), where adoption of healthier diets and technology improvements have the potential to reduce food systems GHG emissions by >40% relative to those in 2010; and India (Green et al. 2017; Vetter et al. 2017), where alternative diet scenarios can affect emissions from the food system by -20 to +15%.

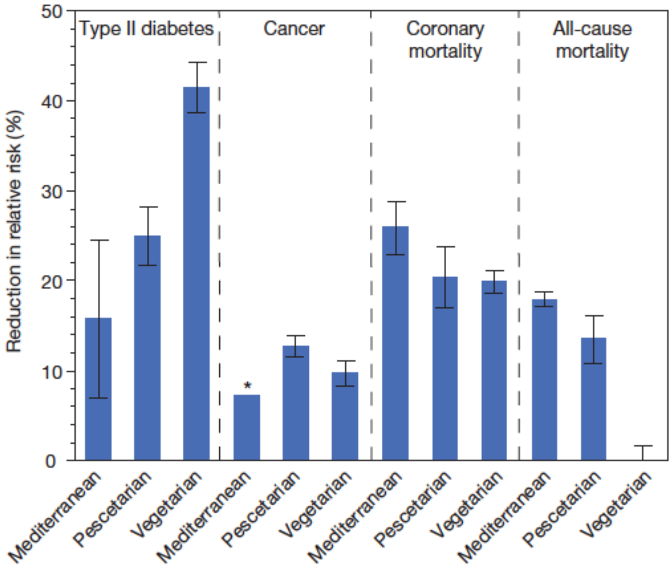

Figure 5.11 Diet and health effects of different consumption scenarios (Tilman and Clark 2014) (* reflects data from a single study, hence no error bars)

Springmann et al (2018a) modelled the role of technology, waste reduction and dietary change in living within planetary boundaries (Rockström et al. 2009), with the climate change boundary being a 66% chance of limiting warming to less than 2°C. They found that all are necessary for achievement of a sustainable food system. Their principal conclusion is that only by adopting a "flexitarian diet", as a global average, would climate change be limited to under two degrees. Their definition of a flexitarian diet is fruits and vegetables, plant-based proteins, modest amounts of animal-based proteins, and limited amounts of red meat, refined sugar, saturated fats, and starchy foods.

Healthy and sustainable diets address both health and environmental concerns (Springmann et al. 2018b). There is high agreement that there are significant opportunities to achieve both objectives simultaneously. Contrasting results of marginal GHG emissions, i.e variations in emissions as a result of variation in one or more dietary components, are found when comparing low to high emissions self-selected diets (diets freely chosen by consumers). (Vieux et al. 2013) found self-selected healthier diets with higher amounts of plant-based food products did not result in lower emissions, while (Rose et al. 2019) found that the lowest emission diets analysed were lower in meat but higher in oil, refined grains and added sugar. (Vieux et al. 2018) concluded that setting nutritional goals with no consideration for the environment may increase GHG emissions (GHGE).

Tukker et al. (2011) also found a slight increase in emissions by shifting diets towards the European dietary guidelines, even with lower meat consumption. Heller and Keoleian (2015) found a 12% increase in GHGE when shifting to iso-caloric diets, i.e., diets with the same caloric intake of diets currently consumed, following the US guidelines and a 1% decrease in GHGE when adjusting caloric intake to recommended levels for moderate activity. There is scarce information on the marginal GHGE that would be associated with following dietary guidelines in developing countries.

Some studies have found a modest mitigation potential of diet shifts when economic and biophysical systems effects are taken into account in association with current dietary guidelines. Tukker et al. (2011), considering economic rebound effects of diet shifts (i.e., part of the gains would be lost due to increased use at lower prices), found maximum changes in emissions of the EU food system of 8% (less than 2% of total EU emissions) when reducing meat consumption by 40 to 58%. Using an economic optimisation model for studying carbon taxation in food but with adjustments of agricultural production systems and commodity markets in Europe (Zech and Schneider 2019) found a reduction of 0.41% in GHG emissions at a tax level of 50 $USDt^{-1}CO_2eq$. They estimate a leakage of 43% of the greenhouse gas emissions reduced by domestic consumption, (i.e., although reducing emissions due to reducing consumption, around 43% of the emissions would not be reduced because part of the production would be directed to exports).

Studying optimised beef production systems intensification technologies in a scenario of no grasslands area expansion (de Oliveira Silva et al. 2016) found marginal GHG emissions to be negligible in response to beef demand in the Brazilian Cerrado. This was because reducing productivity would lead to increased emission intensities, cancelling out the effect of reduced consumption.

In summary, there is significant potential mitigation *(high confidence)* arising from the adoption of diets in line with dietary recommendations made on the basis of health. These are broadly similar across most countries. These are typically capped by at the number of calories and higher in plant-based foods, such as vegetables, fruits, whole grains, legumes, nuts and seeds, and lower in animal-sourced foods, fats and sugar. Such diets have the potential to be both more sustainable and healthy than alternative diets (but healthy diets are not necessarily sustainable and vice versa). The extent to which the mitigation potential of dietary choices can be realised requires both climate change and health being considered together. Socio-economic (prices, rebound effects), political, and cultural contexts would require significant consideration to enable this mitigation potential to be realised.

5.6.4 Sustainable integrated agricultural systems

A range of integrated agricultural systems are being tested to evaluate synergies between mitigation and adaptation and lead to low-carbon and climate-resilient pathways for sustainable food security and ecosystem health *(robust evidence, medium agreement)*. Integration refers to the use of practices that enhance an agroecosystem's mitigation, resilience, and sustainability functions. These systems follow holistic approaches with the objective of achieving biophysical, socio-cultural, and economic benefits from land management systems (Sanz et al. 2017). These integrated systems may include agroecology (FAO et al. 2018; Altieri et al. 2015), climate smart agriculture (FAO 2011c; Lipper et al. 2014; Aggarwal et al. 2018), conservation agriculture (Aryal et al. 2016; Sapkota et al. 2015), and sustainable intensification (FAO 2011d; Godfray 2015), among others.

Many of these systems are complementary in some of their practices, although they tend to be based on diffèrent narratives (Wezel et al. 2015; Lampkin et al. 2015; Pimbert 2015). They have been tested in various production systems around the world (Dinesh et al. 2017; Jat et al. 2016; Sapkota et al. 2015; Neufeldt et al. 2013). Many technical innovations, e.g., precision nutrient management (Sapkota et al. 2014) and precision water management (Jat et al. 2015), can lead to both adaptation and mitigation outcomes and even synergies; although negative adaptation and mitigation outcomes (i.e., trade-offs) are often overlooked. Adaptation potential of ecologically intensive systems includes crop diversification, maintaining local genetic diversity, animal integration, soil organic management, water conservation and harvesting the role of microbial assemblages (See Section 5.3). Technical innovations may encompass not only inputs reduction, but complete redesign of agricultural systems (Altieri et al. 2017) and how knowledge is generated (Levidow et al. 2014), including social and political transformations.

5.6.4.1 Agroecology

Agroecology (see Glossary) (Francis et al. 2003; Gliessman and Engles 2014; Gliessman 2018), provides knowledge for their design and management, including social, economic, political, and cultural dimensions (Dumont et al. 2016). It started with a focus at the farm level but has expanded to include the range of food system activities (Benkeblia 2018). Agroecology builds systems resilience through knowledge-intensive practices relying on traditional farming systems and co-generation of new insights and information with stakeholders through participatory action research (Menéndez et al. 2013). It provides a multidimensional view of food systems within ecosystems, building on indigenous and local knowledge (ILK) and co-evolving with the experiences of local people, available natural resources, access to these resources, and ability to share and pass on knowledge among communities and generations, emphasising the inter-relatedness of all agroecosystem components and the complex dynamics of ecological processes (Vandermeer 1995).

At the farm level, agroecological practices recycle biomass and regenerate soil biotic activities. They strive to attain balance in nutrient flows to secure favorable soil and plant growth conditions, minimise loss of water and nutrients, and improve use of solar radiation. Practices include efficient microclimate management, soil cover, appropriate planting time and genetic diversity. They seek to promote ecological processes and services such as nutrient cycling, balanced predator/prey interactions, competition, symbiosis, and successional changes. The overall goal is to benefit human and non-human communities in the ecological sphere, with fewer negative environmental or social impacts and fewer external inputs (Vandermeer et al. 1998; Altieri et al. 1998). From a food system focus, agroecology provides management options in terms of commercialisation and consumption through the promotion of short food chains and healthy diets (Pimbert and Lemke 2018; Loconto et al. 2018).

Agroecology has been proposed as a key set of practices in building climate resilience (FAO et al. 2018; Altieri et al. 2015). These can enhance on-farm diversity (of genes, species, and ecosystems) through a landscape approach (FAO 2018g). Outcomes include soil conservation and restoration and thus soil carbon sequestration, reduction of the use of mineral and chemical fertilisers, watershed protection, promotion of local food systems, waste reduction, and fair access to healthy food through nutritious and diversified diets (Pimbert and Lemke 2018; Kremen et al. 2012; Goh 2011; Gliessman and Engles 2014).

A principle agroecology is to contribute to food production by smallholder farmers (Altieri 2002). Since climatic events can severely impact smallholder farmers, there is a need to better understand the heterogeneity of small-scale agriculture in order to consider the diversity of strategies that traditional farmers have used and still use to deal with climatic variability. In Africa, many smallholder farmers cope with and even prepare for climate extremes, minimising crop failure through a series of agroecological practices (e.g., biodiversification, soil management, and water harvesting) (Mbow et al. 2014a). Resilience to extreme climate events is also linked to on-farm biodiversity, a typical feature of traditional farming systems (Altieri and Nicholls 2017).

Critiques of agroecology refer to its explicit exclusion of modern biotechnology (Kershen 2013) and the assumption that smallholder farmers are a uniform unit with no heterogeneity in power (and thus gender) relationships (Neira and Montiel 2013; Siliprandi and Zuluaga Sánchez 2014).

5.6.4.2 Climate-smart agriculture

'Climate-smart agriculture' (CSA) is an approach developed to tackle current food security and climate change challenges in a joint and synergistic fashion (Lipper et al. 2014; Aggarwal et al. 2018; FAO 2013c). CSA is designed to be a pathway towards development and food security built on three pillars: increasing productivity and incomes, enhancing resilience of livelihoods and ecosystems and reducing, and removing GHG emissions from the atmosphere (FAO 2013c). Climate-smart agricultural systems are integrated approaches to the closely linked challenges of food security, development, and climate change adaptation/mitigation to enable countries to identify options with maximum benefits and those where trade-offs need management.

Many agricultural practices and technologies already provide proven benefits to farmers' food security, resilience and productivity (Dhanush and Vermeulen 2016). In many cases these can be made implemented by changing the suites of management practices. For example, enhancing soil organic matter to improve water-holding capacity of agricultural landscapes also sequesters carbon. In annual cropping systems, changes from conventional tillage practices to minimum tillage can convert the system from one that either provides only adaptation or mitigation benefits or neither types of benefits to one that provides both adaptation and mitigation benefits (Sapkota et al. 2017a; Harvey et al. 2014a).

Increasing food production by using more fertilisers in agricultural fields could maintain crop yield in the face of climate change, but may result in greater overall GHG emissions. But increasing or maintaining the same level of yield by increasing nutrient-use-efficiency through adoption of better fertiliser management practices could contribute to both food security and climate change mitigation (Sapkota et al. 2017a).

Mixed farming systems integrating crops, livestock, fisheries and agro-forestry could maintain crop yield in the face of climate change, help the system to adapt to climatic risk, and minimise GHG emissions by increasingly improving the nutrient flow in the system (Mbow et al. 2014a; Newaj et al. 2016; Bioversity International 2016). Such systems can help diversify production and/or incomes and support efficient and timely use of inputs thus contributing to increased resilience, but require local seed and input systems and extension services. Recent whole farm modelling exercises have shown the economic and environmental (reduced GH emissions, reduced land use) benefits of integrated crop-livestock systems. Gil et al. (2018) compared different soy-livestock systems across multiple economic and environmental indicators, including climate resilience. However it is important to note that potential benefits are very context specific.

Although climate-smart agriculture involves a holistic approach, some argue that it narrowly focuses on technical aspects at the production level (Taylor 2018; Newell and Taylor 2018). Studying barriers to the adoption and diffusion of technological innovations for climate-smart agriculture in Europe, Long et al. (2016) found that there was incompatibility between existing policies and climate-smart agriculture objectives, including barriers to the adoption of technological innovations.

Climate-smart agricultural systems recognise that the implementation of the potential options will be shaped by specific country contexts and capacities, as well as enabled by access to better information, aligned policies, coordinated institutional arrangements and flexible incentives and financing mechanisms (Aggarwal et al. 2018). Attention to underlying socio-economic factors that affect adoption of practices and access to technologies is crucial for enhancing biophysical processes, increasing productivity, and reducing GHG emissions at scale. The Government of India, for example, has started a program of climate resilient villages (CRV) as a learning platform to design, implement, evaluate and promote various climate-smart agricultural interventions, with the goal of ensuring enabling mechanisms at the community level (Srinivasa Rao et al. 2016).

5.6.4.3 Conservation agriculture

Conservation agriculture (CA) is based on the principles of minimum soil disturbance and permanent soil cover combined with appropriate crop rotation (Jat et al. 2014; FAO 2011e). CA has been shown to respond with positive benefits to smallholder farmers under both economic and environmental pressures (Sapkota et al. 2017a, 2015). This agricultural production system uses a body of soil and residues management practices that control erosion (Blanco Sepúlveda and Aguilar Carrillo 2016) and at the same time to improve soil quality, by increasing organic matter content and improving porosity, structural stability, infiltration and water retention (Sapkota et al. 2017a, 2015; Govaerts et al. 2009)

Intensive agriculture during the second half of the 20th century led to soil degradation and loss of natural resources and contributed to climate change. Sustainable soil management practices can address both food security and climate change challenges faced by these agricultural systems. For example, sequestration of soil organic carbon (SOC) is an important strategy to improve soil quality and to mitigation of climate change (Lal 2004). CA has been reported to increase farm productivity by reducing costs of production (Aryal et al. 2015; Sapkota et al. 2015; Indoria et al. 2017) as well as to reduce GHG emission (Pratibha et al. 2016).

CA brings favourable changes in soil properties that affect the delivery of nature's contribution to people (NCPs) or ecosystem services including climate regulation through carbon sequestration and GHG emissions (Palm et al. 2013; Sapkota et al. 2017a). However, by analysing datasets for soil carbon in the tropics, Powlson et al. (2014, 2016) argued that the rate of SOC increase and resulting GHG mitigation in CA systems, from zero-tillage in particular, has been overstated (see also Chapter 2).

However, there is unanimous agreement that the gain in SOC and its contribution to GHG mitigation by CA in any given soil is largely determined by the quantity of organic matter returned to the soil (Giller et al. 2009; Virto et al. 2011; Sapkota et al. 2017b). Thus, a careful analysis of the production system is necessary to minimise the trade-offs among the multiple use of residues, especially where residues remain an integral part of livestock feeding (Sapkota et al. 2017b). Similarly, replacing mono-cropping systems with more diversified cropping systems and agroforestry as well as afforestation and deforestation can buffer temperatures as well as increase carbon storage (Mbow et al. 2014a; Bioversity International 2016), and provide diversified and healthy diets in the face of climate change.

CA adoption in Africa has been low despite more than three decades of implementation (Giller et al. 2009), although there is promising uptake recently in east and southern Africa. This calls for a better understanding of the social and institutional aspects around CA adoption. Brown et al. (2017a) found that institutional and community constraints hampered the use of financial, physical, human and informational resources to implement CA programs.

Gender is another variable to consider since at intra-household level, decision-making and benefits distribution. CA interventions have implications for labour requirements, labour allocation, and investment decisions, all of which impacting the roles of men and women (Farnworth et al. 2016) (see also Section 5.1.3). For example, in the global South, CA generally reduces labour and production costs and generally leads to increased returns to family labour (Aryal et al. 2015) although a gender shift of the labour burden to women have also been described (Giller et al. 2009).

5.6.4.4 Sustainable intensification

The need to produce about 50% more food by 2050, required to feed the increasing world population (FAO 2018a) may come at the price of significant increases in GHG emissions and environmental impacts, including loss of biodiversity. For instance, land conversion for agriculture is responsible for an estimated 8-10% of all anthropogenic GHG emissions currently (see Section 5.4). Recent calls for sustainable intensification (SI) are based on the premise that damage to the environment through extensification outweighs benefits of extra food produced on new lands (Godfray 2015). However, increasing net production area by restoring already degraded land may contribute to increased production on the one hand and increase carbon sequestration on the other (Jat et al. 2016), thereby contributing to both increased agricultural production and improved natural capital outcomes (Pretty et al. 2018).

Sustainable intensification is a goal but does not specify *a priori* how it could be attained, e.g., which agricultural techniques to deploy (Garnett et al. 2013). It can be combined with selected other improved management practices, e.g., conservation agriculture (see above) or agroforestry, with additional economic, ecosystem services, and carbon benefits. Sustainable intensification , by improving nutrient-, water- and other input-use-efficiency, not only helps to close yield gaps and contribute to food security (Garnett et al. 2013), but also reduces the loss of such production inputs and associated emissions (Sapkota et al. 2017c; Wollenberg et al. 2016). Closing yield gaps is a way to become more efficient in use of land per unit production. Currently, most regions in Africa and South Asia have attained less than 40% of their potential crop production (Pradhan et al. 2015). Integrated farming systems (e.g., mixed crop-livestock, crop-aquaculture) are strategies to produce more products per unit land, which in regard to food security, becomes highly relevant.

Sustainable intensification acknowledges that enhanced productivity needs to be accompanied by maintenance of other ecosystem services and enhanced resilience to shocks (Vanlauwe et al. 2014). SI in intensively farmed areas may require a reduction in production in favour of increasing sustainability in the broad sense (Buckwell et al. 2014) (see Cross-Chapter Box 6: Agricultural Intensification). Hence, moving towards sustainability may imply lower yield growth rates than those maximally attainable in such situations. For areas that contain valuable natural ecosystems, such as the primary forest in the Congo basin, intensification of agriculture is one of the pillars of the strategy to conserve forest (Vanlauwe et al. 2014). Intensification in agriculture is recognised as one of the pathways to meet food security and climate change adaptation and mitigation goals (Sapkota et al. 2017c).

However, SI does not always confer co-benefits in terms of food security and climate change adaption/mitigation. For example, in the case of Vietnam, intensified production of rice and pigs reduced GHG emissions in the short term through land sparing, but after two decades, the emissions associated with higher inputs were likely to outweigh the savings from land sparing (Thu Thuy et al. 2009). Intensification needs to be sustainable in all components of food system by curbing agricultural sprawl, rebuilding soils, restoring degraded lands, reducing agricultural pollution, increasing water use efficiency, and decreasing the use of external inputs (Cook et al, 2015).

A study conducted by Palm et al. (2010) in sub-Saharan Africa, reported that at low population densities and high land availability, food security and climate mitigation goals can be met with intensification scenarios, resulting in surplus crop area for reforestation. In contrast, for high population density and small farm sizes, attaining food security and reducing GHG emissions require use of more mineral fertilisers to make land available for reforestation. However, some forms of intensification in drylands can increase rather than reduce vulnerability due to adverse effects such as environmental degradation and increased social inequity (Robinson et al. 2015).

Sustainable intensification has been critiqued for considering food security only from the supply side, whereas global food security requires attention to all aspects of food system, including access, utilisation, and stability (Godfray 2015). Further, adoption of high-input forms of agriculture under the guise of simultaneously improving yields and environmental performance will attract more investment leading to higher rate of adoption but with the environmental component of SI quickly abandoned (Godfray 2015). Where adopted, SI needs to engage with the sustainable development agenda to (i) identify SI agricultural practices that strengthen rural communities, improve smallholder livelihoods and employment, and avoid negative social and cultural impacts, including loss of land tenure and forced migration; (ii) invest in the social, financial, natural, and physical capital needed to facilitate SI implementation; and (iii) develop mechanisms to pay poor farmers for undertaking sustainability measures (e.g., GHG emissions mitigation or biodiversity protection) that may carry economic costs (Garnett et al. 2013).

In summary, integrated agricultural systems and practices can enhance food system resilience to climate change and reduce GHG emissions, while helping to achieve sustainability (*high confidence*).

Cross-Chapter Box 6: Agricultural intensification: land sparing, land sharing and sustainability

Eamon Haughey (Ireland), Tim Benton (United Kingdom), Annette Cowie (Australia), Lennart Olsson (Sweden), Pete Smith (United Kingdom)

Introduction

The projected demand for more food, fuel and fibre for a growing human population necessitates intensification of current land use to avoid conversion of additional land to agriculture and potentially allow the sparing of land to provide other ecosystem services, including carbon sequestration, production of biomass for energy, and the protection of biodiversity (Benton et al. 2018; Garnett et al. 2013). Land use intensity may be defined in terms of three components; (i) intensity of system inputs (land/soil, capital, labour, knowledge, nutrients and other chemicals), (ii) intensity of system outputs (yield per unit land area or per specific input) and (iii) the impacts of land use on ecosystem services such as changes in soil carbon or biodiversity (Erb et al. 2013). Intensified land use can lead to ecological damage as well as degradation of soil resulting in a loss of function which underpins many ecosystem services (Wilhelm and Smith 2018); (Smith et al. 2016). Therefore, there is a risk that increased agricultural intensification could deliver short-term production goals at the expense of future productive potential, jeopardising long term food security (Tilman et al. 2011).

Agroecosystems which maintain or improve the natural and human capital and services they provide may be defined as sustainable systems, while those which deplete these assets as unsustainable (Pretty and Bharucha 2014). Producing more food, fuel and fibre without the conversion of additional non-agricultural land while simultaneously reducing environmental impacts requires what has been termed sustainable intensification (Godfray et al. 2010; FAO 2011e); see glossary and Cross-Chapter Box 6, Figure 1). Sustainable intensification (SI) may be achieved through a wide variety of means; from improved nutrient and water use efficiency via plant and animal breeding programs, to the implementation of integrated soil fertility and pest management practices, as well as by smarter land use allocation at a larger spatial scale: for example, matching land use to the context and specific capabilities of the land (Benton et al. 2018). However, implementation of SI is broader than simply increasing the technical efficiency of agriculture ("doing more with less"); it sometimes may require a reduction of yields to raise sustainability, and successful implementation can be dependent on place and scale. (Pretty et al. 2018), following (Hill 1985), highlights three elements to SI: (i) increasing efficiency, (ii) substitution of less beneficial or efficient practices for better ones, and (iii) system redesign to adopt new practices and farming systems (see Cross-Chapter Box 6, Table 1).

Under a land sparing strategy, intensification of land use in some areas, generating higher productivity per unit area of land, can allow other land to provide other ecosystem services such as increased carbon sequestration and the conservation of natural ecosystems and biodiversity (Balmford et al. 2018; Strassburg et al. 2014). Conversely under a land sharing strategy less, or no, land is set aside, but lower levels of intensification are applied to agricultural land, providing a combination of provisioning and other functions such as biodiversity conservation from the same land (Green et al. 2005). The two approaches are not mutually exclusive and the suitability of their application is generally system-, scale- and/or location specific (Fischer et al. 2014). One crucial issue for the success of a land sparing strategy is that spared land is protected from further conversion: as the profits from the intensively managed land increase, there is an incentive for conversion of additional land for production (Byerlee et al. 2014). Furthermore, it is implicit that there are limits to the SI of land at a local and also planetary boundary level (Rockström et al. 2009). These may relate to the "health" of soil, the presence of supporting services, such as pollination, local limits to water availability, or limits on air quality. This implies that it may not be possible to meet demand "sustainably" if demand exceeds local and global limits. There are no single global solutions to these challenges and specific in situ responses for different farming systems and locations are required. Bajželj et al. (2014) showed that implementation of SI, primarily through yield gap closure, had better environmental outcomes compared with business as usual trajectories. However, SI alone will not be able to deliver the necessary environmental outcomes from the food system – dietary change and reduced food waste are also required (Springmann et al. 2018a; Bajželj et al. 2014).

Cross-Chapter Box 6, Table 1 Approaches to sustainable intensification of agriculture (Pretty et al. 2018; Hill 1985)

Approach	Sub-category	Examples/notes
Improving efficiency	Precision agriculture	High and low-technology options to optimise resource use.
	Genetic improvements	Improved resource use efficiency through crop or livestock breeding.
	Irrigation technology	Increase production in areas currently limited by precipitation (sustainable water supply required).
	Organisational scale-up	Increasing farm organisational scale (e.g. co-operative schemes) can increase efficiency via facilitation of mechanisation and precision techniques.
Substitution	Green fertiliser	Replacing chemical fertiliser with green manures, compost (including vermicompost), biosolids and digestate (by product of anaerobic digestion) to maintain and improve soil fertility.
	Biological control	Pest control through encouraging natural predators.
	Alternative crops	Replacement of annual with perennial crops reducing the need for soil disturbance and reducing erosion.
	Premium products	Increase farm-level income for less output by producing a premium product.
System redesign	System diversification	Implementation of alternative farming systems: organic, agroforestry and intercropping (including the use of legumes).
	Pest management	Implementing integrated pest and weed management to reduce the quantities of inputs required.
	Nutrient management	Implementing integrated nutrient management by using crop and soil specific nutrient management – guided by soil testing.
	Knowledge transfer	Using knowledge sharing and technology platforms to accelerate the uptake of good agricultural practices.

Improved efficiency – example of precision agriculture

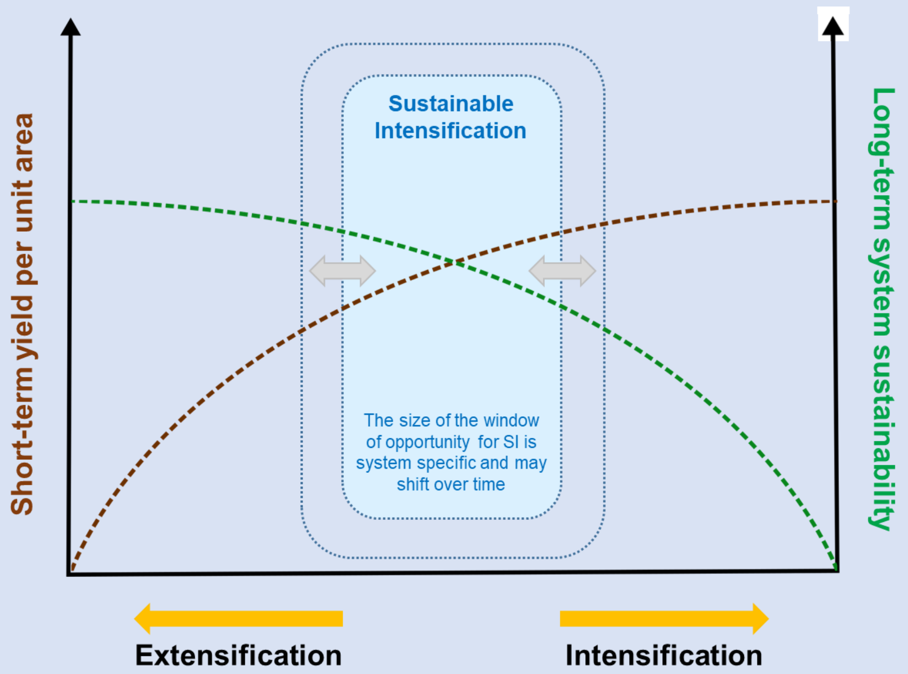
Precision farming usually refers to optimising production in fields through site-specific choices of crop varieties, agrochemical application, precise water management (e.g. in given areas or threshold moistures) and management of crops at a small scale (or livestock as individuals) (Hedley 2015). Precision agriculture has the potential to achieve higher yields in a more efficient and sustainable manner compared with traditional low-precision methods.

Precision agriculture

Precision agriculture is a technologically advanced approach that uses continual monitoring of crop and livestock performance to actively inform management practices. Precise monitoring of crop performance over the course of the growing season will enable farmers to economise on their inputs in terms of water, nutrients and pest management. Therefore, it can contribute to both the food security (by maintaining yields), sustainability (by reducing unnecessary inputs) and land sparing goals associated with SI. The site-specific management of weeds allows a more efficient application of herbicide to specific weed patches within crops (Jensen et al. 2012). Such precision weed control has resulted in herbicide savings of 19 – 22% for winter oilseed rape, 46 – 57% for sugar beet and 60 -77% for winter wheat production (Gutjahr and Gerhards 2010). The use of on-farm sensors for real time management of crop and livestock performance can enhance farm efficiency (Aqeel-Ur-Rehman et al. 2014). Mapping soil nutrition status can allow for more targeted and therefore effective nutrient management practices (Hedley 2015). Using wireless sensors to monitor environmental conditions such as soil moisture, has the potential to allow more efficient crop irrigation (Srbinovska et al. 2015). Controlled traffic farming, where farm machinery is confined to permanent tracks, using automatic steering and satellite guidance, increases yields by minimising soil compaction. However, barriers to the uptake of many of these high-tech precision agriculture technologies remain. In what is described as the 'implementation problem', despite the potential to collect vast quantities of data on crop or livestock performance, applying these data to inform management decisions remains a challenge (Lindblom et al. 2017).

Low-tech precision agriculture

The principle of precision agriculture can be applied equally to low capital-input farming, in the form of low-tech precision agriculture (Conway 2013). The principle is the same but instead of adopting capital-heavy equipment (such as sensor technology connected to the 'internet of things', or large machinery and expensive inputs), farmers use knowledge and experience and innovative approaches often re-purposed, such as a bottle cap as a fertiliser measure for each plant, applied by hand (Mondal and Basu 2009). This type of precision agriculture is particularly relevant to small-scale farming in the global South, where capital investment is major limiting factor. For example, the application of a simple seed priming technique resulted in a 20 to 30% increase in yields of pearl millet and sorghum in semi-arid West Africa (Aune et al. 2017). Low-tech precision agriculture has the potential to increase the economic return per unit land area while also creating new employment opportunities.



Cross-Chapter Box 6, Figure 1 There is a need to balance increasing demands for food, fuel and fibre with long-term sustainability of land use. Sustainable intensification can, in theory, offer a window of opportunity for the intensification of land use without causing degradation. This potentially allows the sparing of land to provide other ecosystem services, including carbon sequestration and the protection of biodiversity. However, the potential for SI is system specific and may change through time (indicated by grey arrows). Current practice may already be outside of this window and be unsustainable in terms of negative impacts on the long-term sustainability of the system

Sustainable intensification through farming system redesign

SI requires equal weight to be placed on the sustainability and intensification components (Benton 2016; Garnett et al. 2013), Cross-Chapter Box 6, Figure 1 outlines the trade-offs which SI necessitates between the intensity of land use against long-term sustainability. One approach to this challenge is through farming system redesign including increased diversification.

Diversification of intensively managed systems

Incorporating higher levels of plant diversity in agroecosystems can improve the sustainability of farming systems (Isbell et al. 2017). Where intensive land use has led to land degradation more diverse land use systems such as intercropping can provide a more sustainable land use option with co-benefits for food security, adaptation and mitigation objectives. For example, in temperate regions, highly productive agricultural grasslands used to produce meat and dairy products are characterised by monoculture pastures with high agrochemical inputs. Multi-species grasslands may provide a route to SI, as even a modest increase in species richness in intensively managed grasslands can result in higher forage yields without increased inputs, such as chemical fertiliser (Finn et al. 2013; Sanderson et al. 2013; Tilman et al. 2011). Recent evidence also indicates multispecies grasslands have greater resilience to drought, indicating co-benefits for adaptation (Hofer et al. 2016; Haughey et al. 2018).

Diversification of production systems

Agroforestry systems (see glossary) can promote regional food security and provide many additional ecosystem services when compared with monoculture crop systems. Co-benefits for mitigation and adaptation include increased carbon sequestration in soils and biomass, improved water and nutrient use efficiency and the creation of favourable micro-climates (Waldron et al. 2017). Silvopasture systems, which combine grazing of livestock and forestry, are particularly useful in reducing land degradation where the risk of soil erosion is high (Murgueitio et al. 2011). Crop and livestock systems can also be combined to provide multiple services. Perennial wheat derivatives produced both high quality forage and substantial volumes of cereal grains (Newell and Hayes 2017), and show promise for integrating cereal and livestock production while sequestering soil carbon (Ryan et al. 2018). A key feature of diverse production systems is the provision of multiple income streams for farming households, providing much needed economic resilience in the face of fluctuation of crop yields and prices.

Landscape Approaches

The land sparing and land sharing approaches which may be used to implement SI are inherently “landscape approaches” (e.g., (Hodgson et al. 2010)). While the term landscape is by no means precise (Englund et al. 2017), landscape approaches, focused for example at catchment scale, are generally agreed to be the best way to tackle competing demands for land (e.g. Sayer et al. 2013), and are the appropriate scale at which to focus the implementation of sustainable intensification. The landscape approach allots land to various uses – cropping, intensive and extensive grazing, forestry, mining, conservation, recreation, urban, industry, infrastructure – through a planning process that seeks to balance conservation and production objectives. With respect to SI, a landscape approach is pertinent to achieving potential benefits for biodiversity conservation, ensuring that land “spared” through SI remains protected, and that adverse impacts of agriculture on conservation land are minimised. Depending on the land governance mechanisms applied in the jurisdiction, different approaches will be appropriate/required. However, benefits are only assured if land use restrictions are devised and enforced.

Summary

Intensification needs to be achieved sustainably, necessitating a balance between productivity today and future potential (*high agreement, medium evidence*). Improving efficiency of agriculture systems can increase production per unit of land through greater resource use efficiency. To achieve SI some intensively managed agricultural systems may have to be diversified as they cannot be further intensified without land degradation. A combination of land sparing and sharing options can be utilised to achieve SI – their application is most likely to succeed if applied using a landscape approach.

5.6.5 Role of urban agriculture

Cities are an important actor in the food system in regard to both demand for food for urban dwellers and production of food in urban and peri-urban areas (see also cross-chapter box 4: Climate Change and Urbanisation in Chapter 2). Both the demand side and supply side roles are important relative to climate change mitigation and adaptation strategies. Urban areas are home to more than half of the world's population, and a minimal proportion of the production; thus, they are important drivers for the development of the complex food systems in place today, in regard to supply chains and dietary preferences.

The increasing separation of urban and rural populations with regard to territory and culture is one of the factors favouring the nutrition transition towards urban diets (Weber and Matthews 2008; Neira et al. 2016). These are primarily based on a high diversity of food products, independent of season and local production, and on the extension of the distances that food travels between production and consumption The transition of traditional diets to more homogeneous diets has also become tied to consumption of animal protein, which has increased GHG emissions globally (see also Section 5.4.6).

Cities are becoming key actors in developing strategies of mitigation to climate change, in their food procurement and in sustainable urban food policies alike (McPhearson et al. 2018). These are being developed by big and medium-sized cities in the world, often integrated within climate change policies (Moragues et al. 2013; Calori and Magarini 2015). A review conducted of 100 cities across the world shows that urban food consumption is one of the largest sources of urban material flows, urban carbon footprint, and land footprint (Goldstein et al. 2017). Additionally, the urban poor have limited capacity to adapt to climate-related impacts, which place their food security at risk under climate change (Dubbeling and de Zeeuw 2011).

Urban and peri-urban areas. In 2010, around 14% of the global population was nourished by food grown in urban and peri-urban areas (Kriewald et al.). A review study on sub-Saharan Africa shows that urban and peri-urban agriculture contributes to climate change adaptation and mitigation (Lwasa et al. 2014, 2015). Urban and peri-urban agriculture reduces food carbon footprint by avoiding long distance food transport and limits GHG emissions by recycling organic waste and wastewater that would otherwise releases methane from landfill and dumping sites (Lwasa et al. 2014). Urban and peri-urban agriculture also contributes in adapting to climate change including extreme events, by reducing urban heat island effect, increasing water infiltration and slowing down run-offs to prevent flooding, etc. (Lwasa et al. 2014, 2015; Kumar et al. 2017a). For example, a scenario analysis shows that urban gardens reduce the surface temperature up to 10°C in comparison to the temperature without vegetation (Tsilini et al. 2015). Urban agriculture can also improve biodiversity and strengthen associated ecosystem services (Lin et al. 2015).

Urban and peri-urban agriculture is exposed to climate risks and urban growth that may undermine its long-term potential to address urban food security (Padgham et al. 2015). Therefore, there is a need to better understand the impact of urban sprawl on peri-urban agriculture; the contribution of urban and peri-urban agriculture to food self-sufficiency of cities; the risks posed by pollutants from urban areas to agriculture and vice-versa; the global and regional extent of urban agriculture; and the role that urban agriculture could play in climate resilience and abating malnutrition (Mok et al. 2014; Hamilton et al. 2014). Globally, urban sprawl is projected to consume 1.8–2.4% and 5% of the current cultivated land by 2030 and 2050 respectively, leading to crop calorie loss of 3–4% and 6–7%, respectively (Pradhan et al. 2014; Bren d'Amour et al. 2017). Kriewald et al. shows that the urban growth has the largest impacts in most of the sub-continents (e.g., Western, Middle, and Eastern Africa) while climate change will mostly reduce potential of urban and peri-urban agriculture in Southern Europe and Northern Africa.

In summary, urban and peri-urban agriculture can contribute to improving urban food security, reducing greenhouse gas emissions, and adapting to climate change impacts *(robust evidence, medium agreement).*

5.6.6 Links to the Sustainable Development Goals

In 2015, the Sustainable Development Goals (SDGs) and the Paris Agreement were two global major international policies adopted by all countries to guide the world to overall sustainability, within the 2030 Sustainable Development Agenda and UNFCCC processes respectively. The 2030 Sustainable Development agenda includes 17 goals and 169 targets, including zero hunger, sustainable agriculture and climate action (United Nations 2015).

This section focuses on intra- and inter-linkages of SDG 2 and SDG 13 based on the official SDG indicators (Figure 5.16), showing the current conditions (see (Roy et al. 2018) and Chapter 7 for further discussion). The second goal (Zero Hunger – SDG 2) aims to end hunger and all forms of malnutrition by 2030 and commits to universal access to safe, nutritious and sufficient food at all times of the year. SDG 13 (Climate Action) calls for urgent action to combat climate change and its impacts. Integrating the SDGs into the global food system can provide opportunities for mitigation and adaptation and enhancement of food security.

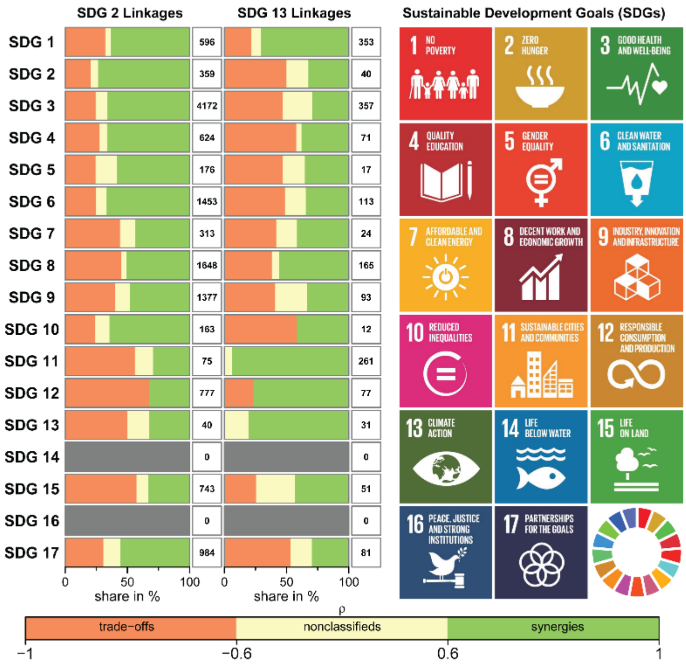


Figure 5.16. Intra and inter-linkages for SDG 2 (*Zero hunger*) and SDG 13 (*Climate action*) at the global level using the official indicators of Sustainable Development Goals that consists data for 122 indicators for a total of 227 countries between the years 1983 and 2016 (United Nations Statistics Division 2016) and applying a statistical approach (Pradhan et al. 2017). Pradhan et al. (2017) defined synergy and trade-offs as significant positive (ρ > 0.6, red bar) and negative (ρ < -0.6, green bar) spearman correlation between SDG indicators, respectively. The ρ between 0.6 and -0.6 is considered as nonclassifieds (yellow bar). The correlation between unique pairs of indicator time-series is carried based on country data, e.g., betweem "prevalence of undernourishment" (an indicator for SDG 2.1) and "maternalmortality ratio" (an indicator for SDG 3.1). The data pairs can belong to the same goal or to two distinct goals. At the global level, intra-linkages of SDGs are quantified by the percentage of synergies, trade-offs, and nonclassifieds of indicator pairs belonging to the same SDG (here, SDG 2 and SDG 13) for all the countries. Similarly, SDG interlinkages are estimated by the percentage of synergies, trade-offs, and nonclassifieds between indicator pairs that fall into two distinct goals for all the countries. The grey bar shows insufficient data for analysis. The number of data pair used for the analysis is presented in the grey box.

Ensuring food security (SDG 2) shows positive relations (synergies) with most goals (Pradhan et al. 2017; International Council for Science (ICSU) 2017), but has trade-offs with SDG 12 (*Responsible Consumption and Production*) and SDG 15 (*Life on Land*) under current development paradigms

(Pradhan et al. 2017). Sustainable transformation of traditional consumption and production approaches can overcome these trade-offs based on several innovative methods (Shove et al. 2012). For example, sustainable intensification and reduction of food waste can minimise the observed negative relations between SDG 2 and other goals (Obersteiner et al. 2016) (see also Cross-Chapter Box 6 and Section 5.5.2). Achieving the target 12.3 of SDG 12 (Responsible Consumption and Production) "by 2030, to halve per capita global food waste at the retail and consumer levels and reduce food losses along production and supply chains, including post-harvest losses" will contribute to climate change mitigation.

Doubling productivity of smallholder farmers and halving food loss and waste by 2030 are targets of SDG 2 and SDG 12, respectively (United Nations Statistics Division 2016). Agroforestry that promotes biodiversity and sustainable land management also contributes to food security (Montagnini and Metzel 2017). Land restoration and protection (SDG 15) can increase crop productivity (SDG 2) (Wolff et al. 2018). Similarly, efficient irrigation practices can reduce water demand for agriculture that could improve health of the freshwater ecosystem (SDG 6 and SDG 15) without reducing food production (Jägermeyr et al. 2017).

Climate action (SDG 13) shows negative relations (trade-offs) with most goals and antagonistic to the 2030 development agenda under the current development paradigm (Figure 5.16) (Lusseau and Mancini 2019; Pradhan 2019). The targets for SDG 13 have a high focus on climate change adaptation and the data for the SDG 13 indicators are limitedly available. SDG 13 shares two indicators with SDG 1 and SDG 11 (United Nations 2017) and therefore, has mainly positive linkages with these two goals. Trade-offs was observed between SDG 2 and SDG 13 for around 50% of the case (Pradhan et al. 2017).

Transformation from current development paradigms and breaking of these lock-in effects can protect climate and achieve food security in future. Sustainable agriculture practices can provide climate change adaptation and mitigation synergies, linking SDG 2 and SDG 13 more positively (International Council for Science (ICSU) 2017). IPCC highlights that most of the current observed trade-offs between SDG 13 and other SDGs can be converted into synergies based on various mitigation options that can be deployed to limit the global warming well below 1.5°C (IPCC 2018b).

In summary, there are fundamental synergies that can facilitate the joint implementation of strategies to achieve SDGs and climate action, with particular reference to those climate response strategies related to both supply side (production and supply chains) and demand side (consumption and dietary choices) described in this chapter (*high agreement and medium evidence*).

5.7 Enabling conditions and knowledge gaps

To achieve mitigation and adaptation to climate change in food systems, enabling conditions are needed to scale up the adoption of effective strategies (such as those described in Sections 5.3 to 5.6 and Chapter 6). These enabling conditions include multi-level governance and multi-sector institutions (Supplementary Material Section SM5.7) and multiple policy pathways (Section 5.7.1, 5.7.2). In this regard, the subnational level is gaining relevance both in food systems and climate change. Just Transitions are needed to address both climate change and food security (Section 5.7.3). Mobilisation of knowledge, education, and capacity will be required (Section 5.7.4) to fill knowledge gaps (Section 5.7.5).

Effective governance of food systems and climate change requires the establishment of institutions responsible for coordinating among multiple sectors (education, agriculture, environment, welfare, consumption, economic, health), levels (local, regional, national, global) and actors (governments, CSO, public sector, private sector, international bodies). Positive outcomes will be enegenderd by participation, learning, flexibility, and cooperation. See Supplementary Material Section SM5.7 for further discussion.

5.7.1 Enabling policy environments

The scope for responses to make sustainable land use inclusive of climate change mitigation and adaptation, and the policies to implement them, are covered in detail in Chapters 6 and 7. Here we highlight some of the major policy areas that have shaped the food system, and might be able to shape responses in future. Although two families of policy – agriculture and trade – have been instrumental in shaping the food system in the past (and potentially have led to conditions that increase climate vulnerability) (Benton and Bailey 2019), a much wider family of policy instruments can be deployed to reconfigure the food system to deliver healthy diets in a sustainable way.

5.7.1.1 Agriculture and trade policy

Agriculture. The thrust of agricultural policies over the last 50 years has been to increase productivity, even if at the expense of environmental sustainability (Benton and Bailey 2019). For example, in 2007-9 46% of OECD support for agriculture was based on measures of output (price support or payments based on yields), 37% of support was based on the current or historical area planted, herd size (or correlated measures of the notional costs of farming), and 13% was payments linked to input prices. In a similar vein, non-OECD countries have promoted productivity growth for their agricultural sectors.

Trade. Along with agricultural policy to grow productivity, the development of frameworks to liberalise trade (such as the General Agreement on Tariffs and Trade (GATT) Uruguay Round, now incorporated into the World Trade Organisation) have been essential in stimulating the growth of a globalised food system. Almost every country has a reliance on trade to fulfil some or all of its local food needs, and trade networks have grown to be highly complex (Puma et al. 2015; MacDonald et al. 2015; Fader et al. 2013; Ercsey-Ravasz et al. 2012). This is because many countries lack the capacity to produce sufficient food due to climatic conditions, soil quality, water constraints, and availability of farmland (FAO 2015b). In a world of liberalised trade, using comparative advantage to maximise production in high-yielding commodities, exporting excess production, and importing supplies of other goods supports economic growth.

City states as well as many small island states, do not have adequate farmland to feed their populations, while sub-Saharan African countries are projected experience high population growth as well as to be negatively impacted by climate change, and thus will likely find it difficult to produce all of their own food supplies (Agarwal et al. 2002). One study estimates that some 66 countries are currently incapable of being self-sufficient in food (Pradhan et al. 2014). Estimates of the proportion of people relying on trade for basic food security vary from ~16% to ~22% (Fader et al. 2013; Pradhan et al. 2014), with this figure rising to between 1.5 and 6 billion people by 2050, depending on dietary shifts, agricultural gains, and climate impacts (Pradhan et al. 2014).

Global trade is therefore essential for achieving food and nutrition security under climate change because it provides a mechanism for enhancing the efficiency of supply chains, reducing the vulnerability of food availability to changes in local weather, and moving production from areas of surplus to areas of deficit (FAO 2018d). However, the benefits of trade will only be realised if trade is managed in ways that maximise broadened access to new markets while minimising the risks of increased exposure to international competition and market volatility (Challinor et al. 2018; Brown et al. 2017b).

As described in Section 5.8.1, trade acts to buffer exposure to climate risks when the market works well. Under certain conditions – such as shocks, or the perception of a shock, coupled with a lack of food stocks or lack of transparency about stocks (Challinor et al. 2018; Marchand et al. 2016) – the market can fail and trade can expose countries to food price shocks.

Furthermore, Clapp (2016) showed that trade, often supported by high levels of subsidy support to agriculture in some countries, can depress world prices and reduce incomes for other agricultural exporters. Lower food prices that result from subsidy support may benefit urban consumers in importing countries, but at the same time they may hurt farmers' incomes in those same countries. The outmigration of smallholder farmers from the agriculture sector across the Global South is significantly attributed to these trade patterns of cheap food imports (Wittman 2011; McMichael 2014; Akram-Lodhi and others 2013). Food production and trade cartels, as well as financial speculation on food futures markets, affect low-income market-dependent populations.

Food sovereignty is a framing developed to conceptualise these issues (Reuter 2015). They directly relate to the ability of local communities and nations to build their food systems, based among other aspects, on diversified crops and indigenous and local knowledge. If a country enters international markets by growing more commodity crops and reducing local crop varieties, it may get economic benefits, but may also expose itself to climate risks and food insecurity by increasing reliance on trade, which may be increasingly disrupted by climate risks. These include a local lack of resilience from reduced diversity of products, but also exposure to food price spikes, which can become amplified by market mechanisms such as speculation.

In summary, countries must determine the balance between locally produced vs imported food (and feed) such that it both minimises climate risks and ensures sustainable food security. There is *medium evidence* that trade has positive benefits but also creates exposure to risks (Section 5.3).

5.7.1.2 Scope for expanded policies

There are a range of ways that policy can intervene to stimulate change in the food system – through agriculture, research and development, food standards, manufacture and storage, changing the food environment and access to food, changing practices to encourage or discourage trade (Table 5.6). Novel incentives can stimulate the market, for example, through reduction in waste or changes in diets to gain benefits from a health or sustainability direction. Different contexts with different needs will require different set of policies at local, regional and national levels. See Supplementary Material Section SM5.7 for further discussion on expanded policies.

Table 5.6 Potential policy "families" for food-related adaptation and mitigation of climate change. The column "scale" refers to scale of implementation: International (I), national (N), sub-national-regional (R), and local (L).

Family	Sub-family	Scale	Interventions	Examples
Supply-side efficiency	Increasing agricultural efficiency and yields	I, N	Agricultural R&D	Investment in research, innovation, knowledge exchange, e.g., on genetics, yield gaps, resilience
		I, N	Supporting precision agriculture	Agricultural engineering, robotics, big data, remote sensing, inputs
		I, N	Sustainable intensification	Soils, nutrients, capital, labour (see

			projects	Cross-Chapter Box 6)
		N, R	Improving farmer training and knowledge sharing	Extension services, online access, field schools, farmer-to-farmer networks (CABI 2019)
	Land use planning	N, R, L	Land use planning for ecosystem services (remote sensing, indigenous and local knowledge	Zoning, protected area networks, multifunctional landscapes, "land sparing" (see Cross-Chapter Box 6; Benton et al. 2018; Jones et al. 2013)
		N, R, L	Conservation agriculture programs	Soil and water erosion control, soil quality improvement (Conservation Evidence 2019)
		N	Payment for ecosystem services	Incentives for farmers/landowners to choose lower-profit but environmentally benign resource use, e.g., Los Negros Valley in Bolivia (Ezzine-de-Blas et al. 2016)
	Market approaches	I, N	Mandated carbon cost reporting in supply chains; public/private incentivised insurance products	Carbon and natural capital accounts (CDP 2019), crop insurance (Müller et al. 2017a)
	Trade	I	Liberalising trade flows; green trade	Reduction in GHG emissions from supply chains (Neumayer 2001)
Raising profitability and quality	Stimulating markets for premium goods	N, R	Sustainable farming standards, agroecology projects, local food movements	Regional policy development, public procurement of sustainable food (Mairie de Paris 2015)
Modifying demand	Reducing food waste	I, N, L	Regulations, taxes	'Pay-As-You-Throw (PAYT)' schemes; EU Landfill Directives; Japan Food Waste Recycling Law 2008; South Africa Draft Waste Classification and Management Regulations 2010 (Chalak et al. 2016)
		I, N, L	Awareness campaigns, education	FAO Global Initiative on Food Loss and Waste Reduction (FAO 2019b)
		I, N	Funding for reducing food waste	Research and investment for shelf life, processing, packaging, cold storage (MOFPI 2019)
		I, N, L	Circular economy using waste as inputs	Biofuels, distribution of excess food to charities (Baglioni et al. 2017)
	Reducing consumptio	I, N, L	Carbon pricing for selected food commodities	Food prices reflective of GHG gas emissions throughout production and

	n of carbon-intensive food			supply chain (Springmann et al. 2017; Hasegawa et al. 2018)
		I, N, L	Changing food choice through education	Nutritional and portion-size labelling, 'nudge' strategies (positive reinforcement, indirect suggestion) (Arno and Thomas 2016)
		I, N, L	Changing food choices through money transfers	Unconditional cash transfers; e-vouchers exchanged for set quantity or value of specific, pre-selected goods (Fenn 2018)
		N, L	Changing food environments through planning	Farmers markets, community food production, addressing 'food deserts' (Ross et al. 2014)
	Combining carbon and health objectives	I, N, L	Changing subsidies, standards, regulations to healthier and more sustainably produced foods	USDA's "Smart Snacks for School" regulation mandating nutritional guidelines (USDA 2016) Incentivising production via subsidies (direct to producer based on output or indirect via subsidising inputs)
		N	Preventative vs curative public health care incentives	Health insurance cost reductions for healthy and sustainable diets
		I, N, L	Food system labelling	Organic certification, nutrition labels, blockchain ledgers (Chadwick 2017)
		N, L	Education and awareness campaigns	School curricula; public awareness campaigns
		N, L	Investment in disruptive technologies (e.g., cultured meat)	Tax breaks for R&D, industrial strategies (European Union 2018)
		N, L	Public procurement	For health: Public Procurement of Food for Health (Caldeira et al. 2017) For environment: Paris Sustainable Food Plan 2015-2020 Public Procurement Code (Mairie de Paris 2015)

In summary, although agriculture is often thought to be shaped predominantly by agriculture and trade policies, there are over twenty families of policy areas that can shape agricultural production directly or indirectly (through environmental regulations or through markets, including by shaping consumer behaviour). Thus, delivering outcomes promoting climate change adaptation and mitigation can arise from policies across many departments, if suitably designed and aligned.

5.7.1.3 Health-related policies and cost savings

The co-benefits arising from mitigating climate change through changing dietary patterns, and thus demand, have potentially important economic impacts (*high confidence*). The gross value added from agriculture to the global economy (GVA) was USD 1.9tn (in 2013 (FAO 2015c)), from a global agriculture economy (GDP) of USD 2.7tn (in 2016). In 2013, the FAO estimated an annual cost of USD 3.5tn for malnutrition (FAO 2013a).

However, this is likely to be an underestimate of the economic health costs of current food systems for several reasons: (1) Lack of data – for example there is little robust data in the UK on the prevalence of malnutrition in the general population (beyond estimates of obesity and surveys of malnourishment of patients in hospital and care homes, from which estimates over 3 million people in the UK are undernourished (BAPEN 2012)); (2) Lack of robust methodology to determine, for example, the exact relationship between overconsumption of poor diets, obesity and non-communicable diseases like diabetes, cardio-vascular disease, a range of cancers or Alzheimer's disease (Pedditizi et al. 2016), (3) Unequal healthcare spending around the world.

In the US, the economic cost of diabetes, a disease strongly associated with obesity and affecting about 23 million Americans, is estimated at USD 327bn in 2017 (American Diabetes Association 2018), with direct healthcare costs of USD 9,600 per person. By 2025, it is estimated that globally there will be over 700 million people with diabetes (NCD-RisC 2016b), over 30 times the number in the US. Even if a global average cost of diabetes per capita were a quarter of that in the US, the total economic cost of diabetes would be approximately the same as global agricultural GDP. Finally, (4) the role of agriculture in causing ill-health beyond dietary health, such as through degrading air quality (e.g., (Paulot and Jacob 2014)).

Whilst data of the healthcare costs associated with the food system and diets are scattered and the proportion of costs directly attributable to diets and food consumption is uncertain, there is potential for more preventative healthcare systems to save significant costs that could incentivise agricultural business models to change what is grown, and how. The potential of moving towards more preventative healthcare is widely discussed in the health economics literature, particularly in order to reduce the life-style-related (including dietary-related) disease component in aging populations (e.g., (Bloom et al. 2015)).

5.7.1.4 Multiple policy pathways

As discussed in more detail in Chapters 6 and 7, there is a wide potential suite of interventions and policies that can potentially enhance the adaptation of food systems to climate change, as well as enhance the mitigation potential of food systems on climate change. There is an increasing number of studies that argue that the key to sustainable land management is not in land management practices but in the factors that determine the demand for products from land (such as food). Public health policy therefore has the potential to affect dietary choice and thus the demand for different amounts of, and types of, food.

Obersteiner et al. (2016) show that increasing the average price of food is an important policy lever that, by reducing demand, reduces food waste, pressure on land and water, impacts on biodiversity and through reducing emissions, mitigates climate change and potentially helps to achieve multiple SDGs. Whilst such policy responses – such as a carbon tax applied to goods including food – has the potential to be regressive, affecting the poor differentially (Frank et al. 2017; Hasegawa et al. 2018;

Kehlbacher et al. 2016), and increasing food insecurity – further development of social safety nets can help to avoid the regressive nature (Hasegawa et al. 2018). Hasegawa et al. (2018) point out that such safety nets for vulnerable populations could be funded from the revenues arising from a carbon tax.

The evidence suggests, as with SR15 (IPCC 2018a) and its multiple pathways to climate change solutions, that there is no single solution that will address the problems of food and climate change, but instead there is a need to deploy many solutions simultaneously adapted to the needs and options available in a given context. For example, Springmann et al. (2018a) indicate that maintaining the food system within planetary boundaries at mid-century, including equitable climate, requires increasing the production (and resilience) of agricultural outputs (i.e., closing yield gaps), reducing waste, and changes in diets towards ones often described as flexitarian (low-meat dietary patterns that are in line with available evidence on healthy eating). Such changes can have significant co-benefits for public health, as well as facing significant challenges to ensure equity (in terms of affordability for those in poverty).

Significant changes in the food system require them to be acceptable to the public ("public license"), or they will be rejected. Focus groups with members of the public around the world, on the issue of changing diets, have shown that there is a general belief that the government plays a key role in leading efforts for change in consumption patterns (Wellesley et al. 2015). If governments are not leading on an issue, or indicating the need for it through leading public dialogue, it signals to their citizens that the issue is unimportant or undeserving of concern

In summary, there is significant potential *(high confidence)* that, through aligning multiple policy goals, multiple benefits can be realised that positively impact public health, mitigation and adaptation (e.g. adoption of healthier diets, reduction in waste, reduction in environmental impact). These benefits may not occur without the alignment across multiple policy areas *(high confidence)*.

5.7.2 Enablers for changing markets and trade

"Demand" for food is not an exogenous variable to the food system but is shaped crucially by its ability to produce, market, and supply food of different types and prices. These market dynamics can be influenced by a variety of factors beyond consumer preferences (e.g., corporate power and marketing, transparency, the food environment more generally), and the ability to reshape the market can also depend on its internal resilience and/or external shocks (Challinor et al. 2018; Oliver et al. 2018)).

5.7.2.1 Capital markets

Two areas are often discussed in regard to role of capital markets in shaping the food system. First, investment in disruptive technologies might stimulate climate-smart food systems (WEF/McKinsey & Company 2018; Bailey and Wellesley 2017), including alternative proteins, such as laboratory or "clean meat" (which has significant ability to impact on land use requirements) (Alexander et al. 2017) (See Section 5.5.1.6). An innovation environment through which disruptive technology can emerge typically requires the support of public policy, whether in directly financing small and emerging enterprises, or funding research and development via reducing tax burdens.

Second, widespread adoption of (and perhaps underpinned by regulation for) natural capital accounting as well as financial accounting are needed. Investors can then be aware of the risk exposure of institutions, which can undermine sustainability through externalising costs onto the environment. The prime example of this in the realm of climate change is the Carbon Disclosure Project, with around 2500 companies voluntarily disclosing their carbon footprint, representing nearly 60% of the world's market capital (CDP 2018).

5.7.2.2 Insurance and re-insurance

The insurance industry can incentivise actors' behaviour towards greater climate mitigation or adaptation, including building resilience. For example, Lloyd's of London analysed the implications of extreme weather for the insurance market, and conclude that the insurance industry needs to examine their exposure to risks through the food supply chain and develop innovative risk-sharing products can make an important contribution to resilience of the global food system (Lloyd 2015).

Many of these potential areas for enabling healthy and sustainable food systems are also knowledge gaps, in that whilst the levers are widely known, their efficacy and the ability to scale-up, in any given context, are poorly understood.

5.7.3 Just transitions to sustainability

Research is limited on how land use transitions would proceed from ruminant production to other socio-ecological farming systems. Ruminants have been associated with humans since the early development of agriculture, and the role of ruminants in many agricultural systems and smallholder communities is substantial. Ruminant production systems have been adapted to a wide range of socioeconomic and environmental conditions in crop, forestry, and food processing settings (Čolović et al. 2019), bioenergy production (de Souza et al. 2019), and food waste recycling (Westendorf 2000). Pasture cultivation in succession to crops is recognised as important to management of pest and diseases cycles and to improve soil carbon stocks and soil quality (Carvalho and Dedieu 2014). Grazing livestock is important as a reserve of food and economic stocks for some smallholders (Ouma et al. 2003).

Possible land-use options for transitions away from livestock production in a range of systems include (a) retain land but reduce investments to run a more extensive production system; (b) change land use by adopting a different production activity; (c) abandon land (or part of the farm) to allow secondary vegetation regrowth (Carvalho et al. 2019; Laue and Arima 2016); and (d) invest in afforestation or reforestation (Baynes et al. 2017). The extensification option could lead to increases rather than decreases in GHG emissions related to reduction in beef consumption. Large-scale abandonment, afforestation, or reforestation would probably have more positive environmental outcomes, but could result in economic and social issues that would require governmental subsidies to avoid decline and migration in some regions (Henderson et al. 2018). Alternative economic use of land, such as bioenergy production, could balance the negative socioeconomic impact of reducing beef output, reduce the tax values needed to reduce consumption, and avoid extensification of ruminant production systems (Wirsenius et al. 2011). However, the analysis of the transition of land use for ruminants to other agricultural production systems is still a literature gap (Cross-Chapter Box 7: Bioenergy and BECCS in mitigation scenarios, in Chapter 6).

Finally, it is important to recognise that, while energy alternatives produce the same function for the consumer, it is questionable that providing the same nutritional value through an optimised mix of dietary ingredients provides the same utility for humans. Food has a central role in human pleasure, socialisation, cultural identity, and health (Röös et al. 2017), including some of the most vulnerable groups, so just transitions and their costs need to be taken into account. Pilot projects are important to provide greater insights for large-scale policy design, implementation, and enforcement.

In summary, more research is needed on how land use transitions would proceed from ruminant production to other farming systems and affect the farmers and other food system actors involved. There is *limited evidence* on what the decisions of farmers under lower beef demand would be.

5.7.4 Mobilising knowledge

Addressing climate change-related challenges and ensuring food security requires all types of knowledge (formal/non-formal, scientific/indigenous, women, youth, technological). Miles et al. (2017) stated that a research and policy feedback that allows transitions to sustainable food systems must have at first a whole system approach. Currently, in transmitting knowledge for food security and land sustainability under climate change there are three major approaches: (1) public technology transfer with demonstration (extension agents); (2) public and private advisory services (for intensification techniques) and; (3) non-formal education with many different variants such as farmers field schools, rural resource centers; facilitation extension where front-line agents primarily work as "knowledge brokers" in facilitating the teaching–learning process among all types of farmers (including women and rural young people), or farmer-to-farmer, where farmers act themselves as knowledge transfer and sharing actors through peer processes.

5.7.4.1 Indigenous and local knowledge

Recent discourse has a strong orientation towards scaling-up innovation and adoption by local farmers. However, autonomous adaptation, indigenous knowledge and local knowledge are both important for agricultural adaptation (Biggs et al. 2013) (See Section 5.3). These involve the promotion of farmer participation in governance structures, research, and the design of systems for the generation and dissemination of knowledge and technology, so that farmers needs and knowledge can be taken into consideration. Klenk et al. (2017) found that mobilisation of local knowledge can inform adaptation decision-making and may facilitate greater flexibility in government-funded research. As an example, rural innovation in terrace agriculture developed on the basis of a local coping mechanism and adopted by peasant farmers in Latin America may serve as an adaptation option or starting place for learning about climate change responses(Bocco and Napoletano 2017). Clemens et al. (2015) found that an open dialogue platform enabled horizontal exchange of ideas and alliances for social learning and knowledge-sharing in Vietnam. Improving local technologies in a participatory manner, through on-farm experimentation, farmer-to-farmer exchange, consideration of women and youths, is also relevant in mobilising knowledge and technologies.

5.7.4.2 Citizen science

Citizen science has been tested as a useful tool with potential for biodiversity conservation (Schmitz et al. 2015) and mobilising knowledge from society. In food systems, knowledge-holders (e.g., farmers and pastoralists) are trained to gather scientific data in order to promote conservation and resource management (Fulton et al. 2019) or to conserve and use traditional knowledge in developed countries relevant to climate change adaptation and mitigation through the use of ICT (Calvet-Mir et al. 2018).

5.7.4.3 Capacity building and education

Mobilising knowledge may also require significant efforts on capacity building and education to scale up food system responses to climate change. This may involve increasing the capacity of farmers to manage current climate risks and to mitigate and adapt in their local contexts, and of citizens and consumers to understand the links between food demand and climate change emissions and impacts, as well as policy makers to take a systemic view of the issues. Capacity building may also require institutional change. For example, alignment of policies towards sustainable and healthy food systems may require building institutional capacity across policy silos.

As a tool for societal transformation, education is a powerful strategy to accelerate changes in the way we produce and consume food. Education refers to early learning and life-long acquisition of skills for higher awareness and actions for solving food system challenges (FAO 2005). Education also entails, vocational training, research and institutional strengthening (Hollinger 2015). Educational focus changes according to the supply side (e.g., crop selection, input resource management, yield improvement, and diversification) and the demand since (nutrition and dietary health implications). Education on food loss and waste spans both the supply and demand sides.

In developing countries, extension learning such as Farmer Field Schools – also known as Rural Resources Centers – are established to promote experiential learning on improved production and food transformation (FAO 2016c). While in developed countries, mass education campaigns are rising to reduce food waste, improved diets or acceptable food, and ultimately changes the structure of food industries that is based on the large-scale food products (Heller 2019; UNCCD 2017).

The design of new education modules from primary to secondary to tertiary education could help create new jobs in the realm of sustainability (e.g., certification programs). For example, one area could be educating managers of recycling programs for food-efficient cities where food and organic waste are recycled to fertilisers (Jara-Samaniego et al. 2017). Research and education need to be coordinated so that knowledge gaps can be filled and greater trust established in shifting behavior of individuals from conventional options to more sustainable ones. Education campaigns can also influence policy and legislation, and help to advance successful outcomes for climate change mitigation and adaptation in regard to supply-side innovations, technologies, trade, and investment, and demand-side evolution of food choices for health and sustainability, and greater gender equality throughout the entire food system. (Heller 2019).

5.7.5 Knowledge gaps and key research areas

Knowledge gaps around options and solutions and their (co-)benefits and trade-offs are increasingly important now that implementation of mitigation and adaptation measures is scaling up.

Research is needed on how a changing climate and interventions to respond to it will affect all aspects of food security, including access, utilisation and stability, not just availability. Knowledge gaps across all the food security pillars are one of the barriers hindering mitigation and adaptation to climate change in the food system and its capacity to deliver food security. The key areas for climate change, food systems, and food security research are enlisted below.

5.7.5.1 Impacts and adaptation

Climate Services (Food availability). Agriculture and food security is a priority area for the Global Framework for Climate Services (GFCS) a program of the World Meteorological Organization (WMO). The GFCS enables vulnerable sectors and populations to better manage climate variability and adapt to climate change (Hansen et al. 2018). Global precipitation datasets and remote sensing technologies can be used to detect local to regional anomalies in precipitation as a tool for devising early-warning systems for drought-related impacts, such as famine (Huntington et al. 2017). Crop model improvements are needed for evapotranspiration to guide crop water management in future climate (Cammarano et al. 2016).

Crop and livestock genetics (Food availability, utilisation). Advances in plant breeding are crucial for enhancing food security under changing climate for a wide variety of crops including fruits and vegetables as well as staples. Genetics improvement is needed in order to breed crops and livestock that can both reduce greenhouse gas emissions, increase drought and heat tolerance (e.g., rice), and enhance nutrition and food security (Nankishore and Farrell 2016; Kole et al. 2015). Many of these characteristics already exist in traditional varieties, including orphan crops and autochthonous breeds, so research in needed to recuperate such varieties and evaluate their potential for adaptation and mitigation.

Phenomics-assisted breeding appears to be a promising tool for deciphering the stress responsiveness of crop and animal species (Papageorgiou 2017; Kole et al. 2015; Lopes et al. 2015; Boettcher et al. 2015). Initially discovered in bacteria and archaea, CRISPR–Cas9 is an adaptive immune system found in prokaryotes and since 2013 has been used as a genome editing tool in plants. The main use of CRISPR systems is to achieve improved yield performance, biofortification, biotic and abiotic stress tolerance, with rice (Oryza sativa) being the most studied crop (Gao 2018; Ricroch et al. 2017).

Climate impact models (Food availability). Understanding the full range of climate impacts on staple crops (especially those important in developing countries), fruits and vegetables is missing in the current climate impact models. Further, CO_2 effects on nutrition quality of different crops are just beginning to be parameterised in the models (Müller et al. 2014). Bridging these gap is essential for projecting future dietary diversity, healthy diets, and food security (Bisbis et al. 2018). Crop model improvements are needed for evapotranspiration to guide crop water management in future climate (Cammarano et al. 2016). Similarly, mores studies are needed to understand the impacts of climate change on global rangelands and livestock and aquaculture, which have received comparatively less attention than the impacts on crop production.

Resilience to extreme events (Food availability, access, utilisation, and stability). On the adaptation side, knowledge gaps include impacts of climate shocks (Rodríguez Osuna et al. 2014) as opposed to impacts of slow-onset climate change, how climate-related harvest failures in one continent may influence food security outcomes in others, impacts of climate change on fruits and vegetables and their nutrient contents.

5.7.5.2 Emissions and mitigation

GHG emissions inventory techniques (Food utilisation). Knowledge gaps include food consumption-based emissions at national scales, embedded emissions (overseas footprints) of food systems, comparison of GHG emissions per type of food systems (e.g., smallholder and large-scale commercial food system), and GHG emissions from land-based aquaculture. An additional knowledge gap is the need for more socio-economic assessments of the potential of various integrated practices to deliver the mitigation potential estimated from a biophysical perspective. While studies often project how much CO_2 could theoretically be sequestered in soil, for instance, there is not yet discussion of the potential for this to be effectively monitored, verified, and implemented, once barriers and incentives to adoption of the techniques, practices, and technologies are considered. Thus, future research needs fill the gaps on evaluation of climate actions in the food system.

Food supply chains (Food availability). The expansion of the cold chain into developing economies means increased energy consumption and GHG emissions at the consumer stages of the food system, but its net impact on GHG emissions for food systems as a whole is complex and uncertain (Heard and Miller 2016). Further understanding of negative side effects in intensive food processing systems is still needed.

Blockchains, as a distributed digital ledger technology which ensures transparency, traceability, and security, is showing promise for easing some global food supply chain management challenges, including the need for documentation of sustainability and the circular economy for stakeholders including governments, communities, and consumers to meet sustainability goals. Blockchain-led transformation of food supply chains is still in its early stages; research is needed on overcoming barriers to adoption (Tripoli and Schmidhuber 2018; Casado-Vara et al. 2018; Mao et al. 2018; Saberi et al. 2019).

5.7.5.3 Synergies and trade-offs

Supply-side and demand-side mitigation and adaptation (Food availability, utilisation). Knowledge gaps exit on potential and risk associated with novel mitigation technologies on supply side (e.g., inhibitors, targeted breeding, cellular agriculture, etc.). Additionally, most integrated assessment models (IAMs) currently have limited regional data on BECCS projects because of little BECCS implementation (Lenzi et al. 2018). Hence, several BECCS scenarios seem to rely on unrealistic assumptions regarding regional climate, soils and infrastructure suitability (Köberle et al. 2019) as well as trade of international trade of bioenergy (Lamers et al. 2011).

Areas for study include how to incentivise, regulate, and raise awareness on the co-benefits of healthy consumption patterns and climate change mitigation and adaptation; to improve access to healthy diets for vulnerable groups through food assistance programs; and to implement policies and campaigns to reduce food loss and food waste. Knowledge gaps also exist on the role of different policies, and underlying uncertainties, to promote changes in food habits towards climate resilience and healthy diets.

Food systems, land use change, and telecoupling (Food availability, access, utilisation). The analytical framework of telecoupling has recently been proposed to address this complexity, particularly the connections, flows, and feedbacks characterising food systems (Friis et al. 2016; Easter et al. 2018). For example, how will climate-induced shifts in livestock and crop diseases affect food production and consumption in the future. Investigating the social and ecological consequences of these changes will contribute to decision making under uncertainty in the future. Research areas include food systems and their boundaries, hierarchies, and scales through metabolism studies, political ecology and cultural anthropology.

Food-Energy-Water Nexus (Food availability, utilisation, stability). Emerging interdisciplinary science efforts are providing new understanding of the interdependence of food, energy, and water systems and these interdependencies are beginning to take into account climate change, food security, and AFOLU assessments (Scanlon et al. 2017; Liu et al. 2017). These science advances, in turn, provide critical information for coordinated management to improve the affordability, reliability, and environmental sustainability of food, energy, and water systems. Despite significant advances within the past decade, there are still many challenges for the scientific community. These include the need for interdisciplinary science related to the food-energy-water nexus; ground-based monitoring and modelling at local-to-regional scales (Van Gaelen et al. 2017); incorporating human and institutional behaviour in models; partnerships among universities, industry, and government to develop policy-relevant data; and systems modelling to evaluate trade-offs associated with food-energy-water decisions (Scanlon et al. 2017). However, the nexus approach, as a conceptual framework, requires the recognition that, although land and the goods and services it provides is finite, potential demand for the goods and services may be greater than the ability to supply them sustainably (Benton et al. 2018). By addressing demand-side issues, as well as supply-side efficiencies, it provides a potential route for minimising trade-offs for different goods and services (Benton et al. 2018) and (Section 5.6).

5.8 Future challenges to food security

A particular concern in regard to the future of food security is the potential for the impacts of increasing climate extremes on food production to contribute to multi-factored complex events such as food price spikes. In this section, we assess literature on food price spikes and potential strategies for increasing resilience to such occurrences. We then assess the potential for such food system events to affect migration and conflict.

5.8.1 Food price spikes

Under average conditions, global food system markets may function well, and equilibrium approaches can estimate demand and supply with some confidence; however, if there is a significant shock, the market can fail to smoothly link demand and supply through price, and a range of factors can act to amplify the effects of the shock, and transmit it across the world (Box 5.5). Given the potential for shocks driven by changing patterns of extreme weather to increase with climate change, there is the potential for market volatility to disrupt food supply through creating food price spikes. This potential is exacerbated by the interconnectedness of the food system (Puma et al. 2015) with other sectors (i.e., the food system depends on water, energy, transport, etc.) (Homer-Dixon et al. 2015), so the impact of shocks can propagate across sectors and geographies (Homer-Dixon et al. 2015). There is also less spare land globally than there has been in the past, such that if prices spike, there are fewer options to bring new production on stream (Marianela et al. 2016).

Increasing extreme weather events can disrupt production and transport logistics. For example, in 2012 the US Corn Belt suffered a widespread drought; US corn yield declined 16% compared to 2011 and 25% compared to 2009. A record yield loss of 2016 in French that is attributed to a conjunction of abnormal warmness in late autumn and abnormal wet in the following spring (Ben-Ari et al. 2018) is another well-documented example. To the extent that such supply shocks are associated with climate change, they may become more frequent and contribute to greater instability in agricultural markets in the future. Furthermore, analogue conditions of past extremes might create significantly greater impacts in a warmer world. A study simulating analogous conditions to the Dustbowl drought in today’s agriculture suggests that Dust-Bowl-type droughts today would have unprecedented consequences, with yield losses about 50% larger than the severe drought of 2012 (Glotter and Elliott 2016). Damages at these extremes are highly sensitive to temperature, worsening by about 25% with each degree centigrade of warming. By mid-century, over 80% of summers are projected to have average temperatures that are likely to exceed the hottest summer in the Dustbowl years (1936) (Glotter and Elliott 2016).

How a shortfall in production – or an interruption in trade due to an event affecting a logistics choke-point (Wellesley et al. 2017) – of any given magnitude may create impacts depends on many interacting factors (Homer-Dixon et al. 015; Tadasse et al. 2016; Challinor et al. 2018). The principal route is by affecting agricultural commodity markets, which respond to a perturbation through multiple routes as in Figure 5.17**Error! Reference source not found.** This includes pressures from ther sectors (such as if biofuels policy is incentivising crops for the production of ethanol, as happened in 2007–2008). The market response can be amplified by poor policies, setting up trade and non-trade barriers to exports, from countries seeking to ensure their local food security (Bailey et al. 2015). Furthermore, the perception of problems can fuel panic buying on the markets that in turn drives up prices.

Thus, the impact of an extreme weather event on markets has both a *trigger* component (the event) and a risk *perception* component (Challinor et al. 2016, 2018). Through commodity markets, prices change across the world because almost every country depends, to a greater or lesser extent, on trade to fulfil local needs. Commodity prices can also affect local market prices by altering input prices, changing the cost of food aid, and through spill-over effects; for example, in 2007–2008 the grain affected by extreme weather was wheat, but there was a significant price spike in rice markets (Dawe 2010).

As discussed by Bailey et al. (2015), there are a range of adaptation measures that can be put in place to reduce the impact of climate-related production shortfalls. These include (a) ensuring transparency of public and private stocks, as well as improved seasonal forecasting to signal forthcoming yield shortfalls (FAO 2016a; Ceglar et al. 2018; Iizumi et al. 2018), (b) building real or virtual stockholdings, (c) increasing local productivity and diversity (as a hedge against a reliance on trade) and (d) ensuring smoother market responses, through, for example, avoiding the imposition of export bans.

In summary, given the likelihood that extreme weather will increase, in both frequency and magnitude (Hansen et al. 2012; Coumou et al. 2014; Mann et al. 2017; Bailey et al. 2015), and the current state of global and cross-sectoral interconnectedness, the food system is at increasing risk of disruption (*medium evidence, medium agreement*), with large uncertainty about how this could manifest. There is therefore a need to build resilience into international trade as well as local supplies.

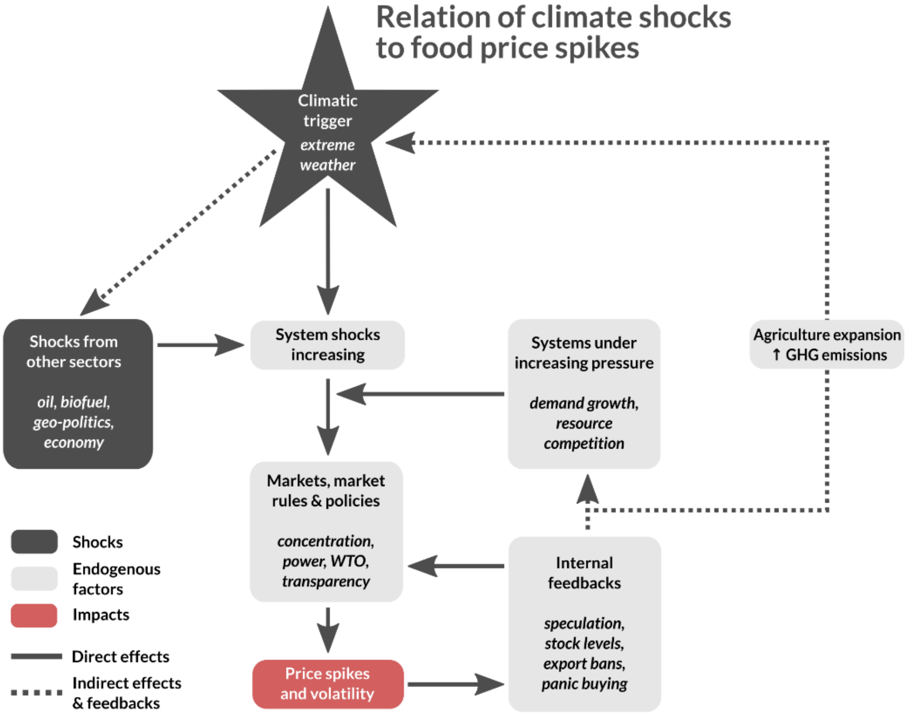

Figure 5.17 Underlying processes that affect the development of a food price spike in agricultural commodity markets (Challinor et al. 2018)

Box 5.5 Market drivers and the consequences of extreme weather in 2010-2011

The 2010–2011 food price spike was initially triggered by the exceptional heat in summer 2010, with an extent from Europe to the Ukraine and Western Russia (Barriopedro et al. 2011; Watanabe et al. 2013; Hoag 2014). The heatwave in Russia was extreme in both temperature (over 40°C) and duration (from July to mid-August in 2010). This reduced wheat yields by approximately one third (Wegren 2011; Marchand et al. 2016). Simultaneously, in the Indus Valley in Pakistan, unprecedented rainfall led to flooding, affecting the lives and livelihoods of 20 million people. There is evidence that these effects were both linked and made more likely through climate change (Mann et al. 2017).

In response to its shortfall in yields, Russia imposed an export ban in order to maintain local food supplies. Other countries responded in a largely uncoordinated ways, each of them driven by internal politics as well as national self-interests (Jones and Hiller 2017). Overall, these measures led to rapid price rises on the global markets (Welton 2011), partly through panic buying, but also through financial speculation (Spratt 2013).

Analysis of responses to higher food prices in the developing world showed that lower-income groups responded by taking on more employment, reducing food intake, limiting expenditures, spending savings (if available), and participating in demonstrations. People often identified their problems as stemming from collusion between powerful incumbent interests (e.g., of politicians and big business) and disregard for the poor (Hossain and Green 2011). This politicised social response helped spark food-related civil protest, including riots, across a range of countries in 2010–2011 (Natalini et al. 2017). In Pakistan, food price rises were exacerbated by the economic impacts of the floods, and which further contributed to food-related riots in 2010.

Price spikes also impact on food security in the developed world. In the UK, global commodity price inflation influenced local food prices, increasing food-price inflation by ~5 times at the end of 2010. Comparing household purchases over the five year period from 2007 to 2011 showed that the amount of food bought declined, on average, by 4.2%, whilst paying 12% more for it. The lowest income decile spent 17% more by 2011 than they did in 2007 (Holding et al. 2013; Tadasse et al. 2016). Consumers also saved money by trading down for cheaper alternatives. For the poorest, in the extreme situation, food became unaffordable: the Trussell Trust, a charity supplying emergency food handouts for people in crisis, noted a 50% increase in handouts in 2010.

5.8.2 Migration and conflict

Since the IPCC AR5 (Porter et al. 2014; Cramer et al. 2014), new work has advanced multi-factor methodological issues related to migration and conflict (e.g., Kelley et al. 2015, 2017; Werrell et al. 2015; Challinor et al. 2018; Pasini et al. 2018). These in particular have addressed systemic risks to food security that result from cascading impacts triggered by droughts and floods and how these are related to a broad range of societal influences.

Climate variability and extremes have short-, medium- and long-term impacts on livelihoods and livelihood assets – especially of the poor – contributing to greater risk of food insecurity and malnutrition (FAO et al. 2018). Drought threatens local food security and nutrition and aggravates humanitarian conditions, which can trigger large-scale human displacement and create a breeding ground for conflict (Maystadt and Ecker 2014). There is *medium agreement* that existing patterns of conflict could be reinforced under climate change affecting food security and livelihood opportunities, for example, already fragile regions with ethnic divides such as North and Central Africa as well as Central Asia (Buhaug 2016; Schleussner et al. 2016) (Box 5.6).

Challinor et al. (2018) have developed a typology for transboundary and transboundary risk transmission that distinguishes the roles of climate and social and economic systems. To understand these complex interactions, they recommend a combination of methods that include expert judgement; interactive scenario building; global systems science and big data; and innovative use of climate and integrated assessment models; and social science techniques (e.g., surveys, interviews, and focus groups).

5.8.2.1 Migration

There has been a surge in international migration in recent years, with around five million people migrating permanently in 2016 (OECD 2017). Though the initial driver of migration may differ across populations, countries and contexts, migrants tend to seek the same fundamental objective: to provide security and adequate living conditions for their families and themselves. Food insecurity is a critical ‘push’ factor driving international migration, along with conflict, income inequality, and population growth. The act of migration itself causes food insecurity, given the lack of income opportunities and adverse conditions compounded by conflict situations.

Warner et al. (2012) found the interrelationships between changing rainfall patterns, food and livelihood security in eight countries in Asia, Africa and Latin America. Several studies in Africa have found that persistent droughts and land degradation contributed to both seasonal and permanent migration (Gray 2011; Gray and Mueller 2012; Hummel 2015; Henry et al. 2004; Folami and Folami 2013), worsening contextual vulnerability conditions of different households (Dasgupta et al. 2014).

Dependency on rainfed agriculture is from 13% in Mexico to more than 30% in Guatemala, Honduras, and Nicaragua, suggesting a high degree of sensitivity to climate variability and change, and undermined food security (Warner et al. 2009). Studies have demonstrated that Mexican migration (Feng et al. 2010; Nawrotzki et al. 2013) and Central American migration (WFP 2017) fluctuate in response to climate variability. The food system is heavily dependent on maize and bean production and long-term climate change and variability significantly affect the productivity of these crops and the livelihoods of smallholder farmers (WFP 2017). In rural Ecuador, adverse environmental conditions prompt out-migration, although households respond to these challenges in diverse ways resulting in complex migratory responses (Gray and Bilsborrow 2013).

Migration patterns have been linked to heat stress in Pakistan (Mueller et al. 2014) and climate variability in the Sundarbans due to decline in food security (Guha and Roy 2016). In Bangladesh, the impacts of climate change have been on the rise throughout the last three decades with increasing migration, mostly of men leaving women and children to cope with increasing effects of natural disasters (Rabbani et al. 2015).

Box 5.6 Migration in the Pacific region: Impacts of climate change on food security

Climate change-induced displacement and migration in the Pacific has received wide attention in the scientific discourse (Fröhlich and Klepp 2019). The processes of climate change and their effects in the region have serious implications for Pacific Island nations as they influence the environments that are their ‘life-support systems’ (Campbell 2014). Climate variability poses significant threats to both agricultural production and food security. Rising temperatures and reductions in groundwater availability, as well as increasing frequency and severity of disaster events translate into substantial impacts on food security causing human displacement, a trend that will be aggravated by future climate impacts (ADB 2017). Declining soil productivity, groundwater depletion, and non-availability of freshwater threatens agricultural production in many remote atolls.

Many countries in the Pacific devote a large share of available land area to agricultural production. For example, more than 60% of land area is cultivated in the Marshall Islands and Tuvalu and more than 40% in Kiribati and Tonga. With few options to expand agricultural area, the projected impacts of climate change on food production are of particular concern (ADB 2013, 2017). The degradation of available land area for traditional agriculture, adverse disruptions of agricultural productivity and diminishing livelihood opportunities through climate change impacts leads to increasing poverty and food insecurity, incentivising migration to urban agglomerations (ADB 2017; FAO et al. 2018).

Campbell (2014) describe the trends that lead to migration. First, climate change, including sea level rise, affect communities’ land security, which is the physical presence on which to live and sustain livelihoods. Second, they impinge on livelihood security (especially food security) of island communities where the productivity of both subsistence and commercial food production systems is reduced. Third, the effects of climate change are especially severe on small-island environments since they result in declining ecological habitat. The effects on island systems are mostly manifested in atolls through erosion and inundation, and on human populations through migration. Population growth and scenarios of climate change is *likely* to further induce food stress as impacts unfolds in coming decades (Campbell 2015).

While the populations of several islands and island groups in the Pacific (e.g., Tuvalu, Carteret Islands, and Kiribati) have been perceived as the first probable victims of rising seas so that their inhabitants would become, and in some quarters already are seen to be, the first 'environmental' or 'climate change refugees,' migration patterns vary. Especially in small islands, the range and nature of the interactions among economic, social, and/or political drivers are complex. For example, in the Maldives, Stojanov et al. (2017) show that while collective perceptions support climate change impacts as being one of the key factors prompting migration, individual perceptions give more credence to other cultural, religious, economic or social factors.

In the Pacific, Tuvalu has long been a prime candidate to disappear due to rising sea level, forcing human migration. However, results of a recent study (Kench et al. 2018) challenge perceptions of island loss in Tuvalu, reporting despite sea level rise, a net increase in land area of 73.5 ha. The findings suggest that islands are dynamic features likely to persist as habitation sites over the next century, presenting opportunities for adaptation that embrace the heterogeneity of island types and processes. Farbotko (2010) and Farbotko and Lazrus (2012) present Tuvalu as a site of 'wishful sinking,' in the climate change discourse. These authors argue that representations of Tuvalu as a laboratory for global climate change migration are visualisations by non-locals.

In Nanumea (Tuvalu), forced displacements and voluntary migrations are complex decisions made by individuals, families and communities in response to discourses on risk, deteriorating infrastructure and other economic and social pressures (Marino and Lazrus 2015). In many atoll nations in western Pacific, migration has increasingly become a sustainable livelihood strategy, irrespective of climate change (Connell 2015).

In Lamen Bay, Vanuatu, migration is both a cause and consequence of local vulnerabilities. While migration provides an opportunity for households to meet their immediate economic needs, it limits the ability of the community to foster longer-term economic development. At the same time, migration adversely affects the ability of the community to maintain food security due to lost labour and changing attitudes towards traditional ways of life among community members (Craven 2015).

Small islands are very sensitive to climate change impacts (*high confidence*) (Nurse et al. 2014) and impacted by multiple climatic stressors (see (IPCC 2018a) and SROCC). Food security in the Pacific, especially in Micronesia, has worsened in the past half century and climate change is *likely* to further hamper local food production, especially in low-lying atolls (Connell 2016) Migration in small islands (internally and internationally) occurs for multiple reasons and purposes, mostly for better livelihood opportunities (*high confidence*).

Beyond sea level rise, effects of increasing frequency and intensity of extreme events such as severe tropical cyclones are *likely* to affect human migration in the Pacific (Connell 2015; Krishnapillai and Gavenda 2014; Charan et al. 2017; Krishnapillai 2017). On Yap Island, extreme weather events are affecting every aspect of atoll communities' existence, mainly due to islands' small size, their low elevation, and extensive coastal areas (Krishnapillai 2018). Displaced atoll communities on Yap Island grow a variety of nutritious vegetables and use alternative crop production methods such as small-plot intensive farming, raised bed gardening, as part of a community-based adaptation program (Krishnapillai and Gavenda 2014; Krishnapillai 2018).

Recurrences of natural disasters and crises threaten food security through impacts on traditional agriculture, causing the forced migration and displacement of coastal communities to highlands in search of better living conditions. Although considerable differences occur in the physical manifestations of severe storms, such climate stressors threaten the life-support systems of many atoll communities (Campbell et al. 2014). Failure of these systems resulting from climate disasters propel vulnerable atoll communities into poverty traps, and low adaptive capacity could eventually force these communities to migrate.

5.8.2.2 Conflict

While climate change will not alone cause conflict, it is often acknowledged as having the potential to exacerbate or catalyse conflict in conjunction with other factors. Increased resource competition can aggravate the potential for migration to lead to conflict. When populations continue to increase, competition for resources will also increase, and resources will become even scarcer due to climate change (Hendrix and Glaser 2007). In agriculture-dependent communities in low-income contexts, droughts have been found to increase the likelihood of violence and prolonged conflict at the local level, which eventually pose a threat to societal stability and peace (FAO et al. 2017). In contrast, conflicts can also have diverging effects on agriculture due to land abandonment, resulting in forest growth, or agriculture expansion causing deforestation, e.g., in Colombia (Landholm et al. 2019).

Several studies have explored the causal links among climate change, drought, impacts on agricultural production, livelihoods, and civil unrest in Syria from 2007-2010, but without agreement as to the role played by climate in subsequent migration (Kelley et al. 2015, 2017; Challinor et al. 2018; Selby et al. 2017; Hendrix 2018). Contributing factors that have been examined include rainfall deficits, population growth, agricultural policies, and influx of refugees that had placed burdens on the region's water resources (Kelley et al. 2015). Drought may have played a role as a trigger, as this drought was the longest and the most intense in the last 900 years (Cook et al. 2016; Mathbout et al. 2018). Some studies linked the drought to widespread crop failure, but the climate hypothesis has been contested (Selby et al. 2017; Hendrix 2018). Recent evidence shows that the severe drought triggered agricultural collapse and displacement of rural farm families with approximately 300,000 families going to Damascus, Aleppo and other cities (Kelley et al. 2017).

Persistent drought in Morocco during the early 1980s resulted in food riots and contributed to an economic collapse (El-Said and Harrigan 2014). A drought in Somalia that fuelled conflict through livestock price changes, establishing livestock markets as the primary channel of impact (Maystadt and Ecker 2014). Cattle raiding as a normal means of restocking during drought in the Great Horn of Africa led to conflict (ICPAC and WFP 2017) whereas a region-wide drought in northern Mali in 2012 wiped out thousands of livestock and devastated the livelihoods of pastoralists, in turn swelling the ranks of armed rebel factions and forcing others to steal and loot for survival (Breisinger et al. 2015).

On the other hand, inter-annual adjustments in international trade can play an important role in shifting supplies from food surplus regions to regions facing food deficits which emerge as a consequence of extreme weather events, civil strife, and/or other disruptions (Baldos and Hertel 2015). A more freely functioning global trading system is tested for its ability to deliver improved long run food security in 2050.

In summary, given increasing extreme events and global and cross-sectoral interconnectedness, the food system is at increasing risk of disruption, e.g., via migration and conflict (*high confidence*). {5.2.3, 5.2.4}

Frequently Asked Questions

FAQ 5.1 How does climate change affect food security?

Climate change negatively affects all four pillars of food security: availability, access, utilisation and stability. Food availability may be reduced by negative climate change impacts on productivity of crops, livestock and fish, for instance due to increases in temperature and changes in rainfall patterns. Productivity is also negatively affected by increased pests and diseases, as well as changing distributions of pollinators under climate change. Food access and its stability may be affected through disruption of markets, prices, infrastructure, transport, manufacture, and retail, as well as direct and indirect changes in income and food purchasing power of low-income consumers. Food utilisation may be directly affected by climate change due to increases in mycotoxins in food and feed with rising temperatures and increased frequencies of extreme events, and indirectly through effects on health. Elevated atmospheric CO_2 concentrations can increase yields at lower temperature increases, but tend to decrease protein content in many crops, reducing their nutritional values. Extreme events, e.g., flooding, will affect the stability of food supply directly through disruption of transport and markets.

FAQ 5.2 How can changing diets help address climate change?

Agricultural activities emit substantial amounts of greenhouse gases (GHGs). Food supply chains activities past the farm gate (e.g., transportation, storage, packaging) also emit GHGs, for instance due to consumption of energy. GHG emissions from food production vary across food types. Producing animal-sourced food (i.e., meat and dairy) emits larger amount of GHGs than growing crops, especially in intensive, industrial livestock systems. This is mainly true for commodities produced by ruminant livestock such as cattle, due to enteric fermentation processes that are large emitters of methane. Changing diets towards a lower share of animal-sourced food, once implemented at scale, reduces the need to raise livestock and changes crop production from animal feed to human food. This reduces the need for agricultural land compared to present and thus generates changes in the current food system. From field to consumer this would reduce overall GHG emissions. Changes in consumer behaviour beyond dietary changes can also have, at scale, effects on overall GHG emissions from food systems. consuming regional and seasonal food can reduce GHG emissions, if they are grown efficiently.

Supplementary Material

Section SM5.1

Table SM5.1 A gendered approach to understanding how climate change affects dimensions of food security across pastoral and agro-pastoral livestock-holders (adapted from McKune et al. (2015); Ongoro and Ogara (2012) and Fratkin et al. (2004). ↑ increased, ↓ decreased

Group	Livelihoods	Health	Nutrition
Pastoral	↑ time demand on *women* and *girls* for water, fuel collection ↑ time demand on *men* to seek out water sources with herd ↑ *men* exposure to attacks from other groups ↑ *men* migration resulting in ↑ *women* workload ↑ productive and reproductive demands on *women* ↓ financial autonomy of *women* due to liquidation of small animal assets ↑ women poverty due to livestock losses of men	↑ disease risk due to proximity of *women's* work to disease agents ↑ *children* health and growth due to reduced milk consumption ↑ *women* and *girls* exposure to insecurity and dangers when looking for water ↑ *women* and *children* vulnerability to water-borne diseases ↑ vulnerability to *maternal mortality* due to ↑ fertility due to sedentarisation ↓ mental and emotional health due to increased stress/loss of social support for both *men and women* ↑ vulnerability of newly sedentarized households, particularly *women*	↑ undernutrition of *men and women* due to ↓ availability of plant and animal foods ↑ undernutrition of *men and women* due to separation of from milk-producing animals ↑ undernutrition in *men and women* due to unfavorable trade-offs in diet between animal products and grains ↑ risk of food insecurity I *men and women* due to ↓ production of livestock and ↑ prices
Agro-pastoral	↑ time demand on *women* due to migration of men for herding or wage labor ↓ financial autonomy of *women* due to liquidation of small animal assets ↑ constraints on herd management due to shifts in responsibilities ↑ susceptibility to market	Earlier weaning, shortened birth intervals, and risk of *maternal depletion* ↑ incidence of anemia and stunting in *children* ↑ susceptibility to infectious diseases that are sensitive to climate change in both *men and women* ↑ *child* mortality rates	↑ exposure of *men and women* to foods that have become spoiled Less varied and less nutritious diets for *men and women* ↑ malnutrition, including overnutrition, in *men and women*

	fluctuations		

1 **Section SM5.2**

2 Table SM5.2 Impacts of selected climate drivers on food security pillars.

Food security pillar	Driver of climate change	Process	Impact	Reference
Availability	Increase in temperature	• Increased water demand • Increased heat and drought stress • Shorter growing period • More frequent heat wave • Terminal heat • Reduced grain filling period • Decreased soil fertility • Land degradation • Higher pre-harvest loss due to disease and pest attack • Negative effects on physiological processes	Decreased crop yield and animal performance	Zhao et al. (2017) Asseng et al. (2015) Myers et al. (2017) Ovalle-Rivera et al. (2015) Rosenzweig et al. (2014) Medina et al. (2017) Paterson and Lima (2011) Schlenker and Roberts (2009)
	CO_2 concentration	• Increased photosynthesis in C3 crops • Increased water use efficiency	Increased crop yield	Franzaring et al. (2013) Mishra and Agrawal (2014) Myers et al. (2014) Ishigooka et al. (2017) Zhu et al. (2018) Loladze (2014) Yu et al. (2014)
	Precipitation (untimely, erratic, decreased)	• Drought and heat stress • Crop failure • Land degradation • Reduced soil fertility	Decreased crop yield and pasture stocking rates and animal performance	Leng and Hall (2019) Zscheischler et al. (2018) Meng et al. (2016) Zimmerman et al. (2017) FAO et al. (2018)

	Extreme events (drought, flood, cyclones etc.)	• Decrease in organic matter • Soil erosion • Crop failure • Disruption of distribution and exchange	Decreased crop yield Increased livestock mortality Decreased distribution and exchange	Leng and Hall (2019) Rivera-Ferre (2014)
Access	Increase in Temperature	• Increase in price • Loss of agricultural income • Disproportionate impact on low-income consumers	Increased food price and reduced purchasing power	Morris et al. (2017) Vermeulen et al. (2012) Abid et al. (2016) Harvey et al. (2014) UNCCD (2017)
	Precipitation (untimely, erratic, decreased)	• Low yield, price increase • Loss of agricultural income due to reduced yield and productivity • Decrease in barley yield • Inability to invest in adaptation and diversification measures to endure price rises	Increased food price and reduced purchasing power	FAO (2016) Kelley et al. (2015) Morris et al. (2017) Vermeulen et al. (2012) Abid et al. (2016) Harvey et al. (2014) UNCCD (2017)
	Extreme Events (drought, flood, cyclones etc.)	• Price increase due to low yield or sporadic crop failure • Loss of agricultural income	Increased food price and reduced purchasing power	Valin et al. (2014) Robinson et al. (2014) Nelson et al. (2013) Schmitz et al. (2014)
Utilization	Increase in Temperature	• Decreased in nutritional content • Increased mycotoxins • Reduced water quantity and	Reduced quality	Tirado and Meerman (2012) Aberman and Tirado (2014) Thompson et al. (2012)

		quality to prepare food • Negative impact on food safety • Higher post-harvest loss both in quantity and quality		
	CO_2 Concentration	• Decreased protein content • Less zinc content • Less iron content • Increased biomass but reduced multiple nutrients • Less radiation interception and less biomass production	Reduced quality	Myers et al. (2014) Smith et al. (2017) Myers et al. (2015) Medek et al. (2017) Bahrami et al. (2017) Rosenzweig and Hillel (2015)
	Extreme Events (drought, flood, cyclones etc.)	• Adverse weather affects food storage and distribution	Reduced quality	Wellesley et al. (2017) Thompson et al. (2012)
Stability	Increase in Temperature	• Disruption of food supply	Fluctuation in production, supply and price	Allen et al. (2017) Tigchelaar et al. (2018)
	Precipitation (untimely, erratic, decreased)	• Disruption of food supply • Yield variability • Fluctuation in yield, supply and price • Crop failure due to extreme drought	Fluctuation in production, supply and price	Schmidhuber and Tubiello (2007) Kelley et al. (2015) Selby et al. (2017) Kelley et al. (2017) Medina-Elizalde and Rohling (2012)

	Extreme Events (drought, flood, cyclones etc.)	• Impacts on world market export prices that carry through to domestic consumer prices • Widespread crop failure contributing to migration and conflict • Disruption of food supply due to civil disturbance and social tension	Fluctuation in production, supply and price	Kelley et al. (2015) Willenbockel (2012) Hendrix (2018) Selby et al. (2017) Kelley et al. (2017)

Detection and attribution methods

Observed impacts of climate change on food security have been noted as a cause of concern (HLPE 2012) and assessed in AR5 (Porter et al. 2014; Cramer et al. 2014) and SR15 (IPCC 2018). Assessing evidence for detection and attribution of observed climate change impacts on the food system remains a challenge because agriculture is a managed system with practices changing over time. Using AR5 and SR15 findings that observed climate changes attributable to human influence include rising temperatures, increases in the intensity and frequency of hot days and nights, more areas with increases than decreases in the frequency, intensity, and or amount of heavy precipitation, and drying trends in some regions especially in the Mediterranean region (including southern Europe, northern Africa and the Near East), we assess recent studies of observed climate change impacts on the food system that utilise IPCC attribution methods (Hegerl et al. 2010), as well as others that depend on local knowledge from the developing world.

New work has addressed observed climate effects on expanded aspects of the food system, including pastoral systems (Rasul et al. 2019; Abiona et al. 2016), pests, diseases, and pollinators (Bebber et al. 2014; Schweiger et al. 2010), and adaptation (Li et al. 2017) (see Section 5.3). Surveys of farmer perceptions of climate changes and their impacts are being increasingly utilised in developing countries for example (Hussain et al. 2016) (Ifeanyi-obi et al. 2016; Onyeneke 2018).

Improvements in projection methods since AR5

Since AR5, methods for assessment of future climate change impacts on food systems have improved in several areas, providing new insights. These methods include greater number of ensembles of multiple climate, crop, and economic models, with improved characterisation of uncertainty (Wiebe et al. 2015); further comparison of results from process-based crop models and statistical models (Zhao et al. 2017); advances in regional integrated assessments (Rosenzweig and Hillel 2015), and new coordinated global and regional studies (Rosenzweig et al. 2017; Ruane et al. 2018). Temperature response functions in crop models have been improved (Wang et al. 2017).

Expanded meta-analyses of free-air carbon dioxide experiments (FACE) have examined effects of high CO_2 on crop nutrients not just on yield (Smith and Myers 2018; Zhu et al. 2018) (Section 5.2.4.2). Recent reviews have confirmed that higher CO_2 concentrations increase crop growth and yield, especially in crops with C3 photosynthetic pathways, but realisation of these direct CO_2 effects depends on nutrient and water availability (Lombardozzi et al. 2018; Toreti et al.; Uddin et al. 2018) *(high confidence)*. New work has considered future impacts of farming systems, extreme events, fruits and vegetables, rangelands and livestock, and aquaculture, as well as food safety, pests and diseases, and food quality (Section 5.2).

However, several sources of uncertainty exist in projection of climate change crop impacts, partly stemming from differences between the models and methods utilised, sparse observations related to current climate trends, and other agro-ecosystem responses (e.g., to CO_2 effects) (Mistry et al. 2017; Li et al. 2015; Bassu et al. 2014; Asseng et al. 2013). The uncertainty in climate simulations is generally larger than, or sometimes comparable to, the uncertainty in crop simulations using a single model (Iizumi et al. 2011), but is less than crop model uncertainty when multiple crop models are used as in AgMIP (Rosenzweig et al. 2014b) and CO_2 is considered (Hasegawa et al. 2018; Müller et al. 2014; Asseng et al. 2013).

Most of the work on projected impacts on climate change impacts on crops continues to focus on the major commodities-wheat, maize, rice, and soybean-while areas still lagging are multi-model ensemble approaches for livestock and fruits and vegetables. While the current reliance on the four major commodities makes assessment of climate change impacts on them important, there is a growing recognition that more than caloric intake is required to achieve food security for all and that assessments need to take into account how climate change will affect the 2 billion malnourished people in the current climate and food system.

Table SM5.3 Observed climate change impacts on crop production, data sources, and detection and attribution methods

Climate observations	Climate data source	Observed impacts	Impact method/source	Time period	Region	Detection &Attribution method	Reference	Continent
Warming temperatures	Chinese Meteorological Administration	If 1980 variety was still grown, maize yield would stagnate or decrease; due to adoption of maize varieties with long growth period yield increased by 7-17% per decade.	China Agricultural Database	1980-2009	Heilongjiang Province, Northeast China	Single step attribution	(Meng et al. 2014)	Asia
Warming temperatures	Chinese Meteorological Administration	Changes in winter wheat phenology; observed dates of sowing, emergence, and beginning of winter dormancy were delayed by 1.2, 1.3, and 1.2 days per decade. Dates of regrowth after dormancy, anthesis, and maturity advanced 2.0, 3.7, and 3.1 days per decade. Growth duration, overwintering period, and vegetation phase shortened by 4.3, 3.1, and 5.0 days per decade. Section SM5.5

Livestock mitigation strategies

Intensification of animal diets. It is well established that appropriate diet regimes may contribute to reduce the amount of GHG produced per unit of animal product (Gerber et al. 2013b), which, within the appropriate implementation including governance, may lead to mitigation of absolute emissions. This increased efficiency can be achieved through improved supplementation practices or through land use management with practices like improved pasture management, including grazing rotation, fertiliser applications, soil pH modification, development of fodder banks, improved pasture species, use of legumes and other high protein feeds, the use of improved crop by-products and novel feeds (i.e., black soldier fly meal, industrially produced microbial protein (Pikaar et al. 2018).

When done through increased feeding of grains, transition to improved diets shifts the contributions of different GHG gases to the total emissions. This is due to the fact that the proportion of methane to total emissions is reduced (due to lower roughage intake), while the proportion of emissions associated with feed manufacture (energy and land use change) increases. Therefore, CO_2 emissions from land use change increase while methane emissions per unit of output decrease (Gill et al. 2010). As a consequence, the quantified benefits of a given strategy wil also depend on the assumed GWP of methane.

Of the available livestock GHG mitigation options, improved feeding systems are relatively easy to implement at the farm level. A prerequisite for these options to work is that the livestock systems need to be geared towards market-oriented production, as otherwise there is little incentive to improve feeding systems. This in turn implies that costs and benefits to farmers are appropriate to incentivise specific management changes and also assess the impact that market-orientation may have in some societies, such as pastoralists (López-i-Gelats et al. 2016). Examples of where this option could be applicable are smallholder dairy-crop mixed systems in Africa and Asia, dual-purpose and dairy production in Latin America and beef cattle operations, where significant mitigation opportunities exist. Other mitigation options include manipulation of rumen microflora, breeding for lower methane production, and the use of feed additives (Hristov et al. 2013).

The largest GHG efficiency gaps are observed in livestock systems where the quality of the diet is the poorest (i.e., grassland-based and some arid and humid mixed systems in the developing world). The highest marginal gains of improving animal diets through simple feeding practices, both biologically and economically, are in these systems (FAO, 2013; Herrero et al. 2013).

Control of animal numbers, shifts in breeds, and improved management. Increases in animal numbers are one of the biggest factors contributing directly to GHG emissions (Tubiello, 2019). Regions with intensive animal production, such as concentrated animal feeding operations (CAFOs), can control animal numbers, conduct breeding programs for efficient animals, and improve feeding management. In the developing world, many low-producing animals could be replaced by fewer but better-fed cross-bred animals of a higher potential, with improved grazing management (i.e., attention to feed, herbage availability, and allowances) playing an important role. In both developed and developing countries these practices are able to reduce total emissions while maintaining or increasing the supply of livestock products.

However, attention must be paid to synergies and trade-offs between livelihoods and specific mitigation strategies, such as controlling animal numbers, recognising the multiple objectives that livestock raising may contribute to within specific settings, especially in low-input systems. Improvements in animal health can also significantly reduce emissions intensity by improved yields and fertility per animal and reductions in mortality (ADAS 2015).

Changes in livestock species. Switching species to better suit particular environments is a strategy that could yield higher productivity per animal for the resources available. At the same time, structural changes in the livestock sector from beef to sheeps and goats, or mainly from ruminants to monogastrics (e.g., from beef to pig or poultry production) could lead to reduced methane emissions and higher efficiency gains. Assessment done using integrated assessment models (IAMs) have shown that these practices could lead to reductions in land use change and its associated emissions (Havlik et al. 2014; Frank et al. 2018).

Managing nitrous oxide emissions from manure. In the developing world, large amounts of nutrients are lost due to poor manure management. In currently adopted feeding systems, large amounts of nutrients and carbon are lost in connection with manure storage (e.g., Herrero et al. 2013). In many places pig manure is not recycled; considered a waste, it is often discharged to water bodies or left to accumulate unused. Yet these farming systems can be highly N and P limited. This practice creates serious problems especially in urban and peri-urban systems by contributing to water and air pollution. Research in intensive African ruminant livestock systems, for instance, has shown that up to 70% of the manure N can be lost within six months of excretion when manure is poorly managed (Tittonell et al. 2009).

Options to manage emissions in the livestock sector are not easy to design because they require systems thinking and awareness of key driving factors in different livestock systems. Reducing N emissions starts with feeding livestock balanced diets so that excreta are not rich in labile N, which is easily lost as ammonia and enters the N cascade (Bouwman et al. 2013). In intensive systems, mineral N can be captured effectively using bedding material, which has been increasingly excluded from livestock facilities to reduce operational costs.

Manure is increasingly handled as slurry in tanks or anaerobic lagoons, which may reduce direct nitrous oxide emissions during storage but can increase methane and ammonia loss and also increase the risk of emissions during land spreading (Velthof and Mosquera 2011). However, optimising land spreading of manures (in terms of timing or placement) to maximise N and P replacement value can minimise ammonia losses while also displacing mineral fertiliser (Bourdin et al. 2014).

In intensive systems, emissions of ammonia and nitrous oxide can be managed by spatially shifting livestock pens or the facilities where they overnight. Other options in more-intensive grazing systems may include nitrification inhibitors, stand-off pads, delayed manure spreading collected in milking sheds, although the fate of the full applied N and its partitioning between direct and indirect emissions as a result of the specific option chosen must be evaluated (e.g., Lam et al., 2017)

Uncertainties in demand-side technical mitigation potential

There are several unresolved issues regarding modelling and quantification of marginal emissions identified in the literature. Diet shift studies often focus on beef production emission intensities, although the cattle industry in many locations includes both meat and dairy production; these activities may be integrated in different types of farming systems (Flysjö et al. 2012) with significantly lower emission intensities (Gerber et al. 2013a; Flysjö et al. 2012). Links between ruminant meat production, the dairy sector (primarily cows and goats), and wool production in sheep are often overlooked in diet shift studies. FAOStat 2017 data indicate there are 278 million dairy cows worldwide, which make significant contributions to meat production (304 million head slaughtered per year) by providing calves (lactating cows must calve to produce milk) and dairy cows (replacements by younger females).

Attributional LCA values are often applied to diet shifts studies, overlooking the feedback loop (rebound effect) of demand on production system emission intensities. There are a few examples of consequential analysis of diet shifts (Tukker et al. 2011) (de Oliveira Silva et al. 2016) (Zech and Schneider 2019), reporting modest potential for mitigation (i.e., from 0-8%) but each of them emphasise only one particular aspect of diet shifts. Further, the application of those models to different regions of the world may require further development.

Current attributional LCA studies present inconsistencies related to the definition of system boundaries, allocation of co-products (including dairy), method of attribution of land use change, and pasture productivity effects on soil carbon stocks (Lynch 2019) (Yan et al. 2011; Dudley et al. 2014). Major differences in the results are due to how land use change affects emissions and soil carbon stocks,, particularly when addressing developing countries where deforestation and intensification can both take place at the same time. Deforestation-related emissions have been attributed to first land use (Bustamante et al. 2012), the activities under a given amortization time (Persson et al. 2014), change in total land covered by the activity (Gerber et al. 2013a), or the missed potential carbon sink, i.e., the opportunity for natural vegetation recovery (Schmidinger and Stehfest 2012) (Schmidt et al. 2015).

Also, variation in soil carbon stocks is not considered in most studies, while a few account for variations up to 0.3 m soil depth, and very rarely consider 1.0 m soil depth for estimating soil carbon variation. Overlooking soil carbon at deeper soil layers largely contributes to underestimating the environmental benefits of transition to more productive systems. Time considerations in soil carbon stocks dynamics also vary among studies, with some applying a standard 20-year equilibrium time instantaneously and others using dynamic (discrete or continuous) models.

The type of food replacement is another major source of uncertainty in calculating the impact of dietary changes (Smetana et al. 2015). Nutritional replacement with animal-based protein candidates such as chicken, eggs, pork, fish, and insects is likely to vary widely in different geographical contexts. While chicken and soybean are currently dominating international trade of protein sources (FAOStat), legumes, pulses, seaweed, and yeast-derived foods are being tested as ingredients by the food industry.

In regard to food quality, reducing meat consumption may lower the iron and zinc nutritional status of certain vulnerable groups. For example, in Europe 22% of preschool children, 25% of pregnant women, and 19% of nonpregnant women already have anemia (WHO, 2008). Reductions in red meat consumption also may have food safety implications. Substituting meat with poultry or seafood might increase foodborne illnesses, whereas replacement with pulses and vegetables would reduce them (Lake et al., 2012).

GHG emissions associated with food preparation and food waste are usually unaccounted for in diet shift studies with rare exceptions (Corrado et al. 2019). Dietary supplements (vitamin, minerals and amino acids) are highly recommended for low-meat diets, but they are not considered in GHG mitigation studies of diet shifts, mostly because of lack of LCA data for supplements (Corrado et al. 2019).

The varying proportions of CO_2, CH_4, and N_2O contributions to ruminant-related emissions, with a high proportion of the short-lived methane, make interpretation sensitive to the global warming metrics adopted (Reisinger and Clark 2018) (Lynch 2019). As more intensive systems or other diet alternatives would alter the relative contributions to food of these gases, the choice of metric often changes the ranking of mitigation options (Lynch and Pierrehumbert 2019)(Garnett, 2011). Most projections related to diet shifts do not account for the potential of methane inhibitors, non-symbiotic nitrogen fixation, advances in livestock and forage genetics, and other emerging technologies in the livestock sector, some of which are close to market launch (Jayanegara et al. 2018).

In a systems view, dairy and wool production can be affected if reductions in ruminant meat demand take place. While beef production sytems are often characterised by low energy and protein efficiency, milk production is as efficient energetically as egg production and second after eggs in protein conversion efficiency among animal-based proteins (Eshel et al. 2016).

In summary, systems level analyses revealed wide variation in mitigation estimates of diet shifts, in part due to differing accounting for the main interactions. There is *robust evidence* that diet shifts can mitigate GHG emissions but *low agreement* on how much could be achieved and what would be the effectiveness of interventions to promote diet shifts. In high-income industrialised countries, there is scope for reducing consumption of livestock produce with tangible environmental benefits; in developing countries, high meat-based diets are less prevalent and scope for reductions may be more limited, but there are options for encouraging nutritition transitions towards healthy diets.

Section SM5.6

Global meat consumption

The issue of global meat consumption as a driver of GHG emission, can be weighed against the requirements of healthy diet. Healthy and sustainable diets are high in coarse grains, pulses, fruits and vegetables, and nuts and seeds; low in energy-intensive animal-sourced and discretionary foods (such as sugary beverages and fats); and have a carbohydrate threshold. Based on the potential impact of suboptimal diets on non-communicable diseases (NCD) mortality and morbidity, the World Health Organization (WHO) and the EAT-LANCET report (Willett et al. 2019) highlighted the need for improving diets across nations and made recommendations on how to balance nutrition to prevent malnutrition. The source of protein is not limited to meat; it is found in fish, vegetable and insects. The range of options in balancing protein sources runs primarily into cultural resistance, food habits, economic conditions and the social and economic factors influencing how the food system affects climate and land.

Most recent analyses, like the EAT-LANCET (Willett et al. 2019) work, show that reductions in consumption, especially of red meat, apply to over-consumers, while scope remains for growth in consumption in Low- and Middle-Income Countries (LMICs).

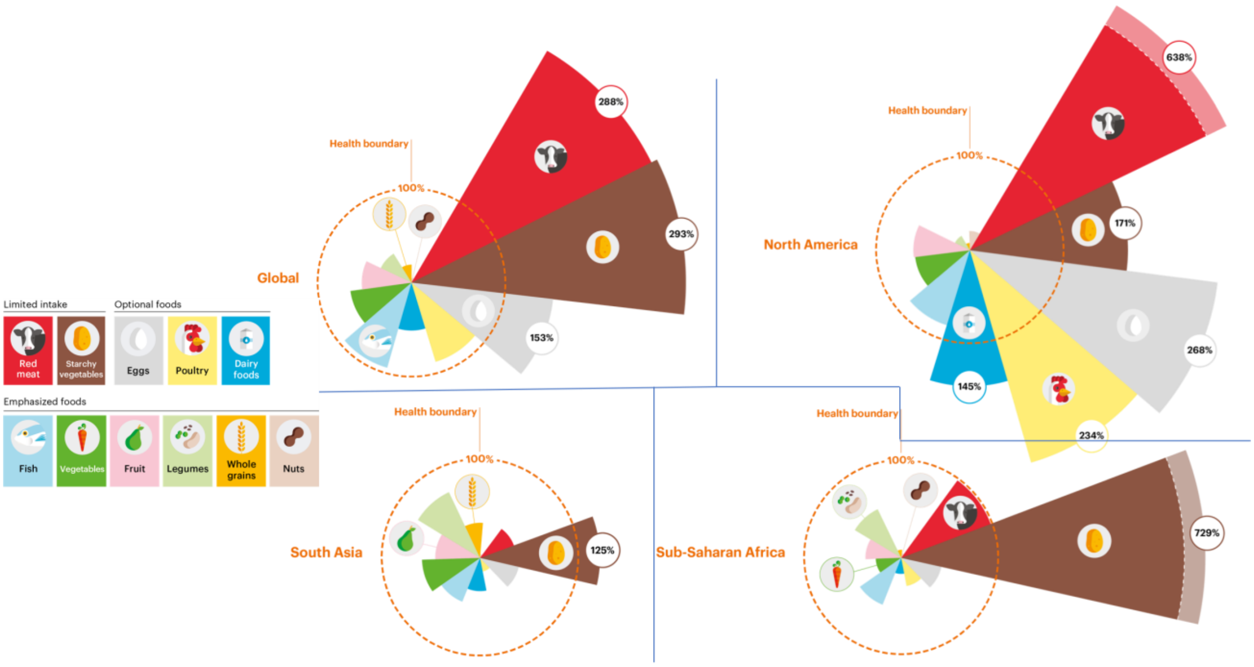

Figure SM5.3 The "diet gap" between current dietary patterns and intakes of food in the planetary health diet (Willett et al. 2019).

From the climate and land perspectives, there is a difference between red meat production and other meat production (Willett et al. 2019). The impacts of meat production will depend on resource use intensity to produce meat calories, the land and climate footprints of the processing and supply chains, and the scale of the production systems (i.e., livestock on crop by-products vs. pasture vs. intensive grain-fed) (Willett et al. 2019). Hence, the question is not about eating less meat for everyone, but to adopt sustainable supply and consumption practices across a broad range of food systems.

The biggest challenge to achieve changes in meat consumption is on how to start a transition that has increasing diversity of food sources with lower land and water requirements and GHG emissions. This could be a gradual transition that recognises the need for just transitions for people whose livelihoods depend on (red) meat production. In this regard, all parts of the food system, including production, trade, and consumption, play important roles.

Section SM5.7

Governance

Governance of climate change and governance of food systems have been developed independently of each other. This section highlights the main characteristics of food and climate governance and assesses what options may exist for establishing arrangements that link the two. See Chapter 7 for important characteristics of governance and institutions; here we describe those relevant for enhancing the interactions between climate change and food systems.

In the governance of climate change, Huitema et al. (2016) highlighted differences between mitigation and adaptation. Mitigation often requires global agreements and national policies while adaptation requires local and regional considerations. However, in the case of food systems this difference does not apply, because mitigation measures also require local actions (e.g., at the farm level), while adaptation actions may also require measures at global and national levels (such as emergency food aid for climate disasters and food safety nets).

Governance of food systems holds particular challenges because it is only recently that a systems approach has been embraced by policy-makers. (Rivera-Ferre et al. 2013) proposed principles for food systems management considering them as complex socioecological systems (SES) including: learning, flexibility, adaptation, participation, diversity enhancement, and precaution. These principles are part of the framework of adaptive governance (see Chapter 7). Termeer et al. (2018) developed a diagnostic framework with five principles to assess governance options appropriate to food systems: 1) system-based problem framing; 2) connectivity across boundaries to span siloed governance structures and include non-state actors; 3) adaptability to flexibly respond to inherent uncertainties and volatility; 4) inclusiveness to facilitate support and legitimacy; and 5) transformative capacity to overcome path dependencies and create conditions to foster structural change.

Both the food and climate systems require integrated governance and institutions (*high confidence*). These need to span government levels and actors across a wide range of sectors including agriculture, environment, economic development, health, education, and welfare (Misselhorn et al. 2012). For climate and food system management, the creation of government entities or ministerial units responsible for coordinating among these ministries (horizontal coordination) and for cutting across different administrative levels (vertical coordination) have been proposed (Orr et al. 2017).

However, integration is not easy. Termeer et al. (2018) analysed three South African governance arrangements that explicitly aim for a holistic system-based approach. They found that they were not delivering the expected outcomes due to reversion to technical one-dimensional problem framing. Issues included dominance of single departments, limited attention to monitoring and flexible responses, and exclusion of those most affected by food insecurity. Newell et al. (2018) analysed the governance process of climate smart agriculture (CSA) from global to local scales for Kenya and found a triple disconnect between global, national, and local scales. Different levels of authority and actors imposed their own framing of CSA, and how to implement it.. As a result of the competition among different actors, siloed policy practices were reproduced.

Food systems governance must also include governance of the resources needed to produce food, which vary from land tenure (see chapter 7) and seed sovereignty (see Chapter 6), to other resources such as soil fertility. Montanarella and Vargas (2012) proposed a supranational structure to guarantee soil conservation on all continents, such as the Global Soil Partnership. This can also apply for the governance of food and climate systems.

Polycentric and multiscalar governance structures have been proposed for coping with climate change to address both mitigation and adaptation (Ostrom 2010), and were suggested by Rivera-Ferre et al.

(2013) for food systems. A polycentric approach provides more opportunities for experimentation and learning across levels (Cole 2015), entails many policy experiments from which policymakers at various levels of governance can learn (Ostrom 2010), and contributes to building trust among stakeholders (e.g., nation states, public and private sectors, civil society). Polycentric approaches have been suggested for the Sustainable Development Goals (SDGs) (Monkelbaan 2019).

Another governance option suggested for the SDGs (Monkelbaan 2019) are already implemented in global atmospheric and marine agreements (e.g., the Montreal protocol (De Búrca et al. 2014; Armeni 2015) is global experimentalist governance). Global experimentalist governance is an institutionalised process of participatory and multilevel collective problem-solving, in which the problems (and the means of addressing them) are framed in an open-ended way, and subjected to periodic revision by peer review in the light of locally generated knowledge (De Búrca et al. 2014), This favours learning, participation and cooperation (Armeni 2015). This form of governance can establish processes that enable unimagined alternatives.

Institutions

As Candel (2014) highlighted, based on a systematic review of food security governance focused on hunger, global governance of food security is lacking because there is no institution with a mandate to address concerns across sectors and levels. No international organisation deals with food security in a holistic and inclusive manner. This results in overlapping (often conflicting) norms, rules and negotiations that generate a "regime complex" (Margulis 2013), particularly in regard to agriculture and food, international trade and human rights (e.g. UN Committee of World Food Security (CFS), WTO, G8, G20). In climate change governance there are also multiple overlapping institutions with often-conflicting rules and actors (Keohane and Victor 2011).

New multi-stakeholder governance arrangements are emerging, such as the Global Agenda for Sustainable Livestock (Breeman et al. 2015) and the CFS (Duncan 2015). Also relevant in food systems and climate change governance is that food security governance is spread across domains, sectors and spatial scales (global, regional, national, local, community, household, or individual) with a lack of coherency and coordination across multiple scales (*high confidence*). Thus, a major challenge is to coordinate all these domains, sectors and scales.

It is important to consider the variety of actors involved in food security governance at all levels (international bodies, civil society organisations (CSOs), nation states, public sector groups, and private sector entities), with different agendas and values. But new in this regard is the participation of CSOs that can provide the policy-making process with bottom-up knowledge to identify food insecurity issues and locally relevant responses. CSOs can also contribute to multi-sector and multi-scalar approaches by bridging government agencies and levels (Candel 2014). Thus, to facilitate coordination and coherence, new adaptive governance enables interactions across multiple levels and scales (Pereira and Ruysenaar 2012) and the use of "boundary organisations" (Candel 2014). To address different narratives regarding food security (Rivera-Ferre 2012; Lang and Barling 2012), a first step is to agree on basic principles and values (Margulis 2013).

In this regard, an opportunity to address food systems governance challenges arises within the UN Committee on World Food Security (CFS), where diverse actors, voices and narratives are integrated in the global food security governance. As a point of departure, the CFS could provide the platform to develop global experimentalist governance in food sytems (Duncan 2015; Duncan and Barling 2012) providing a combination of bottom-up and top-down initiatives (Lambek 2019). However, the existence of overlapping structures with different focuses on food security and power may hinder the potential of this institution. (Margulis and Duncan 2016).

Mainstreaming of collaborative and more inclusive modes of governance, such as those displayed at the CFS, are needed to effectively address thehe impacts of a changing planet on food systems (Barling and Duncan 2015) and improve the balance of sustainable production and food consumption. Despite improvements in global food security, food systems and climate governance, the main focus is still on food security as undernutrition. New challenges will arise from the increasing evidence of the burden of obesity, for which other institutions, focused on nutrition, will be needed. The new Global Strategy Framework for Food Security and Nutrition (Committee on World Food Security 2017) of the CFS provides a new overarching framework for food security and nutrition strategies, policies and actions that includes environmental concerns within a food system approach and a broad vision of food and nutrition security. This framework fits within the "governance through goals" provided by the SDGs (Biermann et al. 2017).

Both in climate change and food systems, the sub-national governance at the level of cities and communities is also becoming relevant in terms of responses (*high evidence, high agreement*). From a climate change perspective (see Chapter 7 for more examples) transnational municipal networks, particularly transnational municipal climate networks, have played a key role in climate change mitigation and have potential to facilitate adaptation (Fünfgeld 2015; Busch et al. 2018; Rosenzweig et al. 2018). Efficient food systems require subnational governments to include food policy councils (Feenstra 2002; Schiff 2008) and cities networks to address food systems challenges (e.g., Sustainable Food Cities in the UK or Agroecological Cities in Spain). Transition Towns are engaged in common principles towards sustainable development, including food systems transformation for food security (Sage 2014), health and well-being (Richardson et al. 2012), and climate change (Taylor Aiken 2015).

Scope for expanded policies

The interaction of production-based support through agricultural policy, coupled with agricultural research investment and the development of frameworks to liberalise trade has led to a range of consequences for global and local food systems. Together, these policies have shaped the food system and incentivised global intensification of agriculture, and significant gains in global production. However, jointly they have also incentivised a concentration on a small number of energy-dense commodity crops grown at large scales (*high confidence*) (just eight crops supply 75% of the world's consumed calories (West et al. 2014)). The production of these commodity crops underpin global dietary transitions, leading to dietary homogenisation (based primarily on starchy grains/tubers, vegetable oil, sugar and livestock produce) (Khoury et al. 2014).

Global intensification of agriculture, as well as increasing the supply of affordable calories, has impacted soil, water, air quality and biodiversity in major and negative ways (Dalin et al. 2017; Tamea et al. 2016; Newbold et al. 2015; García-Ruiz et al. 2015; Amundson et al. 2015; Paulot and Jacob 2014). Importantly in the context of this report, a narrow focus on productivity has led to a food system that emits a large proportion of GHGs (Section 5.4), is fragile in the face of climate shocks (Section 5.3) and from which food is used inefficiently (through waste and over-consumption, Section 5.5.2.5). Mitigation of climate change, as well as adaptation, can then arise from a transformation of the food system to one that provides nutrition and health (Willett et al. 2019; Springmann et al. 2018b,a; Godfray et al. 2018; Ramankutty et al. 2018; Chaudhary et al. 2018). There is therefore *medium confidence*, that continued focus on the past drivers of the food system will be detrimental for climate change and food security.

Addressing this challenge requires action across the food system to enhance synergies and co-benefits and minimise trade-offs among multiple objectives of food security, adaptation and mitigation (Sapkota et al. 2017; Palm et al. 2010; Jat et al. 2016; Sapkota et al. 2015) (Section 5.6), as well as broader environmental goods exemplified by the SDG framework such as water, air-quality, soil health and biodiversity (Obersteiner et al. 2016; Pradhan et al. 2017). In short, this requires greater policy alignment and coherence between traditionally separate policy domains to recognise the systemic nature of the problem. For example, aligning the policy goals of sustainable land management for the purposes of managing both food security and biodiversity (Meyfroidt 2017; Wittman et al. 2017), or public health and agricultural policies (Thow et al. 2018) that can drive mitigation, as well as the enabling conditions of land rights, tenure and ownership. Significant co-benefits can arise from integrated food systems policies, as well as integrated approaches to generating evidence to underpin coherent policy, exemplified, for example, by the EU's integrated research and innovation strategy "Food2030" that aligns agriculture, environment, nutrition and research policy (European Commission 2018).

Executive summary

The land challenges, in the context of this report, are climate change mitigation, adaptation, desertification, land degradation, and food security. The chapter also discusses implications for Nature's Contributions to People (NCP), including biodiversity and water, and sustainable development, by assessing intersections with the Sustainable Development Goals (SDGs). The chapter assesses response options that could be used to address these challenges. These response options were derived from the previous chapters and fall into three broad categories (land management, value chain, and risk management).

The land challenges faced today vary across regions; climate change will increase challenges in the future, while socioeconomic development could either increase or decrease challenges (*high confidence*). Increases in biophysical impacts from climate change can worsen desertification, land degradation, and food insecurity (*high confidence*). Additional pressures from socioeconomic development could further exacerbate these challenges; however, the effects are scenario dependent. Scenarios with increases in income and reduced pressures on land can lead to reductions in food insecurity; however, all assessed scenarios result in increases in water demand and water scarcity (*medium confidence*). {6.1}

The applicability and efficacy of response options are region and context specific; while many value chain and risk management options are potentially broadly applicable, many land management options are applicable on less than 50% of the ice-free land surface (*high confidence*). Response options are limited by land type, bioclimatic region, or local food system context (*high confidence*). Some response options produce adverse side-effects only in certain regions or contexts; for example, response options that use freshwater may have no adverse side effects in regions where water is plentiful, but large adverse side effects in regions where water is scarce (*high confidence*). Response options with biophysical climate effects (e.g., afforestation, reforestation) may have different effects on local climate depending on where they are implemented (*medium confidence*). Regions with more challenges have fewer response options available for implementation (*medium confidence*). {6.1, 6.2, 6.3, 6.4}

Nine options deliver medium to large benefits for all five land challenges (*high confidence*). The options with medium to large benefits for all challenges are increased food productivity, improved cropland management, improved grazing land management, improved livestock management, agroforestry, improved forest management, increased soil organic carbon content, fire management and reduced post-harvest losses. A further two options, dietary change and reduced food waste, have no global estimates for adaptation but have medium to large benefits for all other challenges (*high confidence*). {6.3, 6.4}

Five options have large mitigation potential (> 3 $GtCO_2e\ yr^{-1}$) without adverse impacts on the other challenges (*high confidence*). These are increased food productivity, reduced deforestation and degradation, increased soil organic carbon content, fire management and reduced post-harvest losses. Two further options with large mitigation potential, dietary change and reduced food waste, have no global estimates for adaptation but show no negative impacts across the other challenges. Five options: improved cropland management, improved grazing land managements, agroforestry,

integrated water management and forest management, have moderate mitigation potential, with no adverse impacts on the other challenges (*high confidence*). {6.3.6}

Sixteen response options have large adaptation potential (>25 million people benefit), without adverse side-effects on other land challenges (*high confidence*). These are increased food productivity, improved cropland management, agroforestry, agricultural diversification, improved forest management, increased soil organic carbon content, reduced landslides and natural hazards, restoration and reduced conversion of coastal wetlands, reduced post-harvest losses, sustainable sourcing, management of supply chains, improved food processing and retailing, improved energy use in food systems, livelihood diversification, use of local seeds, and disaster risk management (*high confidence*). Some options (such as enhanced urban food systems or management of urban sprawl) may not provide large global benefits but may have significant positive local effects without adverse effects (*high confidence*). {6.3, 6.4}

Seventeen of 40 options deliver co-benefits or no adverse side-effects for the full range of NCPs and SDGs; only three options (afforestation, bioenergy and BECCS and some types of risk sharing instruments, such as insurance) have potentially adverse side-effects for five or more NCPs or SDGs (*medium confidence*). The 17 options with co-benefits and no adverse side-effects include most agriculture- and soil-based land management options, many ecosystem-based land management options, improved forest management, reduced post-harvest losses, sustainable sourcing, improved energy use in food systems, and livelihood diversification (*medium confidence*). Some of the synergies between response options and SDGs include positive poverty reduction impacts from activities like improved water management or improved management of supply chains. Examples of synergies between response options and NCPs include positive impacts on habitat maintenance from activities like invasive species management and agricultural diversification. However, many of these synergies are not automatic, and are dependent on well-implemented activities requiring institutional and enabling conditions for success. {6.4}

Most response options can be applied without competing for available land; however, seven options result in competition for land (*medium confidence*). A large number of response options do not require dedicated land, including several land management options, all value chain options, and all risk management options. Four options could greatly increase competition for land if applied at scale: afforestation, reforestation, and land used to provide feedstock for BECCS and biochar, with three further options: reduced grassland conversion to croplands, restoration and reduced conversion of peatlands and restoration and reduced conversion of coastal wetlands having smaller or variable impacts on competition for land. Other options such as reduced deforestation and degradation, restrict land conversion for other options and uses. Expansion of the current area of managed land into natural ecosystems could have negative consequences for other land challenges, lead to the loss of biodiversity, and adversely affect a range of NCPs (*high confidence*). {6.3.6, 6.4}

Some options, such as bioenergy and BECCS, are scale dependent. The climate change mitigation potential for bioenergy and BECCS is large (up to 11 $GtCO_2$ yr^{-1}); however, the effects of bioenergy production on land degradation, food insecurity, water scarcity, GHG emissions, and other environmental goals are scale and context specific (*high confidence*). These effects depend on the scale of deployment, initial land use, land type, bioenergy feedstock, initial carbon stocks, climatic region and management regime (*high confidence*). Large areas of monoculture bioenergy crops that displace other land uses can result in land competition, with adverse effects for food production, food consumption, and thus food security, as well as adverse effects for land degradation, biodiversity, and water scarcity (*medium confidence*). However, integration of bioenergy into sustainably managed agricultural landscapes can ameliorate these challenges (*medium confidence*). {6.2, 6.3, 6.4, Cross-Chapter Box 7 in this Chapter}

Response options are interlinked; some options (e.g., land sparing and sustainable land management options) can enhance the co-benefits or increase the potential for other options (*medium confidence*). Some response options can be more effective when applied together (*medium confidence)*; for example, dietary change and waste reduction expand the potential to apply other options by freeing as much as 5.8 Mkm^2 (0.8-2.4 Mkm^2 for dietary change; ~2 Mkm^2 for reduced post-harvest losses, and 1.4 Mkm^2 for reduced food waste) of land (*low confidence*). Integrated water management and increased soil organic carbon can increase food productivity in some circumstances. {6.4}

Other response options (e.g., options that require land) may conflict; as a result, the potentials for response options are not all additive, and a total potential from the land is currently unknown (*high confidence*). Combining some sets of options (e.g., those that compete for land) may mean that maximum potentials cannot be realised, for example reforestation, afforestation, and bioenergy and BECCS all compete for the same finite land resource so the combined potential is much lower than the sum of potentials of each individual option calculated in the absence of alternative uses of the land (*high confidence*). Given the interlinkages among response options and that mitigation potentials for individual options assume that they are applied to all suitable land, the total mitigation potential is much lower than the sum of the mitigation potential of the individual response options (*high confidence*). {6.4}

The feasibility of response options, including those with multiple co-benefits, is limited due to economic, technological, institutional, socio-cultural, environmental and geophysical barriers (*high confidence*). A number of response options (e.g., most agriculture-based land management options, forest management, reforestation and restoration) have already been implemented widely to date (*high confidence*). There is robust evidence that many other response options can deliver co-benefits across the range of land challenges, yet these are not being implemented. This limited application is evidence that multiple barriers to implementation of response options exist (*high confidence*). {6.3, 6.4}

Coordinated action is required across a range of actors, including business, consumers, land managers, indigenous and local communities and policymakers to create enabling conditions for adoption of response options (*high confidence*). The response options assessed face a variety of barriers to implementation (economic, technological, institutional, socio-cultural, environmental and geophysical) that require action across multiple actors to overcome (*high confidence*). There are a variety of response options available at different scales that could form portfolios of measures applied by different stakeholders from farm to international scales. For example, agricultural diversification and use of local seeds by smallholders can be particularly useful poverty reduction and biodiversity conservation measures, but are only successful when higher scales, such as national and international markets and supply-chains, also value these goods in trade regimes, and consumers see the benefits of purchasing these goods. However, the land and food sectors face particular challenges of institutional fragmentation, and often suffer from a lack of engagement between stakeholders at different scales (*medium confidence*). {6.3, 6.4}

Delayed action will result in an increased need for response to land challenges and a decreased potential for land-based response options due to climate change and other pressures (*high confidence*). For example, failure to mitigate climate change will increase requirements for adaptation and may reduce the efficacy of future land-based mitigation options (*high confidence*). The potential for some land management options decreases as climate change increases; for example, climate alters the sink capacity for soil and vegetation carbon sequestration, reducing the potential for increased soil organic carbon (*high confidence*). Other options (e.g., reduced deforestation and degradation) prevent further detrimental effects to the land surface; delaying these options could lead to increased deforestation, conversion, or degradation, serving as increased sources of GHGs and having concomitant negative impacts on NCPs (*medium confidence*). Carbon dioxide removal (CDR) options, like reforestation, afforestation, bioenergy and BECCS, are used to compensate for unavoidable emissions in other sectors; delayed action will result in larger and more rapid deployment later (*high confidence*). Some response options will not be possible if action is delayed too long; for example, peatland restoration might not be possible after certain thresholds of degradation have been exceeded, meaning that peatlands could not be restored in certain locations (*medium confidence*) {6.2, 6.3, 6.4}.

Early action, however, has challenges including technological readiness, upscaling, and institutional barriers (*high confidence*). Some of the response options have technological barriers that may limit their wide-scale application in the near-term (*high confidence*). Some response options, e.g., BECCS, have only been implemented at small-scale demonstration facilities; challenges exist with upscaling these options to the levels discussed in this Chapter (*medium confidence*). Economic and institutional barriers, including governance, financial incentives and financial resources, limit the near-term adoption of many response options, and 'policy lags', by which implementation is delayed by the slowness of the policy implementation cycle, are significant across many options (*medium confidence*). Even some actions that initially seemed like 'easy wins' have been challenging to implement, with stalled policies for REDD+ providing clear examples of how response options need sufficient funding, institutional support, local buy-in, and clear metrics for success, among other necessary enabling conditions. {6.2, 6.4}

Some response options reduce the consequences of land challenges, but do not address underlying drivers (*high confidence*). For example, management of urban sprawl can help reduce the environmental impact of urban systems; however, such management does not address the socioeconomic and demographic changes driving the expansion of urban areas. By failing to address the underlying drivers, there is a potential for the challenge to re-emerge in the future (*high confidence*). {6.4}

Many response options have been practiced in many regions for many years; however, there is limited knowledge of the efficacy and broader implications of other response options (*high confidence*). For the response options with a large evidence base and ample experience, further implementation and upscaling would carry little risk of adverse side-effects (*high confidence*). However, for other options, the risks are larger as the knowledge gaps are greater; for example, uncertainty in the economic and social aspects of many land response options hampers the ability to predict their effects (*medium confidence*). Furthermore, Integrated Assessment Models, like those used to develop the pathways in the IPCC Special Report on Global Warming of 1.5°C (SR15), omit many of these response options and do not assess implications for all land challenges (*high confidence*). {6.4}

6.1 Introduction

6.1.1 Context of this chapter

This chapter focuses on the interlinkages between response options[1] to deliver climate mitigation and adaptation, to address desertification and land degradation, and to enhance food security, and also assesses reported impacts on Nature's Contributions to People (NCP) and contributions to the UN Sustainable Development Goals (SDG). By identifying which options provide the most co-benefits with the fewest adverse side-effects, this chapter aims to provide *integrated response options* that could co-deliver across the range of challenges. This chapter *does not consider*, in isolation, response options that affect only one of climate mitigation, adaptation, desertification, land degradation, or food security, since these are the subjects of Chapters 2–5; this chapter *considers only* interlinkages between response options and two or more of these challenges in the land sector.

Since the aim is to assess and provide guidance on integrated response options, each response option is first described and categorised drawing on previous chapters 2-5 (Section 6.2), and their impact on climate mitigation / adaptation, desertification, land degradation, and food security are quantified (Section 6.3). The feasibility of each response option, respect to costs, barriers, saturation and reversibility is then assessed (Section 6.4.1), before considering their sensitivity to future climate change (Section 6.4.2).

The *co-benefits* and *adverse side-effects*[2] of each integrated response option across the five land challenges, and their impacts on the NCP and the SDG, are then assessed in Section 6.4.3. In section 6.4.4, the spatial applicability of these integrated response options is assessed in relation to the location of the challenges with the aim of identifying which options have the greatest potential to co-deliver across the challenges, and the contexts and circumstances in which they do so. Interlinkages among response options and challenges in future scenarios are also assessed in 6.4.4. Finally, section 6.4.5 discusses the potential consequences of delayed action.

In providing this evidence-based assessment, drawing on the relevant literature, this chapter does not assess the merits of policies to deliver these integrated response options - Chapter 7 assesses the various policy options currently available to deliver these interventions - rather this chapter provides an assessment of the integrated response options and their ability to co-deliver across the multiple challenges addressed in this Special Report.

6.1.2 Framing social challenges and acknowledging enabling factors

In this section we outline the approach used in assessing the evidence for interactions between response options to deliver climate mitigation and adaptation, to prevent desertification and land degradation, and to enhance food security. Overall, while defining and presenting the response options to meet these goals is the primary goal of this chapter, we note that these options must not be considered only as technological interventions, or one-off actions. Rather, they need to be understood as responses to socio-ecological challenges whose success will largely depend on external enabling factors. There have been many previous efforts at compiling positive response options that meet numerous Sustainable Development Goals, but which have not resulted in major shifts in

[1] FOOTNOTE: Many of the response options considered are *sustainable land management* options, but several response options are not based on land management, for example those based on value chain management and governance and risk management options

[2] FOOTNOTE: We use the IPCC AR5 WGIII definitions of co-benefits and adverse side-effect – see glossary. Co-benefits and adverse side-effects can be biophysical and/or socio-economic in nature, and all are assessed as far as the literature allows.

implementation; for example, online databases of multiple response options for sustainable land management (SLM), adaptation, and other objectives have been compiled by many donor agencies, including World Overview of Conservation Approaches and Technologies (WOCAT), Climate Adapt, and the Adaptation Knowledge Portal, (Schwilch et al.,2012)[3]. Yet clearly barriers to adoption remain, or these actions would have been more widely used by now. Much of the scientific literature on barriers to implementing response options focuses on the individual and household level, and discusses limits to adoption, often primarily identified as economic factors (Nigussie et al. 2017; Dallimer et al. 2018). While a useful approach, such studies often are unable to account for the larger enabling factors that might assist in more wide scale implementation (chapter 7 discusses these governance factors and barriers to be overcome in more detail).

Instead, this chapter proposes that each response option identified and assessed needs to be understood as an intervention within complex socio-ecological systems (SES) (introduced in Chapter 1). In this understanding, physical changes affect human decision-making over land and risk management options, as do economics, policies, and cultural factors, which in turn may drive additional ecological change (Rawlins et al.,2010). This co-evolution of responses within an SES provides a more nuanced understanding of the dynamics between drivers of change and impacts of interventions. Thus, in discussions of the 40 specific response options in this chapter, it must be kept in mind that all need to be contextualised within the specific SES in which they are deployed (see Figure 6.1). Framing response options within SESs also recognises the interactions *between* different response options. However, a major problem within SESs is that the choice and use of different response options requires knowledge of the problems they are aimed at solving, which may be unclear, contested, or not shared equally among stakeholders (Carmenta et al., 2017). Drivers of environmental change often have primarily social or economic rather than technological roots, which requires acknowledgement that response options that do not aim at reducing the drivers of change may thus be less successful (Schwilch et al., 2014).

[3] FOOTNOTE: E.g. see https://qcat.wocat.net/en/wocat/; https://climate-adapt.eea.europa.eu; https://www4.unfccc.int/sites/NWPStaging/Pages/Home.aspx

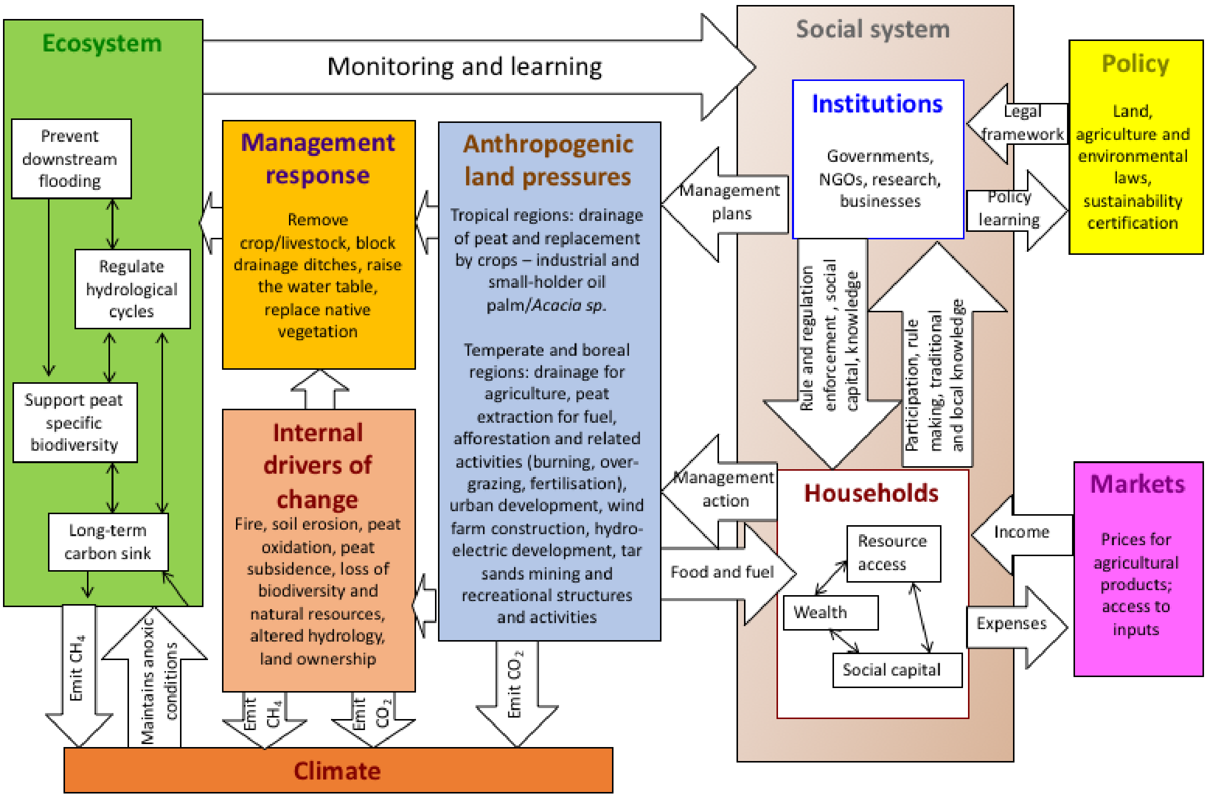

Figure 6.1 Model to represent a social-ecological system of one of the integrated response options in this chapter, using restoration and reduced impact of peatlands as an example. The boxes show systems (ecosystem, social system), external and internal drivers of change and the management response – here enacting the response option. Unless included in the internal drivers of change box, all other drivers of change are external (e.g. climate, policy, markets, anthropogenic land pressures). The arrows represent how the systems can influence each other, with key drivers of impact written in the arrow in the direction of effect.

Response options must also account for the uneven distribution of impacts among populations of both environmental change and intervention responses to this change. Understanding the integrated response options available in a given context requires an understanding of the specificities of social vulnerability, adaptive capacity, and institutional support to assist communities, households and regions to reach their capabilities and achievement of the SDG and other social and land management goals. Vulnerability reflects how assets are distributed within and among communities, shaped by factors that are not easily overcome with technical solutions, including inequality and marginalisation, poverty, and access to resources (Adger et al. 2004; Hallegate et al 2016). Understanding why some people are vulnerable and what structural factors perpetuate this vulnerability requires attention to both micro and meso scales (Tschakert et al. 2013). These vulnerabilities create barriers to adoption of even low-cost high-return response options, such as soil carbon management, that may seem obviously beneficial to implement (Mutoko et al. 2014; Cavanagh et al. 2017). Thus, assessment of the differentiated vulnerabilities that may prevent response option adoption needs to be considered as part of any package of interventions.

Adaptive capacity relates to the ability of institutions or people to modify or change characteristics or behaviour so as to cope better with existing or anticipated external stresses (Moss et al. 2001; Brenkert and Malone 2005; Brooks et al. 2005). Adaptive capacity reflects institutional and policy support networks, and has often been associated at the national level with strong developments in the fields of economics, education, health, and governance and political rights (Smit et al. 2001). Areas with low adaptive capacity, as reflected in low Human Development Index scores, might constrain the ability of communities to implement response options (section 6.4.4.1 and Figure 6.7).

Further, while environmental changes like land degradation have obvious social and cultural impacts, as discussed in the preceding chapters, so do response options, and thus careful thought is needed about what impacts are expected and what trade-offs are acceptable. One potential way to assess the impact of response interventions relates to the idea of capabilities, a concept first proposed by economist Amartya Sen (Sen 1992). Understanding capability as the "freedom to achieve well-being" frames a problem as being a matter of facilitating what people aspire to do and be, rather than telling them to achieve a standardised or predetermined outcome (Nussbaum and Sen 1993). Thus a capability approach is generally a more flexible and multi-purpose framework, appropriate to an SES understanding because of its open-ended approach (Bockstael and Berkes 2017). Thus, one question for any decision-maker approaching schematics of response options is to determine which response options lead to increased or decreased capabilities for the stakeholders who are the objects of the interventions, given the context of the SES in which the response option will be implemented.

Section 6.4.3 examines some of the capabilities that are reflected in the UN Sustainable Development Goals (SDG), such as gender equity and education, and assesses how each of the 40 response options may affect those goals, either positively or negatively, through a review of the available literature.

6.1.2.1 Enabling conditions

Response options are not implemented in a vacuum and rely on knowledge production and socio-economic and cultural strategies and approaches embedded within them to be successful. For example, it is well known that "Weak grassroots institutions characterised by low capacity, failure to exploit collective capital and poor knowledge sharing and access to information, are common barriers to sustainable land management and improved food security" (Oloo and Omondi 2017). Achieving broad goals such as reduced poverty or sustainable land management requires conducive enabling conditions, such as attention to gender issues and the involvement of stakeholders, like indigenous peoples, as well as attention to governance, including adaptive governance, stakeholder engagement, and institutional facilitation (see section 6.4.4.3). These enabling conditions – such as gender-sensitive programming or community-based solutions - are not categorised as individual response options in subsequent sections of this chapter because they are conditions that can potentially help improve *all* response options when used in tandem to produce more sustainable outcomes. Chapter 7 picks up on these themes and discusses the ways various policies to implement response options have tried to minimise unwanted social and economic impacts on participants in more depth, through deeper analysis of concepts such as citizen science and adaptive governance. Here we simply note the importance of assessing the contexts within which response options will be delivered, as no two situations are the same, and no single response option is likely to be a 'silver bullet' to solve all land-climate problems, as each option comes with potential challenges and trade-offs (section 6.2), barriers to implementation (section 6.4.1), interactions with other sectors of society (section 6.4.3), and potential environmental limitations (section 6.4.4).

6.1.3 Challenges and response options in current and historical interventions

Land-based systems are exposed to multiple overlapping challenges including climate change (adaptation and mitigation), desertification (Chapter 3), land degradation (Chapter 4) and food insecurity (Chapter 5), as well as loss of biodiversity, ground water stress (from over-abstraction) and water quality. The spatial distribution of these individual land-based challenges is shown in Figure 6.2, based on recent studies and using the following indicators:

- Desertification attributed to land use is estimated from vegetation remote sensing (Figure 3.7c), mean annual change in NDVImax < -0.001 (between 1982-2015) in dryland areas (Aridity Index > 0.65), noting however that desertification has multiple causes (Chapter 3);
- Land degradation (see Chapter 4) is based on a soil erosion (Borrelli et al. 2017) proxy (annual erosion rate of 3 t ha^{-1} or above);
- The climate change challenge for adaptation is based on a dissimilarity index of monthly means of temperature and precipitation between current and end of century scenarios (dissimilarity index equal to 0.7 or above, Netzel and Stepinski 2018), noting however that rapid warming could occur in all land regions (Chapter 2);
- The food security challenge is estimated as the prevalence of chronic undernourishment (higher or equal to 5%) by country in 2015 (FAO 2017a), noting however that food security has several dimensions (see Chapter 5);
- The biodiversity challenge uses threatened terrestrial biodiversity hotspots (areas where exceptional concentrations of endemic species are undergoing exceptional loss of habitat, (Mittermeier et al. 2011), noting however that biodiversity concerns more than just threatened endemic species;
- The groundwater stress challenge is estimated as groundwater abstraction over recharge ratios above one (Gassert et al. 2014) in agricultural areas (croplands and villages);
- The water quality challenge is estimated as critical loads (higher or equal to 1000 kg N km^{-2} or 50 kg P km^{-2}) of nitrogen (N) and phosphorus (P) (Xie and Ringler 2017)

Overlapping land-based challenges affect all land use categories: croplands, rangelands, semi-natural forests, villages, dense settlements, wild forests and sparse trees and barren lands. These land use categories can be defined as anthropogenic biomes, or anthromes, and their global distribution was mapped by Ellis and Ramankutty (2008) (Figure 6.2).

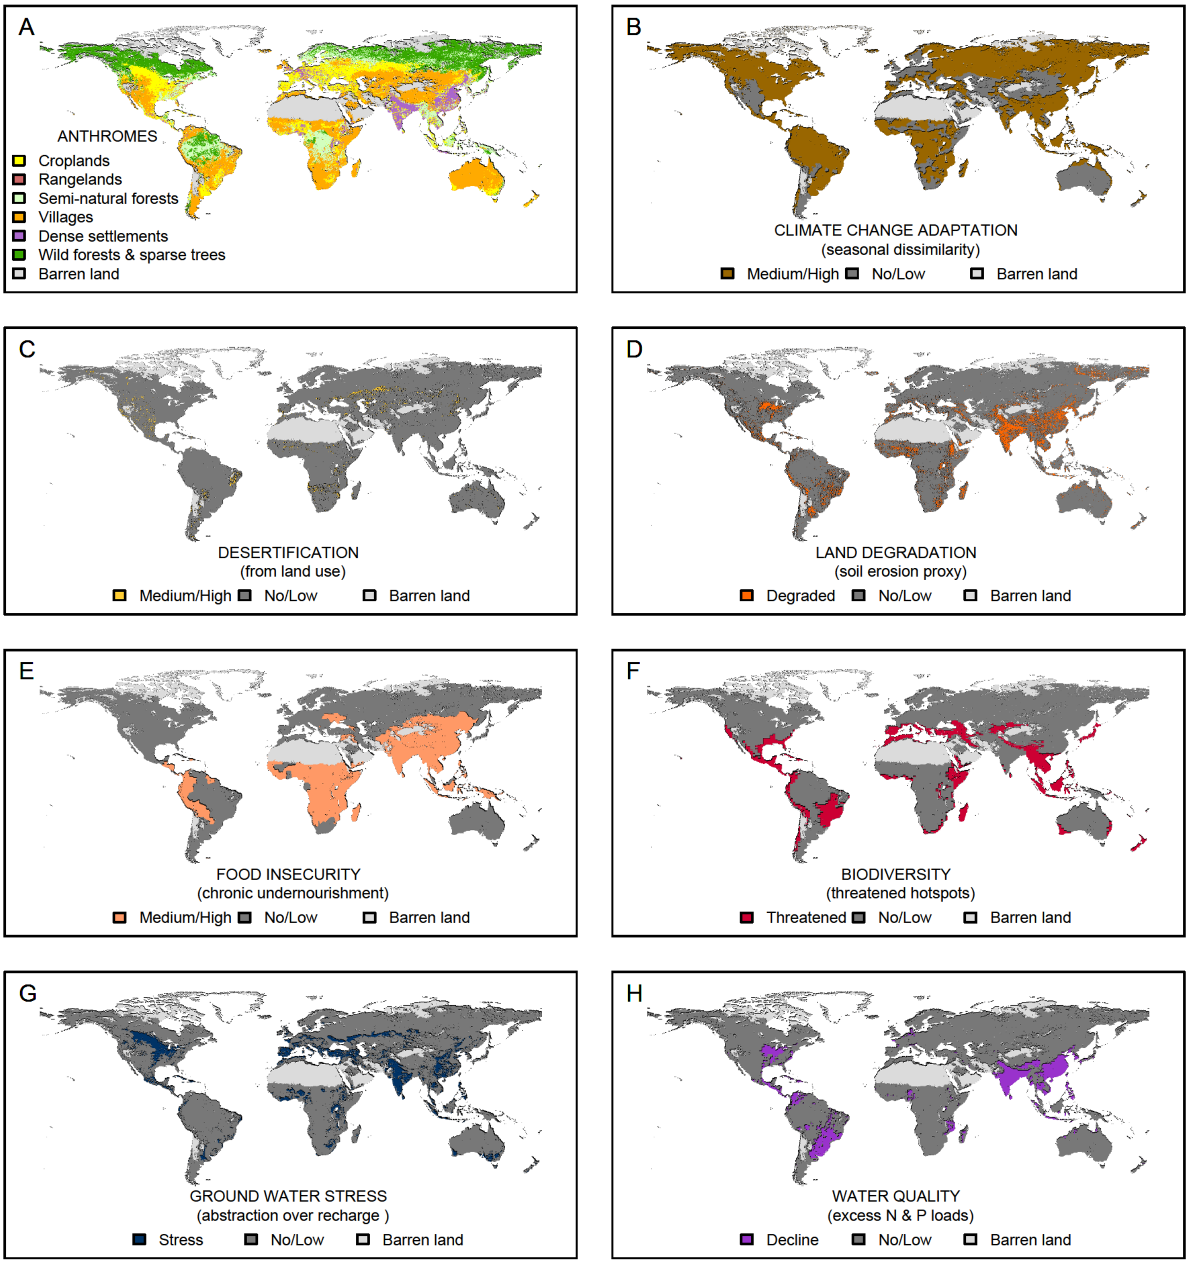

Figure 6.2 Global distributions of land use types and individual land-based challenges. A, land use types (or anthromes, after Ellis and Ramankutty 2008); B, climate change adaptation challenge (estimated from dissimilarity between current and end of century climate scenarios, Netzel and Stepinski 2018); C, desertification challenge (after Chapter 3, Figure 3.7c); D, land degradation challenge (estimated from a soil erosion proxy, one indicator of land degradation Borrelli et al. 2017); E, food security challenge (estimated from chronic undernourishment, a component of food security, FAO 2017a); F, biodiversity challenge (estimated from threatened biodiversity hotspots, a component of biodiversity, Mittermeier et al. 2011); G, groundwater stress challenge (estimated from water over-abstraction, Gassert et al. 2014); H, water quality challenge (estimated from critical N and P loads of water systems, Xie and Ringler 2017).

Table 6.1 Global area of land use types (or anthromes) and current percentage area exposure to individual (overlapping) land-based challenges. See Figure 6.2 and text for further details on criteria for individual challenges.

Land use type (anthrome[a])	Anthrome area	Climate change adaptation (dissimilarity index proxy)[b]	Land degradation (soil erosion proxy)[c]	Desertification (ascribed to land use)[d]	Food security (chronic under nourishment)[e]	Biodiversity (threatened hotspot)[f]	Ground water stress (over abstraction)[g]	Water quality (critical N-P loads)[h]
	% of ice-free land area [1]	*% anthrome area exposed to an individual challenge*						
Dense settlement	1	76	20	3	30	32	-	30
Village	5	70	49	3	78	28	77	59
Cropland	13	68	21	7	28	27	65	20
Rangeland	26	46	14	7	43	21	-	10
Semi-natural forests	14	91	17	0.7	-	21	-	7
Wild forests and sparse trees	17	98	4	0.5	-	2	-	0.3
Barren	19	53	6	0.9	2	4	-	0.4
***Organic soils**	4	95	10	2	9	13	-	6
***Coastal wetlands**	0.6	74	11	2	24	33	-	26
All anthromes	100	69	13	3.2	20	15	12	10

[a] Ellis and Ramankutty (2008) - the global ice-free land area is estimated at 134 Mkm^2; [b] Borrelli et al. 2017; [c] Netzel and Stepinski 2018; [d] From Figure 3.7c, chapter 3; [e] FAO 2017a; [f] Mittermeier et al. 2011; [g] Gassert et al 2014; [h] Xie and Ringler 2017

The majority of the global population is concentrated in dense settlements and villages accounting for less than 7% of the global ice-free land area, while croplands and rangelands use 39% of land. The remainder of the ice-free land area (more than half) is used by semi-natural forests, by wild forests and sparse trees and by barren lands (Table 6.1).

Land use types (or anthromes) are exposed to multiple overlapping challenges. Climate change could induce rapid warming in all land areas (see Chapter 2). In close to 70% of the ice-free land area, the climate change adaptation challenge could be reinforced by a strong dissimilarity between end of century and current temperature and precipitation seasonal cycles (Netzel and Stepinski 2018). Chronic undernourishment (a component of food insecurity) is concentrated in 20% of global ice-free land area. Severe soil erosion (a proxy of land degradation) and desertification from land use affect 13 and 3% of ice-free land area, respectively. Both groundwater stress and severe water quality decline (12 and 10% of ice-free land area, respectively) contribute to the water challenge. Threatened biodiversity hot-spots (15% of ice-free land area) are significant for the biodiversity challenge (Table 6.1).

Since land-based challenges overlap, part of the ice-free land area is exposed to combinations of two or more challenges. For instance, land degradation (severe soil erosion) or desertification from land use and food insecurity (chronic undernourishment) are combined with a strong climate change adaptation challenge (dissimilarity in seasonal cycles) in 4.5% of the ice-free land area (Figure 6.3).

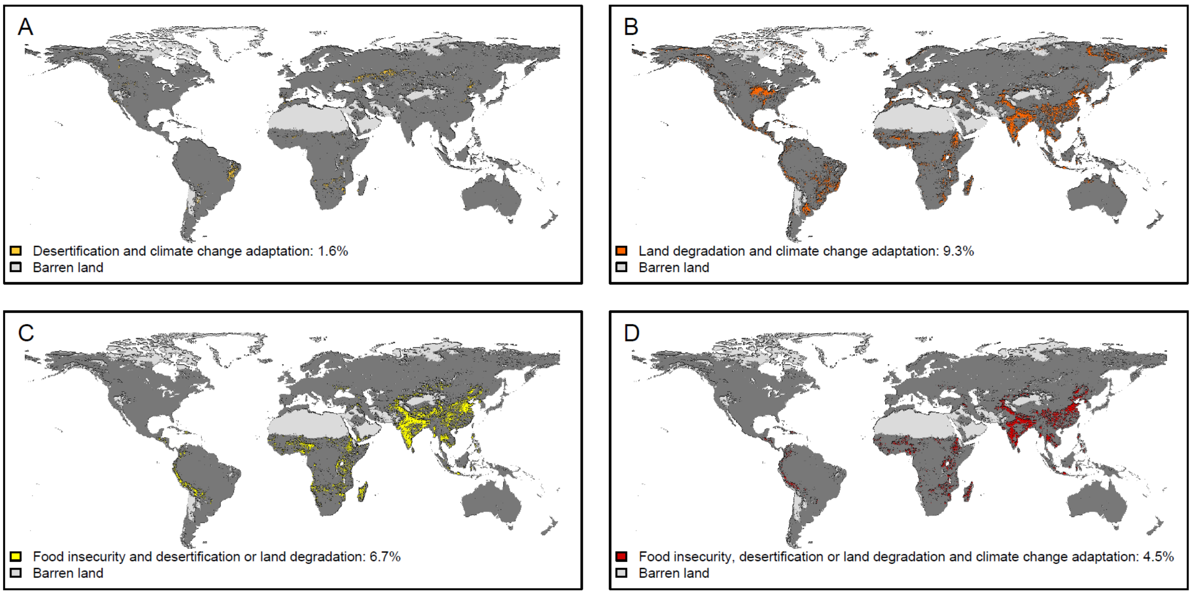

Figure 6.3 Example of overlap between land challenges. A. Overlap between the desertification (from land use) challenge and the climate change adaptation (strong dissimilarity in seasonal cycles) challenge. B. Overlap between the land degradation (soil erosion proxy) challenge and the climate change adaptation challenge. C. Overlap between the desertification or land degradation challenges and the food insecurity (chronic undernourishment) challenge. D. Overlap between challenges shown in C and the climate change adaptation challenge. For challenges definitions, see text; references as in Figure 6.2.

The global distribution of land area by the number of overlapping land challenges (Figure 6.4) shows: the least exposure to land challenges in barren lands; less frequent exposure to two or more challenges in wild forests than in semi-natural forests; more frequent exposure to two or more challenges in agricultural anthromes (croplands and rangelands) and dense settlements than in forests; most frequent exposure to 3 or more challenges in villages compared to other land use types. Therefore, land use types intensively used by humans are, on average, exposed to a larger number of challenges than land use types (or anthromes) least exposed to human use.

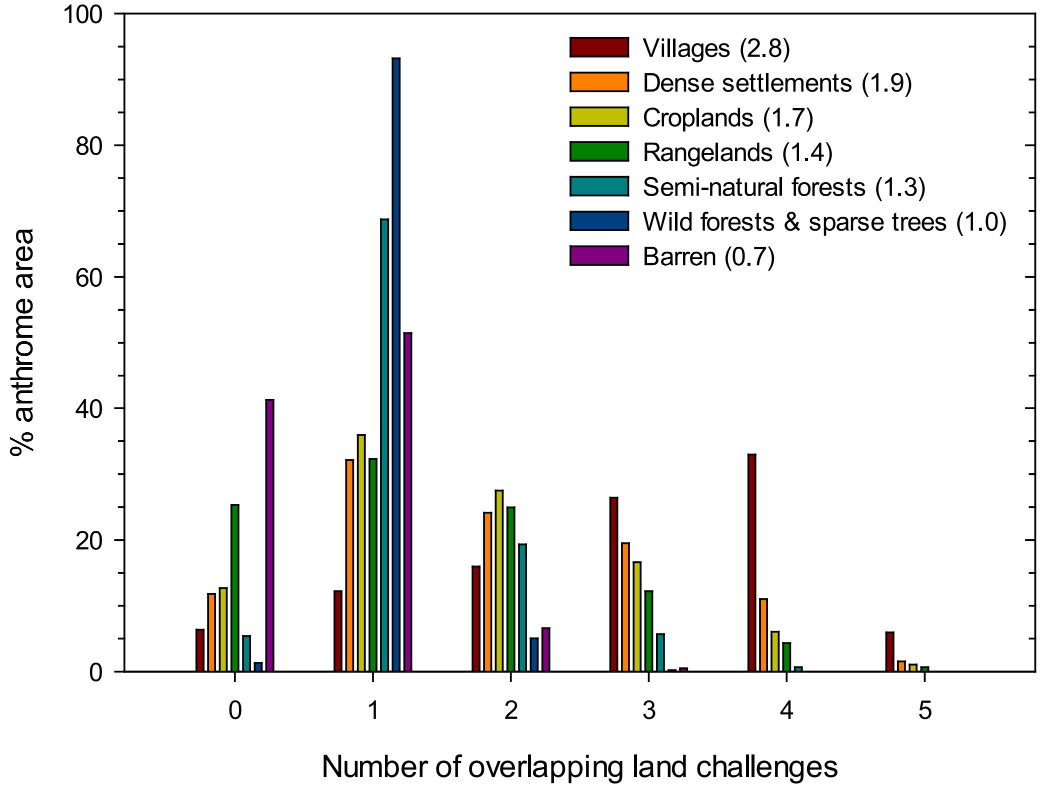

Figure 6.4 Percentage distribution of land use type (or anthrome) area by number of overlapping land challenges for the villages, dense settlements, croplands, rangelands, semi-natural forests, wild forests & sparse trees and barren land use types. Values in brackets show the mean number of land challenges per land use type. Land challenges include desertification (from land use), land degradation (soil erosion proxy), climate change adaptation (seasonal dissimilarity proxy), food security (chronic undernourishment), biodiversity (threatened hot spots), groundwater stress (over abstraction) and water quality (critical N and P loads).

Case studies located in different world regions are presented for each anthrome, in order to provide historical context on the interlinkages between multiple challenges and responses (Box 6.1: A to E). Taken together, these case studies illustrate the large contrast across anthromes in land-based interventions and the way these interventions respond to combinations of challenges.

Box 6.1 Case studies by anthrome type showing historical interlinkages between land-based challenges and the development of local responses

A. Croplands. Land degradation, groundwater stress and food insecurity: soil and water conservation measures in the Tigray region of Ethiopia

In northern Ethiopia, the Tigray region is a drought-prone area that has been subjected to severe land degradation (Frankl et al. 2013) and to recurrent drought and famine during 1888–1892, 1973–1974 and 1984–1985 (Gebremeskel et al. 2018). The prevalence of stunting and being underweight among children under five years is high (Busse et al. 2017) and the region was again exposed to a severe drought during the strong El Niño event of 2015–2016. Croplands are the dominant land-use type, with approximately 90% of the households relying on small-scale plough-based cultivation. Gullies affect nearly all slopes and frequently exceed 2 m in depth and 5 m in top width. Landsat imagery shows that cropland area peaked in 1984–1986 and increased erosion rates in the 1980s and 1990s caused the drainage density and volume to peak in 1994 (Frankl et al. 2013). Since ca. 2000, the large-scale implementation of Soil and Water Conservation (SWC) measures, integrated catchment management, conservation agriculture and indigenous tree regeneration has started to yield positive effects on the vegetation cover and led to the stabilisation of about 25% of the gullies by 2010 (Frankl et al. 2013). Since 1991, farmers have provided labour for SWC in January as a free service for 20 consecutive working days, followed by food for work for the remaining days of the dry season. Most of the degraded landscapes have been restored, with positive impacts over the last two decades on soil fertility, water availability and crop productivity. However, misuse of fertilisers, low survival of tree seedlings and lack of income from exclosures may affect the sustainability of these land restoration measures (Gebremeskel et al. 2018).

B. Rangelands. Biodiversity hotspot, land degradation and climate change: pasture intensification in the Cerrados of Brazil

Cerrados are a tropical savannah ecoregion in Brazil corresponding to a biodiversity hot spot with less than 2% of its region protected in national parks and conservation areas (Cava et al. 2018). Extensive cattle ranching (limited mechanisation, low use of fertiliser and seed inputs) has led to pasture expansion, including clearing forests to secure properties rights, occurring mainly over 1950–1975 (Martha et al. 2012). Despite observed productivity gains made over the last three decades (Martha et al. 2012), more than half of the pasture area is degraded to some extent and challenges remain to reverse grassland degradation while accommodating growing demand and simultaneously avoiding the conversion of natural habitats (de Oliveira Silva et al. 2018). The largest share of production is on unfertilised pastures, often sown with perennial forage grasses of African origin, mainly *Brachiaria* spp. (Cardoso et al. 2016). This initial intensification era was partly at the expense of significant uncontrolled deforestation and average animal stocking rates remained well below the potential carrying capacity (Strassburg et al. 2014). Changes in land use are difficult to reverse since pasture abandonment does not lead to the spontaneous restoration of old-growth savannah (Cava et al. 2018); moreover pasture to crop conversion is frequent, supporting close to half of cropland expansion in Mato Grosso state over 2000–2013 (Cohn et al. 2016). Pasture intensification through liming, fertilisation and controlled grazing could increase soil organic carbon and reduce net GHG emission intensity per unit meat product, but only at increased investment cost per unit of area (de Oliveira Silva et al. 2017). Scenarios projecting a decoupling between deforestation and increased pasture intensification, provide the basis for a Nationally Determined Contribution (NDC) of Brazil that is potentially consistent with accommodating an upward trend in livestock production to meet increasing demand (de Oliveira Silva et al. 2018). Deforestation in Brazil has declined significantly between 2004 and 2014 in the national inventory but recent data and analyses suggest that the decrease in deforestation and the resulting GHG emissions reductions have slowed down or even stopped (UNEP 2017).

C. Semi-natural forests. Biodiversity hotspot, land degradation, climate change and food insecurity: restoration and resilience of tropical forests in Indonesia

During the last two decades, forest cover in Indonesia declined by 150,000 km^2 in the period 1990-2000 (Stibig et al. 2014) and approximately 158,000 km^2 in the period 2000–2012 (Hansen et al. 2013a), most of which was converted to agricultural lands (e.g., oil palm, pulpwood plantations). According to recent estimates, deforestation in Indonesia mainly concerns primary forests, including intact and degraded forests, thus leading to biodiversity loss and reduced carbon sequestration potentials (e.g., Margono et al. 2014). For example, Graham et al. (2017) estimated that the following strategies to reduce deforestation and degradation may cost-effectively increase carbon sequestration and reduce carbon emissions in 30 years: reforestation (3.54 Gt CO_2), limiting the expansion of oil palm and timber plantations into forest (3.07 Gt CO_2 and 3.05 Gt CO_2, respectively), reducing illegal logging (2.34 Gt CO_2), and halting illegal forest loss in Protected Areas (1.52 Gt CO_2) at a total cost of 15.7 USD tC^{-1}. The importance of forest mitigation in Indonesia is indicated by the NDC, where between half and two-thirds of the 2030 emission target relative to business-as-usual scenario is from reducing deforestation, forest degradation, peatland drainage and fires (Grassi et al. 2017). Avoiding deforestation and reforestation could have multiple co-benefits by improving biodiversity conservation and employment opportunities, while reducing illegal logging in protected areas. However, these options could also have adverse side-effects if they deprive local communities of access to natural resources (Graham et al. 2017). The adoption of the Roundtable on Sustainable Palm Oil certification in oil palm plantations reduced deforestation rates by approximately 33% in the period 2001–2015 (co-benefits with mitigation), and fire rates much more than for non-certified plantations (Carlson et al. 2018). However, given that large-scale oil palm plantations are one of largest drivers of deforestation in Indonesia, objective information on the baseline trajectory for land clearance for oil palm is needed to further assess commitments, regulations and transparency in plantation development (Gaveau et al. 2016). For adaptation options, the community forestry scheme "Hutan Desa" (Village Forest) in Sumatra and Kalimantan helped to avoid deforestation (co-benefits with mitigation) by between 0.6 and 0.9 ha km^{-2} in Sumatra and 0.6 and 0.8 ha km^{-2} in Kalimantan in the period 2012–2016; Santika et al. 2017), improve local livelihood options, and restore degraded ecosystems (positive side-effects for NCP provision) (e.g., Pohnan et al. 2015). Finally, the establishment of Ecosystem Restoration Concessions in Indonesia (covering more than 5.5 thousand km^2 of forests now, and 16 thousand km^2 allocated for the future) facilitates the planting of commercial timber species (co-benefits with mitigation), while assisting natural regeneration, preserving important habitats and species, and improving local well-being and incomes (positive side-effects for Nature's Contributions to People provision), at relatively lower costs compared with timber concessions (Silalahi et al. 2017).

D. Villages. Land degradation, groundwater overuse, climate change and food insecurity: climate smart villages in India

Indian agriculture, which includes both monsoon-dependent rainfed (58%) and irrigated agriculture, is exposed to climate variability and change. Over the past years, the frequency of droughts, cyclones, and hailstorms has increased, with severe droughts in 8 of 15 years between 2002 and 2017 (Srinivasa Rao et al. 2016; Mujumdar et al. 2017). Such droughts result in large yield declines for major crops like wheat in the Indo-Gangetic plain (Zhang et al. 2017). The development of a submersible pump technology in the 1990s, combined with public policies that provide farmers free electricity for groundwater irrigation, resulted in a dramatic increase in irrigated agriculture (Shah et al. 2012). This shift has led to increased dependence on irrigation from groundwater and induced a groundwater crisis, with large impacts on socio-ecosystems. An increasing number of farmers report bore-well failures either due to excessive pumping of an existing well or a lack of water in new wells. The decrease in the groundwater table level has suppressed the recharge of river beds, turning permanent rivers into ephemeral streams (Srinivasan et al. 2015). Wells have recently been drilled in upland areas, where groundwater irrigation is also increasing (Robert et al. 2017). Additional challenges are declining soil organic matter and fertility under monocultures and rice/wheat systems. Unoccupied land is scarce, meaning that the potential for expanding the area farmed is very limited (Aggarwal et al. 2018). In rural areas, diets are deficient in protein, dietary fibre and iron, and mainly comprised of cereals and pulses grown and/or procured through welfare programs (Vatsala et al. 2017). Cultivators are often indebted and suicide rates are much higher than the national average, especially for those strongly indebted (Merriott 2016). Widespread use of diesel pumps for irrigation, especially for paddies, high use of inorganic fertilisers and crop residue burning lead to high GHG emissions (Aggarwal et al. 2018). The Climate-Smart Village (CSV) approach aims at increasing farm yield, income, input use efficiency (water, nutrients, and energy) and reducing GHG emissions (Aggarwal et al. 2018). Climate-smart agriculture interventions are considered in a broad sense by including practices, technologies, climate information services, insurance, institutions, policies, and finance. Options differ based on the CSV site, its agro-ecological characteristics, level of development, and the capacity and interest of farmers and the local government (Aggarwal et al. 2018). Selected interventions included crop diversification, conservation agriculture (minimum tillage, residue retention, laser levelling), improved varieties, weather-based insurance, agro-advisory services, precision agriculture and agroforestry. Farmers' cooperatives were established to hire farm machinery, secure government credit for inputs, and share experiences and knowledge. Tillage practices and residue incorporation increased rice–wheat yields by 5–37%, increased income by 28–40%, reduced GHG emissions by 16–25%, and increased water-use efficiency by 30% (Jat et al., 2014). The resulting portfolio of options proposed by the CSV approach has been integrated with the agricultural development strategy of some states like Haryana.

E. Dense settlements. Climate change and food: green infrastructures

Extreme heat events have led to particularly high rates of mortality and morbidity in cities as urban populations are pushed beyond their adaptive capacities, leading to an increase in mortality rates of 30–130% in major cities in developed countries (Norton et al. 2015). Increased mortality and morbidity from extreme heat events are exacerbated in urban populations by the urban heat island effect (Gabriel and Endlicher 2011; Schatz and Kucharik 2015), which can be limited by developing green infrastructure in cities. Urban green infrastructure includes public and private green spaces, including remnant native vegetation, parks, private gardens, golf courses, street trees, urban farming and more engineered options such as green roofs, green walls, biofilters and raingardens (Norton et al. 2015). Increasing the amount of vegetation, or green infrastructure, in a city is one way to help reduce urban air temperature maxima and variation. Increasing vegetation by 10% in Melbourne, Australia was estimated to reduce daytime urban surface temperatures by approximately 1°C during extreme heat events (Coutts and Harris 2013). Urban farming (a type of urban green infrastructure) is largely driven by the desire to reconnect food production and consumption (Whittinghill and Rowe 2012; see Chapter 5). Even though urban farming can only meet a very small share of the overall urban food demand, it provides fresh and local food, especially perishable fruits and crops that are usually shipped from far and sold at high prices (Thomaier et al. 2015). Food-producing urban gardens and farms are often started by grassroots initiatives (Ercilla-Montserrat et al. 2019) that occupy vacant urban spaces. In recent years, a growing number of urban farming projects (termed Zero-Acreage farming, or Z-farming, Thomaier et al. 2015) were established in and on existing buildings, using rooftop spaces or abandoned buildings through contracts between food businesses and building owners. Almost all Z-farms are located in cities with more than 150,000 inhabitants, with a majority in North American cities such as New York City, Chicago and Toronto (Thomaier et al. 2015). They depend on the availability of vacant buildings and roof tops thereby competing with other uses, such as roof-based solar systems. Urban farming, however, has potentially high levels of soil pollution and air pollutants, which may lead to crop contamination and health risks. These adverse effects could be reduced on rooftops (Harada et al. 2019) or in controlled environments.

6.1.4 Challenges represented in future scenarios

In this section, the evolution of several challenges (climate change, mitigation, adaptation, desertification, land degradation, food insecurity, biodiversity and water) in the future are assessed, focusing on global analyses. The effect of response options on these land challenges in the future is discussed in Section 6.4.4. Where possible, studies quantifying these challenges in the Shared Socio-economic Pathways (SSPs) (Chapter 1; Cross-Chapter Box 1: Scenarios, Chapter 1; Cross-Chapter Box 9: Illustrative Climate and Land Pathways, in this chapter; O'Neill et al. 2014), as these studies can be used to assess which future scenarios could experience multiple challenges in the future.

Climate change: Absent any additional efforts to mitigate, global mean temperature rise is expected to increase by anywhere from 2°C to 7.8°C in 2100 relative to the 1850-1900 reference period (Clarke et al. 2014a; Chapter 2). The level of warming varies depending on the climate model (Collins et al. 2013), uncertainties in the Earth system (Clarke et al. 2014), and socioeconomic/technological assumptions (Clarke et al. 2014a; Riahi et al. 2017) Warming over land is 1.2 to 1.4 times higher than global mean temperature rise; warming in the arctic region is 2.4 to 2.6 times higher than warming in the tropics (Collins et al. 2013). Increases in global mean temperature are accompanied by increases in global precipitation; however, the effect varies across regions with some regions projected to see increases in precipitation and others to see decreases (Collins et al. 2013; Chapter 2). Additionally, climate change also has implications for extreme events (e.g., drought, heat waves, etc.), freshwater availability, and other aspects of the terrestrial system (Chapter 2).

Mitigation: Challenges to mitigation depend on the underlying emissions and "mitigative capacity", including technology availability, policy institutions, and financial resources (O'Neill et al. 2014b). Challenges to mitigation are high in the SSP3 and SSP5, medium in SSP2, and low in SSP1 and SSP4 (O'Neill et al. 2014b, 2017; Riahi et al. 2017a).

Adaptation: Challenges to adaptation depend on climate risk and adaptive capacity, including technology availability, effectiveness of institutions, and financial resources (O'Neill et al. 2014b). Challenges to adaptation are high in the SSP3 and SSP4, medium in SSP2, and low in SSP1 and SSP5 (O'Neill et al. 2014b, 2017; Riahi et al. 2017a).

Desertification: The combination of climate and land use changes can lead to decreases in soil cover in drylands (Chapter 3). Population living in drylands is expected to increase by 43% in the SSP2-Baseline, due to both population increases and an expansion of dryland area (UNCCD 2017).

Land degradation: Future changes in land use and climate have implications for land degradation, including impacts on soil erosion, vegetation, fire, and coastal erosion (Chapter 4; Scholes et al. 2018). For example, soil organic carbon is expected to decline by 99 $GtCO_2e$ in 2050 in an SSP2-Baseline scenario, due to both land management and expansion in agricultural area (Brink et al. 2018).

Food insecurity: Food insecurity in future scenarios varies significantly, depending on socio-economic development and study. For example, the population at risk of hunger ranges from 0 to 800 million in 2050 (Hasegawa et al. 2015a; Ringler et al. 2016; Fujimori et al. 2018b; Hasegawa et al. 2018; Fujimori et al. 2018a; Baldos and Hertel 2015) and 0–600 million in 2100 (Hasegawa et al. 2015a). Food prices in 2100 in non-mitigation scenarios range from 0.9 to about 2 times their 2005 values (Hasegawa et al. 2015a; Calvin et al. 2014a; Popp et al. 2017). Food insecurity depends on both income and food prices (Fujimori et al. 2018b). Higher income (e.g., SSP1, SSP5), higher yields (e.g., SSP1, SSP5), and less meat intensive diets (e.g., SSP1) tend to result in reduced food insecurity (Hasegawa et al. 2018; Fujimori et al. 2018b).

Biodiversity: Future species extinction rates vary from modest declines to 100-fold increases from 20th century rates, depending on the species (e.g., plants, vertebrates, invertebrates, birds, fish, corals), the degree of land-use change, the level of climate change, and assumptions about migration (Pereira et al.,2010). Mean species abundance (MSA) is also estimated to decline in the future by 10–20% in 2050 (Vuuren et al., 2015; Pereira et al. 2010). Scenarios with greater cropland expansion lead to larger declines in MSA (UNCCD 2017) and species richness (Newbold et al., 2015).

Water stress: Changes in both water supply (due to climate change) and water demand (due to socioeconomic development) in the future have implications for water stress. Water withdrawals for irrigation increase from about 2500 $km^3 yr^{-1}$ in 2005 to between 2900 and 9000 $km^3 yr^{-1}$ at the end of the century (Chaturvedi et al. 2013; Kim et al. 2016; Bonsch et al.,2015; Wada and Bierkens 2014; Graham et al. 2018; Hejazi et al. 2014); total water withdrawals at the end of the century range from 5000 to 13000 $km^3 yr^{-1}$ (Wada and Bierkens 2014a; Hejazi et al. 2014a; Graham et al. 2018; Kim et al. 2016). The magnitude of change in both irrigation and total water withdrawals depend on population, income, and technology (Hejazi et al. 2014a; Graham et al. 2018a). The combined effect of changes in water supply and water demand will lead to an increase of between 1 and 6 billion people living in water stressed areas (Schlosser et al. 2014; Hanasaki et al. 2013a; Hejazi et al. 2014c). Changes in water quality are not assessed here but could be important (Liu et al. 2017).

Scenarios with Multiple Challenges: Table 6.2 summarises the challenges across the five SSP Baseline scenarios.

Table 6.2: Assessment of future challenges to climate change, mitigation, adaptation, desertification, land degradation, food insecurity, water stress, and biodiversity in the SSP Baseline scenarios

SSP	Summary of Challenges
SSP1	The SSP1 (van Vuuren et al. 2017b) has low challenges to mitigation and adaptation. The resulting Baseline scenario includes: • Continued, but moderate, *climate change*: global mean temperature increases by 3 to 3.5°C in

Subject to Copy-editing

	2100 (Riahi et al. 2017a; Huppmann et al. 2018), • Low levels of *food insecurity*: malnourishment is eliminated by 2050 (Hasegawa et al. 2015b), • Declines in *biodiversity*: biodiversity loss increases from 34% in 2010 to 38% in 2100 (UNCCD 2017), and • High *water stress*: global water withdrawals decline slightly from the baseline in 2071-2100, but ~2.6 billion people live in water stressed areas (Hanasaki et al. 2013b). Additionally, this scenario is likely to have lower challenges related to desertification, land degradation, and biodiversity loss than the SSP2 as it has lower population, lower land use change and lower climate change (Riahi et al. 2017a).
SSP2	The SSP2 (Fricko et al. 2017) is a scenario with medium challenges to mitigation and high challenges to adaptation. The resulting Baseline scenario includes: • Continued *climate change*: global mean temperature increases by 3.8 to 4.3°C in 2100 (Fricko et al. 2017; Riahi et al. 2017a; Huppmann et al. 2018), • Increased challenges related to *desertification*: the population living in drylands is expected to increase by 43% in 2050 (UNCCD 2017), • Increased *land degradation*: soil organic carbon is expected to decline by 99 $GtCO_2e$ in 2050 (Brink et al. 2018), • Low levels of *food insecurity*: malnourishment is eliminated by 2100 (Hasegawa et al. 2015b), • Declines in *biodiversity*: biodiversity loss increases from 34% in 2010 to 43% in 2100 (UNCCD 2017), and • High *water stress*: global water withdrawals nearly doubles from the baseline in 2071-2100, with ~4 billion people living in water stressed areas (Hanasaki et al. 2013).
SSP3	The SSP3 (Fujimori et al.,2017) is a scenario with high challenges to mitigation and high challenges to adaptation. The resulting Baseline scenario includes: • Continued *climate change*: global mean temperature increases by 4 to 4.8°C in 2100 (Riahi et al. 2017a; Huppmann et al. 2018), • High levels of *food insecurity*: about 600 million malnourished in 2100 (Hasegawa et al. 2015b), • Declines in *biodiversity*: biodiversity loss increases from 34% in 2010 to 46% in 2100 (UNCCD 2017), and • High *water stress*: global water withdrawals more than double from the baseline in 2071-2100, with ~5.5 billion people living in water stressed areas (Hanasaki et al. 2013). Additionally, this scenario is likely to have higher challenges to desertification, land degradation, and biodiversity loss than the SSP2 as it has higher population, higher land use change and higher climate change (Riahi et al. 2017a).
SSP4	The SSP4 (Calvin et al. 2017a) has high challenges to adaptation but low challenges to mitigation. The resulting Baseline scenario includes: • Continued *climate change*: global mean temperature increases by 3.4 to 3.8°C in 2100 (Calvin et al. 2017b; Riahi et al. 2017a; Huppmann et al. 2018), • High levels of *food insecurity*: about 400 million malnourished in 2100 (Hasegawa et al. 2015b), and • High *water stress*: about 3.5 billion people live in water stressed areas in 2100 (Hanasaki et al. 2013). Additionally, this scenario is likely to have similar effects on biodiversity loss as the SSP2 as it has similar land use change and similar climate change (Riahi et al. 2017a).
SSP5	The SSP5 (Kriegler et al. 2017) has high challenges to mitigation but low challenges to adaptation. The resulting Baseline scenario includes: • Continued *climate change*: global mean temperature increases by 4.6 to 5.4°C in 2100 (Kriegler et al. 2017; Riahi et al. 2017a; Huppmann et al. 2018), • Low levels of *food insecurity*: malnourishment is eliminated by 2050 (Hasegawa et al. 2015b), and • Increased water use and water scarcity: global water withdrawals increase by ~80% in 2071-

	2100 with nearly 50% of the population living in water stressed areas (Hanasaki et al. 2013b). Additionally, this scenario is likely to have higher effects on biodiversity loss as the SSP2 as it has similar land use change and higher climate change (Riahi et al. 2017a).

6.2 Response options, co-benefits and adverse side-effects across the land challenges

This section describes the integrated response options available to address the land challenges of climate change mitigation, climate change adaptation, desertification, land degradation and food security. These can be categorised into options that rely on a) land management, b) value chain management and c) risk management (Figure 6.5). The land management integrated response options can be grouped according to those that are applied in agriculture, in forests, on soils, in other/all ecosystems and those that are applied specifically for carbon dioxide removal (CDR). The value chain management integrated response options can be categorised as those based demand management and supply management. The risk management options are grouped together (Figure 6.5).

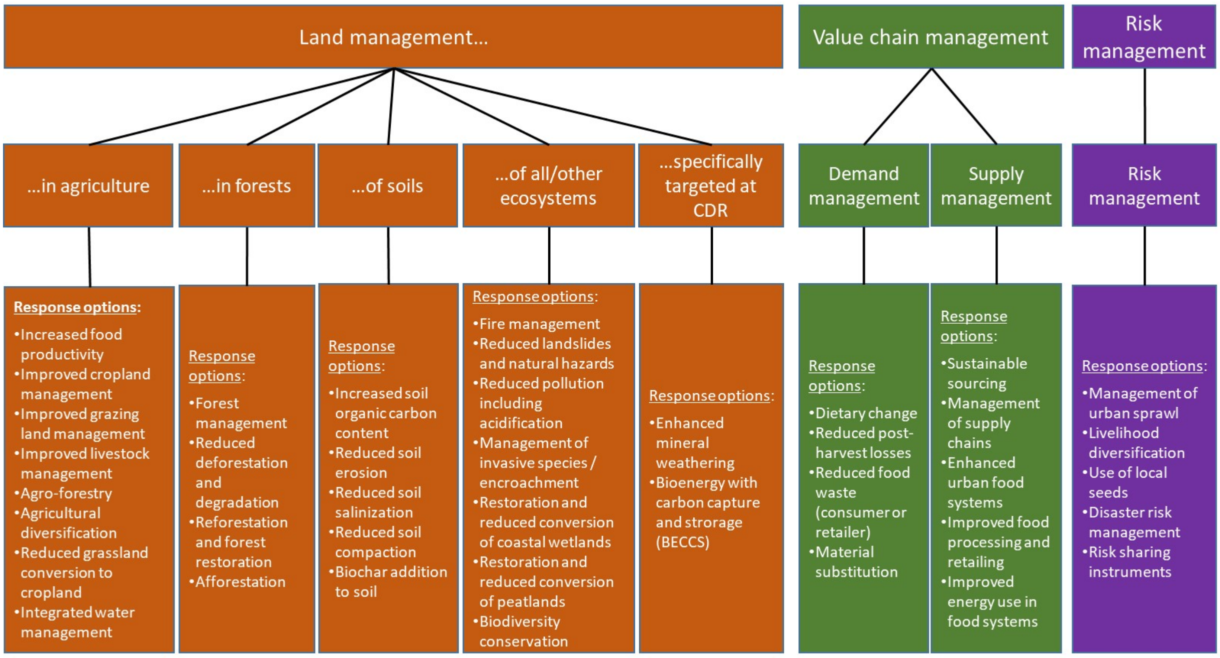

Figure 6.5 Broad categorisation of response options categorised into three main classes and eight sub-classes.

Note that the integrated response options are not mutually exclusive (e.g. cropland management might also increase soil organic matter stocks), and a number of the integrated response options are comprised of a number of practices (e.g., improved cropland management is a collection of practices consisting of a) management of the crop: including high input carbon practices, e. g., improved crop varieties, crop rotation, use of cover crops, perennial cropping systems, agricultural biotechnology; b) nutrient management: including optimised fertiliser application rate, fertiliser type [organic and mineral], timing, precision application, inhibitors; c) reduced tillage intensity and residue retention; d) improved water management: including drainage of waterlogged mineral soils and irrigation of crops in arid / semi-arid conditions; and e) improved rice management: including water management such as mid-season drainage and improved fertilisation and residue management in paddy rice systems).

In this section we deal only with integrated response options, not the policies that are currently / could be implemented to enable their application; that is the subject of Chapter 7. Also note that enabling conditions such as indigenous and local knowledge, gender issues, governance etc. are not categorised as integrated response options (see Section 6.1.2). Some suggested methods to address land challenges are better described as *overarching frameworks* than as integrated response options. For example, *climate smart agriculture* is a collection of integrated response options aimed at delivering mitigation and adaptation in agriculture, including improved cropland management, grazing land management and livestock management. Table 6.3 shows how a number of overarching frameworks are comprised of a range of integrated response options.

Similarly, policy goals, such as *land degradation neutrality* (discussed further in Chapter 7), are not considered as integrated response options. For this reason, *land degradation neutrality*, and overarching frameworks, such as those described in Table 6.3 do not appear as response options in the following sections, but the component integrated response options that contribute to these policy goals or over-arching frameworks are addressed in detail.

Table 6.3 Examples of overarching frameworks that consist of a range of response options, showing how various response options contribute to the overarching frameworks

The SR15 considered a range of response options (from a mitigation / adaptation perspective only). Table 6.4 shows how the SR15 options map on to the response options considered in this report (SRCCL). Note that this report excludes most of the energy-related options from SR15, as well as green infrastructure and sustainable aquaculture.

Table 6.4 Mapping of response options considered in this report (SRCCL) and SR15

SRCCL Response Option or Options	SR15 Response Option or Options
Afforestation	Afforestation
Reforestation and forest restoration	Reforestation and reduced land degradation and forest restoration

Agricultural diversification	Mixed crop-livestock systems
Agroforestry	Agroforestry and silviculture
Biochar addition to soil	Biochar
Biodiversity conservation	Biodiversity conservation
Bioenergy and BECCS	Biomass use for energy production with carbon capture and sequestration (BECCS) (through combustion, gasification, or fermentation)
Dietary change	Dietary changes, reducing meat consumption
Disaster risk management	Climate services
	Community-based adaptation
Enhanced urban food systems	Urban and peri-urban agriculture and forestry
Enhanced weathering of minerals	Mineralisation of atmospheric CO2 through enhanced weathering of rocks
Fire management	Fire management and (ecological) pest control
Improved forest management	Forest management
Improved cropland management	Methane reductions in rice paddies
Improved cropland management	Nitrogen pollution reductions, e.g., by fertiliser reduction, increasing nitrogen fertiliser efficiency, sustainable fertilisers
	Precision agriculture
	Conservation agriculture
Improved food processing and retailing	
Improved grazing land management	Livestock and grazing management, for example, methane and ammonia reductions in ruminants through feeding management or feed additives, or manure management for local biogas production to replace traditional biomass use
Improved livestock management	
	Manure management
Increased energy efficiency in food systems	
Increased food productivity	Increasing agricultural productivity
Increased soil organic carbon content	Changing agricultural practices enhancing soil carbon
	Soil carbon enhancement, enhancing carbon sequestration in biota and soils, e.g. with plants with high carbon sequestration potential (also AFOLU measure)
Integrated water management	Irrigation efficiency
Livelihood diversification	
Management of invasive species / encroachment	
Management of supply chains	
Management of urban sprawl	Urban ecosystem services
	climate resilient land use
Material substitution	Material substitution of fossil CO_2 with bio-CO_2 in industrial application (e.g. the beverage industry)
	Carbon Capture and Usage – CCU; bioplastics (bio-based materials replacing fossil fuel uses as feedstock in the production of chemicals and polymers), carbon fibre
Reduced soil erosion	
Reduced soil compaction	
Reduced deforestation	Reduced deforestation, forest protection, avoided forest conversion
Reduced food waste (consumer or retailer)	Reduction of food waste (incl. reuse of food processing waste for fodder)
Reduced grassland conversion to cropland	
Reduced landslides and natural hazards	
Reduced pollution including acidification	Reduced air pollution
Reduced post-harvest losses	

Reduced soil salinisation	
Restoration and reduced conversion of coastal wetlands	Managing coastal stress Restoration of wetlands (e.g., coastal and peat-land restoration, blue carbon) and wetlands management
Restoration and reduced conversion of peatlands	
Risk sharing instruments	Risk sharing
Sustainable sourcing	
Use of local seeds	

Before providing the quantitative assessment of the impacts of each response option in addressing mitigation, adaptation, desertification, land degradation and food security in section 6.3, the integrated response options are descried in section 6.2.1 and any context specificities in the effects are noted.

6.2.1 Integrated response options based on land management

6.2.1.1 Integrated response options based on land management in agriculture

Integrated response options based on land management in agriculture are described in Table 6.5, which also notes any context specificities in the effects of the response options and provides the evidence base.

6.2.1.2 Integrated response options based on land management in forests

Integrated response options based on land management in forests are described in Table 6.6, which also notes any context specificities in the effects of the response options and provides the evidence base.

6.2.1.3 Integrated response options based on land management of soils

Integrated response options based on land management of soils are described in Table 6.7, which also notes any context specificities in the effects of the response options and provides the evidence base.

6.2.1.4 Integrated response options based on land management of all/other ecosystems

Integrated response options based on land management in all/other ecosystems are described in Table 6.8, which also notes any context specificities in the effects of the response options and provides the evidence base.

6.2.1.5 Integrated response options based on land management specifically for carbon dioxide removal (CDR)

Integrated response options based on land management specifically for CDR are described in Table 6.9, which also notes any context specificities in the effects of the response options and provides the evidence base.

Table 6.5 Integrated response options based on land management in agriculture

Integrated response option	Description	Context and caveats	Supporting evidence
Increased food productivity	Increased food productivity arises when the output of food commodities increases per unit of input, e.g. per unit of land or water. It can be realised through many other interventions such as improved cropland, grazing land and livestock management.	Many interventions to increase food production, particularly those predicated on very large inputs of agro-chemicals, have a wide range of negative externalities leading to the proposal of sustainable intensification as a mechanism to deliver future increases in productivity that avoid these adverse outcomes. Intensification through additional input of N fertiliser, for example, would result in negative impacts on climate, soil, water and air pollution. Similarly, if implemented in a way that over-exploits the land significant negative impacts would occur, but if achieved through sustainable intensification, and used to spare land, it could reduce the pressure on land.	Cross-Chapter Box 6 on Agricultural Intensification, Chapter 5; Chapter 3; Burney et al. 2010; Foley et al. 2011; Garnett et al. 2013; Godfray et al. 2010; Lal 2016; Lamb et al. 2016; Lobell et al 2008.; Shcherbak et al. 2014; Smith et al. 2013; Tilman et al. 2014; Scholes et al. 2018; Balmford et al. 2018
Improved cropland management	Improved cropland management is a collection of practices consisting of a) *management of the crop*: including high input carbon practices, for example, improved crop varieties, crop rotation, use of cover crops, perennial cropping systems, integrated production systems, crop diversification, agricultural biotechnology, b) *nutrient management*: including optimised fertiliser application rate, fertiliser type (organic manures, compost and mineral), timing, precision application, nitrification inhibitors, c) *reduced tillage intensity and residue retention*, d) *improved water management*: including drainage of waterlogged mineral soils and irrigation of crops in arid / semi-arid conditions, e) *improved rice management*: including water management such as mid-season drainage and improved fertilisation and residue management in paddy rice systems, and f) *biochar application*.	Improved cropland management can reduce greenhouse gas emissions and create soil carbon sinks, though if poorly implemented, it could increase N_2O and CH_4 emissions from N fertilisers, crop residues and organic amendments. It can improve resilience of food crop production systems to climate change and can be used to tackle desertification and land degradation by improving sustainable land management. It can also contribute to food security by closing crop yield gaps to increase food productivity.	Chapter 4; Chapter 3; Chapter 2; Chapter 5; Bryan et al. 2009; Chen et al. 2010; Labrière et al. 2015; Lal 2011; Poeplau and Don 2015; Porter et al. 2014a; Smith et al. 2014b; Smith 2008; Tilman et al. 2011
Improved grazing land	Improved grazing land management is a collection of practices consisting of a) *management of vegetation*: including improved grass varieties / sward composition, deep rooting grasses,	Improved grazing land management can increase soil carbon sinks, reduce greenhouse gas emissions, improve the resilience of grazing lands to future	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Section 6.3; Archer et al. 2011; Briske et al. 2015;

management	increased productivity, and nutrient management, b) *animal management*: including appropriate stocking densities fit to carrying capacity, fodder banks, and fodder diversification, and c) *fire management*: improved use of fire for sustainable grassland management, including fire prevention and improved prescribed burning (see also fire management as a separate response option; Table 6.8).	climate change, help reduce desertification and land degradation by optimising stocking density and reducing overgrazing, and can enhance food security through improved productivity.	Conant et al. 2017; Herrero et al. 2016; Porter et al. 2014a; Schwilch et al. 2014; Smith et al. 2014b; Tighe et al. 2012
Improved livestock management	Improved livestock management is a collection of practices consisting of a) *improved feed and dietary additives* (e.g., bioactive compounds, fats), used to increase productivity and reduce emissions from enteric fermentation; b) *breeding* (e.g., breeds with higher productivity or reduced emissions from enteric fermentation), c) *herd management,* including decreasing neo-natal mortality, improving sanitary conditions, animal health and herd renewal, and diversifying animal species, d) *emerging technologies* (of which some are not legally authorised in several countries) such as propionate enhancers, nitrate and sulphate supplements, archaea inhibitors and archaeal vaccines, methanotrophs, acetogens, defaunation of the rumen, bacteriophages and probiotics, ionophores / antibiotics; and e) *improved manure management,* including manipulation of bedding and storage conditions, anaerobic digesters; biofilters, dietary change and additives, soil-applied and animal-fed nitrification inhibitors, urease inhibitors, fertiliser type, rate and timing, manipulation of manure application practices, and grazing management.	Improved livestock management can reduce greenhouse gas emissions, particularly from enteric methane and manure management. It can improve the resilience of livestock production systems to climate change by breeding better adapted livestock. It can help with desertification and land degradation, e.g. through use of more efficient and adapted breeds to allow reduced stocking densities. Improved livestock sector productivity can also increase food production.	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Archer et al. 2011; Herrero et al. 2016; Miao et al. 2015; Porter et al. 2014a; Rojas-Downing et al. 2017; Smith et al. 2008, 2014b; Squires et al. 2005; Tighe et al. 2012
Agroforestry	Agroforestry involves the deliberate planting of trees in croplands and silvo-pastoral systems.	Agroforestry sequesters carbon in vegetation and soils. The use of leguminous trees can enhance biological N fixation and resilience to climate change. Soil improvement and the provision of perennial vegetation can help to address desertification and land degradation. Agroforestry can increase agricultural productivity, with benefits for food security. Additionally, agroforestry can enable payments to farmers for ecosystem services and reduce vulnerability to climate shocks.	Antwi-Agyei et al. 2014; Mbow et al. 2014a; Mutuo et al. 2005; Rosenstock et al. 2014; Sain et al. 2017; Sida et al. 2018; Vignola et al. 2015; Yirdaw et al. 2017 Benjamin et. al. 2018; Guo et al. 2018; Herder et al. 2017; Mosquera-Losada et al. 2018; Nair et al. 2014; Ram et al. 2017; Santiago-Freijanes et. al. 2018;

Agricultural diversification	Agricultural diversification includes a set of agricultural practices and products obtained in the field that aim to improve the resilience of farmers to climate variability and climate change and to economic risks posed by fluctuating market forces. In general, the agricultural system is shifted from one based on low-value agricultural commodities to one that is more diverse, composed of a basket of higher value-added products.	Agricultural diversification is targeted at adaptation but could also deliver a small carbon sink, depending on how it is implemented. It could reduce pressure on land, benefiting desertification, land degradation, food security and household income. However, the potential to achieve household food security is influenced by the market orientation of a household, livestock ownership, non-agricultural employment opportunities, and available land resources.	Birthal et al. 2015; Campbell et al. 2014; Cohn et al. 2017; Lambin and Meyfroidt 2011; Lipper et al. 2014; Massawe et al. 2016; Pellegrini and Tasciotti 2014; Waha et al. 2018
Reduced grassland conversion to cropland	Grasslands can be converted to croplands by ploughing of grassland and seeding with crops. Since croplands have a lower soil carbon content than grasslands and are also more prone to erosion than grasslands, reducing conversion of grassland to croplands will prevent soil carbon losses by oxidation and soil loss through erosion. These processes can be reduced if the rate of grassland conversion to cropland is reduced.	Stabilising soils by retaining grass cover also improves resilience, benefiting adaptation, desertification and land degradation. Since conversion of grassland to cropland usually occurs to remedy food security challenges, food security could be adversely affected, since more land is required to produce human food from livestock products on grassland than from crops on cropland.	Chapter 3; Chapter 4; Chapter 5; Clark and Tilman 2017; Lal 2001a; de Ruiter et al. 2017; Poore & Nemecek, 2018
Integrated water management	Integrated water management is the process of creating holistic strategies to promote integrated, efficient, equitable and sustainable use of water for agroecosystems. It includes a collection of practices including water-use efficiency and irrigation in arid/semi-arid areas, improvement of soil health through increases in soil organic matter content, and improved cropland management, agroforestry and conservation agriculture. Increasing water availability, and reliability of water for agricultural production, can be achieved by using different techniques of water harvesting, storage, and its judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas can benefit adaptation.	These practices can reduce aquifer and surface water depletion, and prevent over extraction, and the management of climate risks. Many technical innovations, e.g., precision water management, can have benefits for both adaptation and mitigation, although trade-offs are possible. Maintaining the same level of yield through use of site-specific water management-based approach could have benefits for both food security and mitigation.	Chapter 3; Chapter 4; Chapter 5; Brindha and Pavelic 2016; Jat et al. 2016; Jiang 2015; Keesstra et al. 2018; Liu et al. 2017; Nejad 2013; Rao et al. 2017; Shaw et al. 2014; Sapkota et al. 2017; Scott et al. 2011; Waldron et al. 2017

Table 6.6 Integrated response options based on land management in forests

Integrated response option	Description	Context and caveats	Supporting evidence
Improved forest management	Improved forest management refers to management interventions in forests for the purpose of climate change mitigation. It includes a wide variety of practices affecting the growth of trees and the biomass removed, including improved regeneration (natural or artificial) and a better schedule, intensity and execution of operations (thinning, selective logging, final cut; reduced impact logging, etc.). Sustainable forest management is the stewardship and use of forests and forest lands in a way, and at a rate, that maintains their biodiversity, productivity, regeneration capacity, vitality and their potential to fulfil, now and in the future, relevant ecological, economic and social functions, at local, national, and global levels, and that does not cause damage to other ecosystems.	Sustainable forest management can enhance the carbon stock in biomass, dead organic matter, and soil – while providing wood-based products to reduce emissions in other sectors through material and energy substitution. A trade-off exists between different management strategies: higher harvest decreases the carbon in the forest biomass in the short term but increases the carbon in wood products and the potential for substitution effects. Sustainable forest management, also through close-to-nature silvicultural techniques, can potentially offer many co-benefits in terms of climate change mitigation, adaptation, biodiversity conservation, microclimatic regulation, soil erosion protection, coastal area protection and water and flood regulation. Forest management strategies aimed at increasing the biomass stock levels may have adverse side-effects, such as decreasing the stand-level structural complexity, biodiversity and resilience to natural disasters. Forest management also affects albedo and evapotranspiration.	Chapter 2; Chapter 4; D'Amato et al. 2011; Dooley and Kartha 2018a; Ellison et al. 2017; Erb et al. 2017; Grassi et al. 2018; Griscom et al. 2017a; Jantz et al. 2014; Kurz et al. 2016; Locatelli 2011; Luyssaert et al. 2018; Nabuurs et al. 2017; Naudts et al. 2016; Putz et al. 2012; Seidl et al. 2014; Smith et al. 2014a; Smyth et al. 2014; Stanturf et al. 2015; Forest Europe 2016 Pingoud et al. 2018
Reduced deforestation and degradation	Reduced deforestation and forest degradation includes conservation of existing carbon pools in forest vegetation and soil by controlling the drivers of deforestation (i.e., commercial and subsistence agriculture, mining, urban expansion) and forest degradation (i.e., overharvesting including fuelwood collection, poor harvesting practices, overgrazing, pest outbreaks, and extreme wildfires), also through establishing protected areas, improving law enforcement, forest governance and land tenure, supporting community forest management and introducing forest certification.	Reducing deforestation and degradation is a major strategy to reduce global GHG emissions. The combination of reduced GHG emissions and biophysical effects results in a large climate mitigation effect, with benefits also at local level. Reduced deforestation preserves biodiversity and ecosystem services more efficiently and at lower costs than afforestation/reforestation. Efforts to reduce deforestation and forest degradation may have potential adverse side-effects, for example, reducing availability of land for farming, restricting the rights and access of local people to forest resources (e.g. firewood), or increasing the dependence of local people to insecure external funding.	Chapter 2; Alkama and Cescatti 2016; Baccini et al. 2017; Barlow et al. 2016; Bayrak et al. 2016; Caplow et al. 2011; Curtis et al. 2018; Dooley and Kartha 2018; Griscom et al. 2017a; Hansen et al. 2013b; Hosonuma et al. 2012; Houghton et al. 2015; Lewis et al. 2015; Pelletier et al. 2016; Rey Benayas et al. 2009
Reforestation	Reforestation is the conversion to forest of land that has	Reforestation is similar to afforestation with respect to the co-	Chapter 2; Dooley and

and forest restoration	previously contained forests but that has been converted to some other use. Forest restoration refers to practices aimed at regaining ecological integrity in a deforested or degraded forest landscape. As such, it could fall under reforestation if it were re-establishing trees where they have been lost, or under forest management if it were restoring forests where not all trees have been lost. For practical reasons, here forest restoration is treated together with reforestation.	benefits and adverse side-effects among climate change mitigation, adaptation, desertification, land degradation and food security (see row on Afforestation below). Forest restoration can increase terrestrial carbon stocks in deforested or degraded forest landscapes and can offer many co-benefits in terms of increased resilience of forests to climate change, enhanced connectivity between forest areas and conservation of biodiversity hotspots. Forest restoration may threaten livelihoods and local access to land if subsistence agriculture is targeted.	Kartha 2018; Ellison et al. 2017; Locatelli 2011; Locatelli et al. 2015a; Smith et al. 2014b; Stanturf et al. 2015
Afforestation	Afforestation is the conversion to forest of land that historically have not contained forests (see also reforestation).	Afforestation increases terrestrial carbon stocks but can also change the physical properties of land surfaces, such as surface albedo and evapotranspiration with implications for local and global climate. In the tropics, enhanced evapotranspiration cools surface temperatures, reinforcing the climate benefits of CO_2 sequestration in trees. At high latitudes and in areas affected by seasonal snow cover, the decrease in surface albedo after afforestation becomes dominant and causes an annual average warming that counteracts carbon benefits. Net biophysical effects on regional climate from afforestation is seasonal and can reduce the frequency of climate extremes, such as heat waves, improving adaptation to climate change and reducing the vulnerability of people and ecosystems. Afforestation helps to address land degradation and desertification, as forests tend to maintain water quality by reducing runoff, trapping sediments and nutrients, and improving groundwater recharge. However, food security could be hampered since an increase in global forest area can increase food prices through land competition. Other adverse side-effects occur when afforestation is based on non-native species, especially with the risks related to the spread of exotic fast-growing tree species. For example, exotic species can upset the balance of evapotranspiration regimes, with negative impacts on water availability, particularly in dry regions.	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Alkama and Cescatti 2016; Arora and Montenegro 2011; Bonan 2008; Boysen et al. 2017; Brundu and Richardson 2016; Cherubini et al. 2017; Ciais et al. 2013; Ellison et al. 2017; Findell et al. 2017; Idris Medugu et al. 2010; Kongsager et al. 2016; Kreidenweis et al. 2016a; Lejeune et al 2018.; Li et al. 2015; Locatelli et al. 2015a; Perugini et al. 2017; Salvati et al. 2014; Smith et al. 2013, 2014b; Trabucco et al. 2008;

1 **Table 6.7 Integrated response options based on land management of soils**

Integrated response option	**Description**	**Context and caveats**	**Supporting evidence**
Increased soil organic carbon content	Practices that increase soil organic matter content include a) *land use change* to an ecosystem with higher equilibrium soil carbon levels (e.g. from cropland to forest), b) *management of the vegetation*: including high input carbon practices, for example, improved varieties, rotations and cover crops, perennial cropping systems, biotechnology to increase inputs and recalcitrance of below ground carbon, c) *nutrient management and organic material input* to increase carbon returns to the soil: including optimised fertiliser and organic material application rate, type, timing and precision application, d) *reduced tillage intensity and residue retention*, and e) *improved water management*: including irrigation in arid / semi-arid conditions.	Increasing soil carbon stocks removes CO_2 from the atmosphere and increases the water holding capacity of the soil thereby conferring resilience to climate change and enhancing adaptation capacity. It is a key strategy for addressing both desertification and land degradation. There is some evidence that crop yields and yield stability increase by increased organic matter content, though some studies show equivocal impacts. Some practices to increase soil organic matter stocks vary in their efficacy. For example, the impact of no till farming and conservation agriculture on soil carbon stocks is often positive, but can be neutral or even negative, depending on the amount of crop residues returned to the soil. If soil organic carbon stocks were increased by increasing fertiliser inputs to increase productivity, emissions of nitrous oxide from fertiliser use could offset any climate benefits arising from carbon sinks. Similarly, if any yield penalty is incurred from practices aimed at increasing soil organic carbon stocks (e.g. through extensification), emissions could be increased through indirect land use change, and there could also be adverse side-effects on food security.	Bestelmeyer and Briske 2012; Cheesman et al. 2016; Frank et al. 2017; Gao et al. 2018; Keesstra et al 2016.; Lal 2016, 2006; Lambin and Meyfroidt 2011; de Moraes Sá et al. 2017; Palm et al. 2014; Pan et al. 2009; Paustian et al. 2016; Powlson et al. 2014, 2016, Smith et al. 2013, 2016a, 2014b; Soussana et al. 2019a; Steinbach et al 2006.; VandenBygaart 2016; Hijbeek et al., 2017; Schjønning et al., 2018;
Reduced soil erosion	Soil erosion is the removal of soil from the land surface by water, wind or tillage, which occurs worldwide but it is particularly severe in Asia, Latin America and the Caribbean, and the Near East and North Africa. Soil erosion management includes conservation practices (e.g., the use of minimum tillage or zero tillage, crop rotations and cover crops, rational grazing systems), engineering-like practices (e.g., construction of terraces and contour cropping for controlling water erosion), or forest barriers and strip	The fate of eroded soil carbon is uncertain, with some studies indicating a net source of CO_2 to the atmosphere and others suggesting a net sink. Reduced soil erosion has benefits for adaptation as it reduces vulnerability of soils to loss under climate extremes, increasing resilience to climate change. Some management practices implemented to control erosion, such as increasing ground cover, can reduce the vulnerability of soils to degradation / landslides, and prevention of soil erosion is a key measure used to tackle desertification. Because it protects the capacity of land to produce food, it also contributes positively to food security.	Chapter 3; Chen 2017; Derpsch et al. 2010; FAO and ITPS 2015; FAO 2015; Garbrecht et al. 2015; Jacinthe and Lal 2001; de Moraes Sá et al. 2017; Poeplau and Don 2015; Smith et al. 2001; Stallard 1998; Lal and Moldenhauer 1987; Van Oost et al. 2007; Lugato et al. 2016; Smith et al. 2005; Lal 2001a

	cultivation for controlling wind erosion. In eroded soils, the advance of erosion gullies and sand dunes can be limited by increasing plant cover, among other practices.		
Reduced soil salinisation	Soil salinisation is a major process of land degradation that decreases soil fertility and affects agricultural production, aquaculture and forestry. It is a significant component of desertification processes in drylands. Practices to reduce soil salinisation include improvement of water management (e.g., water-use efficiency and irrigation/drainage technology in arid/semi-arid areas, surface and groundwater management), improvement of soil health (through increase in soil organic matter content) and improved cropland, grazing land and livestock management, agroforestry and conservation agriculture.	Techniques to prevent and reverse soil salinisation may have small benefits for mitigation by enhancing carbon sinks. These techniques may benefit adaptation and food security by maintaining existing crop systems and closing yield gaps for rainfed crops. These techniques are central to reducing desertification and land degradation, since soil salinisation is a primary driver of both.	Section 3.5; Chapter 4; Chapter 5; Baumhardt et al. 2015; Dagar et al. 2016a; Datta et al. 2000; DERM 2011; Evans and Sadler 2008; He et al. 2015; D'Odorico et al. 2013; Prathapar 1988; Qadir et al. 2013; Rengasamy 2006; Singh 2009; UNCTAD 2011; Wong et al. 2010
Reduced soil compaction	Reduced soil compaction mainly includes agricultural techniques (e.g. crop rotations, control of livestock density) and control of agricultural traffic.	Techniques to reduce soil compaction have variable impacts on GHG emissions but may benefit adaptation by improving soil climatic resilience. Since soil compaction is a driver of both desertification and land degradation, a reduction of soil compaction could benefit both. It could also help close yield gaps in rainfed crops.	Chamen et al. 2015; Epron et al. 2016; ITPS-FAO 2015; Hamza and Anderson 2005; Soane and van Ouwerkerk 1994; Tullberg et al. 2018
Biochar addition to soil	The use of biochar, a solid product of the pyrolysis process, as a soil amendment increases the water-holding capacity of soil. It may therefore provide better access to water and nutrients for crops and other vegetation types (so can form part of cropland, grazing land and improved forest management).	The use of biochar increases carbon stocks in the soil. It can enhance yields in the tropics (but less so in temperate regions), thereby benefiting both adaptation and food security. Since it can improve soil water holding capacity and nutrient use efficiency, and can ameliorate heavy metal pollution and other impacts, it can benefit desertification and land degradation. The positive impacts could be tempered by additional pressure on land if large quantities of biomass are required as feedstock for biochar production.	Chapter 2; Chapter 3; Chapter 4; Chapter 5; Jeffery et al. 2017; Smith 2016; Sohi 2012; Woolf et al. 2010

Table 6.8 Integrated response options based on land management of all/other ecosystems

Integrated response option	Description	Context and caveats	Supporting evidence
Fire management	Fire management is a land management option aimed at safeguarding life, property and resources through the prevention, detection, control, restriction and suppression of fire in forest and other vegetation. It includes the improved use of fire for sustainable forestry management, including wildfire prevention and prescribed burning. Prescribed burning is used to reduce the risk of large, uncontrollable fires in forest areas, and controlled burning is among the most effective and economic methods of reducing fire danger and stimulating natural reforestation under the forest canopy and after clear felling.	The frequency and severity of large wildfires have increased around the globe in recent decades, which has impacted forest carbon budgets. Fire can cause various greenhouse gas emissions such as CO_2, CH_4, and N_2O, and others such as CO, volatile organic carbon, and smoke aerosols. Fire management can reduce GHG emissions and can reduce haze pollution, which has significant health and economic impacts. Fire management helps to prevent soil erosion and land degradation and is used in rangelands to conserve biodiversity and to enhance forage quality.	Chapter 2; Cross-Chapter Box 3 on fire and climate; Esteves et al. 2012; FAO 2006; Lin et al. 2017; O'Mara 2012; Rulli et al. 2006; Scasta et al. 2016; Seidl et al. 2014; Smith et al. 2014b; Tacconi 2016; Valendik et al. 2011; Westerling et al. 2006; Whitehead et al. 2008; Yong and Peh 2016
Reduced landslides and natural hazards	Landslides are mainly triggered by human activity (e.g. legal and illegal mining, fire, deforestation) in combination with climate. Management of landslides and natural hazards (e.g. floods, storm surges, droughts) is based on vegetation management (e.g. afforestation) and engineering works (e.g. dams, terraces, stabilisation and filling of erosion gullies).	Management of landslides and natural hazards is important for adaptation and is a very important intervention for managing land degradation, since landslides and natural hazards are among the most severe degradation processes. In countries where mountain slopes are planted with food crops, reduced landslides will help deliver benefits for food security. Most deaths caused due to different disasters have occurred in developing countries, in which poverty, poor education and health facilities, and other aspects of development increase exposure, vulnerability and risk.	IPCC AR5 WG2 Chapter 14; Arnáez J et al. 2015; Campbell 2015; ITPS-FAO 2015; Gariano and Guzzetti 2016; Mal et al. 2018
Reduced pollution including acidification	Management of air pollution is connected to climate change by emission sources of air polluting materials and their impacts on climate, human health, and ecosystems, including agriculture. Acid deposition is one of the many consequences of air pollution, harming trees and other vegetation, as well as being a significant driver of land degradation. Practices that reduce acid deposition include prevention of emissions of nitrogen oxides (NO_x) and sulphur dioxide (SO_2), which also reduce GHG emissions and	There are a few potential adverse side effects of reduction in air pollution to carbon sequestration in terrestrial ecosystems, because some forms of air pollutants can enhance crop productivity by increasing diffuse sunlight, compared to direct sunlight. Reactive N deposition could also enhance CO_2 uptake in boreal forests and increase soil carbon pools to some extent. Air pollutants have different impacts on climate depending primarily on the composition, with some aerosols (and clouds seeded by them) increasing the reflection of solar radiation to space leading to net cooling, while others (e.g. black carbon and tropospheric ozone) having a net warming effect. Therefore, control of these different pollutants will have both positive and negative impacts on climate mitigation.	Chapter 2; Anderson et al. 2017; Chum et al. 2013; Carter et al. 2015; Coakley; Maaroufi et al. 2015; Markandya et al. 2018; Melamed and Schmale 2016; Mostofa et al 2016.; Nemet et al. 2010; Ramanathan et al. 2001; Seinfeld and

	other Short-Lived Climate Pollutants (SLCPs). Reductions of SLCPs reduce warming in the near term and the overall rate of warming, which can be crucial for plants that are sensitive to even small increases in temperature. Management of harmful air pollutants such as fine particulate matter (PM2.5) and ozone (O_3) also mitigate the impacts of incomplete fossil fuel combustion and GHG emissions. In addition, management of pollutants such as tropospheric O_3 has beneficial impacts on food production, since O_3 decreases crop production. Control of urban and industrial air pollution would also mitigate the harmful effects of pollution and provide adaptation co-benefits *via* improved human health. Management of pollution contributes to aquatic ecosystem conservation since controlling air pollution, rising atmospheric CO_2 concentrations, acid deposition, and industrial waste will reduce acidification of marine and freshwater ecosystems.		Pandis; Smith et al. 2015b; UNEP 2017; Wild et al. 2012 UNEP and WMO 2011; Xu & Ramanathan, 2017; Xu et al., 2013
Management of invasive species / encroachment	Agriculture and forests can be diverse but often, much of the diversity is non-native. Invasive species in different biomes have been introduced intentionally or unintentionally through export of ornamental plants or animals, and through the promotion of modern agriculture and forestry. Non-native species tend to be more numerous in larger than in smaller human-modified landscapes (e.g. over 50% of species in an urbanised area or extensive agricultural fields can be non-native). Invasive alien species in the United States cause major environmental damage amounting to almost USD120 billion yr^{-1}. There are approximately 50,000 foreign species and the number is increasing. About 42% of the species on the Threatened or Endangered species lists are at risk primarily because of alien-invasive species. Invasive species can be managed	Exotic species are used in forestry where local indigenous forests cannot produce the type, quantity and quality of forest products required. Planted forests of exotic tree species make significant contributions to the economy and provide multiple products and Nature's Contributions to People. In general, exotic species are selected to have higher growth rates than native species and produce more wood per unit of area and time. In 2015, the total area of planted forest with non-native tree species was estimated to around 0.5 Mkm^2. Introduced species were dominant in South America, Oceania and Eastern and Southern Africa, where industrial forestry is dominant. The use of exotic tree species has played an important role in the production of roundwood, fibre, firewood and other forest products. The challenge is to manage existing and future plantation forests of alien trees to maximise current benefits, while minimising present and future risks and negative impacts, and without compromising future benefits. In many countries or regions, non-native trees planted for production or other purposes often lead to sharp conflicts of interest when they become invasive, and to negative impacts on Nature's Contributions to People and nature conservation.	Brundu and Richardson 2016; Cossalter and Pye-Smith 2003; Dresner et al. 2015; Payn et al. 2015; Pimentel et al. 2005; Vilà et al. 2011

	through manual clearance of invasive species, while in some areas, natural enemies of the invasive species are introduced to control them.		
Restoration and reduced conversion of coastal wetlands	Coastal wetland restoration involves restoring degraded / damaged coastal wetlands including mangroves, salt marshes and seagrass ecosystems.	Coastal wetland restoration and avoided coastal wetland impacts have the capacity to increase carbon sinks and can provide benefits by regulating water flow and preventing downstream flooding. Coastal wetlands provide a natural defence against coastal flooding and storm surges by dissipating wave energy, reducing erosion and by helping to stabilise shore sediments. Since large areas of global coastal wetlands are degraded, restoration could provide benefits land degradation. Since some areas of coastal wetlands are used for food production, restoration could displace food production and damage local food supply (Section 6.3.4), though some forms (e.g. mangrove restoration) can improve local fisheries.	Griscom et al. 2017a; Lotze et al. 2006; Munang et al. 2014; Naylor et al. 2000
Restoration and reduced conversion of peatlands	Peatland restoration involves restoring degraded / damaged peatlands which both increases carbon sinks, but also avoids ongoing CO_2 emissions from degraded peatlands, so it both prevents future emissions and creates a sink, as well as protecting biodiversity.	Avoided peat impacts and peatland restoration can provide significant mitigation, though restoration can lead to an increase in methane emissions, particularly in nutrient rich fens. There may also be benefits for climate adaptation by regulating water flow and preventing downstream flooding. Considering that large areas of global peatlands are degraded, peatland restoration is a key tool in addressing land degradation. Since large areas of tropical peatlands and some northern peatlands have been drained and cleared for food production, their restoration could displace food production and damage local food supply, potentially leading to adverse impacts on food security locally, though the global impact would be limited due to the relatively small areas affected.	Griscom et al. 2017a; Jauhiainen et al. 2008; Limpens et al. 2008; Munang et al. 2014
Biodiversity conservation	Biodiversity conservation refers to practices aiming at maintaining components of biological diversity. It includes conservation of ecosystems and natural habitats, maintenance and recovery of viable populations of species in their natural surroundings (*in-situ* conservation) and, in the case of domesticated or cultivated species, in the surroundings where they have developed their distinctive properties outside their natural habitats (*ex-situ* conservation). Examples of biodiversity conservation measures are establishment of protected areas to achieve specific conservation objectives, preservation of biodiversity hotspots, land management to recover natural habitats, interventions to expand	Biodiversity conservation measures interact with the climate system through many complex processes, which can have either positive or negative impacts. For example, establishment of protected areas can increase carbon storage in vegetation and soil, and tree planting to promote species richness and natural habitats can enhance carbon uptake capacity of ecosystems. Management of wild animals can influence climate *via* emissions of GHGs (from anaerobic fermentation of plant materials in the rumen), impacts on vegetation (*via* foraging), changes in fire frequency (as grazers lower grass and vegetation densities as potential fuels), and nutrient cycling and transport (by adding nutrients to soils). Conserving and restoring megafauna in northern regions also prevents thawing of permafrost and reduces woody encroachment, thus avoiding methane emissions and increases in albedo. Defaunation affects carbon storage in tropical forests and savannahs. In the tropics, the loss of mega-faunal frugivores is estimated be responsible for up to 10% reduction in carbon storage of global tropical forests. Frugivore	Bello et al. 2015; Campbell et al. 2008; Cromsigt et al. 2018; Kapos et al. 2008; Osuri et al. 2016; Schmitz et al. 2018a; Secretariat of the Convention on Biological Diversity 2008

	or control selective plant or animal species in productive lands or rangelands (e.g., rewilding).	rewilding programmes in the tropics are seen as carbon sequestration options that can be equally effective as tree planting schemes. Biodiversity conservation measures generally favour adaptation, but can interact with food security, land degradation or desertification. Protected areas for biodiversity reduce the land available for food production, and abundancies in some species like large animals can influence land degradation processes by grazing, trampling and compacting soil surfaces, thereby altering surface temperatures and chemical reactions affecting sediment and carbon retention.	

Table 6.9 Integrated response options based on land management specifically for CDR

Integrated response option	Description	Context and caveats	Supporting evidence
Enhanced weathering of minerals	The enhanced weathering of minerals that naturally absorb CO_2 from the atmosphere has been proposed as a CDR technology with a large mitigation potential. The rocks are ground to increase the surface area and the ground minerals are then applied to the land where they absorb atmospheric CO_2.	Enhanced mineral weathering can remove atmospheric CO_2. Since ground minerals can increase pH, there could be some benefits for efforts to prevent or reverse land degradation where acidification is the driver of degradation. Since increasing soil pH in acidified soils can increase productivity, the same effect could provide some benefit for food security. Minerals used for enhanced weathering need to be mined, and mining has large impacts locally, though the total area mined is likely to be small on the global scale.	Lenton 2010; Schuiling and Krijgsman 2006; Smith et al. 2016a; Taylor et al. 2016a; Beerling et al. 2018
Bioenergy and BECCS	Bioenergy production can mitigate climate change by delivering an energy service, therefore avoiding combustion of fossil energy. It is the most common renewable energy source used today in the world and has a large potential for future deployment (see Cross-Chapter Box 7 on bioenergy in this chapter). BECCS entails the use of bioenergy technologies (e.g. bioelectricity or biofuels) in combination with CO_2 capture and storage (see also Glossary). BECCS simultaneously provides energy and can reduce atmospheric CO_2 concentrations (see Chapter 2 and Cross-Chapter Box 7 on bioenergy in this chapter) for a discussion of potentials and atmospheric	Bioenergy and BECCS can compete for land and water with other uses. Increased use of bioenergy and BECCS can result in large expansion of cropland area, significant deforestation, and increased irrigation water use and water scarcity. Large-scale use of bioenergy can result in increased food prices and can lead to an increase in the population at risk of hunger. As a result of these effects, large-scale bioenergy and BECCS can have negative impacts for food security. Interlinkages of bioenergy and BECCS with climate change adaptation, land degradation, desertification, and biodiversity are highly dependent on local factors such as the type of energy crop, management practice, and previous land use. For example, intensive agricultural practices aiming to achieve high crop yields, as is the case for some bioenergy systems, may have significant effects on soil health, including depletion of soil organic matter, resulting in negative impacts on land degradation and desertification. However, with low inputs of fossil fuels and chemicals, limited irrigation, heat/drought tolerant species, using marginal land, biofuel programs can be beneficial to future adaptation of ecosystems. Planting bioenergy crops, like perennial grasses, on degraded land can increase soil carbon and ecosystem quality (including biodiversity), thereby helping to preserve soil quality, reverse land degradation, prevent desertification processes, and reduce food insecurity. These effects depend on the scale of deployment, the feedstock, the prior land use, and which other response options are included (see Section 6.4.4.2). Large-scale production of	Cross-Chapter Box 7 on Bioenergy in this chapter; IPCC SR15; Chapter 2; Chapter 4; Section 6.4; Chapter 7; Baker et al. 2019a; Calvin et al. 2014c; Chaturvedi et al. 2013; Chum et al. 2011; Clarke et al. 2014a; Correa et al. 2017; Creutzig et al. 2015; Dasgupta et al. 2014; Don et al. 2012; Edelenbosch et al. 2017; Edenhofer et al. 2011; FAO 2011; Favero and Mendelsohn 2014; Fujimori et al. 2018a; Fuss et al. 2016, 2018a; Hejazi et al. 2015a; Kemper 2015; Kline et al. 2017; Lal 2014; Lotze-Campen et al. 2013; Mello et al. 2014b; Muratori et al. 2016; Noble et al. 2014; Obersteiner et al. 2016a; Popp et al. 2011c, 2014a, 2017; Riahi et al. 2017a; Robertson et al. 2017b; Sánchez et al. 2017; Searchinger et al. 2018; Sims et al. 2014; Slade et al. 2014; Smith

	effects); thus, BECCS is considered a CDR technology. While several BECCS demonstration projects exist, it has yet to be deployed at scale. Bioenergy and BECCS are widely-used in many future scenarios as a climate change mitigation option in the energy and transport sector, especially those scenarios aimed at a stabilisation of global climate at 2°C or less above pre-industrial levels.	bioenergy can require significant amounts of land, increasing potential pressures for land conversion and land degradation. Low levels of bioenergy deployment require less land, leading to smaller effects on forest cover and food prices; however, these land requirements could still be substantial. In terms of feedstocks, some feedstocks, grown in some regions, may not need irrigation, and thus would not compete for water with food crops. Additionally, the use of residues or microalgae could limit competition for land and biodiversity loss; however, residues could result in land degradation or decreased soil organic carbon. Whether woody bioenergy results in increased competition for land or not is disputed in the literature, with some studies suggesting reduced competition and others suggesting enhanced. One study noted that this effect changes over time, with complementarity between woody bioenergy and forest carbon sequestration in the near-term, but increased competition for land with afforestation/reforestation in the long-term. Additionally, woody bioenergy could also result in land degradation.	et al. 2016a; Torvanger 2018; van Vuuren et al. 2011, 2015b, 2016; Wise et al. 2015; Tian et al. 2018;

6.2.3.1 Risk management options

Integrated response options based on risk management described in Table 6.12, which also notes any context specificities in the effects of the response options and provides the evidence base.

1 **Table 6.10 Integrated response options based on value chain management through demand management**

Integrated response option	Description	Context and caveats	Supporting evidence
Dietary change	Sustainable healthy diets represent a range of dietary changes to improve human diets, to make them healthy in terms of the nutrition delivered, and also (economically, environmentally and socially) sustainable. A "contract and converge" model of transition to sustainable healthy diets would involve a reduction in overconsumption (particularly of livestock products) in over-consuming populations, with increased consumption of some food groups in populations where minimum nutritional needs are not met. Such a conversion could result in a decline in undernourishment, as well as reduction in the risk of morbidity and mortality due to over-consumption.	A dietary shift away from meat can reduce greenhouse gas emissions, reduce cropland and pasture requirements, enhance biodiversity protection, and reduce mitigation costs. Additionally, dietary change can both increase potential for other land-based response options and reduce the need for them by freeing land. By decreasing pressure on land, demand reduction through dietary change could also allow for decreased production intensity, which could reduce soil erosion and provide benefits to a range of other environmental indicators such as deforestation and decreased use of fertiliser (N and P), pesticides, water and energy, leading to potential benefits for adaptation, desertification, and land degradation.	Chapter 5; Section 6.4.4.2; Aleksandrowicz et al. 2016a; Bajželj et al. 2014; Bonsch et al. 2016; Erb et al. 2016; Godfray et al. 2010; Haberl et al. 2011; Havlík et al. 2014; Muller et al. 2017a; Smith et al. 2013; Springmann et al. 2018a; Stehfest et al. 2009; Tilman and Clark 2014; Wu et al. 2019
Reduced post-harvest losses	Approximately one-third of the food produced for human consumption is wasted in post-production operations. Most of these losses are due to poor storage management. Post-harvest food losses underlie the food system's failure to equitably enable accessible and affordable food in all countries. Reduced post-harvest food losses can improve food security in developing countries (while food loss in developed countries mostly occurs at the retail/consumer stage). The key drivers for post-harvest waste in developing countries are structural and infrastructure deficiencies. Thus, reducing food waste at the post-harvest stage requires responses that process,	Differences exist between farm food waste reduction technologies between small-scale agricultural systems and large-scale agricultural systems. A suite of options includes farm level storage facilities, trade or exchange processing technologies including food drying, onsite farm processing for value addition, and improved seed systems. For large scale agri-food systems, options include cold chains for preservation, processing for value addition and linkages to value chains that absorb the harvests almost instantly into the supply chain. In addition to the specific options to reduce food loss and waste, there are more systemic possibilities related to food systems. Improving and expanding the 'dry chain' can significantly reduce food losses at the household level. Dry chains are analogous to the	Chapter 5; Ansah et al. 2017; Bajželj et al. 2014; Billen et al. 2018; Bradford et al. 2018; Chaboud and Daviron 2017; Göbel et al. 2015; Gustavsson et al. 2011; Hengsdijk and de Boer 2017; Hodges et al. 2011; Ingram et al. 2016;

	preserve and, where appropriate, redistribute food to where it can be consumed immediately.	cold chain and refers to the 'initial dehydration of durable commodities to levels preventing fungal growth' followed by storage in moisture-proof containers. Regional and local food systems are now being promoted to enable production, distribution, access and affordability of food. Reducing post-harvest losses has the potential to reduce emissions and could simultaneously reduce food costs and increase availability. The perishability and safety of fresh foods are highly susceptible to temperature increase.	Kissinger et al. 2018; Kumar and Kalita 2017; Ritzema et al. 2017; Sheahan and Barrett 2017; Wilhelm et al. 2016
Reduced food waste (consumer or retailer)	Since approximately 9-30% of all food is wasted, reducing food waste can reduce pressure on land (see also reducing post-harvest losses).	Reducing food waste could lead to a reduction in cropland area and GHG emissions, resulting in benefits for mitigation. By decreasing pressure on land, food waste reduction could allow for decreased production intensity, which could reduce soil erosion and provide benefits to a range of other environmental indicators such as deforestation and decreases in use of fertiliser (N and P), pesticides, water and energy, leading to potential benefits for adaptation, desertification, and land degradation.	Alexander et al. 2016; Bajželj et al. 2014; Gustavsson et al. 2011; Kummu et al. 2012a; Muller et al. 2017a; Smith et al. 2013; Vermeulen et al. 2012b
Material substitution	Material substitution involves the use of wood or agricultural biomass (e.g. straw bales) instead of fossil fuel-based materials (e.g. concrete, iron, steel, aluminium) for building, textiles or other applications.	Material substitution reduces carbon emissions both because the biomass sequesters carbon in materials while re-growth of forests can lead to continued sequestration, and because it reduces the demand for fossil fuels, delivering a benefit for mitigation. However, a potential trade-off exists between conserving carbon stocks and using forests for wood products. If the use of material for substitution was large enough to result in increased forest area, then the adverse side-effects for adaptation and food security would be similar to that of reforestation and afforestation. In addition, some studies indicate that wooden buildings, if properly constructed, could reduce fire risk compared to steel, creating a co-benefit for adaptation. The effects of material substitution on land degradation depend on management practice; some forms of logging can lead to increased land degradation. Long-term forest management with carbon storage in long-lived products also results in atmospheric carbon dioxide (CO_2) removal.	Chapter 4; Dugan et al. 2018; Eriksson et al. 2012; Gustavsson et al. 2006; Kauppi et al. 2018; Leskinen et al. 2018; McLaren 2012; Oliver and Morecroft 2014; Ramage et al. 2017; Sathre and O'Connor 2010; Smyth et al. 2014; Kurz et al. 2016; Miner 2010; Iordan et al. 2018

Table 6.11 Integrated response options based on value chain management through supply management

Integrated response option	Description	Context and caveats	Supporting evidence
Sustainable sourcing	Sustainable sourcing includes approaches to ensure that the production of goods is done in a sustainable way, such as through low-impact agriculture, zero-deforestation supply chains, or sustainably harvested forest products. Currently around 8% of global forest area has been certified in some manner, and 25% of global industrial roundwood comes from certified forests. Sustainable sourcing also aims to enabling producers to increase their percentage of the final value of commodities. Adding value to products requires improved innovation, coordination and efficiency in the food supply chain, as well as labelling to ensure consumer demands. As such, sustainable sourcing is an approach that combines both supply and demand-side management. Promoting sustainable and value-added products can reduce the need for compensatory extensification of agricultural areas and is a specific commitment of some sourcing programs (such as forest certification programs). Table 7.3 (Chapter 7) provides examples of the many sustainable sourcing programs now available globally.	Sustainable sourcing is expanding but accounts for only a small fraction of overall food and material production; many staple food crops do not have strong sustainability standards. Sustainable sourcing provides potential benefits for both climate mitigation and climate adaptation by reducing drivers of unsustainable land management, and by diversifying and increasing flexibility in the food system to climate stressors and shocks. Sustainable sourcing can lower expenditures of food processors and retailers by reducing losses. Adding value to products can extend a producer's marketing season and provide unique opportunities to capture niche markets thereby increasing their adaptive capacity to climate change. Sustainable sourcing can also provide significant benefits for food security, while simultaneously creating economic alternatives for the poor. Sustainable sourcing programmes often also have positive impacts on the overall efficiency of the food supply chain and can create closer and more direct links between producers and consumers. In some cases, processing of value-added products could lead to higher emissions or demand of resources in the food system, potentially leading to small adverse impacts on land degradation and desertification challenges.	Chapter 2; Chapter 3; Chapter 5; Section 6.4; Accorsi et al. 2017; Bajželj et al. 2014; Bustamante et al. 2014a; Clark and Tilman 2017; Garnett 2011; Godfray et al. 2010a; Hertel 2015; Ingram et al. 2016a; James and James 2010a; Muller et al. 2017a; Tilman and Clark 2014a; Springer et al. 2015; Tayleur et al. 2017
Management of supply chains	Management of supply chains include a set of polycentric governance processes focused on improving efficiency and sustainability across the supply chain for each product, to reduce climate risk and profitably reduce emissions. Trade-driven food supply chains are becoming increasingly complex and contributing to emissions. Improved management of supply chains can include both: 1) better food transport and increasing the economic value or reduce risks	Successful implementation of supply chain management practices is dependent on organisational capacity, the agility and flexibility of business strategies, the strengthening of public-private policies and effectiveness of supply-chain governance. Existing practices include a) greening supply chains (e.g. utilising products and services with a reduced impact on the environment and human health), b) adoption of specific sustainability instruments among agri-food companies (e.g. eco-	Chapter 5; Barthel and Isendahl 2013; Haggblade et al. 2017; Lewis and Witham 2012; Michelini et al. 2018; Minot 2014; Mundler and Rumpus 2012; Tadasse et al.

	of commodities through production processes (e.g., packaging, processing, cooling, drying, extracting) and 2) improved policies for stability of food supply, as globalised food systems and commodity markets are vulnerable to food price volatility. The 2007-2008 food price shocks negatively affected food security for millions, most severely in Sub-Saharan Africa. Increasing the stability of food supply chains is a key goal to increase food security, given that climate change threatens to lead to more production shocks in the future.	innovation practices), c) adopting emission accounting tools (e.g. carbon and water foot-printing), and d) implementing "demand forecasting" strategies (e.g. changes in consumer preference for 'green' products). In terms of food supply, measures to improve stability in traded markets can include: 1) financial and trade policies, such as reductions on food taxes and import tariffs; 2) shortening food supply chains (SFSCs); 3) increasing food production; 4) designing alternative distribution networks; 5) increasing food market transparency and reducing speculation in futures markets; 6) increasing storage options; and 7) increasing subsidies and food-based safety nets.	2016; Wheeler and von Braun 2013; Wilhelm et al. 2016; Wodon and Zaman 2010; The World Bank 2011
Enhanced urban food systems	Urban areas are becoming the principal territories for intervention in improving food access through innovative strategies that aim to reduce hunger and improve livelihoods. Interventions include Urban and Peri-urban Agriculture and Forestry and local food policy and planning initiatives such as Food Policy Councils and city-region-wide regional food strategies. Such systems have demonstrated inter-linkages of the city and its citizens with surrounding rural areas to create sustainable, and more nutritious food supplies for the city, while improving the health status of urban dwellers, reducing pollution levels, adapting to and mitigating climate change, and stimulating economic development. Options include support for urban and peri-urban agriculture, green infrastructure (e.g., green roofs), local markets, enhanced social (food) safety nets and development of alternative food sources and technologies, such as vertical farming.	Urban territorial areas have a potential to reduce GHG emissions through improved food systems to reduce vehicle miles of food transportation, localised carbon capture and food waste reduction. The benefits of Urban food forests that are intentionally planted woody perennial food producing species, are also cited for their carbon sequestration potentials. However, new urban food systems may have diverse unexpected adverse side-effects with climate systems, such as lower efficiencies in food supply and higher costs than modern large-scale agriculture. Diversifying markets, considering value added products in the food supply system may help to improve food security by increasing its economic performance and revenues to local farmers.	Akhtar et al. 2016; Benis and Ferrão 2017; Brinkley et al. 2013, 2016; Chappell et al. 2016; Goldstein et al. 2016; Kowalski and Conway 2018; Lee-Smith 2010; Barthel and Isendahl 2013; Lwasa et al. 2014, 2015; Revi et al. 2014; Specht et al. 2014; Tao et al. 2015; UPAF (date)
Improved food processing and retailing	Improved food processing and retailing involves several practices related to a) greening supply chains (e.g., utilising products and services with a reduced impact on the environment and human health), b) adoption of specific sustainability instruments among agri-food companies (e.g., eco-innovation practices), c) adopting emission accounting tools (e.g., carbon and water foot-printing), d) implementing "demand forecasting" strategies (e.g., changes in consumer	Improved food processing and retailing can provide benefits for climate mitigation since GHG-friendly foods can reduce agri-food GHG emissions from transportation, waste and energy use. In cases where climate extremes and natural disasters disrupt supply chain networks, improved food processing and retailing can benefit climate adaptation by buffering the impacts of changing temperature and rainfall patterns on upstream agricultural production. It can provide benefits for food security	Chapter 2; Chapter 5; Avetisyan et al. 2014; Garnett et al. 2013; Godfray et al. 2010; Mohammadi et al. 2014; Porter et al. 2016; Ridoutt et al. 2016; Song et al. 2017

	preference for 'green' products) and, e) supporting polycentric supply-chain governance processes.	by supporting healthier diets and reducing food loss and waste. Successful implementation is dependent on organisational capacity, the agility and flexibility of business strategies, the strengthening of public-private policies and effectiveness of supply-chain governance.	
Improved energy use in food systems	Energy efficiency of agriculture can be improved to reduce the dependency on non-renewable energy sources. This can be realised either by decreased energy inputs, or through increased outputs per unit of input. In some countries, managerial inefficiency (rather than a technology gap) is the main source for energy efficiency loss. Heterogenous patterns of energy efficiency exist at the national scale and promoting energy efficient technologies along with managerial capacity development can reduce the gap and provide large benefits for climate adaptation. Improvements in carbon monitoring and calculation techniques such as the foot-printing of agricultural products can enhance energy efficiency transition management and uptake in agricultural enterprises.	Transformation to low carbon technologies such as renewable energy and energy efficiency can offer opportunities for significant climate change mitigation by providing a substitute to transport fuel (for example) that could benefit marginal agricultural resources, while simultaneously contributing to long term economic growth. In poorer nations, increased energy efficiency in agricultural value-added production, in particular, can provide large mitigation benefits. Under certain scenarios, the efficiency of agricultural systems can stagnate and could exert pressure on grasslands and rangelands, thereby impacting land degradation and desertification. Rebound effects can also occur, with adverse impacts on emissions.	Al-Mansour F and Jejcic V 2017; Baptista et al. 2013; Gunatilake et al. 2014; Begum et al. 2015; Jebli and Youssef 2017; van Vuuren et al. 2017b

Table 6.12 Integrated response options based on risk management

Integrated response option	Description	Context and caveats	Supporting evidence
Management of urban sprawl	Unplanned urbanisation leading to sprawl and extensification of cities along the rural-urban fringe has been identified as a driver of forest and agricultural land loss and a threat to food production around cities. It has been estimated that urban expansion will result in a 1.8–2.4% loss of global croplands by 2030. This rapid urban expansion is especially strong in new emerging towns and cities in Asia and Africa. Policies to prevent such urbanisation have included integrated land use planning, agricultural zoning ordinances and agricultural districts, urban redevelopment, arable land reclamation, and transfer/purchase of development rights or easements.	The prevention of uncontrolled urban sprawl may provide adaptation co-benefits, but adverse side effects for adaptation might arise due to restricted ability of people to move in response to climate change.	Barbero-Sierra et al. 2013a; Bren d'Amour et al. 2016; Cai et al. 2013; Chen 2007; Francis et al. 2012a; Gibson et al. 2015; Lee et al. 2015; Qian et al. 2015; Shen et al. 2017; Tan et al. 2009
Livelihood diversification	When households' livelihoods depend on a small number of sources of income without much diversification, and when those income sources are in fields that are highly climate dependent, like agriculture and fishing, this dependence can put food security and livelihoods at risk. Livelihood diversification (drawing from a portfolio of dissimilar sources of livelihood as a tool to spread risk) has been identified as one option to increase incomes and reduce poverty, increase food security, and promote climate resilience and risk reduction.	Livelihood diversification offers benefits for desertification and land degradation, particularly through non-traditional crops or trees in agroforestry systems which improve soil. Livelihood diversification may increase on-farm biodiversity due to these investments in more ecosystem-mimicking production systems, like agroforestry and polycultures. Diversification into non-agricultural fields, such as wage labour or trading, is increasingly favoured by farmers as a low-cost strategy, particularly to respond to increasing climate risks.	Adger 1999; Ahmed and Stepp 2016a; Antwi-Agyei et al. 2014; Barrett et al. 2001; Berman et al. 2012; Bryceson 1999; DiGiano and Racelis 2012; Ellis 1998, 2008; Ngigi et al. 2017; Rakodi 1999; Thornton and Herrero 2014; Little et al. 2001
Use of local seeds	Using local seeds (also called seed sovereignty) refers to use of non-improved, non-commercial seeds varieties. These can be used and stored by local farmers as low-cost inputs and can often help contribute to the conservation of local varieties and land races, increasing local biodiversity. Many local seeds also require no pesticide or fertiliser use, leading to less land degradation in their use.	Use of local seeds is important in the many parts of the developing world that do not rely on commercial seed inputs. Promotion of local seed saving initiatives can include seed networks, banks and exchanges, and non-commercial open source plant breeding. These locally developed seeds can both help protect local agrobiodiversity and can often be more climate resilient than generic commercial varieties, although	Bowman 2015; Campbell and Veteto 2015; Coomes et al. 2015; Kloppenberg 2010; Luby et al. 2015; van Niekerk and Wynberg 2017; Patnaik et al. 2017; Reisman 2017;

		the impacts on food security and overall land degradation are inconclusive.	Vasconcelos et al. 2013; Wattnem 2016
Disaster risk management	Disaster risk management encompasses many approaches to try to reduce the consequences of climate and weather-related disasters and events on socio-economic systems. The Hyogo Plan of Action is a UN framework for nations to build resilience to disasters through effective integration of disaster risk considerations into sustainable development policies. For example, in Vietnam a national strategy on disasters based on Hyogo has introduced the concept of a "four-on-the-spot" approach for disaster risk management of: proactive prevention; timely response; quick and effective recovery; and sustainable development. Other widespread approaches to disaster risk management include using early warning systems that can encompass 1) education systems; 2) hazard and risk maps; 3) hydrological and meteorological monitoring (such as flood forecasting or extreme weather warnings); and 4) communications systems to pass on information to enable action. These approaches have long been considered to reduce the risk of household asset damage during one-off climate events and are increasingly being combined with climate adaptation policies.	Community-based disaster risk management has been pointed to as one of the most successful ways to ensure information reaches people, who need to be participants in risk reduction. Effective disaster risk management approaches must be 'end-to-end,' both reaching communities at risk and supporting and empowering vulnerable communities to take appropriate action. The most effective early warning systems are not simply technical systems of information dissemination, but utilise and develop community capacities, create local ownership of the system, and are based on a shared understanding of needs and purpose. Tapping into existing traditional or local knowledge has also been recommended for disaster risk management approaches to reducing vulnerability.	Ajibade and McBean 2014; Alessa et al. 2016; Bouwer et al. 2014; Carreño et al. 2007; Cools et al. 2016; Djalante et al. 2012; Garschagen 2016; Maskrey 2011; Mercer 2010; Sternberg and Batbuyan 2013; Thomalla et al. 2006; Vogel and O'Brien 2006; Schipper and Pelling 2006
Risk sharing instruments	Risk sharing instruments can encompass a variety of approaches. Intra-household risk pooling is a common strategy in rural communities, such as through extended family financial transfers; one study found 65% of poor households in Jamaica report receiving transfers, and such transfers can account for up to 75% of household income or more after crisis events. Community rotating credit associations (ROSCAs) have long been used for general risk pooling and can be a source of financing to cope with climate variability as well. Credit services have been shown to be important for adaptation actions and risk reduction. Insurance of various kinds is also a form of risk pooling. Commercial crop insurance is one of the most widely used risk-hedging	Locally developed risk pooling measures show general positive impacts on household livelihoods. However, more commercial approaches have mixed effects. Commercial crop insurance is highly subsidised in much of the developed world. Index insurance programmes have often failed to attract sufficient buyers or have remained financially unfeasible for commercial insurance sellers. The overall impact of index insurance on food production supply and access has also not been assessed. Traditional crop insurance has generally been seen as positive for food security as it leads to expansion of agricultural production areas and increased food supply. However, insurance may also 'mask' truly risky agriculture and prevent farmers from seeking less risky	Akter et al. 2016; Annan and Schlenker 2015; Claassen et al. 2011; Fenton et al. 2017; Giné et al. 2008; Goodwin and Smith 2003; Hammill et al. 2008; Havemenn and Muccione 2011; Jaworski 2016; Meze-Hausken et al. 2009; Morduch and Sharma 2002; Bhattamishra and Barrett 2010; Peterson 2012;

	financial vehicles, and can involve both traditional indemnity-based insurance that reimburses clients for estimated financial losses from shortfalls, or index insurance that pays out the value of an index (such as weather events) rather than actual losses; the former is more common for large farms in the developed world and the latter for smaller non-commercial farms in developing countries.	production strategies. Insurance can also provide perverse incentives for farmers to bring additional lands into crop production, leading to greater risk of degradation.	Sanderson et al. 2013; Skees and Collier 2012; Smith and Glauber 2012

Cross-Chapter Box 7: Bioenergy and Bioenergy with Carbon Dioxide Capture and Storage (BECCS) in mitigation scenarios

Katherine Calvin (The United States of America), Almut Arneth (Germany), Luis Barioni (Brazil), Francesco Cherubini (Norway/Italy), Annette Cowie (Australia), Joanna House (United Kingdom), Francis X. Johnson (Sweden), Alexander Popp (Germany), Joana Portugal Pereira (United Kingdom), Mark Rounsevell (United Kingdom), Raphael Slade (United Kingdom), Pete Smith (United Kingdom)

Bioenergy and BECCS potential

Using biomass to produce heat, electricity and transport fuels (bioenergy) instead of coal, oil, and natural gas can reduce GHG emissions. Combining biomass conversion technologies with systems that capture CO_2 and inject it into geological formations (bioenergy with carbon dioxide capture and storage (BECCS)) can deliver net negative emissions. The net climate effects of bioenergy and BECCS depend on the magnitude of bioenergy supply chain emissions and land/climate interactions, described further below.

Biomass in 2013 contributed ~60 EJ (10%) to global primary energy[4] (WBA 2016). In 2011, the IPCC *Special Report on Renewable Energy Sources* concluded that biomass supply for energy could reach 100-300 EJ yr^{-1} by 2050 with the caveat that the technical potential[5] cannot be determined precisely while societal preferences are unclear; that deployment depends on "factors that are inherently uncertain"; and that biomass use could evolve in a "sustainable" or "unsustainable" way depending on the governance context (IPCC, 2011). The IPCC WGIII AR5 report noted, in addition, that high deployment levels would require extensive use of technologies able to convert lignocellulosic biomass such as forest wood, agricultural residues, and lignocellulosic crops. The SR15 noted that high levels of bioenergy deployment may result in adverse side-effects for food security, ecosystems, biodiversity, water use, and nutrients (de Coninck et al. 2018).

Although estimates of potential are uncertain, there is *high confidence* that the most important factors determining future biomass supply are land availability and land productivity. These factors are in turn determined by competing uses of land and a myriad of environmental and economic considerations (Dornburg et al. 2010; Batidzirai et al. 2012; Erb et al. 2012; Slade 2014, Searle and Malins 2014). Overlaying estimates of technical potential with such considerations invariably results in a smaller estimate. Recent studies that have attempted to do this estimate that 50-244 EJ biomass could be produced on 0.1-13 Mkm^2 (Fuss et al. 2018a; Schueler et al. 2016; Searle and Malins 2014; IPCC SR15; Wu et al. 2019; Heck et al. 2018; de Coninck et al. 2018). While preferences concerning economic, social and environmental objectives vary geographically and over time, studies commonly estimate "sustainable" potentials by introducing restrictions intended to protect environmental values and avoid negative effects on poor and vulnerable segments in societies.

Estimates of global geological CO_2 storage capacity are large – ranging from 1680 $GtCO_2$ to 24000 $GtCO_2$ (McCollum et al. 2014) – however the potential of BECCS may be significantly constrained by socio-political and technical and geographical considerations, including limits to knowledge and experience (Chapter 6, 7).

---

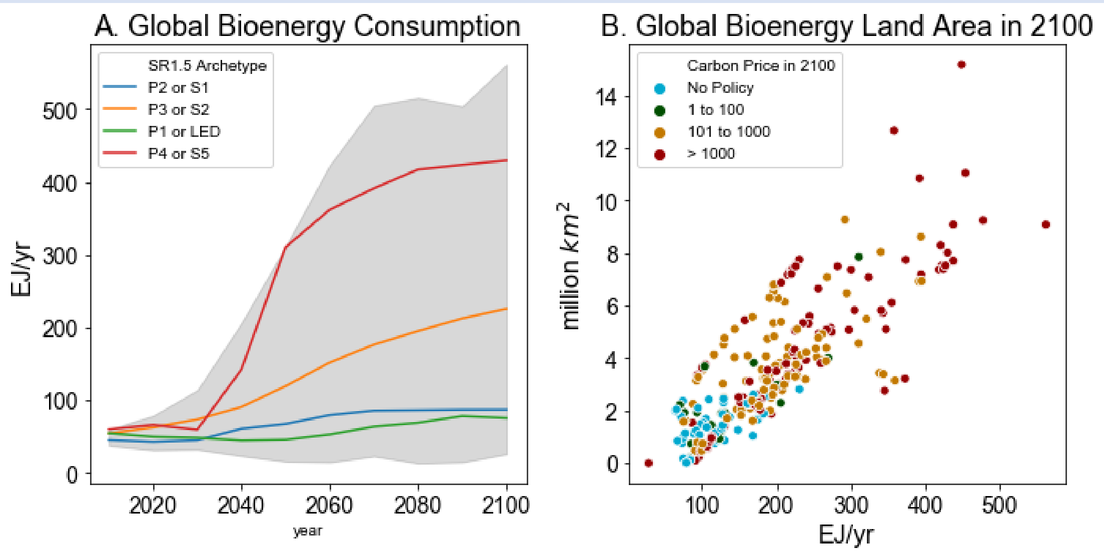
[4] FOOTNOTE: Of this, more than half was traditional biomass, predominately used for cooking and heating in developing regions, bioelectricity accounted for ~1.7EJ, and transport biofuels for 3.19EJ. (Cross-Chapter Box 12 on Traditional Biomass, Chapter 7)

[5] FOOTNOTE: The future availability of biomass is usually discussed in terms of a hierarchy of potentials: theoretical>technical>economic. Caution is required, however, as these terms are not always defined consistently and estimates depend on the specific definitions and calculation methodologies.

Bioenergy and BECCS use in mitigation scenarios

Most mitigation scenarios include substantial deployment of bioenergy technologies (Clarke et al. 2014; Fuss et al. 2014; IPCC SR15). Across all scenarios, the amount of bioenergy and BECCS ranges from 0 EJ yr^{-1} to 561 EJ yr^{-1} in 2100 (Cross-Chapter Box 7 Figure 1, left panel). Notably, all 1.5°C pathways include bioenergy, requiring as much as 7 Mkm^2 to be dedicated to the production of energy crops in 2050 (Rogelj et al. 2018a). If BECCS is excluded as a mitigation option, studies indicate that more biomass may be required in order to substitute for a greater proportion of fossil fuels (Muratori et al. 2016; Rose et al. 2014a).

Different Integrated Assessment Models (IAMs) use alternative approaches to land allocation when determining where and how much biomass is used, with some relying on economic approaches and some relying on rule-based approaches (Popp et al. 2014b). Despite these differences a consistent finding across models is that increasing biomass supply to the extent necessary to support deep decarbonisation is likely to involve substantial land use change (Popp et al. 2017) (Cross-Chapter Box 9). In model runs, bioenergy deployment and the consequent demand for biomass and land, is influenced by assumptions around the price of bioenergy, the yield of bioenergy crops, the cost of production (including the costs of fertiliser and irrigation if used), the demand for land for other uses, and the inclusion of policies (e.g., subsidies, taxes, constraints) that may alter land use or bioenergy demand. In general, higher carbon prices result in greater bioenergy deployment (Cross-Chapter Box 7 Figure 1, right panel) and a larger percentage of BECCS. Other factors can also strongly influence bioenergy use, including the cost and availability of fossil fuels (Calvin et al. 2016a), socioeconomics (Popp et al. 2017), and policy (Calvin et al. 2014a; Reilly et al. 2012a).



Cross-Chapter Box 7 Figure 1: Global bioenergy consumption in IAM scenarios. Data is from an update of the IAMC Scenario Explorer developed for the SR15 (Huppmann et al. 2018; Rogelj et al. 2018a). The left panel shows bioenergy deployment over time for the entire scenario database (grey areas) and the four illustrative pathways from SR15 (Rogelj et al. 2018a). The right panel shows global land area for energy crops in 2100 versus total global bioenergy consumption in 2100; colours indicate the carbon price in 2100 (in 2010 USD per tCO_2). Note that this figure includes 409 scenarios, many of which exceed 1.5ºC.

Co-benefits, adverse side effect, and risks associated with bioenergy

The production and use of biomass for bioenergy can have co-benefits, adverse side effects, and risks for land degradation, food insecurity, GHG emissions, and other environmental goals. These impacts are context specific and depend on the scale of deployment, initial land use, land type, bioenergy feedstock, initial carbon stocks, climatic region and management regime (Qin et al. 2016; Del Grosso et al. 2014; Alexander et al. 2015; Popp et al. 2017; Davis et al. 2013a; Mello et al. 2014b; Hudiburg et al. 2015; Carvalho et al. 2016; Silva-Olaya et al. 2017; Whitaker et al. 2018; Robledo-Abad et al. 2017; Jans et al. 2018).

Synergistic outcomes with bioenergy are possible, for example, strategic integration of perennial bioenergy crops with conventional crops can provide multiple production and environmental benefits including management of dryland salinity, enhanced biocontrol and biodiversity, and reduced eutrophication (Davis et al. 2013b; Larsen et al. 2017; Cacho et al. 2018; Odgaard et al. 2019). Additionally, planting perennial bioenergy crops on low carbon soil could enhance soil carbon sequestration (Bárcena et al. 2014; Schröder et al. 2018; Walter et al. 2015; Robertson et al. 2017a; Rowe et al. 2016; Chadwick et al. 2014; Immerzeel et al. 2014; Del Grosso et al. 2014; Mello et al. 2014c; Whitaker et al. 2018). However, large-scale expansion of bioenergy may also result in increased competition for land (DeCicco 2013; Humpenöder et al. 2018a; Bonsch et al. 2016; Harris et al. 2015; Richards et al. 2017; Ahlgren et al. 2017; Bárcena et al. 2014), increased greenhouse gas emissions from land use change and land management, loss in biodiversity, and nutrient leakage (Harris et al. 2018; Harper et al. 2018; Popp et al. 2011c; Wiloso et al. 2016; Behrman et al. 2015; Valdez et al. 2017; Hof et al. 2018). If biomass crops are planted on land with a high carbon stock, the carbon loss due to land conversion may take decades to over a century to be compensated by either fossil fuel substitution or CCS (Harper et al. 2018). Competition for land may be experienced locally or regionally and is one of the determinants of food prices, food security (Popp et al. 2014a; Bailey 2013; Pahl-Wostl et al. 2018; Rulli et al. 2016; Yamagata et al. 2018; Franz et al. 2017; Kline et al. 2017; Schröder et al. 2018) and water availability (Rulli et al. 2016; Bonsch et al. 2015b; Pahl-Wostl et al. 2018; Bailey 2013; Chang et al. 2016; Bárcena et al. 2014).

Experience in countries at quite different levels of economic development (Brazil, Malawi and Sweden) has shown that persistent efforts over several decades to combine improved technical standards and management approaches with strong governance and coherent policies, can facilitate long-term investment in more sustainable production and sourcing of liquid biofuels (Johnson and Silveira 2014). For woody biomass, combining effective governance with active forest management over long time periods can enhance substitution-sequestration co-benefits, such as in Sweden where bioenergy has tripled during the last 40 years (currently providing about 25% of total energy supply) while forest carbon stocks have continued to grow (Lundmark et al. 2014). A variety of approaches are available at landscape level and in national and regional policies to better reconcile food security, bioenergy and ecosystem services, although more empirical evidence is needed (Mudombi et al. 2018; Manning et al. 2015; Kline et al. 2017; Maltsoglou et al. 2014; Lamers et al.).

Thus, while there is *high confidence* that the technical potential for bioenergy and BECCS is large, there is also *very high confidence* that this potential is reduced when environmental, social and economic constraints are considered. The effects of bioenergy production on land degradation, water scarcity, biodiversity loss, and food insecurity are scale and context specific (*high confidence*). Large areas of monoculture bioenergy crops that displace other land uses can exacerbate these challenges, while integration into sustainably managed agricultural landscapes can ameliorate them (*medium confidence*).

Inventory reporting for BECCS and bioenergy

One of the complications in in assessing the total GHG flux associated with bioenergy under UNFCCC reporting protocols is that fluxes from different aspects of bioenergy life cycle are reported in different sectors and are not linked. In the energy sector, bioenergy is treated as carbon neutral at the point of biomass combustion because all change in land carbon stocks due to biomass harvest or land use change related to bioenergy are reported under AFOLU sector. Use of fertilisers is captured in the Agriculture sector, while fluxes related to transport/conversion and removals due to CCS are reported in the energy sector. IAMs follow a similar reporting convention. Thus, the whole life cycle

GHG effects of bioenergy systems are not readily observed in national GHG inventories or modelled emissions estimates (see also IPCC 2006; SR15 Chapter 2 Technical Annex; Chapter 2).

Bioenergy in this report

Bioenergy and BECCS are discussed throughout this special report. Chapter 1 provides an introduction to bioenergy and BECCS and its links to land and climate. Chapter 2 discusses mitigation potential, land requirements and biophysical climate implications. Chapter 4 includes a discussion of the threats and opportunities with respect to land degradation. Chapter 5 discusses linkages between bioenergy and BECCS and food security. Chapter 6 synthesises the co-benefits and adverse side-effects for mitigation, adaptation, desertification, land degradation, and food security, as well as barriers to implementation (e.g., cost, technological readiness, etc.). Chapter 7 includes a discussion of risk, policy, governance, and decision-making with respect to bioenergy and BECCS.

6.3 Potentials for addressing the land challenges

In this section, we assess how each of the integrated response options described in Section 6.2 address the land challenges of climate change mitigation (6.3.1), climate change adaptation (6.3.2), desertification (6.3.3), land degradation (6.3.4), and food security (6.3.5). The quantified potentials across all of mitigation, adaptation, desertification, land degradation and food security are summarised and categorised for comparison in section 6.3.6.

6.3.1 Potential of the integrated response options for delivering mitigation

In this section, the impacts of integrated response options on climate change mitigation are assessed.

6.3.1.1 Integrated response options based on land management

In this section, the impacts on climate change mitigation of integrated response options based on land management are assessed. Some of the caveats of these potential mitigation studies are discussed in Chapter 2 and section 6.2.1.

6.3.1.1.1 Integrated response options based on land management in agriculture

Increasing the productivity of land used for food production can deliver significant mitigation by avoiding emissions that would occur if increased food demand were met through expansion of the agricultural land area (Burney et al., 2010). If pursued through increased agrochemical inputs, numerous adverse impacts on greenhouse gas emissions (and other environmental sustainability) can occur (Table 6.5), but if pursued through sustainable intensification, increased food productivity could provide high levels of mitigation. For example, yield improvement has been estimated to have contributed to emissions savings of >13 $GtCO_2$ yr^{-1} since 1961 (Burney et al., 2010; Table 6.13). This can also reduce the greenhouse gas intensity of products (Bennetzen et al., 2016) which means a smaller environmental footprint of production, since demand can be met using less land and/or with fewer animals.

Improved cropland management could provide moderate levels of mitigation (1.4-2.3 $GtCO_2e$ yr^{-1}; Smith et al. 2008, 2014c; Pradhan et al., 2013; Table 6.13). The lower estimate of potential is from Pradhan et al. (2013) for decreasing emissions intensity, and the upper end of technical potential is estimated by adding technical potentials for cropland management (about 1.4 $GtCO_2e$ yr^{-1}), rice management (about 0.2 $GtCO_2e$ yr^{-1}) and restoration of degraded land (about 0.7 $GtCO_2e$ yr^{-1}) from Smith et al. (2008) and Smith et al. (2014c). Note that much of this potential arises from soil carbon sequestration so there is an overlap with that response option (see 6.3.1.1.3).

Grazing lands can store large stocks of carbon in soil and root biomass compartments (Conant and Paustian 2002; O'Mara 2012; Zhou et al. 2017). The global mitigation potential is moderate (1.4–1.8 $GtCO_2$ yr^{-1}), with the lower value in the range for technical potential taken from Smith et al. (2008)

which includes only grassland management measures, and the upper value in the range from Herrero et al. (2016), which includes also indirect effects and some components of livestock management, and soil carbon sequestration, so there is overlap with these response options (see below and 6.3.1.1.3). Conant et al. (2005) caution that increases in soil carbon stocks could be offset by increases in N_2O fluxes.

The mitigation potential of improved livestock management is also moderate (0.2–1.8 $GtCO_2e\ yr^{-1}$; Smith et al. (2008) including only direct livestock measures; Herrero et al. (2016) include also indirect effects, and some components of grazing land management and soil carbon sequestration) to high (6.13 Gt CO2e yr^{-1}; Pradhan et al., 2013; Table 6.13). There is an overlap with other response options (see above and 6.3.1.1.3).

Zomer et al. (2017) reported that the trees agroforestry landscapes have increased carbon stock by 7.33 $GtCO_2$ between 2000–2010, which is equivalent to 0.7 $GtCO_2\ yr^{-1}$. Estimates of global potential range from 0.1 $GtCO_2\ yr^{-1}$ to 5.7 $GtCO_2\ yr^{-1}$ (from an optimum implantation scenario of Hawken, 2014), based on an assessment of all values in Griscom et al. (2017a), Hawken (2014), Zomer et al 2016., and Dickie et al. (2014) (Table 6.13).

Agricultural diversification mainly aims at increasing climate resilience, but it may have a small (but globally unquantified) mitigation potential as a function of type of crop, fertiliser management, tillage system, and soil type (Campbell et al. 2014; Cohn et al. 2017).

Reducing conversion of grassland to cropland could provide significant climate mitigation by retaining soil carbon stocks that might otherwise be lost. When grasslands are converted to croplands, they lose about 36% of their soil organic carbon stocks after 20 years (Poeplau et al. 2011). Assuming an average starting soil organic carbon stock of grasslands of 115 t C ha^{-1} (Poeplau et al. 2011), this is equivalent to a loss of 41.5 t C ha^{-1} on conversion to cropland. Mean annual global cropland conversion rates (1961–2003) have been around 47000 $km^2\ yr^{-1}$ (Krause et al. 2017), or 940000 km^2 over a 20 year period. The equivalent loss of soil organic carbon over 20 years would therefore be 14 Gt CO_2e = 0.7 Gt $CO_2\ yr^{-1}$. Griscom et al. (2017a) estimate a cost-effective mitigation potential of 0.03 Gt $CO_2\ yr^{-1}$ (Table 6.13).

Integrated water management provides moderate benefits for climate mitigation due to interactions with other land management strategies. For example, promoting soil carbon conservation (e.g. reduced tillage) can improve the water retention capacity of soils. Jat et al. (2015) found that improved tillage practices and residue incorporation increased water-use efficiency by 30%, rice–wheat yields by 5–37%, income by 28–40% and reduced GHG emission by 16–25%. While irrigated agriculture accounts for only 20% of the total cultivated land, the energy consumption from groundwater irrigation is significant. However, current estimates of mitigation potential are limited to reductions in greenhouse gas emissions mainly in cropland and rice cultivation (Chapter 2; Table 6.13; Smith et al. 2008, 2014c). Li et al. (2006) estimated a 0.52-0.72 $GtCO_2\ yr^{-1}$ reduction using the alternate wetting and drying technique. Current estimates of N_2O release from terrestrial soils and wetlands accounts for 10-15% of anthropogenically fixed nitrogen on the Earth System (Wang et al. 2017).

Table 6.13 summarises the mitigation potentials for agricultural response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

[a] Note that Chapter 2 reports mitigation potential for subcategories within this response option and not the combined total reported here.

6.3.1.1.2 Integrated response options based on land management in forests

Improved forest management could potentially contribute to moderate mitigation benefits globally, up to about 2 Gt CO_2e yr^{-1} (Chapter 2, Table 6.14). For managed forests, the most effective forest carbon mitigation strategy is the one that, through increasing biomass productivity, optimises the carbon stocks (in forests and in long-lived products) as well as the wood substitution effects for a given time frame (Smyth et al. 2014; Grassi et al. 2018; Nabuurs et al. 2007; Lewis et al. 2019) (Kurz et al. 2016; Erb et al. 2018). Estimates of the mitigation potential vary also depending on the counterfactual, such as business-as-usual management (e.g. Grassi et al. 2018) or other scenarios. Climate change will affect the mitigation potential of forest management due to an increase in extreme events like fires, insects and pathogens (Seidl et al. 2017). More detailed estimates are available at regional or biome level. For instance, according to Nabuurs et al. (2017), the implementation of Climate-Smart Forestry (a combination of improved forest management, expansion of forest areas, energy substitution, establishment of forest reserves, etc.) in the European Union has the potential to contribute to an additional 0.4 Gt CO_2 yr^{-1} mitigation by 2050. Sustainable forest management is often associated with a number of co-benefits for adaptation, ecosystem services, biodiversity conservation, microclimatic regulation, soil erosion protection, coastal area protection and water and flood regulation (Locatelli 2011). Forest management mitigation measures are more likely to be long-lasting if integrated into adaptation measures for communities and ecosystems, for example, through landscape management (Locatelli et al. 2011). Adoption of reduced-impact logging and wood processing technologies along with financial incentives can reduce forest fires, forest degradation, maintain timber production, and retain carbon stocks (Sasaki et al. 2016). Forest certification may support sustainable forest management, helping to prevent forest degradation and over-logging (Rametsteiner and Simula 2003). Community forest management has proven a viable model for sustainable forestry, including for carbon sequestration (Chhatre and Agrawal 2009, Chapter 7, section 7.6.4).

Reducing deforestation and forest degradation rates represents one of the most effective and robust options for climate change mitigation, with large mitigation benefits globally (Chapter 2, Chapter 4, Table 6.14). Because of the combined climate impacts of GHGs and biophysical effects, reducing deforestation in the tropics has a major climate mitigation effect, with benefits at local levels too

(Chapter 2, Alkama and Cescatti 2016). Reduced deforestation and forest degradation typically lead to large co-benefits for other ecosystem services (Table 6.14).

A large range of estimates exist in the scientific literature for the mitigation potential of reforestation and forest restoration, and they sometimes overlap with estimates for afforestation. At global level the overall potential for these options is large, reaching about 10 $GtCO_2$ yr^{-1} (Chapter 2, Table 6.14). The greatest potential for these options is in tropical and subtropical climate (Houghton and Nassikas 2018). Furthermore, climate change mitigation benefits of afforestation, reforestation and forest restoration are reduced at high latitudes owing to the surface albedo feedback (see Chapter 2).

Table 6.14 summarises the mitigation potentials for forest response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.14 Mitigation effects of response options based on land management in forests

Integrated response option	Potential	Confidence	Citation
Improved forest management	0.4-2.1 Gt CO_2e yr^{-1}	Medium confidence	Chapter 2; Griscom 2017; Sasaki et al. 2016
Reduced deforestation and degradation	0.4-5.8 Gt CO_2e yr^{-1}	High confidence	Chapter 2; Houghton & Nassikas 2018; Griscom 2017; Baccini 2017; Hawken 2017; Houghton et al 2015; Smith et al. 2014a
Reforestation and forest restoration	1.5-10.1 Gt CO_2e yr^{-1}	Medium confidence	Chapter 2; Dooley and Kartha 2018a; Hawken 2017; Houghton & Nassikas 2018; Griscom 2017. Estimates partially overlapping with Afforestation.
Afforestation	0.5-8.9 Gt CO_2e yr^{-1}	Medium confidence	Chapter 2; Fuss et al. 2018; Hawken 2017; Kreidenweis et al. 2016; Lenton 2010. Estimates partially overlapping with Reforestation.

6.3.1.1.3 Integrated response options based on land management of soils

The global mitigation potential for increasing soil organic matter stocks in mineral soils is estimated to be in the range of 1.3–5.1 $GtCO_2e$ yr^{-1}, though the full literature range is wider (Smith et al. 2008; Smith 2016; Fuss et al 2018.; Sanderman et al. 2017; Sommer & Bossio 2014; Lal 2004; Lal et al. 2010; Table 6.15).

The management and control of erosion may prevent losses of organic carbon in water- or wind-transported sediments, but since the final fate of eroded material is still debated, ranging from a source of 1.36–3.67 $GtCO_2$ yr^{-1} (Jacinthe and Lal 2001; Lal et al., 2004) to a sink of 0.44–3.67 $GtCO_2$ yr^{-1} (Stallard 1998; Smith et al. 2001, 2005; Van Oost et al. 2007; Table 6.15), the overall impact of erosion control on mitigation is context-specific and at the uncertain at the global level (Hoffmann et al., 2013).

Salt-affected soils are highly constrained environments that require permanent prevention of salinisation. Their mitigation potential is likely to be small (Wong et al. 2010; UNCTAD 2011; Dagar et al. 2016b).

Soil compaction prevention could reduce N_2O emissions by minimising anoxic conditions favourable for denitrification (Mbow et al. 2010), but its carbon sequestration potential depends on crop management and the global mitigation potential, though globally unquantified, is likely to be small (Chamen et al. 2015; Epron et al. 2016; Tullberg et al. 2018; Table 6.15).

For biochar, a global analysis of technical potential, in which biomass supply constraints were applied to protect against food insecurity, loss of habitat and land degradation, estimated technical potential abatement of 3.7–6.6 $GtCO_2e\ yr^{-1}$ (including 2.6–4.6 $GtCO_2e\ yr^{-1}$ carbon stabilisation). Considering all published estimates by Woolf et al. (2010), Smith (2016), Fuss et al. (2018b), Griscom et al. (2017), Hawken (2017), Paustian et al. (2016), Powell & Lenton (2012), Dickie et al. (2014), Lenton (2010), Lenton (2014), Roberts et al. (2010), Pratt & Moran (2010) and IPCC (2018), the low value for the range of potentials of 0.03 $GtCO_2e\ yr^{-1}$ is for the "plausible" scenario of Hawken, 2017; Table 6.15). Fuss et al. (2018) propose a range of 0.5–2 $GtCO_2e\ yr^{-1}$ as the sustainable potential for negative emissions through biochar, similar to the range proposed by Smith (2016) and IPCC (2018).

Table 6.15 summarises the mitigation potentials for soil-based response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.1.1.4 Integrated response options based on land management in all/other ecosystems

For fire management, total emissions from fires have been in the order of 8.1 $GtCO_2e\ yr^{-1}$ for the period 1997-2016 (see Chapter 2, Cross-Chapter Box 3) and there are important synergies between air pollution and climate change control policies. Reduction in fire CO_2 emissions due to fire suppression and landscape fragmentation associated with increases in population density is calculated to enhance land carbon uptake by 0.48 Gt CO_2e yr^{-1} for the 1960–2009 period (Arora and Melton 2018; Table 6.16).

Management of landslides and natural hazards is a key climate adaptation option but due to limited global areas vulnerable to landslides and natural hazards, its mitigation potential is likely to be modest (Noble et al. 2015).

In terms of management of pollution, including acidification, UNEP and WMO (2011) and Shindell et al. (2012) identified measures targeting reduction in SLCP emissions that reduce projected global mean warming about 0.5°C by 2050. Bala et al. (2013) reported that a recent coupled modelling study showed N deposition and elevated CO_2 could have a synergistic effect, which could explain 47% of terrestrial carbon uptake in the 1990s. Estimates of global terrestrial carbon uptake due to current N deposition ranges between 0.55 and 1.28 $GtCO_2$ yr^{-1} (de Vries et al. 2006; de Vries et al. 2009; Bala et al. 2013; Zaehle and Dalmonech 2011; Table 6.16).

There are no global data on the impacts of management of invasive species / encroachment on mitigation.

Coastal wetland restoration could provide high levels of climate mitigation, with avoided coastal wetland impacts and coastal wetland restoration estimated to deliver 0.3-3.1 $GtCO_2e$ yr^{-1} in total when considering all global estimates from Griscom et al. (2017a), Hawken (2017), Pendleton et al. (2012), Howard et al. (2017) and Donato et al. (2010) (Table 6.16).

Peatland restoration could provide moderate levels of climate mitigation, with avoided peat impacts and peat restoration estimated to deliver 0.6-2 $GtCO_2e$ yr^{-1} from all global estimates published in Griscom et al. (2017a), Hawken (2017), Hooijer et al. (2010), Couwenberg et al. (2010) and Joosten and Couwenberg (2008), though there could be an increase in methane emissions after restoration (Jauhiainen et al. 2008; Table 6.16).

Mitigation potential from biodiversity conservation varies depending on the type of intervention and specific context. Protected areas are estimated to store over 300 Gt carbon, roughly corresponding to 15% of terrestrial carbon stocks (Kapos et al. 2008; Campbell et al. 2008). At global level, the potential mitigation resulting from protection of these areas for the period 2005-2095 is on average about 0.9 $GtCO_2$-eq. yr^{-1} relative to a reference scenario (Calvin et al. 2014a). The potential effects on the carbon cycle of management of wild animal species are case context dependent. For example, moose browsing in boreal forests can decrease the carbon uptake of ecosystems by up to 75% (Schmitz et al. 2018b), and reducing moose density through active population management in Canada is estimated to be a carbon sink equivalent to about 0.37 Gt CO_2e yr^{-1} (Schmitz et al. 2014).

Table 6.16 summarises the mitigation potentials for land management response options in all/other ecosystems, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.1.1.5 Integrated response options based on land management specifically for CDR

Enhanced mineral weathering provides substantial climate mitigation, with a global mitigation potential in the region of about 0.5–4 $GtCO_2e\ yr^{-1}$ (Beerling et al 2018.; Lenton 2010; Smith et al. 2016c; Taylor et al. 2016; Table 6.17).

The mitigation potential for bioenergy and BECCS derived from bottom-up models is large (IPCC SR15; Chapter 2; Cross-Chapter Box 7 on Bioenergy in this chapter), with technical potential estimated at 100-300 EJ yr^{-1} (IPCC 2011; Cross-Chapter Box 7 in this chapter) or up to ~11 $GtCO_2\ yr^{-1}$ (Chapter 2). These estimates, however, exclude N_2O associated with fertiliser application and land-use change emissions. Those effects are included in the modelled scenarios using bioenergy and BECCS, with the sign and magnitude depending on where the bioenergy is grown (Wise et al. 2015), at what scale, and whether N fertiliser is used.

Table 6.17 summarises the mitigation potentials for land management options specifically for CDR, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.1.2 Integrated response options based on value chain management

In this section, the impacts on climate change mitigation of integrated response options based on value chain management are assessed.

6.3.1.2.1 Integrated response options based on value chain management through demand management

Dietary change and waste reduction can provide large benefits for mitigation, with potentials of 0.7-8 $GtCO_2\ yr^{-1}$ for both (Bajželj et al. 2014; Stehfest et al. 2009; Tilman and Clark 2014b; Aleksandrowicz et al. 2016; Herrero et al. 2016; Springmann et al. 2016; Smith et al. 2013; Dickie et al. 2014;Popp et al. 2010; Hawken 2017; Hedenus (2014)). Estimates for food waste reduction

(Hawken 2017; Hic et al. 2016; Dickie et al. 2014) (Bajželj et al. 2014) include both consumer / retailed waste and post-harvest losses (Table 6.18).

Some studies indicate that material substitution has the potential for significant mitigation, with one study estimating a 14–31% reduction in global CO_2 emissions (Oliver et al. 2014); other studies suggest more modest potential (Gustavsson et al. 2006; Table 6.18).

Table 6.18 summarises the mitigation potentials for demand management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Reduced food waste (consumer or retailer)	0.8 to 4.5 $GtCO_2\ yr^{-1}$	High confidence	Chapter 5; Bajželj et al. 2014; Dickie et al. 2014; Hawken 2017; Hic et al. 2016
Material substitution	0.25 to 1 $GtCO_2\ yr^{-1}$	Medium confidence	Chapter 2; Dugan et al. 2018; Gustavsson et al. 2006; Leskinen et al. 2018; McLaren 2012; Sathre and O'Connor 2010; Miner 2010;Kauppi 2001; Smyth et al. 2016

6.3.1.2.2 Integrated response options based on value chain management through supply management

While sustainable sourcing presumably delivers a mitigation benefit, there are no global estimates of potential. Palm oil production alone is estimated to contribute 0.038 to 0.045 GtC yr^{-1}, and Indonesian palm oil expansion contributed up to 9% of tropical land use change carbon emissions in the 2000s (Carlson and Curran 2013), however, the mitigation benefit of sustainable sourcing of palm oil has not been quantified. There are no estimates of the mitigation potential for urban food systems.

Efficient use of energy and resources in food transport and distribution contribute to a reduction in GHG emissions, estimated to be 1% of global CO_2 emissions (James and James 2010; Vermeulen et al. 2012). Given that global CO_2 emissions in 2017 were 37 $GtCO_2$, this equates to 0.37 $GtCO_2\ yr^{-1}$ (covering food transport and distribution, improved efficiency of food processing and retailing, and improved energy efficiency; Table 6.19).

Table 6.19 summarises the mitigation potentials for supply management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Improved energy use in food	0.37 $GtCO_2\ yr^{-1}$	Low confidence	James and James

systems			2010b; Vermeulen et al. 2012b

6.3.1.3 Integrated response options based on risk management

In this section, the impacts on climate change mitigation of integrated response options based on risk management are assessed. In general, because these options are focused on adaptation and other benefits, the mitigation benefits are modest, and mostly unquantified.

Extensive and less dense urban development tends to have higher energy usage, particularly from transport (Liu et al. 2015), such that a 10% reduction of very low density urban fabrics is correlated with 9% fewer emissions per capita in Europe (Baur et al. 2015). However, the exact contribution to mitigation from the prevention of land conversion in particular has not been well quantified (Thornbush et al. 2013). Suggestions from select studies in the US are that biomass decreases by half in cases of conversion from forest to urban land uses (Briber et al. 2015), and a study in Bangkok found a decline by half in carbon sinks in the urban area in the past 30 years (Ali et al. 2018).

There is no literature specifically on linkages between livelihood diversification and climate mitigation benefits, although some forms of diversification that include agroforestry would likely result in increased carbon sinks (Altieri et al. 2015; Descheemaeker et al. 2016). There is no literature exploring linkages between local seeds and GHG emission reductions, although use of local seeds likely reduces emissions associated with transport for commercial seeds, though the impact has not been quantified.

While disaster risk management can presumably have mitigation co-benefits, as it can help reduce food loss on-farm (e.g. crops destroyed before harvest or avoided animal deaths during droughts and floods meaning reduced production losses and wasted emissions), there is no quantified global estimate for this potential.

Risk sharing instruments could have some mitigation co-benefits if they buffer household losses and reduce the need to expand agricultural lands after experiencing risks. However, the overall impacts of these are unknown. Further, commercial insurance may induce producers to bring additional land into crop production, particularly marginal or land with other risks that may be more environmentally sensitive (Claassen et al. 2011). Policies to deny crop insurance to farmers who have converted grasslands in the US resulted in a 9% drop in conversion, which likely has positive mitigation impacts (Claassen et al. 2011). Estimates of emissions from cropland conversion in the US in 2016 were 23.8 Mt CO_2e, only some of which could be attributed to insurance as a driver.

Table 6.20 summarises the mitigation potentials for risk management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence is based.

Table 6.20 Mitigation effects of response options based on risk management

Livelihood diversification	No global estimates	No evidence	
Use of local seeds	No global estimates	No evidence	
Disaster risk management	No global estimates	No evidence	
Risk sharing instruments	->0.024 GtCO_2e yr^{-1} for crop insurance; likely some benefits for other risk sharing instruments	Low confidence	Claussen et al 2011; EPA 2018

6.3.2 Potential of the integrated response options for delivering adaptation

In this section, the impacts of integrated response options on climate change adaptation are assessed.

6.3.2.1 Integrated response options based on land management

In this section, the impacts on climate change adaptation of integrated response options based on land management are assessed.

6.3.2.1.1 Integrated response options based on land management in agriculture

Increasing food productivity by practices such as sustainable intensification improves farm incomes and allows households to build assets for use in times of stress, thereby improving resilience (Campbell et al. 2014). By reducing pressure on land and increasing food production, increased food productivity could be beneficial for adaptation (Chapter 2; Section 6.3; Campbell et al. 2014). Pretty et al. (2018) report that 163 million farms occupying 4.53 Mkm^2 have passed a redesign threshold for application of sustainable intensification, suggesting the minimum number of people benefiting from increased productivity and adaptation benefits under sustainable intensification is >163 million, with the total likely to be far higher (Table 6.21).

Improved cropland management is a key climate adaptation option, potentially affecting more than 25 million people, including a wide range of technological decisions by farmers. Actions towards adaptation fall into two broad overlapping areas: (1) accelerated adaptation to progressive climate change over decadal time scales, for example integrated packages of technology, agronomy and policy options for farmers and food systems, including changing planting dates and zones, tillage systems, crop types and varieties, and (2) better management of agricultural risks associated with increasing climate variability and extreme events, for example improved climate information services and safety nets (Vermeulen et al. 2012b; Challinor et al. 2014; Lipper et al. 2014; Lobell 2014). In the same way, improved livestock management is another technological adaptation option potentially benefiting 1–25 million people. Crop and animal diversification are considered the most promising adaptation measures (Porter et al. 2014; Rojas-Downing et al. 2017a). In grasslands and rangelands, regulation of stocking rates, grazing field dimensions, establishment of exclosures and locations of drinking fountains and feeders are strategic decisions by farmers to improve grazing management (Taboada et al. 2011; Mekuria and Aynekulu 2013; Porter et al. 2014).

Around 30% of the world's rural population use trees across 46% of all agricultural landscapes (Lasco et al. 2014), meaning that up to 2.3 billion people benefit from agroforestry, globally (Table 6.21).

Agricultural diversification is key to achieve climatic resilience (Campbell et al. 2014; Cohn et al. 2017). Crop diversification is one important adaptation option to progressive climate change (Vermeulen et al. 2012) and it can improve resilience by engendering a greater ability to suppress pest outbreaks and dampen pathogen transmission, as well as by buffering crop production from the effects of greater climate variability and extreme events (Lin 2011).

Reduced conversion of grassland to cropland may lead to adaptation benefits by stabilising soils in the face of extreme climatic events (Lal 2001b), thereby increasing resilience, but since it would likely have a negative impact on food production / security (since croplands produce more food per unit area than grasslands), the wider adaptation impacts would likely be negative. However, there is no literature quantifying the global impact of avoidance of conversion of grassland to cropland on adaptation.

Integrated water management provides large co-benefits for adaptation (Dillon and Arshad 2016) by improving the resilience of food crop production systems to future climate change (Chapter 2; Table 6.7; Porter et al. 2014). Improving irrigation systems and integrated water resource management, such as enhancing urban and rural water supplies and reducing water evaporation losses (Dillon and

Arshad 2016), are significant options for enhancing climate adaptation. Many technical innovations (e.g., precision water management) can lead to beneficial adaptation outcomes by increasing water availability and the reliability of agricultural production, using different techniques of water harvesting, storage, and its judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas. Integrated water management response options that use freshwater would be expected to have few adverse side effects in regions where water is plentiful, but large adverse side effects in regions where water is scarce (Grey and Sadoff 2007; Liu et al. 2017; Scott et al. 2011).

Table 6.21 summarises the potentials for adaptation for agricultural response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.21 Adaptation effects of response options based on land management in agriculture

Integrated response option	Potential	Confidence	Citation
Increased food productivity	>163 million people	Medium confidence	Pretty et al. 2018

Improved grazing land management	1-25 million people	Low confidence	Porter et al. 2014
Improved livestock management	1-25 million people	Low confidence	Porter et al. 2014; Rojas-Downing et al. 2017
Agroforestry	2300 million people	Medium confidence	Lasco et al. 2014
Agricultural diversification	>25 million people	Low confidence	Campbell et al. 2014; Cohn et al. 2017; Vermeulen et al. 2012b
Reduced grassland conversion to cropland	No global estimates	No evidence	
Integrated water management	250 million people	Low confidence	Dillon and Arshad 2016; Liu et al. 2017

6.3.2.1.2 Integrated response options based on land management in forestry

Improved forest management positively impacts adaptation through limiting the negative effects associated with pollution (of air and fresh water), infections and other diseases, exposure to extreme weather events and natural disasters, and poverty (e.g., Smith et al. 2014c). There is high agreement on the fact that reduced deforestation and forest degradation positively impact adaptation and resilience of coupled human-natural systems. Based on the number of people affected by natural disasters (CRED 2015), the number of people depending to varying degrees on forests for their livelihoods (World Bank et al. 2009) and the current deforestation rate (Keenan et al. 2015), the estimated global potential effect for adaptation is large positive for improved forest management, and moderate positive for reduced deforestation when cumulated till the end of the century (Table 6.22). The uncertainty of these global estimates is high, e.g. the impact of reduced deforestation may be higher when the large biophysical impacts on the water cycle (and thus drought) from deforestation (e.g. Alkama & Cescatti 2016, etc) are taken into account (see Chapter 2).

More robust qualitative and some quantitative estimates are available at local and regional level. According to Karjalainen et al. (2009), reducing deforestation and habitat alteration contributes to limiting infectious diseases such as malaria in Africa, Asia, and Latin America, thus lowering the expenses associated with healthcare treatments. Bhattacharjee and Behera (2017) found that human lives lost due to floods increase with reducing forest cover and increasing deforestation rates in India. In addition, maintaining forest cover in urban contexts reduces air pollution and therefore avoids mortality of about one person per year per city in US, and up to 7.6 people per year in New York City

(Nowak et al. 2014). There is also evidence that reducing deforestation and degradation in mangrove plantations potentially improves soil stabilisation, and attenuates the impact of tropical cyclones and typhoons along the coastal areas in South and Southeast Asia (Chow 2018). At local scale, co-benefits between REDD+ and adaptation of local communities can potentially be substantial (Long 2013; Morita & Matsumoto 2017), even if often difficult to quantify, and not explicitly acknowledged (McElwee et al. 2017b).

Forest restoration may facilitate the adaptation and resilience of forests to climate change by enhancing connectivity between forest areas and conserving biodiversity hotspots (Locatelli et al. 2011, 2015c; Ellison et al. 2017; Dooley and Kartha 2018b). Furthermore, forest restoration may improve ecosystem functionality and services, provide microclimatic regulation for people and crops, wood and fodder as safety nets, soil erosion protection and soil fertility enhancement for agricultural resilience, coastal area protection, water and flood regulation (Locatelli et al. 2015c).

Afforestation and reforestation are important climate change adaptation response options (Reyer et al. 2009; Ellison et al. 2017a; Locatelli et al. 2015c), and can potentially help a large proportion of the global population to adapt to climate change and to associated natural disasters (Table 6.22). For example, trees general mitigate summer mean warming and temperature extremes (Findell et al. 2017; Sonntag et al. 2016).

Table 6.22 summarises the potentials for adaptation for forest response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.2.1.3 Integrated response options based on land management of soils

Soil organic carbon increase is promoted as an action for climate change adaptation. Since increasing soil organic matter content is a measure to address land degradation (see Section 6.2.1), and restoring degraded land helps to improve resilience to climate change, soil carbon increase is an important option for climate change adaptation. With around 120 thousand km^2 lost to degradation every year, and over 3.2 billion people negatively impacted by land degradation globally (IPBES 2018), practices designed to increase soil organic carbon have a large potential to address adaptation challenges (Table 6.23).

Since soil erosion control prevents land degradation and desertification, it improves the resilience of agriculture to climate change and increases food production (Lal 1998; IPBES 2018), though the global number of people benefiting from improved resilience to climate change has not been reported in the literature. Using figures from (FAO et al. 2015), Scholes et al. (2018) estimates that land losses due to erosion are equivalent to 1.5 Mkm^2 of land used for crop production to 2050, or 45 thousand km^2 yr^{-1} (Foley et al. 2011). Control of soil erosion (water and wind) could benefit 11 Mkm^2 of degraded land (Lal 2014), and improve the resilience of at least some of the 3.2 billion people affected by land degradation (IPBES 2018), suggesting positive impacts on adaptation. Management of erosion is an important climate change adaptation measure, since it reduces the vulnerability of soils to loss under climate extremes, thereby increasing resilience to climate change (Garbrecht et al. 2015).

Prevention and/or reversion of topsoil salinisation may require a combined management of groundwater, irrigation techniques, drainage, mulching and vegetation, with all of these considered relevant for adaptation (Qadir et al. 2013; UNCTAD 2011; Dagar et al. 2016b). Taking into account the widespread diffusion of salinity problems, many people can benefit from its implementation by farmers. The relation between compaction prevention and/or reversion and climate adaption is less evident, and can be related to better hydrological soil functioning (Chamen et al. 2015; Epron et al. 2016; Tullberg et al. 2018b).

Biochar has potential to benefit climate adaptation by improving the resilience of food crop production systems to future climate change by increasing yield in some regions and improving water holding capacity (Chapter 2; Section 6.4; Woolf et al. 2010; Sohi 2012). By increasing yield by 25% in the tropics (Jeffery et al. 2017), this could increase food production for 3.2 billion people affected by land degradation (IPBES 2018), thereby potentially improving their resilience to climate change shocks (Table 6.23). A requirement for large areas of land to provide feedstock for biochar could adversely impact adaptation, though the impact has not been quantified globally.

Table 6.23 summarises the potentials for adaptation for soil-based response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.23 Adaptation effects of response options based on land management of soils

Reduced soil compaction	<1 million people	Low confidence	Chamen et al. 2015c; Epron et al. 2016; Tullberg et al. 2018b
Biochar addition to soil	Up to 3200 million people; but potential negative (unquantified) impacts from land required from feedstocks	Low confidence	Jeffery et al. 2017

6.3.2.1.4 Integrated response options based on land management across all/other ecosystems

For fire management, Doerr et al. (2016) showed the number of people killed by wildfire was 1940, and the total number of people affected was 5.8 million from 1984 to 2013, globally. Johnston et al. (2012) showed the average mortality attributable to landscape fire smoke exposure was 339 thousand deaths annually. The regions most affected were sub-Saharan Africa (157 thousand) and Southeast Asia (110 thousand). Estimated annual mortality during La Niña was 262 thousand, compared with around 100 thousand excess deaths across Indonesia, Malaysia and Singapore (Table 6.24).

Management of landslides and natural hazards are usually listed among planned adaptation options in mountainous and sloped hilly areas, where uncontrolled runoff and avalanches may cause climatic disasters, affecting millions of people from both urban and rural areas. Landslide control requires both increasing plant cover and engineering practices (see Table 6.8).

For management of pollution, including acidification, Anenberg et al. (2012) estimated that, for PM2.5 and ozone, respectively, fully implementing reduction measures could reduce global population-weighted average surface concentrations by 23–34% and 7–17% and avoid 0.6–4.4 and 0.04–0.52 million annual premature deaths globally in 2030. UNEP and WMO (2011) considered emission control measures to reduce ozone and black carbon (BC) and estimated that 2.4 million annual premature deaths (with a range of 0.7 to 4.6 million) from outdoor air pollution could be avoided. West et al. (2013) estimated global GHG mitigation brings co-benefits for air quality and would avoid 0.5±0.2, 1.3±0.5, and 2.2±0.8 million premature deaths in 2030, 2050, and 2100, respectively.

There are no global data on the impacts of management of invasive species / encroachment on adaptation.

Coastal wetlands provide a natural defence against coastal flooding and storm surges by dissipating wave energy, reducing erosion and by helping to stabilise shore sediments, so restoration may provide significant benefits for adaptation. The Ramsar Convention on Wetlands covers 1.5 Mkm^2 across 1674 sites Keddy et al. (2009). Coastal floods currently affect 93–310 million people (in 2010) globally, and this could rise to 600 million people in 2100 with sea level rise, unless adaptation measures are taken (Hinkel et al. 2014). The proportion of the flood-prone population that could avoid these impacts through restoration of coastal wetlands has not been quantified, but this sets an upper limit.

Avoided peat impacts and peatland restoration can help to regulate water flow and prevent downstream flooding (Munang et al. 2014), but the global potential (in terms of number of people who could avoid flooding through peatland restoration) has not been quantified.

There are no global estimates about the potential of biodiversity conservation to improve the adaptation and resilience of local communities to climate change, in terms of reducing the number of people affected by natural disasters. Nevertheless, it is widely recognised that biodiversity, ecosystem health and resilience improves the adaptation potential (Jones et al. 2012). For example, tree species mixture improves the resistance of stands to natural disturbances, such as drought, fires, and windstorms (Jactel et al. 2017), as well as stability against landslides (Kobayashi and Mori 2017). Moreover, Protected Areas play a key role for improving adaptation (Watson et al. 2014; Lopoukhine et al. 2012), through reducing water flow, stabilising rock movements, creating physical barriers to coastal erosion, improving resistance to fires, and buffering storm damages (Dudley et al. 2010). 33 out of 105 of the largest urban areas worldwide rely on protected areas for some, or all, of their drinking water (Secretariat of the Convention on Biological Diversity 2008), indicating that many millions are likely benefit from conservation practices.

Table 6.24 summarises the potentials for adaptation for soil-based response options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.2.1.5 Integrated response options based on land management specifically for CDR

Enhanced weathering of minerals has been proposed as a mechanism of improving soil health and food security (Beerling et al. 2018), but there is no literature estimating the global adaptation benefits.

Large-scale bioenergy and BECCS can require substantial amounts of cropland (Popp et al. 2017; Calvin et al. 2014a; Smith et al. 2016c), forestland (Baker et al. 2019b; Favero and Mendelsohn 2017), and water (Chaturvedi et al. 2013; Smith et al. 2016; Fuss et al. 2018; Popp et al. 2011; Hejazi et al. 2015b) suggesting that bioenergy and BECCS could have adverse side-effects for adaptation. In some contexts, e.g., low inputs of fossil fuels and chemicals, limited irrigation, heat/drought tolerant species, and using marginal land, bioenergy can have co-benefits for adaptation (Dasgupta et al. 2014; Noble et al. 2014). However, no studies were found that quantify the magnitude of the effect.

Table 6.25 summarises the impacts on adaptation of land management response options specifically for CDR, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.2.2 Integrated response options based on value chain management

In this section, the impacts on climate change adaptation of integrated response options based on value chain management are assessed.

6.3.2.2.1 Integrated response options based on value chain management through demand management

Decreases in pressure on land and decreases in production intensity associated with sustainable healthy diets or reduced food waste could also benefit adaptation; however, the size of this effect is not well quantified (Muller et al. 2017b).

Reducing food waste losses can relieve pressure on the global freshwater resource, thereby aiding adaptation. Food losses account for 215 km^3 yr^{-1} of freshwater resources, which (Kummu et al. 2012) report to be about 12–15% of the global consumptive water use. Given that 35% of the global population is living under high water stress or shortage (Kummu et al. 2010), reducing food waste could benefit 320–400 million people (12–15% of the 2681 million people affected by water stress / shortage).

While no studies report quantitative estimates of the effect of material substitution on adaptation, the effects are expected to be similar to reforestation and afforestation if the amount of material substitution leads to an increase in forest area. Additionally, some studies indicate that wooden buildings, if properly constructed, could reduce fire risk compared to steel, which softens when burned (Gustavsson et al. 2006; Ramage et al. 2017a).

Table 6.26 summarises the impacts on adaptation of demand management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Reduced food waste (consumer or retailer)	No global estimates	No evidence	Muller et al. 2017b
Material substitution	No global estimates	No evidence	

6.3.2.2.2 Integrated response options based on value chain management through supply management

It is estimated that 500 million smallholder farmers depend on agricultural businesses in developing countries (World Bank, 2017), meaning that better promotion of value-added products and improved efficiency and sustainability of food processing and retailing could potentially help up to 500 million people to adapt to climate change. However, figures on how sustainable sourcing in general could help farmers and forest management is mostly unquantified. More than 1 million farmers have currently been certified through various schemes (Tayleur et al. 2017), but how much this has helped them prepare for adaptation is unknown.

Management of supply chains has the potential to reduce vulnerability to price volatility. Consumers in lower income countries are most affected by price volatility, with sub-Saharan Africa and South Asia at highest risk (Regmi and Meade 2013; Fujimori et al. 2018a). However, understanding of the stability of food supply is one of the weakest links in global food system research (Wheeler and von Braun 2013) as instability is driven by a confluence of factors (Headey and Fan 2008). Food price spikes in 2007 increased the number of people under the poverty line by between 100 million people (Ivanic and Martin 2008) and 450 million people (Brinkman et al. 2009), and caused welfare losses of 3% or more for poor households in many countries (Zezza et al. 2009). Food price stabilisation by China, India and Indonesia alone in 2007/2008 led to reduced staple food price for 2 billion people (Timmer 2009). Presumably, spending less on food frees up money for other activities, including adaptation, but it is unknown how much (Zezza et al. 2009; Ziervogel and Ericksen 2010). One example of reduction in staple food price costs to consumers in Bangladesh from food stability policies saved rural households USD887 million total (Torlesse et al. 2003b). Food supply stability through improved supply chains also potentially reduces conflicts (by avoiding food price riots, which occurred in countries with over 100 million total in population in 2007/2008), and thus increases adaptation capacity (Raleigh et al. 2015a).

There are no global estimates of the contribution of improved food transport and distribution, or of urban food systems, in contributing to adaptation, but since the urban population in 2018 was 4.2 billion people, this sets the upper limit on those that could benefit.

Given that 65% (760 million) of poor working adults make a living through agriculture, increased energy efficiency in agriculture could benefit this 760 million people.

Table 6.27 summarises the impacts on adaptation of supply management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.2.3 Integrated response options based on risk management

In this section, the impacts on climate change adaptation of integrated response options based on risk management are assessed.

Reducing urban sprawl is likely to provide adaptation co-benefits *via* improved human health (Frumkin 2002; Anderson 2017), as sprawl contributes to reduced physical activity, worse air pollution, and exacerbation of urban heat island effects and extreme heat waves (Stone et al. 2010). The most sprawling cities in the US have experienced extreme heat waves more than double those of denser cities, and "urban albedo and vegetation enhancement strategies have significant potential to reduce heat-related health impacts" (Stone et al. 2010). Other adaption co-benefits are less well understood. There are likely to be cost savings from managing planning growth (one study found 2% savings in metropolitan budgets, which can be then spent on adaptation planning) (Deal and Schunk 2004).

Diversification is a major adaptation strategy and form of risk management, as it can help households smooth out income fluctuations and provide a broader range of options for the future (Osbahr et al. 2008; Adger et al. 2011; Thornton and Herrero 2014). Surveys of farmers in climate variable areas find that livelihood diversification is increasingly favoured as an adaptation option (Bryan et al. 2013), although it is not always successful, since it can increase exposure to climate variability (Adger et al. 2011). There are over 570 million small farms in the world (Lowder et al. 2016), and many millions of smallholder agriculturalists already practice livelihood diversification by engaging in multiple forms of off-farm income (Rigg 2006). It is not clear, however, how many farmers have not yet practiced diversification and thus how many would be helped by supporting this response option.

Currently, millions of farmers still rely to some degree on local seeds. Use of local seeds can facilitate adaptation for many smallholders, as moving to use of commercial seeds can increase costs for farmers (Howard 2015). Seed networks and banks protect local agrobiodiversity and landraces, which are important to facilitate adaptation, as local landraces may be resilient to some forms of climate change (Coomes et al. 2015a; van Niekerk and Wynberg 2017a; Vasconcelos et al. 2013).

Disaster risk management is an essential part of adaptation strategies. The Famine Early Warning System funded by the USAID has operated across 3 continents since the 1980s, and many millions of people across 34 countries have access to early information on drought. Such information can assist communities and households in adapting to onset conditions (Hillbruner and Moloney 2012).

However, concerns have been raised as to how many people are actually reached by disaster risk management and early warning systems; for example, less than 50% of respondents in Bangladesh had heard a cyclone warning before it hit, even though an early warning system existed (Mahmud and Prowse 2012). Further, there are concerns that current early warning systems "tend to focus on response and recovery rather than on addressing livelihood issues as part of the process of reducing underlying risk factors," (Birkmann et al. 2015a), leading to less adaptation potential being realised.

Local risk sharing instruments like rotating credit or loan groups can help buffer farmers against climate impacts and help facilitate adaptation. Both index and commercial crop insurance offers some potential for adaptation, as it provides a means of buffering and transferring weather risk, saving farmers the cost of crop losses (Meze-Hausken et al. 2009; Patt et al. 2010). However, overly subsidised insurance can undermine the market's role in pricing risks and thus depress more rapid adaptation strategies (Skees and Collier 2012; Jaworski 2016) and increase the riskiness of decision-making (McLeman and Smit 2006). For example, availability of crop insurance was observed to reduce farm-level diversification in the US, a factor cited as increasing adaptive capacity (Sanderson et al. 2013b) and crop insurance-holding soybean farmers in the US have been less likely to adapt to extreme weather events than those not holding insurance (Annan and Schlenker 2015). It is unclear how many people worldwide use insurance as an adaptation strategy; (Platteau et al. 2017) suggest less than 30% of smallholders take out any form of insurance), but it is likely in the millions.

Table 6.28 summarises the impacts on adaptation of risk management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.3 Potential of the integrated response options for addressing desertification

In this section, the impacts of integrated response options on desertification are assessed.

6.3.3.1 Integrated response options based on land management

In this section, the impacts on desertification of integrated response options based on land management are assessed.

6.3.3.1.1 Integrated response options based on land management in agriculture

Burney et al. (2010) estimated that an additional global cropland area of 11.11–15.14 Mkm^2 would have been needed if productivity had not increased between 1961 and 2000. Given that agricultural expansion is a main driver of desertification (FAO et al. 2015), increased food productivity could have prevented up to 11.11–15.14 Mkm^2 from exploitation and desertification (Table 6.10).

Improved cropland, livestock and grazing land management are strategic options aiming at prevention of desertification, and may include crop and animal selection, optimised stocking rates, changed tillage and/or cover crops, to land use shifting from cropland to rangeland, in general targeting increases in ground cover by vegetation, and protection against wind erosion (Schwilch et al. 2014; Bestelmeyer et al. 2015). Considering the widespread distribution of deserts and desertified lands globally, more than 10 Mkm^2 could benefit from improved management techniques.

Agroforestry can help stabilise soils to prevent desertification (Section 6.3.2.1.1), so given that there are is around 10 Mkm^2 of land with more than 10% tree cover (Garrity, 2012), agroforestry could benefit up to 10 Mkm^2 of land.

Agricultural diversification to prevent desertification may include the use of crops with manures, legumes, fodder legumes and cover crops combined with conservation tillage systems (Schwilch et al. 2014). These practices can be considered to be part of improved crop management options (see above) and aim at increasing ground coverage by vegetation and controlling wind erosion losses.

Since shifting from grassland to the annual cultivation of crops increases erosion and soil loss, there are significant benefits for desertification control, by stabilising soils in arid areas (Chapter 3). Cropland expansion during 1985 to 2005 was 359 thousand km^2, or 17.4 thousand $km^2\ yr^{-1}$ (Foley et al. 2011). Not all of this expansion will be from grasslands or in desertified areas, but this value sets the maximum contribution of prevention of conversion of grasslands to croplands, a small global benefit for desertification control (Table 6.10).

Integrated water management strategies such as water-use efficiency and irrigation, improve soil health through increase in soil organic matter content, thereby delivering benefits for prevention or reversal of desertification (Chapter 3; Baumhardt et al. 2015; Datta et al. 2000; Evans and Sadler 2008; He et al. 2015). Climate change will amplify existing stress on water availability and on agricultural systems, particularly in semi-arid environments (AR5; Chapter 3). In 2011, semiarid ecosystems in the southern hemisphere contributed 51% of the global net carbon sink (Poulter et al., 2014). These results suggest that arid ecosystems could be an important global carbon sink, depending on soil water availability.

Table 6.29 summarises the impacts on desertification of agricultural options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.29 Effects on desertification of response options in agriculture

6.3.3.1.2 Integrated response options based on land management in forestry

Forests are important to help to stabilise land and regulate water and microclimate (Locatelli et al. 2015c). Based on the extent of dry forest at risk of desertification (Núñez et al. 2010; Bastin et al.

2017), the estimated global potential effect for avoided desertification is large for both improved forest management and for reduced deforestation and forest degradation when cumulated for at least 20 years (Table 6.30). The uncertainty of these global estimates is high. More robust qualitative and some quantitative estimates are available at regional level. For example, it has been simulated that human activity (i.e., land management) contributed to 26% of the total land reverted from desertification in Northern China between 1981 and 2010 (Xu et al. 2018). In Thailand, it was found that the desertification risk is reduced when the land use is changed from bare lands to agricultural lands and forests, and from non-forests to forests; conversely, the desertification risk increases when converting forests and denuded forests to bare lands (Wijitkosum 2016).

Afforestation, reforestation and forest restoration are land management response options that are used to prevent desertification. Forests tend to maintain water and soil quality by reducing runoff and trapping sediments and nutrients (Idris Medugu et al. 2010a; Salvati et al. 2014a), but planting of non-native species in semi-arid regions can deplete soil water resources if they have high evapotranspiration rates (Feng et al.; Yang et al.). Afforestation and reforestation programmes can be deployed over large areas of the Earth, so can create synergies in areas prone to desertification. Global estimates of land potentially available for afforestation are up to 25.8 Mkm^2 by the end of the century, depending on a variety of assumptions on socio-economic developments and climate policies (Griscom et al. 2017; Kreidenweis et al. 2016a; Popp et al. 2017). The higher end of this range is achieved under the assumption of a globally uniform reward for carbon uptake in the terrestrial biosphere, and it is halved by considering tropical and subtropical areas only to minimise albedo feedbacks (Kreidenweis et al. 2016a). When safeguards are introduced (e.g., excluding existing cropland for food security, boreal areas, etc.), the area available declines to about 6.8 Mkm^2 (95% confidence interval of 2.3 and 11.25 Mkm^2), of which about 4.72 Mkm^2 is in the tropics and 2.06 Mkm^2 is in temperate regions (Griscom et al. 2017a; Table 6.30).

Table 6.30 summarises the impacts on desertification of forestry options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.3.1.3 Integrated response options based on land management of soils

With over 2.7 billion people affected globally by desertification (IPBES 2018), practices to increase soil organic carbon content are proposed as actions to address desertification, and could be applied to an estimated 11.37 Mkm^2 of desertified soils (Lal 2001a; Table 6.31).

Control of soil erosion could have large benefits for desertification control. Using figures from (FAO et al. 2015), Scholes et al. (2018) estimated that land losses due to erosion to 2050 are equivalent to 1.5 Mkm^2 of land from crop production, or 45 thousand km^2 yr^{-1} (Foley et al. 2011), so soil erosion control could benefit up to 1.50 Mkm^2 of land in the coming decades. Lal (2001a) estimated that desertification control (using soil erosion control as one intervention) could benefit 11.37 Mkm^2 of desertified land globally (Table 6.10).

Oldeman et al. (1991) estimated the global extent soil affected by salinisation is 0.77 Mkm^2 yr^{-1}, which sets the upper limit on the area that could benefit from measures to address soil salinisation (Table 6.31).

In degraded arid grasslands, shrublands and rangelands, desertification can be reversed by alleviation of soil compaction through installation of enclosures and removal of domestic livestock (Allington et al. 2010), but there are no global estimates of potential (Tale 6.31).

Biochar could potentially deliver benefits in efforts to address desertification though improving water holding capacity (Woolf et al. 2010; Sohi 2012), but the global effect is not quantified.

Table 6.31 summarises the impacts on desertification of soil-based options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.31 Effects on desertification of land management of soils

Reduced soil compaction	No global estimates	No evidence	FAO and ITPS 2015; Hamza and Anderson 2005b
Biochar addition to soil	No global estimates	No evidence	

6.3.3.1.4 Integrated response options based on land management across all/other ecosystems

For fire management, Arora and Melton (2018) estimated, using models and GFED4.1s0 data, that burned area over the 1997–2014 period was 4.834-4.855 Mkm^2 yr^{-1}. Randerson et al. (2012) estimated small fires increased total burned area globally by 35% from 3.45 to 4.64 Mkm^2 yr^{-1} during the period 2001–2010. Tansey et al. (2004) estimated over 3.5 Mkm^2 yr^{-1} of burned areas were detected in the year 2000 (Table 6.32).

Although slope and slope aspect are predictive factors of desertification occurrence, the factors with the greatest influence are land cover factors, such as normalised difference vegetation index (NDVI) and rangeland classes (Djeddaoui et al. 2017). Therefore, prevention of landslides and natural hazards exert indirect influence on the occurrence of desertification.

The global extent of chemical soil degradation (salinisation, pollution, and acidification) is about 1.03 Mkm^2 yr^{-1} (Oldeman et al. 1991), giving the maximum extent of land that could benefit from the management of pollution and acidification.

There are no global data on the impacts of management of invasive species / encroachment on desertification, though the impact is presumed to be positive. There are no studies examining the potential role of restoration and avoided conversion of coastal wetlands on desertification.

There are no impacts of peatland restoration for prevention of desertification, as peatlands occur in wet areas and deserts in arid areas, so they are not connected.

For management of pollution, including acidification, Oldeman et al. (1991) estimated global extent of chemical soil degradation, with 0.77 Mkm^2 yr^{-1} affected by salinisation, 0.21 Mkm^2 yr^{-1} affected by pollution, and 0.06 Mkm^2 yr^{-1} affected by pollution (total: 1.03 Mkm^2 yr^{-1}), so this is the area that could potentially benefit from pollution management measures.

Biodiversity conservation measures can interact with desertification, but the literature contains no global estimates of potential.

Table 6.32 summarises the impacts on desertification of options on all/other ecosystems, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.3.1.5 Integrated response options based on land management specifically for CDR

While spreading of crushed minerals onto land as part of enhanced weathering may provide soil / plant nutrients in nutrient-depleted soils (Beerling et al. 2018), there is no literature reporting on the potential global impacts of this in addressing desertification.

Large-scale production of bioenergy can require significant amounts of land (Smith et al. 2016d; Clarke and Jiang 2014a; Popp et al. 2017), with as much as 15 Mkm^2 in 2100 in 2°C scenarios (Popp et al. 2017), increasing pressures for desertification (Table 6.33).

Table 6.33 summarises the impacts on desertification of options specifically for CDR, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.3.2 Integrated response options based on value chain management

In this section, the impacts on desertification of integrated response options based on value chain management are assessed.

6.3.3.2.1 Integrated response options based on value chain management through demand management

Dietary change and waste reduction both result in decreased cropland and pasture extent (Bajželj et al. 2014a; Stehfest et al. 2009; Tilman and Clark 2014), reducing the pressure for desertification (Table 6.34).

Reduced post-harvest losses could spare 1.98 Mkm^2 of cropland globally (Kummu et al. 2012). Not all of this land could be subject to desertification pressure, so this represents that maximum area that could be relieved from desertification pressure by reduction of post-harvest losses. No studies were found linking material substitution to desertification.

Table 6.34 summarises the impacts on desertification of demand management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Improved energy use in food systems	No global estimates	No evidence	

6.3.3.3 Integrated response options based on risk management

In this section, the impacts on desertification of integrated response options based on risk management are assessed.

There are regional case studies of urban sprawl contributing to desertification in Mediterranean climates in particular (Barbero-Sierra et al. 2013b; Stellmes et al. 2013), but no global figures.

Diversification may deliver some benefits for addressing desertification when it involves greater use of tree crops that may reduce the need for tillage (Antwi-Agyei et al. 2014). Many anti-desertification programmes call for diversification (Stringer et al. 2009), but there is little evidence on how many households had done so (Herrmann and Hutchinson 2005). There are no numbers for global impacts.

The literature is unclear on whether the use of local seeds has any relationship to desertification, although some local seeds are likely more adapted to arid climates and less likely to degrade land than commercial introduced varieties (Mousseau 2015). Some anti-desertification programmes have also shown more success using local seed varieties (Bassoum and Ghiggi 2010; Nunes et al. 2016).

Some disaster risk management approaches can have impacts on reducing desertification, like the Global Drought Early Warning System (GDEWS) (currently in development), which will monitor precipitation, soil moisture, evapotranspiration, river flows, groundwater, agricultural productivity and natural ecosystem health. It may have some potential co-benefits to reduce desertification (Pozzi et al. 2013). However, there are no figures yet for how much land area will be covered by such early warning systems.

Risk sharing instruments, like pooling labour or credit, could help communities invest in anti-desertification actions, but evidence is missing. Commercial crop insurance is likely to deliver no co-benefits for prevention and reversal of desertification, as evidence suggests that subsidised insurance, in particular, can increase crop production in marginal lands. Crop insurance could have been responsible for shifting up to 0.9% of rangelands to cropland in the Upper US Midwest (Claassen et al. 2011).

Table 6.36 summarises the impact on desertification for options based on risk management, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.4 Potential of the integrated response options for addressing land degradation

In this section, the impacts of integrated response options on land degradation are assessed.

6.3.4.1 Integrated response options based on land management

In this section, the impacts on land degradation of integrated response options based on land management are assessed.

6.3.4.1.1 Integrated response options based on land management in agriculture

Burney et al. (2010) estimated that an additional global cropland area of 11.11–15.14 Mkm^2 would have been needed if productivity had not increased between 1961 and 2000. As for desertification, given that agricultural expansion is a main driver of land degradation (FAO and ITPS 2015), increased food productivity has prevented up to 11.11–15.14 Mkm^2 from exploitation and land degradation (Table 6.37).

Land degradation can be addressed by the implementation of improved cropland, livestock and grazing land management practices, such as those outlined in the recently published Voluntary Guidelines for Sustainable Soil Management (FAO 2017b). Each one could potentially affect extensive surfaces, not less than 10 Mkm^2. The Guidelines include a list of practices aiming at minimising soil erosion, enhancing soil organic matter content, fostering soil nutrient balance and cycles, preventing, minimising and mitigating soil salinisation and alkalinisation, soil contamination, soil acidification, and soil sealing, soil compaction, and improving soil water management. Land cover and land cover change are key factors and indicators of land degradation. In many drylands, land cover is threatened by overgrazing, so management of stocking rate and grazing can help to prevent the advance of land degradation Smith et al. (2016c).

Agroforestry can help stabilise soils to prevent land degradation, so given that there are is around 10 Mkm^2 of land with more than 10% tree cover (Garrity, 2012), agroforestry could benefit up to 10 Mkm^2 of land.

Agricultural diversification usually aims at increasing climate and food security resilience, such as under "climate smart agriculture" approaches (Lipper et al. 2014). Both objectives are closely related to land degradation prevention, potentially affecting 1–5 Mkm^2.

Shifting from grassland to tilled crops increases erosion and soil loss, so there are significant benefits for addressing land degradation, by stabilising degraded soils (Chapter 3). Since cropland expansion during 1985 to 2005 was 17.4 thousand km^2 yr^{-1} (Foley et al.,2009), and not all of this expansion will be from grasslands or degraded land, the maximum contribution of prevention of conversion of grasslands to croplands is 17.4 thousand km^2 yr^{-1}, a small global benefit for control of land degradation (Tale 6.37).

Most land degradation processes that are sensitive to climate change pressures (e.g. erosion, decline in soil organic matter, salinisation, waterlogging, drying of wet ecosystems) can benefit from integrated water management. Integrated water management options include management to reduce aquifer and surface water depletion, and to prevent over extraction, and provide direct co-benefits for prevention of land degradation. Land management practices implemented for climate change mitigation may also affect water resources. Globally, water erosion is estimated to result in the loss of 23–42 MtN and 14.6–26.4 MtP annually (Pierzynski et al., 2017). Forests influence the storage and flow of water in watersheds (Eisenbies et al. 2007) and are therefore important for regulating how climate change will impact landscapes.

Table 6.37 summarises the impact on land degradation of options in agriculture, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Integrated water management	0.01 Mkm^2	Medium confidence	Pierzynski et al., 2017; UNCCD, 2011

6.3.4.1.2 Integrated response options based on land management in forestry

Based on the extent of forest exposed to degradation (Gibbs and Salmon 2015), the estimated global potential effect for reducing land degradation, e.g. through reduced soil erosion (Borrelli et al. 2017), is large for both improved forest management and for reduced deforestation and forest degradation when cumulated for at least 20 years (Table 6.38) The uncertainty of these global estimates is high. More robust qualitative and some quantitative estimates are available at regional level. For example, in Indonesia, Santika et al. (2017) demonstrated that reduced deforestation (Sumatra and Kalimantan islands) contributed to reduce significantly land degradation.

Forest restoration is a key option to achieve the overarching frameworks to reduce land degradation at global scale, such as for example, Zero Net Land Degradation (ZNLD; UNCCD 2012) and Land Degradation Neutrality (LDN), not only in drylands (Safriel 2017). Indeed, it has been estimated that more than 20 Mkm^2 are suitable for forest and landscape restoration, of which 15 Mkm^2 may be devoted to mosaic restoration (UNCCD 2012). Moreover, the Bonn Challenge aims to restore 1.5 Mkm^2 of deforested and degraded land by 2020, and 3.5 Mkm^2 by 2030 (http://www.bonnchallenge.org/content/challenge). Under a restoration and protection scenario (implementing restoration targets), Wolff et al. (2018) simulated that there will be a global increase in net tree cover of about 4 Mkm^2 by 2050 (Table 6.38). At local level, Brazil's Atlantic Restoration Pact aims to restore 0.15 Mkm^2 of forest areas in 40 years (Melo et al. 2013). The Y Ikatu Xingu campaign (launched in 2004) aims to contain deforestation and degradation processes by reversing the liability of 3 thousand km^2 in the Xingu Basin, Brazil (Durigan et al. 2013).

Afforestation and reforestation are land management options frequently used to address land degradation (see Section 6.3.3.1.2 for details; Table 6.38).

Table 6.38 summarises the impact on land degradation of options in forestry, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.4.1.3 Integrated response options based on land management of soils

Increasing soil organic matter content is a measure to address land degradation. With around 120 thousand km^2 lost to degradation every year, and over 3.2 billion people negatively impacted by land degradation globally (IPBES 2018), practices designed to increase soil organic carbon have a large potential to address land degradation, estimated to affect over 11 Mkm^2 globally (Lal, 2004; Table 6.39).

Control of soil erosion could have large benefits for addressing land degradation. Soil erosion control could benefit up to 1.50 Mkm^2 of land to 2050 (IPBES 2018). Lal (2004) suggested interventions to prevent wind and water erosion (two of the four main interventions proposed to address land degradation), could restore 11 Mkm^2 of degraded and desertified soils globally (Table 6.39).

Oldeman et al. (1991) estimated the global extent soil affected by salinisation is 0.77 Mkm^2 yr^{-1}, which sets the upper limit on the area that could benefit from measures to address soil salinisation

(Table 6.39). The global extent of chemical soil degradation (salinisation, pollution, and acidification) is about 1.03 Mkm^2 (Oldeman et al. 1991) giving the maximum extent of land that could benefit from the management of pollution and acidification.

Biochar could provide moderate benefits for the prevention or reversal of land degradation, by improving water holding capacity, improving nutrient use efficiency, managing heavy metal pollution and other co-benefits (Sohi 2012), though the global effects are not quantified.

Table 6.39 summarises the impact on land degradation of soil-based options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Reduced soil compaction	10 Mkm^2	Low confidence	FAO and ITPS 2015; Hamza and Anderson 2005a
Biochar addition to soil	Positive but not quantified globally	Low confidence	Chapter 4

6.3.4.1.4 Integrated response options based on land management across all/other ecosystems

For fire management, details of estimates of the impact of wildfires (and thereby the potential impact of their suppression) are given in Section 6.3.3.1.4 (Table 6.40).

Management of landslides and natural hazards aims at controlling a severe land degradation process affecting sloped and hilly areas, many of them with poor rural inhabitants (FAO et al. 2015; Gariano and Guzzetti 2016b), but the global potential has not been quantified.

There are no global data on the impacts of management of invasive species / encroachment on land degradation, though the impact is presumed to be positive.

Since large areas of coastal wetlands are degraded, restoration could potentially deliver moderate benefits for addressing land degradation, with 0.29 Mkm^2 globally considered feasible for restoration (Griscom et al. 2017a; Table 6.40).

Considering that large areas (0.46 Mkm^2) of global peatlands are degraded and considered suitable for restoration (Griscom et al. 2017), peatland restoration could deliver moderate benefits for addressing land degradation (Table 6.40).

There are no global estimates of the effects of biodiversity conservation on reducing degraded lands. However, at local scale, biodiversity conservation programmes have been demonstrated to stimulate gain of forest cover over large areas over the last three decades (e.g. in China; Zhang et al. 2013). Management of wild animals can influence land degradation processes by grazing, trampling and compacting soil surfaces, thereby altering surface temperatures and chemical reactions affecting sediment and carbon retention (Cromsigt et al. 2018).

Table 6.40 summarises the impact on land degradation of options in all/other ecosystems, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.40 Effects on land degradation of response options in all/other ecosystems

Integrated response option	Potential	Confidence	Citation
Fire management	Up to 3.5-4.9 $Mkm^2\ yr^{-1}$	Medium confidence	Arora and Melton 2018; Randerson et al. 2012; Tansey et al. 2004

Biodiversity conservation	No global estimates	No evidence	

6.3.4.1.5 Integrated response options based on land management specifically for CDR

While spreading of crushed minerals onto land as part of enhanced weathering can provide soil / plant nutrients in nutrient-depleted soils, can increase soil organic carbon stocks and can help to replenish eroded soil (Beerling et al. 2018), there is no literature on the global potential for addressing land degradation.

Large-scale production of bioenergy can require significant amounts of land (Smith et al. 2016c; Clarke and Jiang 2014b; Popp et al. 2017), much as 15 Mkm^2 in 2°C scenarios (Popp et al. 2017), increasing pressures for land conversion and land degradation (Table 6.13). However, bioenergy production can either increase (Robertson et al. 2017c; Mello et al. 2014a) or decrease (FAO 2011; Lal 2014) soil organic matter, depending on where it is produced and how it is managed. These effects are not included in the quantification in Table 6.41.

Table 6.41 summarises the impact on land degradation of options specifically for CDR, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.4.2 Integrated response options based on value chain management

In this section, the impacts on land degradation of integrated response options based on value change management are assessed.

6.3.4.2.1 Integrated response options based on value chain management through demand management

Dietary change and waste reduction both result in decreased cropland and pasture extent (Bajželj et al. 2014; Stehfest et al. 2009; Tilman and Clark 2014a), reducing the pressure for land degradation (Table 6.15). Reduced post-harvest losses could spare 1.98 Mkm^2 of cropland globally (Kummu et al. 2012) meaning that land degradation pressure could be relieved from this land area through reduction of post-harvest losses. The effects of material substitution on land degradation depend on management practice; some forms of logging can lead to increased land degradation (Chapter 4).

Table 6.42 summarises the impact on land degradation of demand management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.42 Effects on land degradation of response options based on demand management

Reduced food waste (consumer or retailer)	7 Mkm^2	Medium confidence	Bajželj et al. 2014
Material substitution	No global estimates	No evidence	

6.3.4.2.2 Integrated response options based on value chain management through supply management

There are no global estimates of the impact on land degradation of enhanced urban food systems, improved food processing, retailing, or improved energy use in food systems.

There is evidence that sustainable sourcing could reduce land degradation, as the explicit goal of sustainable certification programs is often to reduce deforestation or other unsustainable land uses. Over 4 Mkm^2 of forests are certified for sustainable harvesting (PEFC/FSC 2018), although it is not clear if all these lands would be at risk of degradation without certification. While the food price instability of 2007/2008 increased financial investment in crop expansion (especially through so-called land grabbing), and thus better management of supply chains might have reduced this amount, no quantification of the total amount of land acquired, nor the possible impact of this crop expansion on degradation, has been recorded (McMichael and Schneider 2011a; McMichael 2012).

Table 6.43 summarises the impact on land degradation of supply management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Enhanced urban food systems	No global estimates	No evidence	
Improved food processing and retailing	No global estimates	No evidence	
Improved energy use in food systems	No global estimates	No evidence	

6.3.4.3 Integrated response options based on risk management

In this section, the impacts on land degradation of integrated response options based on risk management are assessed.

Urban expansion has been identified as a major culprit in soil degradation in some countries; for example, urban expansion in China has now affected 0.2 Mkm^2, or almost one-sixth of the cultivated land total, causing an annual grain yield loss of up to 10 Mt, or around 5-6% of cropland production. Cropland production losses of 8-10% by 2030 are expected under model scenarios of urban expansion (Bren d'Amour et al. 2016). Pollution from urban development has included water and soil pollution from industry and wastes and sewage as well as acid deposition from increasing energy use in cities (Chen 2007a), all resulting in major losses to Nature's Contributions to People from urban conversion (Song and Deng 2015). Soil sealing from urban expansion is a major loss of soil productivity across many areas. The World Bank has estimated that new city dwellers in developing countries will require 160–500 m^2 per capita, converted from non-urban to urban land (Barbero-Sierra et al. 2013a; Angel et al 2005).

Degradation can be a driver leading to livelihood diversification (Batterbury 2001; Lestrelin and Giordano 2007). Diversification has the potential to deliver some reversal of land degradation, if diversification involves adding non-traditional crops or trees that may reduce the need for tillage (Antwi-Agyei et al. 2014). China's Sloping Land conversion programme has had livelihood diversification benefits and is said to have prevented degradation of 93 thousand km^2 of land (Liu et al. 2015). However, Warren (2002) provides conflicting evidence that more diverse-income households had increased degradation on their lands in Niger, and Palacios et al. (2013) associate landscape fragmentation with increased livelihood diversification in Mexico.

Use of local seeds may play a role in addressing land degradation due to the likelihood of local seeds being less dependent on inputs such as chemical fertilisers or mechanical tillage; for example, in India, local legumes are retained in seed networks while commercial crops like sorghum and rice dominate food markets (Reisman 2017a). However, there are no global figures.

Disaster Risk Management systems can have some positive impacts on prevention and reversal of land degradation, like the Global Drought Early Warning System (see section 6.3.3.3) (Pozzi et al. 2013).

Risk sharing instruments could have benefits for reduced degradation, but there are no global estimates. Commercial crop insurance is likely to deliver no co-benefits for prevention and reversal of degradation. One study found a 1% increase in farm receipts generated from subsidised farm programmes (including crop insurance and others) increased soil erosion by 0.3 t ha^{-1} (Goodwin and Smith 2003**)**. Wright and Wimberly (2013) found a 5310 km^2 decline in grasslands in the Upper Midwest of the US during 2006-2010 due to crop conversion driven by higher prices and access to insurance.

Table 6.44 summarises the impact on land degradation of risk management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.5 Potential of the integrated response options for addressing food security

In this section, the impacts of integrated response options on food security are assessed.

6.3.5.1 Integrated response options based on land management

In this section, the impacts on food security of integrated response options based on land management are assessed.

6.3.5.1.1 Integrated response options based on land management in agriculture

Increased food productivity has fed many millions of people, who could not have otherwise been fed. Erisman et al. (2008) estimated that over 3 billion people worldwide could not have been fed without increased food productivity arising from N fertilisation (Table 6.45).

Improved cropland management to achieve food security aims at closing yield gaps by increasing use efficiency of essential inputs such as water and nutrients. Large production increases (45–70% for most crops) are possible from closing yield gaps to 100% of attainable yield, by increasing fertiliser use and irrigation, but overuse of nutrients could cause adverse environmental impacts (Mueller et al. 2012). This improvement can impact 1000 million people.

Improved grazing land management includes grasslands, rangelands and shrublands, and all sites on which pastoralism is practiced. In general terms, continuous grazing may cause severe damage to topsoil quality, through e.g. compaction. This damage may be reversed by short grazing exclusion periods under rotational grazing systems (Greenwood and McKenzie 2001; Drewry 2006; Taboada et al. 2011). Due to the widespread diffusion of pastoralism, improved grassland management may potentially affect more than 1000 million people, many of them under subsistence agricultural systems.

Meat, milk, eggs, and other animal products, including fish and other seafoods, will play an important role in achieving food security (Reynolds et al. 2015). Improved livestock management with different animal types and feeds may also impact one million people (Herrero et al. 2016). Ruminants are efficient converters of grass into human edible energy and protein and grassland-based food production can produce food with a comparable carbon footprint to mixed systems (O'Mara 2012b). However, in the future, livestock production will increasingly be affected by competition for natural resources, particularly land and water, competition between food and feed and by the need to operate in a carbon-constrained economy (Thornton et al. 2009a).

Currently, over 1.3 billion people are on degrading agricultural land, and the combined impacts of climate change and land degradation could reduce global food production by 10% by 2050. Since agroforestry could help to address land degradation, up to 1.3 billion people could benefit in terms of food security through agroforestry.

Agricultural diversification is not always economically viable; technological, biophysical, educational, and cultural barriers may emerge that limit the adoption of more diverse farming systems by farmers (Section 6.4.1). Nevertheless, diversification could benefit 1000 million people, many of them under subsistence agricultural systems (Birthal et al. 2015; Massawe et al. 2016; Waha et al. 2018).

Cropland expansion during 1985 to 2005 was 17 thousand km^2 yr^{-1} (Foley et al. 2005). Given that cropland productivity (global average of 250 kg protein ha^{-1} yr^{-1} for wheat; (Clark and Tilman 2017) is greater than that of grassland (global average of about 10 kg protein ha^{-1} yr^{-1} for beef/mutton; (Clark and Tilman 2017), prevention of this conversion to cropland would have led to a loss of about 0.4 Mt protein yr^{-1} globally. Given an average protein consumption in developing countries of 25.5 kg protein yr^{-1} (equivalent to 70g $person^{-1}$ day^{-1}; FAO, 2018), this is equivalent to the protein consumption of 16.4 million people each year (Table 6.45).

Integrated water management provides direct benefits to food security by improving agricultural productivity (Chapter 5; Tilman et al. 2011; Godfray and Garnett 2014), thereby potentially impacting the livelihood and well-being of >1000 million people (Campbell et al. 2016) affected by hunger and highly impacted by climate change. Increasing water availability and reliable supply of water for agricultural production using different techniques of water harvesting, storage, and its judicious utilisation through farm ponds, dams, and community tanks in rainfed agriculture areas have been presented by Rao (2017) and Rivera-Ferre et al. (2016).

Table 6.45 summarises the impact on food security of options in agriculture, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Integrated water management	>1000 million people	High confidence	Campbell et al. 2016

6.3.5.1.2 Integrated response options based on land management in forestry

Forests play a major role in providing food to local communities (non-timber forest products, mushrooms, fodder, fruits, berries etc.), and diversify daily diets directly or indirectly through improving productivity, hunting, diversifying tree-cropland-livestock systems, and grazing in forests. Based on the extent of forest contributing to food supply, considering the people undernourished (Rowland et al. 2017; FAO, IFAD, and WFP, 2013), and the annual deforestation rate (Keenan et al. 2015), the global potential to enhance food security is moderate for improved forest management and small for reduced deforestation (Table 6.46). The uncertainty of these global estimates is high. More robust qualitative and some quantitative estimates are available at regional level. For example, managed natural forests, shifting cultivation and agroforestry systems are demonstrated to be crucial to food security and nutrition for hundreds of million people in rural landscapes worldwide (Sunderland et al. 2013; Vira et al. 2015). According to Erb et al. (2016), deforestation would not be needed to feed the global population by 2050, in terms of quantity and quality of food. At local level, Cerri et al. (2018) suggested that reduced deforestation, along with integrated cropland-livestock management, would positively impact more than 120 million people in the Cerrado, Brazil. In Sub-Saharan Africa, where population and food demand are projected to continue to rise substantially, reduced deforestation may have strong positive effects on food security (Doelman et al. 2018).

Afforestation and reforestation negatively impact food security (Boysen et al. 2017b; Frank et al. 2017; Kreidenweis et al. 2016b). It is estimated that large-scale afforestation plans could cause increases in food prices of 80% by 2050 (Kreidenweis et al. 2016b), and more general mitigation measures in the AFOLU sector can translate into a rise in undernourishment of 80–300 million people (Frank et al. 2017) (Table 6.16). For reforestation, the potential adverse side-affects with food security are smaller than afforestation, because forest regrows on recently deforested areas, and its impact would be felt mainly through impeding possible expansion of agricultural areas. On a smaller scale, forested land also offers benefits in terms of food supply, especially when forest is established on degraded land, mangroves, and other land that cannot be used for agriculture. For example, food from forests represents a safety-net during times of food and income insecurity (Wunder et al., 2014), and wild harvested meat and freshwater fish provides 30-80% of protein intake from many rural communities (McIntyre et al., 2016; Nasi et al., 2011).

Table 6.46 summarises the impact on food security of options in forestry, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Afforestation	Negative impact on > 100 million people	Medium confidence	Boysen et al. 2017b; Frank et al. 2017; Kreidenweis et al. 2016b

6.3.5.1.3 Integrated response options based on land management of soils

Increasing soil organic matter stocks can increase yield and improve yield stability (Lal 2006b; Pan et al. 2009; Soussana et al. 2019), though this is not universally seen (Hijbeek et al., 2017). Lal (2006b) concludes that crop yields can be increased by 20–70 kg ha^{-1}, 10–50 kg ha^{-1} and 30–300 kg ha^{-1} for maize for wheat, rice and maize, respectively, for every 1 t C ha^{-1} increase in soil organic carbon in the root zone. Increasing soil organic carbon by 1 t C ha^{-1} could increase food grain production in developing countries by 32 Mt yr^{-1} (Lal 2006b). Frank et al. (2017) estimate that soil carbon sequestration could reduce calorie loss associated with agricultural mitigation measures by 65%, saving 60–225 million people from undernourishment compared to a baseline without soil carbon sequestration (Table 6.47).

Lal (1998) estimated the risks of global annual loss of food production due to accelerated erosion to be as high as 190 Mt yr^{-1} of cereals, 6 Mt yr^{-1} of soybean, 3 Mt yr^{-1} of pulses and 73 Mt yr^{-1} of roots and tubers. Considering only cereals, if we assume per-capita annual grain consumption in developing countries to be 300 kg yr^{-1} (estimated based on data included in Pradhan et al., 2013; FAO, 2018; FAO et al., 2018; and World Bank 2018a), the loss of 190 Mt yr^{-1} of cereals is equivalent to that consumed by 633 million people, annually (Table 6.47).

Though there are biophysical barriers, such as access to appropriate water sources and limited productivity of salt-tolerant crops, prevention / reversal of soil salinisation could benefit 1–100 million people (Qadir et al. 2013a). Soil compaction affects crop yields, so prevention of compaction could benefit an estimated 1–100 million people globally (Anderson and Peters 2016).

Biochar on balance, could provide moderate benefits for food security by improving yields by 25% in the tropics, but with more limited impacts in temperate regions (Jeffery et al. 2017), or through improved water holding capacity and nutrient use efficiency (Chapter 5; Sohi 2012). These benefits could, however, be tempered by additional pressure on land if large quantities of biomass are required as feedstock for biochar production, thereby causing potential conflicts with food security (Smith 2016b). Smith (2016b) estimated that 0.4–2.6 Mkm^2 of land would be required for biomass feedstock to deliver 2.57 $GtCO_2e$ yr^{-1} of CO_2 removal. If biomass production occupied 2.6 Mkm^2 of cropland, equivalent to around 20% of the global cropland area, this could potentially have a large effect on food security, although Woolf et al. (2010) argue that abandoned cropland could be used to supply biomass for biochar, thus avoiding competition with food production. Similarly, Woods et al (2015) estimate that 5-9 Mkm^2 of land is available for biomass production without compromising food security and biodiversity, considering marginal and degraded land and land released by pasture intensification (Table 6.47).

Table 6.47 summarises the impact on food security of soil-based options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.47 Effects on food security of soil-based response options

Integrated response option	Potential	Confidence	Citation
Increased soil organic carbon content	60-225 million people	Low confidence	Frank et al. 2017
Reduced soil erosion	633 million people yr^{-1}	Low confidence	FAO, 2018; FAO et al. 2018; Lal 1998; Pradhan et al. 2013; World Bank 2018a
Reduced soil salinisation	1-100 million people	Low confidence	Qadir et al. 2013a
Reduced soil compaction	1-100 million people	Low confidence	Anderson and Peters 2016
Biochar addition to soil	Range from positive impact in the tropics from biochar addition to soil to a maximum potential negative impact on >100 million people by worst-case conversion of 20% of global cropland	Low confidence	Jeffery et al. 2017; worse case negative impacts calculated from area values in Smith 2016b

6.3.5.1.4 Integrated response options based on land management across all/other ecosystems

FAO (2015) calculated that damage from forest fires between 2003 and 2013 impacted a total of 49 thousand km^2 of crops with the vast majority in Latin America. Based on the world cereal yield in 2013 reported by Word Bank (2018b) (3.8 t ha^{-1}), the loss of 49 thousand km^2 of crops is equivalent to 18.6 Mt yr^{-1} of cereals lost. Assuming annual grain consumption per capita to be 300 kg yr^{-1} (estimated based on data included in Pradhan et al., 2013; FAO, 2018; FAO et al., 2018; and World Bank 2018a), the loss of 18.6 Mt yr^{-1} would remove cereal crops equivalent to that consumed by 62 million people (Table 6.48).

Landslides and other natural hazards affect 1–100 Million people globally, so preventing them could provide food security benefits to this many people.

In terms of measures to tackle pollution, including acidification, Shindell et al. (2012) considered about 400 emission control measures to reduce ozone and black carbon (BC). This strategy increases annual crop yields by 30–135 Mt due to ozone reductions in 2030 and beyond. If annual grain consumption per capita is assumed as 300 kg yr^{-1} (estimated based on data included in Pradhan et al., 2013; FAO, 2018; FAO et al., 2018; and World Bank 2018a), increase in annual crop yields by 30–135 Mt feeds 100–450 million people.

There are no global data on the impacts of management of invasive species / encroachment on food security.

Since large areas of converted coastal wetlands are used for food production (e.g., mangroves converted for aquaculture; (Naylor et al. 2000b), restoration of coastal wetlands could displace food production and damage local food supply, potentially leading to adverse impacts on food security, though these effects are likely to be very small given that only 0.3% of human food comes from the oceans and other aquatic ecosystems (Pimentel 2006), and that the impacts could be offset by careful management, such as the careful siting of ponds within mangroves (Naylor et al. 2000b) (Table 6.46).

Around 14-20% (0.56–0.80 Mkm^2) of the global 4 Mkm^2 of peatlands are used for agriculture, mostly for meadows and pasture, meaning that if all of these peatlands were removed from production, 0.56–0.80 Mkm^2 of agricultural land would be lost. Assuming livestock production on this land (since it is mostly meadow and pasture) with a mean productivity of 9.8 kg protein ha^{-1} yr^{-1} (calculated from land footprint of beef/mutton in (Clark and Tilman 2017)), and average protein consumption in developing countries of 25.5 kg protein yr^{-1} (equivalent to 70g $person^{-1}$ day^{-1}; FAO, 2018), this would be equivalent to 21–31 million people no longer fed from this land (Table 6.46).

There are no global estimates on how biodiversity conservation improves nutrition (i.e. number of nourished people). Biodiversity, and its management, is crucial for improving sustainable and diversified diets (Global Panel on Agriculture and Food Systems for Nutrition 2016). Indirectly, the loss of pollinators (due to combined causes, including the loss of habitats and flowering species) would contribute to 1.42 million additional deaths per year from non-communicable and malnutrition-related diseases, and 27.0 million lost disability-adjusted life-years (DALYs) per year (Smith et al. 2015). However, at the same time, some options to preserve biodiversity, like protected areas, may potentially conflict with food production by local communities (Molotoks et al. 2017).

Table 6.48 summarises the impact on food security of response options in all/other ecosystems, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

6.3.5.1.5 Integrated response options based on land management specifically for CDR

The spreading of crushed minerals on land as part of enhanced weathering on nutrient-depleted soils can potentially increase crop yield by replenishing plant available silicon, potassium and other plant nutrients (Beerling et al. 2018), but there are no estimates in the literature reporting the potential magnitude of this effect on global food production.

Competition for land between bioenergy and food crops can lead to adverse side-effects for food security. Many studies indicate that bioenergy could increase food prices (Calvin et al. 2014a; Popp et al. 2017; Wise et al. 2009a). Only three studies were found linking bioenergy to the population at risk of hunger; they estimate an increase in the population at risk of hunger of between 2 million and 150 million people (Table 6.49).

Table 6.49 summarises the impact on food security of response options specifically for CDR, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Bioenergy and BECCS	Negative impact on up to 150 million people	Medium confidence	Baldos and Hertel 2014a; Fujimori et al. 2018b

6.3.5.2 Integrated response options based on value chain management

In this section, the impacts on food security of integrated response options based on value change management are assessed.

6.3.5.2.1 Integrated response options based on value chain management through demand management

Dietary change can free up agricultural land for additional production (Bajželj et al. 2014; Stehfest et al. 2009; Tilman and Clark 2014b) and reduce the risk of some diseases (Tilman and Clark 2014b; Aleksandrowicz et al. 2016b) , with large positive impacts on food security (Table 6.50).

Kummu et al. (2012a) estimate that an additional billion people could be fed if food waste was halved globally. This includes both post-harvest losses and retail and consumer waste, and measures such as improved food transport and distribution could also contribute to this waste reduction (Table 6.50).

While no studies quantified the effect of material substitution on food security, the effects are expected to be similar to reforestation and afforestation if the amount of material substitution leads to an increase in forest area.

Table 6.50 summarises the impact on food security of demand management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.50 Effects on food security of demand management options

Integrated response option	Potential	Confidence	Citation
Dietary change	821 million people	High confidence	Aleksandrowicz et al. 2016b; Tilman and Clark 2014b
Reduced post-harvest losses	1000 million people	Medium confidence	Kummu et al. 2012
Reduced food waste (consumer or retailer)	700-1000 million people	Medium confidence	FAO 2018; Kummu et al. 2012
Material substitution	No global estimates	No evidence	

6.3.5.2.2 Integrated response options based on value chain management through supply management

Since 810 million people are undernourished (FAO, 2018), this sets the maximum number of those that could potentially benefit from sustainable sourcing or better management of supply chains. Currently however, only 1 million people are estimated to benefit from sustainable sourcing (Tayleur et al. 2017). For the latter, food price spikes affect food security and health; there are clearly documented effects of stunting among young children as a result of the 2007/2008 food supply crisis (de Brauw 2011; Arndt et al. 2012; Brinkman et al. 2010; Darnton-Hill and Cogill 2010) with a 10% increase in wasting attributed to the crisis in South Asia (Vellakkal et al. 2015). There is conflicting evidence on the impacts of different food price stability options for supply chains, and little quantification (Byerlee et al. 2006; del Ninno et al. 2007; Alderman 2010; Braun et al. 2014). Reduction in staple food prices due to price stabilisation resulted in more expenditure on other foods and increased nutrition (e.g., oils, animal products), leading to a 10% reduction in malnutrition among children in one study (Torlesse et al. 2003a). Comparison of two African countries shows that protectionist policies (food price controls) and safety nets to reduce price instability resulted in a 20% decrease in risk of malnutrition (Nandy et al. 2016). Models using policies for food aid and domestic food reserves to achieve food supply and price stability showed the most effectiveness of all options in achieving climate mitigation and food security goals (e.g. more effective than carbon taxes) as they did not exacerbate food insecurity and did not reduce ambitions for achieving temperature goals (Fujimori et al. 2018a).

For urban food systems, increased food production in cities combined with governance systems for distribution and access can improve food security, with a potential to produce 30% of food consumed in cities. The urban population in 2018 was 4.2 billion people, so 30% represents 1230 million people who could benefit in terms of food security from improved urban food systems (Table 6.51).

It is estimated that 500 million smallholder farmers depend on agricultural businesses in developing countries (World Bank, 2017), which sets the maximum number of people who could benefit from improved efficiency and sustainability of food processing, retail and agri-food industries.

Up to 2500 million people could benefit from increased energy efficiency in agriculture, based on the estimated number of people worldwide lacking access to clean energy and instead relying on biomass fuels for their household energy needs (IEA, 2014).

Table 6.51 summarises the impact on food security of supply management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.51 Effects on food security of supply management options

Integrated response option	Potential	Confidence	Citation
Sustainable sourcing	> 1 million people	Low confidence	Tayleur et al. 2017
Management of supply chains	> 1 million people	Low confidence	FAO 2018; Kummu et al. 2012
Enhanced urban food systems	Up to 1260 million people	Low confidence	Benis and Ferrão 2017b; Padgham et al.; Specht et al. 2014; de Zeeuw & Drechsel 2015;
Improved food processing and retailing	500 million people	Low confidence	World Bank 2017
Improved energy use in food systems	Up to 2500 million people	Low confidence	IEA 2014

6.3.5.3 Integrated response options based on risk management

In this section, the impacts on food security of integrated response options based on risk management are assessed.

Evidence in the US indicates ambiguous trends between sprawl and food security; on one hand, most urban expansion in the US has primarily been on lands of low and moderate soil productivity with only 6% of total urban land on highly productive soil. On the other hand, highly productive soils have experienced the highest rate of conversion of any soil type (Nizeyimana et al. 2001). Specific types of agriculture are often practiced in urban-influenced fringes, such as fruits, vegetables, and poultry and eggs in the US, the loss of which can have an impact on the types of nutritious foods available in urban areas (Francis et al. 2012b). China is also concerned with food security implications of urban sprawl, and a loss of 30 Mt of grain production from 1998–2003 in eastern China was attributed to urbanisation (Chen 2007b). However, overall global quantification has not been attempted.

Diversification is associated with increased welfare and incomes and decreased levels of poverty in several country studies (Arslan et al. 2018a; Asfaw et al. 2018). These are likely to have large food security benefits (Barrett et al. 2001; Niehof 2004), but there is little global quantification.

Local seed use can provide considerable benefits for food security because of the increased ability of farmers to revive and strengthen local food systems (McMichael and Schneider 2011b); studies have reported more diverse and healthy food in areas with strong food sovereignty networks (Coomes et al. 2015b; Bisht et al. 2018). Women in particular may benefit from seed banks for low value but nutritious crops (Patnaik et al. 2017). Many hundreds of millions of smallholders still rely on local seeds and they provision many hundreds of millions of consumers (Altieri et al. 2012a; McGuire and Sperling 2016), so keeping their ability to do so through seed sovereignty is important. However, there may be lower food yields from local and unimproved seeds, so the overall impact of local seed use on food security is ambiguous (McGuire and Sperling 2016).

Disaster risk management approaches can have important impacts on reducing food insecurity, and current systems for drought warning and other storms currently reach over 100 million people. When these early warning systems can help farmers harvest crops in advance of impending weather events or otherwise make agricultural decisions to prepare for adverse events, there are likely to be positive impacts on food security (Fakhruddin et al. 2015). Surveys with farmers reporting food insecurity from climate impacts have indicated their strong interest in having such early warning systems (Shisanya and Mafongoya 2016). Additionally, famine early warning systems have been successful in Sahelian Africa to alert authorities of impending food shortages so that food acquisition and transportation from outside the region can begin, potentially helping millions of people (Genesio et al. 2011; Hillbruner and Moloney 2012).

Risk sharing instruments are often aimed at sharing food supplies and reducing risk, and thus are likely to have important, but unquantified, benefits for food security. Crop insurance in particular has generally led to (modest) expansions in cultivated land area and increased food production (Claassen et al. 2011; Goodwin et al. 2004).

Table 6.52 summarises the impact on food security of risk management options, with confidence estimates based on the thresholds outlined in Table 6.53 in section 6.3.6, and indicative (not exhaustive) references upon which the evidence in based.

Table 6.52 Effects on food security of risk management options

Integrated response option	Potential	Confidence	Citation
Management of urban sprawl	>1 million likely	Low confidence	Bren d'Amour et al. 2016; Chen 2017
Livelihood diversification	>100 million	Low confidence	Morton 2007
Use of local seeds	>100 million	Low confidence	Altieri et al. 2012a
Disaster risk management	> 100 million	Medium confidence	Genesio et al. 2011; Hillbruner and Moloney 2012
Risk sharing instruments	>1 million likely	Low confidence	Claassen et al. 2011; Goodwin et al. 2004

6.3.6 Summarising the potential of the integrated response options across mitigation, adaptation, desertification land degradation and food security

Using the quantification provided in tables 6.13 to 6.52, the impacts are categorised as either positive or negative, and are designated as large, moderate and small according to the criteria given in Table 6.53[6].

[6] FOOTNOTE: Note that: 1) The response options often overlap, so are not additive. For example, increasing food productivity will involve changes to cropland, grazing land and livestock management, which in turn my include increasing soil carbon stocks. The response options cannot therefore be summed, nor regarded as entirely mutually exclusive interventions. 2) The efficacy of a response option for addressing the primary challenge for which it is implemented needs to be weighed against any co-benefits and adverse side-effects for the other challenges, e.g. if a response option has a major impact in addressing one challenge but results in relatively minor and manageable adverse-side effects for another challenge, it may remain a powerful response option despite the adverse side-effects, particularly if they can be minimised or managed. 3) Though the impacts of integrated response options have been quantified as far as possible in Section 6.3, there is no equivalence implied in terms benefits or adverse side-effects, either in number or in magnitude of the impact, i.e. one benefit *does not equal* one adverse side-effect. As a consequence: a) Large benefits for one challenge might outweigh relatively minor adverse side-effects in addressing another challenge, and b) Some response options may deliver mostly benefits with few adverse-side effects, but the benefits might be small in magnitude, i.e. the response options do no harm, but present only minor co-benefits. A number of benefits and adverse side-effects are context specific; the context specificity has been discussed in section 6.2 and is further examined Section 6.4.5.1.

Table 6.53 Key for criteria used to define magnitude of impact of each integrated response option

	Mitigation	Adaptation	Desertification	Land Degradation	Food
Large positive	More than 3 $GtCO_2$-eq yr^{-1}	Positively impacts more than around 25 million people	Positively impacts more than around 3 million km^2	Positively impacts more than around 3 million km^2	Positively impacts more than around 100 million people
Moderate positive	0.3 to 3 $GtCO_2$-eq	1 million to 25 million	0.5 to 3 million km^2	0.5 to 3 million km^2	1 million to 100 million
Small positive	>0	Under 1 million	>0	>0	Under 1 million
Negligible	0	No effect	No effect	No effect	No effect
Small negative	<0	Under 1 million	<0	<0	Under 1 million
Moderate negative	-0.3 to -3 $GtCO_2$-eq	1 million to 25 million	0.5 to 3 million km^2	0.5 to 3 million km^2	1 million to 100 million
Large negative	More than -3 $GtCO_2$-eq yr^{-1}	Negatively impacts more than around 25 million people	Negatively impacts more than around 3 million km^2	Negatively impacts more than around 3 million km^2	Negatively impacts more than around 100 million people

Note: All numbers are for global scale; all values are for technical potential. For mitigation, the target is set at around the level of large single mitigation measure (about 1 GtC yr^{-1} = 3.67 $GtCO_2$-eq yr^{-1}) (Pacala and Socolow 2004), with a combined target to meet 100 $GtCO_2$ in 2100, to go from baseline to 2˚C (Clarke and Jiang 2014b). For adaptation, numbers are set relative to the about 5 million lives lost per year attributable to climate change and a carbon-based economy, with 0.4 million per year attributable directly to climate change. This amounts to 100 million lives predicted to be lost between 2010 and 2030 due to climate change and a carbon-based economy (DARA 2012), with the largest category representing 25% of this total. For desertification and land degradation, categories are set relative to the 10–60 million km^2 of currently degraded land (Gibbs and Salmon 2015) with the largest category representing 30% of the lower estimate. For food security, categories are set relative to the roughly 800 million people currently undernourished (HLPE 2017) with the largest category representing around 12.5% of this total.

Tables 6.54 to 6.61 summarise the potentials of the integrated response options across mitigation, adaptation, desertification, land degradation and food security. Cell colours correspond to the large, moderate and small impact categories shown in Table 6.53.

As seen in tables 6.54 to 6.61, three response options across the 14 for which there are data for every land challenge: *increased food productivity, agroforestry* and *increased soil organic carbon content*, deliver large benefits across all five land challenges.

A further six response options: *improved cropland management, improved grazing land management, improved livestock management, agroforestry, fire management* and *reduced post-harvest losses*, deliver either large or moderate benefits for all land challenges.

Three additional response options: *dietary change, reduced food waste* and *reduced soil salinisation*, each missing data to assess global potential for just one of the land challenges, deliver large or moderate benefits to the four challenges for which there are global data.

Eight response options: *increased food productivity, reforestation and forest restoration, afforestation, increased soil organic carbon content, enhanced mineral weathering, dietary change,* *reduced post-harvest losses*, and *reduced food waste*, have large mitigation potential (>3 $GtCO_2e\ yr^{-1}$) without adverse impacts on other challenges.

Sixteen response options: *increased food productivity, improved cropland management, agroforestry, agricultural diversification, improved forest management, increased soil organic carbon content, reduced landslides and natural hazards, restoration and reduced conversion of coastal wetlands, reduced post-harvest losses, sustainable sourcing, management of supply chains, improved food processing and retailing, improved energy use in food systems, livelihood diversification, use of local seeds,* and *disaster risk management*, have large adaptation potential at global scale (positively affecting >25 million people) without adverse side-effects for other challenges.

Thirty-three of the 40 response options can be applied without requiring land use change and limiting available land. A large number of response options do not require dedicated land, including several land management options, all value chain options, and all risk management options. Four options, in particular, could greatly increase competition for land if applied at scale: *afforestation, reforestation,* and land used to provide feedstock for *bioenergy (with or without BECCS)* and *biochar*, with three further options: *reduced grassland conversion to croplands, restoration and reduced conversion of peatlands and restoration* and *reduced conversion of coastal wetlands* having smaller or variable impacts on competition for land. Other options such as *reduced deforestation and degradation*, restrict land conversion for other options and uses.

Some response options can be more effective when applied together; for example, dietary change and waste reduction expand the potential to apply other options by freeing as much as 25 Mkm^2 (4-25 Mkm^2 for dietary change; Alexander et al. 2016; Bajželj et al. 2014; Stehfest et al. 2009; Tilman and Clark 2014b and 7 Mkm^2 for reduced food waste; Bajželj et al. 2014).

In terms of the categories of response options, most agricultural land management response options (all except for reduced grassland conversion to cropland which potentially adversely affects food security), deliver benefits across the five land challenges (Table 6.54). Among the forest land management options, afforestation and reforestation have the potential to deliver large co-benefits across all land challenges except for food security, where these options provide a threat due to competition for land (Table 6.55). Among the soil-based response options, some global data are missing, but none except biochar shows any potential for negative impacts, with that potential negative impact arising from additional pressure on land if large quantities of biomass feedstock are required for biochar production (Table 6.56). Where global data exists, most response options in other/all ecosystems deliver benefits except for a potential moderate negative impact on food security by restoring peatlands currently used for agriculture (Table 6.57). Of the two response options specifically targeted at CDR, there are missing data for enhanced weathering of minerals for three of the challenges, but large-scale bioenergy and BECCS shows a potential large benefit for mitigation, but small to large adverse impacts on the other four land challenges (Table 6.58), mainly driven by increased pressure on land due to feedstock demand.

While data allow the impact of material substitution to be assessed only for mitigation, the three other demand-side response options: dietary change, reduced post-harvest losses and reduced food waste provide large or moderate benefits across all challenges for which data exist (Table 6.59). For none of the supply-side response options is data available to assess the impact on more than three of the land challenges, but there are large to moderate benefits for all those for which data are available (Table 6.60). Data are not available to assess the impact of risk management-based response options on all of the challenges, but there are small to large benefits for all of those for which data are available (Table 6.61).

Table 6.54 Summary of direction and size of impact of land management options in agriculture on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	**Mitigation**	**Adaptation**	**Desertification**	**Land degradation**	**Food security**	**Context and evidence base for magnitude of effect**
Increased food productivity						These estimates assume that increased food production is implemented sustainably (e.g. through sustainable intensification: Garnett et al. 2013b; Pretty et al. 2018) rather than through increasing external inputs, which can have a range of negative impacts. Mitigation: ***Large benefits*** (Table 6.13). Adaptation: ***Large benefits*** (Chapter 2; Table 6.21; Campbell et al. 2014). Desertification: ***Large benefits*** (Chapter 3; Table 6.29; Dai 2010). Land degradation: ***Large benefits*** (Chapter 4; Table 6.37; Clay et al., 1995). Food security: ***Large benefits*** (Chapter 5; Table 6.45; Godfray et al. 2010b; Tilman et al. 2011; Godfray and Garnett 2014).
Improved cropland management						Mitigation: ***Moderate benefits*** by reducing greenhouse gas emissions and creating soil carbon sinks (Chapter 2; Table 6.13; Smith et al. 2008, 2014a). Adaptation: ***Large benefits*** by improving the resilience of food crop production systems to future climate change (Chapter 2; Table 6.21; Porter et al. 2014). Desertification: ***Large benefits*** by improving sustainable use of land in dry areas (Chapter 3; Table 6.29; Bryan et al. 2009b; Chen et al. 2010). Land degradation: ***Large benefits*** by forming a major component of sustainable land management (Chapter 4; Table 6.37; Labrière et al. 2015). Food security: ***Large benefits*** by improving agricultural productivity for food production (Chapter 5; Table 6.45; Porter et al. 2014).
Improved grazing land management						Mitigation: ***Moderate benefits*** by increasing soil carbon sinks and reducing greenhouse gas emissions (Chapter 2; Table 6.13; Herrero et al. 2016). Adaptation: ***Moderate benefits*** by improving the resilience of grazing lands to future climate change (Chapter 2; Table 6.21; Porter et al. 2014). Desertification: ***Moderate benefits*** by tackling overgrazing in dry areas to reduce desertification (Chapter 3; Table 6.29; Archer et al. 2011). Land degradation: ***Large benefits*** by optimising stocking density to reduce land degradation (Chapter 4; Table 6.37; Table 6.45; Tighe et al. 2012). Food security: ***Large benefits*** by improving livestock sector productivity to increase food production (Chapter 5; Table 6.45; Herrero et al. 2016).
Improved livestock management						Mitigation: ***Moderate benefits*** by reducing greenhouse gas emissions, particularly from enteric methane and manure management (Chapter 2; Table 6.13; Smith et al. 2008, 2014a). Adaptation: ***Moderate benefits*** by improving resilience of livestock production systems to climate change (Chapter 2; Table 6.21; Porter et al. 2014). Desertification: ***Moderate benefits*** by tackling overgrazing in dry areas (Chapter 3; Table 6.29; Archer et al. 2011). Land degradation: ***Large benefits*** by reducing overstocking which can reduce land degradation (Chapter 4; Table 6.37; Table 6.45; Tighe et al. 2012). Food security: ***Large benefits*** by improving livestock sector productivity to increase food production (Chapter 5; Table 6.45; Herrero et al. 2016).
Agroforestry						Mitigation: ***Moderate benefits*** by increasing carbon sinks in vegetation and soils (Chapter 2; Table 6.13; Delgado 2010; Mbow et al. 2014a; Griscom et al. 2017a). Adaptation: ***Large benefits*** by improving the resilience of agricultural lands to climate change (Chapter 2; Table 6.21; Mbow et al. 2014a). Desertification: ***Large benefits*** through e.g. provides perennial vegetation in dry areas (Chapter 3; Table 6.29; Nair et al. 2010; Lal 2001a). Land degradation: ***Large benefits*** by stabilising soils through perennial

						vegetation (Chapter 4; Table 6.37; Narain et al. 1997; Lal 2001a). Food production: ***Large benefits*** since well-planned agroforestry can enhance productivity (Chapter 5; Table 6.45; Bustamante et al. 2014b; Sasha et al., 2018).
Agricultural diversification						Agricultural diversification is a collection of practices aimed at deriving more crops or products per unit of area (e.g. intercropping) or unit of time (e.g. double cropping, ratoon crops etc.). Mitigation: ***Limited benefits*** (Table 6.13). Adaptation: ***Large benefits*** through improved household income (Pellegrini and Tasciotti 2014; Table 6.21). Desertification: ***Moderate benefits***, limited by global dryland cropped area (Table 6.29). Land degradation: ***Large benefits*** by reducing pressure on land (Table 6.37; Lambin and Meyfroidt 2011). Food security: ***Large benefits*** for food security by provision of more diverse foods (Chapter 5; Table 6.45; Birthal et al. 2015; Massawe et al. 2016; Waha et al. 2018).
Reduced grassland conversion to cropland		ND				Mitigation: ***Moderate benefits*** by retaining soil carbon stocks that might otherwise be lost. Historical losses of soil carbon have been on the order of 500 $GtCO_2$ (Table 6.13; Sanderman et al. 2017). Mean annual global cropland conversion rates (1961–2003) have been 0.36% per year (Krause et al. 2017), i.e. around 47 thousand km^2 yr^{-1} – so preventing conversion could potentially save moderate emissions of CO_2. Adaptation: No literature (Table 6.21). Desertification: ***Limited benefits*** by shifting from annual crops to permanent vegetation cover under grass in dry areas (Chapter 3; Table 6.29). Land degradation: ***Limited benefits*** by shifting from annual crops to permanent vegetation cover under grass (Chapter 4; Table 6.37). Food security: ***Moderate negative impacts***, since more land is required to produce human food from livestock products on grassland than from crops on cropland, meaning that a shift to grassland could reduce total productivity and threaten food security (Chapter 5; Table 6.45; Clark and Tilman 2017).
Integrated water management						Mitigation: M***oderate benefits*** by reducing greenhouse gas emissions mainly in cropland and rice cultivation (Chapter 2; Table 6.13; Smith et al. 2008, 2014a). Adaptation: ***Large benefits*** by improving the resilience of food crop production systems to future climate change (Chapter 2; Table 6.21; Porter et al. 2014). Desertification: ***Limited benefits*** by improving sustainable use of land in dry areas (Chapter 3; Table 6.29). Land degradation: ***Limited benefits*** by forming a major component of sustainable land and water management (Chapter 4; Table 6.37). Food security: ***Large benefits*** by improving agricultural productivity for food production (Chapter 5; Table 6.45; Tilman et al. 2011; Godfray and Garnett 2014).

Note: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.55 Summary of direction and size of impact of land management options in forests on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	**Mitigation**	**Adaptation**	**Desertification**	**Land degradation**	**Food security**	**Context and evidence base for magnitude of effect**
Improved forest						Mitigation: ***Moderate benefits*** by conserving and enhancing carbon stocks in forests and long-lived products, through for example, selective logging (Table 6.14; Smith et al. 2014a). Adaptation: ***Large benefits***, including through improving ecosystem

management						functionality and services, with mostly qualitative evidence at global scale and more robust estimates at regional level and local scale (Table 6.22; Locatelli et al. 2015d). Desertification and land degradation: ***Large benefits*** by helping to stabilise land and regulate water and microclimate (Chapters 3 and 4; Tables 6.30 and 6.38; Locatelli et al. 2015d). Food security: ***Moderate benefits*** with mostly qualitative estimate at global level, by providing food to local communities, and diversify daily diets (Chapter 5; Table 6.46).
Reduced deforestation and degradation						Mitigation: ***Large benefits*** by maintaining carbon stocks in forest ecosystems (Chapter 2; Table 6.14). Adaptation ***Moderate benefits*** at global scale when effect is cumulated till the end of the century; local scale, co-benefits between REDD+ and adaptation of local communities can be more substantial (Long 2013; Morita & Matsumoto 2017), even if often difficult to quantify and not explicitly acknowledged (McElwee et al. 2017a; Table 6.22). Desertification and land degradation: ***Large benefits*** at global scale when effects are cumulated for at least 20 years, e.g. through reduced soil erosion (Borrelli et al. 2017; Tables 6.30 and 6.38). The uncertainty of these global estimates is high, while more robust qualitative and some quantitative estimates are available at regional level. Food security: ***Small benefits***; difficult to quantify at global level (Chapter 5; Table 6.46).
Reforestation and forest restoration						Mitigation: ***Large benefits*** by rebuilding the carbon stocks in forest ecosystems, although decreases in surface albedo can reduce the net climate benefits, particularly in areas affected by seasonal snow cover (Chapter 2; Table 6.14; Sonntag et al. 2016; Mahmood et al. 2014). Adaptation: ***Large benefits*** by provision of Nature's Contributions to People, including improving ecosystem functionality and services, providing microclimatic regulation for people and crops, wood and fodder as safety nets, soil erosion protection and soil fertility enhancement for agricultural resilience, coastal area protection, water and flood regulation (Locatelli et al. 2015d; Table 6.22). Desertification: ***Large benefits*** through restoring forest ecosystems in dryland areas (Chapter 3; Table 6.30; Idris Medugu et al. 2010a; Salvati et al. 2014b). Land degradation: ***Large benefits*** by re-establishment of perennial vegetation (Chapter 4; Table 6.38; Ellison et al. 2017b). Food security: ***Moderate negative impacts*** due to potential competition for land for food production (Chapter 5; Table 6.46; Frank et al. 2017).
Afforestation						Mitigation: ***Large benefits*** for mitigation (Chapter 2; Table 6.14), especially if it occurs in the tropics and in areas that are not significantly affected by seasonal snow cover. Adaptation: ***Large benefits*** on adaptation (Chapter 2; Table 6.22; Kongsager et al. 2016; Reyer et al. 2009). Desertification: ***Large benefits*** by providing perennial vegetation in dry areas to help control desertification (Chapter 3; Table 6.30; Idris Medugu et al. 2010a; Salvati et al. 2014b). Land degradation: ***Large benefits*** by stabilising soils through perennial vegetation (Chapter 4; Table 6.38; Lal 2001a). Food security: ***Large negative impacts*** due to competition for land for food production (Chapter 5; Table 6.46; Kreidenweis et al. 2016b; Smith et al. 2013b).

Note: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.56 Summary of direction and size of impact of soil-based land management options on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	Mitigation	Adaptation	Desertification	Land degradation	Food security	Context and evidence base for magnitude of effect
Increased soil organic carbon content						Mitigation: ***Large benefits*** by creating soil carbon sinks (Table 6.15). Adaptation: ***Large benefits*** by improving resilience of food crop production systems to climate change (Chapter 2; Table 6.24; IPBES 2018). Desertification: ***Large benefits*** by improving soil health and sustainable use of land in dry areas (Chapter 3; Table 6.31; D'Odorico et al. 2013). Land degradation: ***Large benefits*** since it forms a major component of recommended practices for sustainable land management (Chapter 4; Table 6.39; Altieri and Nicholls 2017). Food security: ***Large benefits*** since it can increase yield and yield stability to enhance food production, though this is not always the case (Chapter 5; Table 6.47; Pan et al. 2009; Soussana et al. 2019; Hijbeek et al., 2017; Schjønning et al., 2018).
Reduced soil erosion						Mitigation: ***Large benefits or large negative impacts***, since the final fate of eroded material is still debated, at the global level it is debated whether it is a large source or a large sink (Chapter 2; Table 6.15; Hoffmann et al. 2013). Adaptation: ***Large benefits*** since soil erosion control prevents desertification (***large benefits***) and land degradation (***large benefits***), thereby improving the resilience of agriculture to climate change (Chapter 2, 3 and 4; Table 6.23, 6.30 and 6.39; Lal 1998; FAO and ITPS 2015). Food security: ***Large benefits*** mainly through the preservation of crop productivity (Chapter 5; Table 6.47; Lal 1998).
Reduced soil salinisation	ND					Techniques to prevent and reverse soil salinisation include groundwater management by drainage systems and/or crop rotation and use of amendments to alleviate soil sodicity. Mitigation: There are no studies to quantify the global impacts (Table 6.15). Adaptation: ***Moderate benefits*** by allowing existing crop systems to be maintained, reducing the need to abandon land (Table 6.23; UNCTAD 2011; Dagar et al. 2016b). Desertification and land degradation: ***Moderate benefits*** since soil salinisation is a main driver of both desertification and land degradation (Chapters 3 and 4; Tables 6.31 and 6.39; Rengasamy 2006; Dagar et al. 2016b). Food security: ***Moderate benefits*** by maintaining existing cropping systems and helping to close yield gaps in rainfed crops (Table 6.47).
Reduced soil compaction	ND		ND			Techniques to prevent and reverse soil compaction are based on the combination of suitable crop rotations, tillage and regulation of agricultural traffic (Hamza and Anderson 2005b). Mitigation: The global mitigation potential has not been quantified (Table 6.15; Chamen et al. 2015a; Epron et al. 2016; Tullberg et al. 2018b). Adaptation: ***Limited benefits*** by improving productivity but on relatively small global areas (Table 6.22). Desertification: no global data (Table 6.31). Land degradation: ***Large benefits*** since soil compaction is a main driver of land degradation (Table 6.39; FAO and ITPS 2015). Food security: ***Moderate benefits*** by helping to close yield gaps where compaction is a limiting factor (Table 6.47; Anderson and Peters 2016).
Biochar addition to soil		ND	ND			Mitigation: ***Large benefits*** by increasing recalcitrant carbon stocks in the soil (Chapter 2; Table 6.15; Smith 2016b; Fuss et al. 2018b; IPCC 2018). Adaptation: There are no global estimates of the impact of biochar on climate adaptation (Table 6.23). Desertification: There are no global estimates of the impact of biochar on desertification (Table 6.31). Land degradation: ***Limited benefits*** by improving the soil water holding capacity, nutrient use efficiency, and potentially ameliorating heavy metal pollution (Table 6.39; Sohi 2012). Food security: ***Limited benefits*** by increasing crop yields in the tropics (though not in temperate regions; Jeffery et al. 2017), but potentially ***Large negative impacts*** by creating additional pressure on land if large quantities of biomass

						feedstock are required for biochar production (Table 6.47).

<u>Note</u>: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.57 Summary of direction and size of impact of land management in all/other ecosystems on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	Mitigation	Adaptation	Desertification	Land degradation	Food security	Context and evidence base for magnitude of effect
Fire management						<u>Mitigation</u>: ***Large benefits*** by reduced size, severity, and frequency of wildfires, thereby preventing emissions and preserving carbon stocks (Table 6.16; Chapter 2, Cross-Chapter Box 3; Arora and Melton 2018). <u>Adaptation</u>: ***Moderate benefits*** by reducing mortality attributable to landscape fire smoke exposure, fire management provides adaptation benefits (Table 6.24; Doerr and Santín 2016; Johnston et al. 2012; Shannon et al., 2016). <u>Desertification</u>: ***Large benefits*** since control of wildfires and long-term maintenance of tree stock density protects against soil erosion (Table 6.32; Neary et al. 2009a; Arora and Melton 2018). <u>Land degradation</u>: ***Large benefits*** by stabilising forest ecosystems (Table 6.40; Neary et al. 2009a; Arora and Melton 2018). <u>Food security</u>: ***Moderate benefits*** by maintaining forest food product availability and preventing fire expansion to agricultural land (Table 6.48; FAO 2015; FAO 2018; FAO et al., 2018; Pradhan et al., 2013; World Bank 2018a,b).
Reduced landslides and natural hazards						<u>Mitigation</u>: The prevention of landslides and natural hazards benefits mitigation, but because of the limited impact on GHG emissions and eventual preservation of topsoil carbon stores, the impact is estimated to be small globally (Table 6.16; IPCC AR5 WG2, Chapter 14). <u>Adaptation</u>: Provides structural/physical adaptations to climate change (Table 6.24; IPCC AR5 WG2, Chapter 14). <u>Desertification</u>: Due to the small global areas affected within global drylands, the benefits for desertification control are limited (Chapter 3; Table 6.32). <u>Land degradation</u>: Since landslides and natural hazards are among the most severe degradation processes, prevention will have a large positive impact on land degradation (Chapter 4; Table 6.40; FAO and ITPS 2015). <u>Food security</u>: In countries in which mountain slopes are cropped for food, such as in the Pacific Islands (Campbell 2015), the management and prevention of landslides can deliver benefits for food security, though the global areas are limited (Table 6.48).
Reduced pollution including acidification						<u>Mitigation</u>: ***Large benefits*** since measures to reduce emissions of Short-Lived Climate Pollutants (SLCPs) can slow projected global mean warming (UNEP and WMO 2011), with early intervention providing 0.5°C cooling by 2050 (Table 6.16; UNEP and WMO 2011). But ***moderate negative impacts*** are also possible since reduced reactive N deposition could decrease terrestrial carbon uptake (Table 6.16). <u>Adaptation</u>: ***Moderate benefits*** since controlling PM2.5 and ozone improves human health (Table 6.24; Anenberg et al. 2012). <u>Desertification:</u> ***Moderate benefits*** since salinisation, pollution, and acidification are stressors for desertification (Table 6.32; Oldeman et al. 1991). <u>Land degradation</u>: Moderate benefits since acid deposition is a significant driver of land degradation (Table 6.40; Oldeman et al. 1991; Smith et al. 2015). <u>Food security</u>: ***Large benefits*** since ozone is harmful to crops, so measures to reduce air pollution would be expected to increase crop production (Table 6.48; Shindell et al. 2012; Pradhan

						et al., 2013; FAO, 2018; FAO et al., 2018; World Bank 2018a).
Management of invasive species / encroachment	N D	N D	N D	N D	N D	There is no literature that assesses the global potential of management of invasive species on <u>mitigation, adaptation, desertification, land degradation</u> or on <u>food security</u> (Table 6.16; Table 6.24; Table 6.33; Table 6.40; Table 6.48).
Restoration and reduced conversion of coastal wetlands						<u>Mitigation</u>: ***Large benefits*** since coastal wetland restoration and avoided coastal wetland impacts deliver moderate carbon sinks by 2030 (Table 6.16; Griscom et al. 2017a). <u>Adaptation</u>: ***Large benefits*** by providing a natural defence against coastal flooding and storm surges by dissipating wave energy, reducing erosion and by helping to stabilise shore sediments (Table 6.24). <u>Desertification</u>: There is likely negligible impact of coastal wetland restoration for prevention of desertification (Table 6.32). <u>Land degradation</u>: Limited benefits since large areas of global coastal wetlands are degraded (Lotze et al. 2006; Griscom et al. 2017a; Table 6.40). <u>Food security</u>: ***Small benefits*** to ***small adverse impacts*** since large areas of converted coastal wetlands are used for food production (e.g. mangroves converted for aquaculture), restoration could displace food production and damage local food supply, though mangrove restoration can also restore local fisheries (Table 6.48; Naylor et al. 2000b).
Restoration and reduced conversion of peatlands		N D				<u>Mitigation</u>: ***Moderate benefits*** since avoided peat impacts and peat restoration deliver moderate carbon sinks by 2030 (Table 6.16; Griscom et al. 2017a), though there can be increases in methane emissions after restoration (Jauhiainen et al. 2008). <u>Adaptation</u>: Likely to be benefits by regulating water flow and preventing downstream flooding (Table 6.24; Munang et al. 2014a), but the global potential has not been quantified. <u>Desertification</u>: No impact since peatlands occur in wet areas and deserts in dry areas. <u>Land degradation</u>: ***Moderate benefits*** since large areas of global peatlands are degraded (Table 6.40; Griscom et al. 2017a). <u>Food security</u>: ***Moderate adverse impacts*** since restoration of large areas of tropical peatlands and some northern peatlands that have been drained and cleared for food production, could displace food production and damage local food supply (Table 6.48).
Biodiversity conservation			N D	N D	N D	<u>Mitigation</u>: ***Moderate benefits*** from carbon sequestration in protected areas (Table 6.16; Calvin et al. 2014a). <u>Adaptation</u>: ***Moderate benefits*** – likely many millions benefit adaptation and resilience of local communities to climate change (Table 6.24; CBD, 2008), though global potential is poorly quantified. <u>Desertification</u>: No global data (Table 6.32). <u>Land degradation</u>: No global data (Table 6.40). <u>Food security</u>: No global data (Table 6.48).

<u>Note</u>: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.58 Summary of direction and size of impact of land management options specifically for CDR on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	**Mitigation**	**Adaptation**	**Desertification**	**Land degradation**	**Food security**	**Context and evidence base for magnitude of effect**
Enhanced		N	N		N	<u>Mitigation</u>: ***Moderate to large benefits*** by removing atmospheric CO_2 (Table 6.17; Lenton 2010; Smith et al. 2016b; Taylor et al.

weathering of minerals		D	D		D	2016b). <u>Adaptation</u>: There is no literature to assess the global impacts of enhanced mineral weathering on adaptation (Table 6.25) nor on <u>desertification</u> (Table 6.33). <u>Land degradation</u>: ***Limited benefits*** expected since ground minerals can increase pH where acidification is the driver of degradation (Table 6.41; Taylor et al. 2016b). <u>Food security</u>: Though there may be co-benefits for food production (Beerling et al. 2018), these have not been quantified globally (Table 6.49).
Bioenergy and BECCS						<u>Mitigation</u>: ***Large benefits*** of large-scale bioenergy and BECCS by potential to remove large quantities of CO_2 from the atmosphere (Table 6.17). <u>Adaptation</u>: ***Limited adverse impacts*** of large-scale bioenergy and BECCS by increasing pressure on land (Table 6.25). <u>Desertification</u>: Moderate adverse impacts of large-scale bioenergy and BECCS through increased pressure on land (Table 6.33). <u>Land degradation</u>: ***Large adverse impacts*** of large-scale bioenergy and BECCS through increased pressure on land (Table 6.41). <u>Food security</u>: ***Large adverse impacts*** of large-scale bioenergy and BECCS through increased competition for land for food (Table 6.49). These potentials and effects assume large areas of bioenergy crops resulting in large mitigation potentials (i.e. >3 $GtCO_2$ yr^{-1}). The sign and magnitude of the effects of bioenergy and BECCS depends on the scale of deployment, the type of bioenergy feedstock, which other response options are included, and where bioenergy is grown (including prior land use and indirect land use change emissions). For example, limiting bioenergy production to marginal lands or abandoned cropland would have negligible effects on biodiversity, food security, and potentially small co-benefits for land degradation; however, the benefits for mitigation would also be smaller (Cross-Chapter Box 7 on Bioenergy (Chapter 6); Table 6.13).

<u>Note</u>: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.59 Summary of direction and size of impact of demand management options on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	**Mitigation**	**Adaptation**	**Desertification**	**Land degradation**	**Food security**	**Context and evidence base for magnitude of effect**
Dietary change		ND				<u>Mitigation</u>: ***Large benefits*** for mitigation by greatly reducing GHG emissions (Chapter 5; Table 6.18). <u>Adaptation</u>: While it would be expected to help with adaptation by reducing agricultural land area, there are no studies providing global quantifications (Table 6.26). <u>Desertification</u>: Potential ***moderate benefits*** by decreasing pressure on land (restricted by relatively limited global area; Table 6.34). <u>Land degradation</u>: ***Large benefits*** by decreasing pressure on land (Table 6.42). Food security: Large benefits by decreasing competition for land allowing more food to be produced from less land (Table 6.50).
Reduced post-harvest losses						<u>Mitigation</u>: ***Large benefits*** by reducing food sector GHG emissions and reducing area required to produce the same quantity of food (Table 6.18), though increased use of refrigeration could increase emissions from energy use. <u>Adaptation</u>: ***Large benefits*** by reducing pressure on land (Table 6.26). <u>Desertification</u> and <u>land degradation</u>: ***Moderate benefits*** for both by reducing pressure on land (Table 6.34; Table 6.42). <u>Food security</u>: ***Large benefits*** since most of the food wasted in developing countries arises from post-harvest losses (Chapter 5; Table 6.50; Ritzema et al. 2017).

Reduced food waste (consumer or retailer)		ND				Mitigation: ***Large benefits*** by reducing food sector GHG emissions and reducing area required to produce the same quantity of food (Table 6.18). Adaptation: While it would be expected to help with adaptation by reducing agricultural land area, there are no studies quantifying global adaptation impacts (Table 6.26). Desertification: ***Moderate benefits*** by reducing pressure on land (Table 6.34). Land degradation: ***Large benefits*** by reducing pressure on land (Table 6.42). Food security: ***Large benefits*** since 30% of all food produced globally is wasted (Table 6.50; Kummu et al. 2012).
Material substitution		ND	ND	ND	ND	Mitigation: ***Moderate benefits*** through long-lived carbon storage, and by substitution of materials with higher embedded GHG emissions (Table 6.18). No global studies available to assess the quantitative impact on adaptation, desertification, land degradation or food security (Table 6.26; Table 6.34; Table 6.42; Table 6.50).

Note: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.60 Summary of direction and size of impact of supply management options on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	**Mitigation**	**Adaptation**	**Desertification**	**Land degradation**	**Food security**	**Context and evidence base for magnitude of effect**
Sustainable sourcing	ND		ND			Mitigation: No studies available to assess the global impact (Table 6.19). Adaptation: ***Moderate benefits*** by diversifying and increasing flexibility in the food system to climate stressors and shocks while simultaneously creating economic alternatives for the poor (thereby strengthening adaptive capacity) and lowering expenditures of food processors and retailers by reducing losses (Chapter 5; Table 6.27; Muller et al. 2017a). Desertification: No studies available to assess the global impact (Table 6.35; Table 6.43). Land degradation: Potentially ***large benefits***, as over 4 Mkm^2 currently certified for sustainable forest production, which could increase in future (Table 6.44). Food security: ***Moderate benefits*** by diversifying markets and developing value-added products in the food supply system, by increasing its economic performance and revenues to local farmers (Reidsma et al. 2010), by strengthening the capacity of food production chains to adapt to future markets and to improve income of smallholder farmers (Chapter 5; Table 6.51; Murthy and Madhava Naidu 2012). It may also provide more direct links between producers and consumers.
Management of supply chains	ND		ND	ND		Mitigation: There are no studies assessing the mitigation potential globally (Table 6.19). Adaptation: ***Large benefits*** by improving resilience to price increases or reducing volatility of production (Table 6.27; Fafchamps et al. 1998; Haggblade et al. 2017). Desertification and land degradation: No studies assessing global potential (Table 6.35; Table 6.43). Food security: ***Moderate benefits*** through helping to manage food price increases and volatility (Table 6.51; Vellakkal et al. 2015; Arndt et al. 2016).
Enhanced urban food	ND	ND	ND	ND		There are no studies that assess the global potential to contribute to mitigation, adaptation, desertification or land degradation (Table 6.19; Table 6.27; Table 6.35; Table 6.43). Food security: ***Large benefits*** by increasing food access to urban dwellers and

systems						shortening of supply chains (Chapter 5; Table 6.51; Chappell et al. 2016).
Improved food processing and retailing			ND	ND		<u>Mitigation</u>: ***Moderate benefits*** through reduced energy consumption, climate-friendly foods and reduced GHG emissions from transportation (Avetisyan et al. 2014), waste (Porter et al. 2016b), and energy use (Table 6.19; Mohammadi et al. 2014; Song et al. 2017). <u>Adaptation</u>: Large benefits among poor farmers through reduced costs and improved resilience (Table 6.27). <u>Desertification</u> and <u>land degradation</u>: There are no studies assessing global potential (Table 6.35; Table 6.43). <u>Food security</u>: ***Large benefits*** by supporting healthier diets and reducing food loss and waste (Chapter 5; Table 6.51; Garnett 2011).
Improved energy use in food systems			ND	ND		<u>Mitigation</u>: ***Moderate benefits*** by reducing GHG emissions through decreasing use of fossil fuels and energy-intensive products, though the emission reduction is not accounted for in the AFOLU sector (Table 6.19; Smith et al. 2014a; IPCC AR5 WG3 Chapter 11). <u>Adaptation</u>: ***Large benefits*** for small farmers by reducing costs and increasing their resilience to climate change (Table 6.27). <u>Desertification</u> and <u>land degradation</u>: There are no studies assessing global potential (Table 6.35; Table 6.43). <u>Food security</u>: ***Large benefits***, largely by improving efficiency for 2.5 million people still using traditional biomass for energy (Chapter 5; Table 6.51).

<u>Note</u>: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

Table 6.61 Summary of direction and size of impact of risk management options on mitigation, adaptation, desertification, land degradation and food security

Integrated response option	**Mitigation**	**Adaptation**	**Desertification**	**Land degradation**	**Food security**	**Context and evidence base for magnitude of effect**
Management of urban sprawl	ND					<u>Mitigation</u>: There are no studies assessing the global potential (Table 6.20). <u>Adaptation</u>: ***Moderate benefits*** - though poorly quantified globally, likely to affect many millions of people (Table 6.28). <u>Desertification</u>: ***Limited benefits*** - though poorly quantified globally, 5000 km^2 is at risk from urban sprawl in Spain alone; Table 6.36). <u>Land degradation</u>: ***Limited benefits*** - though poorly quantified globally, urban sprawl effects millions of ha of land (Table 6.44). <u>Food security</u>: ***Moderate benefits*** estimated from impacts on food supply in models (Table 6.52; Bren d'Amour et al. 2016).
Livelihood diversification	ND					<u>Mitigation</u>: There are no studies assessing the global potential (Table 6.20). <u>Adaptation</u>: ***Large benefits*** through helping households to buffer income fluctuations and providing a broader range of options for the future (Table 6.28; Ahmed and Stepp 2016b; Thornton and Herrero 2014). <u>Desertification</u>: There are no studies assessing the global potential, although there are anecdotal reports of ***limited benefits*** from improved land management resulting from diversification (Batterbury 2001; Herrmann and Hutchinson 2005; Stringer et al. 2009) (Table 6.36). <u>Land degradation</u>: ***Limited benefits***, for example through improved land use mosaics (Ribeiro et al 2013), larger-scale adoption in China's Sloping Land Conversion program to diversify income and reduce degradation has impacted 0.1 Mkm^2 (Liu and Lan 2015; Table 6.44). <u>Food security</u>: ***Large benefits*** since many of the world's 700 million smallholders practice diversification, helping to provide economic access to food (Table 6.52; Morton 2007).

Use of local seeds	ND		ND	ND		<u>Mitigation</u>: There are no studies assessing the global potential (Table 6.19). <u>Adaptation</u>: ***Large benefits*** given that 60 to 100% of seeds used in various countries of the global South are likely local farmer-bred (non-commercial) seed and moving to the use of commercial seed would increase costs considerably for these farmers. Seed networks and banks protect local agrobiodiversity and landraces, which are important to facilitate adaptation, and can provide crucial lifelines when crop harvests fail (Table 6.28; Louwaars 2002; Howard 2015; Coomes et al. 2015b; van Niekerk and Wynberg 2017b; Vasconcelos et al. 2013; Reisman 2017). <u>Desertification</u> and <u>land degradation</u>: There are no studies assessing global potential (Table 6.36; Table 6.44). <u>Food security</u>: ***Large benefits*** since local seeds increases the ability of farmers to revive and strengthen local food systems; several studies have reported more diverse and healthy food in areas with strong food sovereignty networks (Table 6.52; Coomes et al. 2015b; Bisht et al. 2018).
Disaster risk management	ND		ND	ND		<u>Mitigation</u>: There are no studies to assess the global mitigation potential of different DRM approaches (Table 6.19). <u>Adaptation</u>: ***Large benefits*** due to widespread use of Early Warning Systems that reach hundreds of millions (Table 6.28; Hillbruner and Moloney 2012; Mahmud and Prowse 2012; Birkmann et al. 2015b). <u>Desertification</u> and <u>land degradation</u>. There are no studies assessing the global potential (Table 6.36; Table 6.44). <u>Food security</u>: ***Moderate benefits*** by helping farmers to harvest crops in advance of impending weather events or otherwise to make agricultural decisions to prepare for adverse events (Table 6.52; Fakhruddin et al. 2015; Genesio et al. 2011; Hillbruner and Moloney 2012).
Risk sharing instruments			ND			<u>Mitigation</u>: ***Variable impacts***- poor global coverage in the literature though studies from the US suggest a small increase in emissions from crop insurance and likely benefits from other risk sharing instruments(Table 6.20). <u>Adaptation</u>: ***Moderate benefits*** by buffering and transferring weather risk, saving farmers the cost of crop losses. However, overly subsidised insurance can undermine the market's role in pricing risks and thus depress more rapid adaptation strategies (Table 6.28; Meze-Hausken et al. 2009; Skees and Collier 2012; Jaworski 2016). <u>Desertification</u>: The impacts of risk sharing globally have not been quantified (Table 6.36). <u>Land degradation</u>: ***Variable impacts*** as evidence suggests that subsidised insurance in particular can increase crop production in marginal lands, and reforming this would lead to benefits (Table 6.44). <u>Food security</u>: ***Small*** to ***moderate benefits*** for food security, as risk sharing often promotes food supply sharing (Table 6.52).

<u>Note</u>: Cell colours correspond to the large, moderate and small categories shown in Table 6.53. Dark blue = large positive; mid-blue = moderate positive; light blue = small positive; no colour = no effect; light red = small negative; mid-red = moderate negative; dark red = large negative; green = variable; ND = no data.

6.4 Managing interactions and interlinkages

Having assessed the potential of each response option for contributing to addressing mitigation, adaptation, desertification, land degradation and food security is section 6.3, this section assesses the feasibility of each response option with respect to cost, barriers, and issues of saturation and reversibility (6.4.1), before assessing the sensitivity of the response options to future climate change (6.4.2) and examining the contribution of each response option to ecosystem services (classified according to Nature's Contribution to People (IPBES 2018) and to sustainable development (assessed against the UN Sustainable Development Goals) (6.4.3). Section 6.4.4 examines opportunities for implementation of integrated response options, paving the way to potential policies examined in Chapter 7, before the consequences of delayed action are assessed in section 6.4.5.

6.4.1 Feasibility of the integrated response options with respect to costs, barriers, saturation and reversibility

For each of the response options, Tables 6.62-6.69 summarise the feasibility with respect to saturation and reversibility and cost, technological, institutional, socio-cultural and environmental and geophysical barriers (the same barrier categories used in SR15).

Many land management options face issues of saturation and reversibility; however, these are not of concern for the value chain and risk management options. Reversibility is an issue for all options that increase terrestrial carbon stock, either through increased soil carbon or changes in land cover (e.g., reforestation, afforestation), since future changes in climate or land cover could result in reduced carbon storage (Smith 2013). In addition, the benefits of options that improve land management (e.g., improved cropland management, improved grazing management) will cease if the practice is halted, reversing any potential benefits.

The cost of the response options varies substantially, with some options having relatively low cost (e.g., the cost of agroforestry is less than USD 10 tCO_2e^{-1}) while others have much higher costs (e.g., the cost of BECCS could be as much as USD 250 tCO_2e^{-1}). In addition to cost, other economic barriers may prevent implementation; for example, agroforestry is a low- cost option (Smith et al. 2014a), but lack of reliable financial support could be a barrier (Hernandez-Morcillo et al. 2018). Additionally, there are a number of reasons why even no cost options are not adopted, including risk aversion, lack of information, market structure, externalities, and policies (Jaffe 2019).

Some of the response options have technological barriers that may limit their wide-scale application in the near-term. For example, BECCS has only been implemented at small-scale demonstration facilities (Kemper 2015a); challenges exist with upscaling these options to the levels discussed in this Chapter.

Many response options have institutional and socio-cultural barriers. Institutional barriers include governance, financial incentives and financial resources. For example, management of supply chains faces challenges related to political will within trade regimes, economic laissez-faire policies that discourage interventions in markets, and the difficulties of coordination across economic sectors (Poulton et al. 2006; Cohen et al. 2009; Gilbert 2012a). Implementation of other options, e.g., BECCS, is limited by the absence of financial incentives.

Options like dietary change face socio-cultural barriers; while diets have changed in the past, they are deeply culturally embedded and behaviour change is extremely difficult to effect, even when health benefits are well known (Macdiarmid et al. 2018). For some options, the specific barrier is dependent on the region. For example, barriers to reducing food waste in industrialised countries include inconvenience, lack of financial incentives, lack of public awareness, and low prioritisation (Kummu et al. 2012; Graham-Rowe et al. 2014). Barriers in developing countries include reliability of transportation networks, market reliability, education, technology, capacity, and infrastructure (Kummu et al. 2012).

Table 6.62 Feasibility of land management response options in agriculture, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility. See also supplementary material.

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical	Context and sources
Increased food productivity								Biophysical: only if limited by climatic and environmental factors. Sources: Barnes and Thomson 2014; Martin et al. 2015; Olesen and Bindi 2002; Pretty and Bharucha 2014; Schut et al. 2016
Improved cropland management								Institutional: only in some regions (e.g., poor sustainability frameworks). Sources: Bryan et al. 2009b; Bustamante et al. 2014b; Madlener et al. 2006; Reichardt et al. 2009; Roesch-McNally et al. 2017; Singh and Verma 2007; Smith et al. 2008, 2014a
Improved grazing land management								Institutional: only in some regions (e.g., need for extension services). Sources: Herrero et al. 2016; Singh and Verma 2007; Smith et al. 2008, 2015; McKinsey & Co., 2011; Ndoro et al., 2014;
Improved livestock management								Economic: improved productivity is cost negative, but others (e.g. dietary additives) are expensive. Institutional: only in some regions (e.g. need for extension services). Sources: Herrero et al. 2016; McKinsey and Company 2009; Rojas-Downing et al. 2017b; Smith et al. 2008; Thornton et al. 2009; Beauchemin et al., 2008; Ndoro et al., 2014;
Agroforestry								Economic: low cost but may lack reliable financial support. Institutional: only in some regions (e.g., seed availability). Sources: Lillesø et al. 2011; Meijer et al. 2015; Sileshi et al. 2008; Smith et al. 2007, 2014a
Agricultural diversification								More support from extension services, access to inputs and markets, economic incentives for producing a certain crop or livestock product, research and investments focused on adapted varieties and climatic resilient systems, a combination of agricultural and non-agricultural activities (e.g., off farm jobs) are all important interventions aimed at overcoming barriers to agricultural diversification. Sources: Ahmed and Stepp 2016b; Barnes et al. 2015; Barnett and Palutikof 2015; Martin and Lorenzen 2016; Roesch-McNally et al. 2016; Waha et al. 2018
Reduced grassland conversion to cropland								Economics: Avoiding conversion is low cost, but there may be significant opportunity costs associated with foregone production of crops. Institutional: only in some regions (e.g., poor governance to prevent conversion)
Integrated water								Institutional: effective implementation is dependent on the adoption of a combination of 'hard',

management								infrastructural, and 'soft' institutional measures. <u>Socio-cultural</u>: Education can be a barrier and some strategies (e.g. site-specific water management, drip irrigation) can be expensive. Cultural / behavioural barriers are likely to be small. <u>Sources</u>: Dresner et al. 2015; Erwin 2009; Lotze et al. 2006; Thornton et al. 2009

<u>Note</u>: For saturation and reversibility, a blue cell indicates that these issues are not important, and a red cell indicates that saturation and reversibility are concerns. For the cost column, a blue cell indicates low cost (< USD10 tCO_2e^{-1} or < USD20 ha^{-1}), a yellow cell indicates medium cost (USD10-USD100 tCO_2e^{-1} or USD20-USD100 ha^{-1}), and a red cell indicates high cost (>USD100 tCO_2e^{-1} or USD200 ha^{-1}). The cost thresholds in USD tCO_2e^{-1} are from Griscom et al. (2017a); thresholds in USD ha^{-1} are chosen to be comparable, but precise conversions will depend on the response option. For the technological, institutional, socio-cultural and environmental and geophysical barriers, dark blue indicates high current feasibility (no barriers), mid-blue indicates medium current feasibility (moderate barriers) and light blue indicates low current feasibility (large barriers). Green represents variable barriers.

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical	Context and sources
Increased soil organic carbon content								Institutional: only in some regions (e.g., lack of institutional capacity). Sources: Smith et al. 2008; McKinsey and Company 2009; Baveye et al. 2018; Bustamante et al. 2014b; Reichardt et al. 2009; Smith 2006; Smith et al. 2007; Wollenberg et al. 2016
Reduced soil erosion								Sources: Haregeweyn et al. 2015
Reduced soil salinisation								Barriers depend on how salinisation and sodification are implemented. Sources: Bhattacharyya et al. 2015; CGIAR 2016; Dagar et al. 2016b; Evans and Sadler 2008; Greene et al. 2016; Machado and Serralheiro 2017
Reduced soil compaction								Sources: Antille et al. 2016; Chamen et al. 2015a
Biochar addition to soil								Saturation and reversibility issues lower than for soil organic carbon. Economics: In general, biochar has high costs. However, a small amount of biochar potential could be available at negative cost, and some at low cost, depending on markets for the biochar as a soil amendment. Institutional: only in some regions (e.g., lack of quality standards). Sources: Chapter 4; Dickinson et al. 2014; Guo et al. 2016; Meyer et al. 2011; Shackley et al. 2011; Woolf et al. 2010

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical	Context and sources
Fire management								Economic: the cost of its implementation is moderate, since it requires constant maintenance, and can be excessive for some local communities. Sources: Freeman et al. 2017; Hurteau et al. 2014; North et al. 2015
Reduced landslides and								Sources: Gill and Malamud 2017; Maes et al. 2017; Noble et al. 2014

natural hazards								
Reduced pollution including acidification								Sources: Begum et al., 2011; Shah et al., 2018; Yamineva & Romppanen, 2017; WMO 2015
Management of invasive species / encroachment								Technological: in the case of natural enemies. Socio-cultural: Education can be a barrier, where populations are unaware of the damage caused by the invasive species, but cultural / behavioural barriers are likely to be small. Institutional: where agricultural extension and advice services are poorly developed. Source: Dresner et al. 2015
Restoration and reduced conversion of coastal wetlands								Economic: can be cost-effective at scale. Institutional: only in some regions (e.g., poor governance of wetland use). Socio-cultural: educational barriers (e.g., lack of knowledge of impact of wetland conversion), though cultural / behavioural barriers are likely to be small. Sources: Erwin 2009; Lotze et al. 2006
Restoration and reduced conversion of peatlands								Institutional: only in some regions (e.g., lack of inputs). Sources: Bonn et al. 2014; Worrall et al. 2009
Biodiversity conservation								Economic: While protected areas and other forms of biodiversity conservation can be cost-effective, they are often underfunded relative to needs. Institutional: There have been challenges in getting systematic conservation planning to happen, due to institutional fragmentation and overlapping mandates. Socio-cultural: Despite the fact that biodiversity conservation may provide co-benefits like water or carbon protection, local populations often have had social and cultural conflicts with protected areas and other forms of exclusionary biodiversity conservation that are imposed in a top-down fashion or which restrict livelihood options. Sources: Emerton et al. 2006; Hill et al. 2015; Langford et al. 2011; Larsen et al. 2012; Schleicher 2018; Wei et al. 2018; Wilkie et al. 2001

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical	Context and sources
Sustainable sourcing								Economic: the cost of certification and sustainable sourcing can lead to higher production costs. Institutional: there are some barriers to adopting sustainable sourcing in terms of getting governments on board with market-based policies. Socio-cultural: barriers include consumers unfamiliar with sustainably sourced goods. Sources: Capone et al. 2014; Ingram et al. 2016b
Management of supply chains								Economic: Supply chain management and management of price volatility faces challenges from businesses in terms of economic costs of change. Technological: barriers like supply chain tracking. Institutional: barriers like political will against government action in markets. Sources: Cohen et al. 2009; Gilbert 2012; Poulton et al. 2006
Enhanced urban food systems								
Improved food processing and retailing								Economic: The implementation of strategies to improve the efficiency and sustainability of retail and agri-food industries can be expensive. Institutional: Successful implementation is dependent on organisational capacity, the agility and flexibility of business strategies, the strengthening of public-private policies and effectiveness of supply-chain governance.
Improved energy use in food systems								Sources: Baudron et al. 2015; Vlontzos et al. 2014

Note: See footnotes for Table 6.62.

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical	Context and sources
Management of urban sprawl								There are economic and political forces that benefit from less-regulated urban development. Sources: Tan et al. 2009

Livelihood diversification								Economic: Expanded diversification can cost additional financial resources. Socio-cultural: problems with adoption of new or unfamiliar crops and livelihoods. Sources: Ahmed and Stepp 2016b; Berman et al. 2012; Ngigi et al. 2017
Use of local seeds								Economic: Local seeds are highly cost effective, and do not require new technology. Institutional: barriers from agronomy departments and businesses promoting commercial seeds. Socio-cultural: preferences for some non-local seed sourced crops. Sources: Reisman 2017; Timmermann and Robaey 2016
Disaster risk management								Economic: DRM systems can be initially costly, but usually pay for themselves over time. Institutional: some barriers in terms of getting initial support and will behind new systems. Sources: Birkmann et al. 2015b; Hallegatte 2012
Risk sharing instruments								There are few barriers to risk sharing instruments, as they are often low cost and low technology. Socio-cultural: some barriers to instruments like crop insurance, which some farmers in developing countries are not familiar with. Sources: Goodwin and Smith 2013

Note: See footnotes for Table 6.62.

6.4.2 Sensitivity of the Integrated Response Options to climate change impacts

With continued increases in warming, there are risks to the efficacy of some of the response options due to future climate change impacts, such as increased climate variability and extreme events. While many of the response options can help increase capacity to deliver adaptation benefits (section 6.3.2), beyond certain thresholds of climate impacts they may be less effective or increasingly risky options. This requires that some response options need to anticipate these climate impacts in their implementation. We outline some of these impacts below.

Agriculture response options: Increased food productivity as a response option is highly sensitive to climate change impacts. Chapter 5 (section 5.2.3.1) notes that global mean yields of some crops (maize and soybean) decrease with warming, while others (rice and wheat) increase with warming, up to a threshold of 3ºC. Similarly, improved cropland management response options that rely on crop diversification or improved varieties may face challenges in efficacy from production declines. Improved grazing land management may continue to be feasible as a response option in the future under climate change in northern regions but will likely become more difficult in tropical regions and Australia as temperature rises will reduce the carrying capacity of lands (section 5.2.3.2; Nardone et al. 2010). Improved livestock management also faces numerous challenges, particularly related to stresses on animals from temperatures, water, and diseases; overall, livestock numbers are projected to decline 7.5–9.6% by 2050 (section 5.2.3.2; Rivera-Ferre et al. 2016; Boone et al. 2018). Pastoralists may also be less likely to implement improved measures due to other risks and vulnerabilities under climate change (Thornton et al. 2009a).

The impact of climate change on agroforestry is more difficult to model than single crops in process-based crop models, as agroforestry systems are far more complex (Luedeling et al. 2014); thus, it is unknown how the efficacy of this response option might be impacted. Agricultural diversification has been promoted as an adaptive strategy to climate impacts, given that diversity is known to increase resiliency of agricultural and natural systems, such as in resistance to increased pests or diseases; it also can provide diversified income portfolios when some crops may become sensitive to climate events (Bradshaw et al. 2004; Lin 2011). Diversified farms are expected to increase in Africa by 2060 as specialised farms with single crops face challenges under climate change (Seo 2010). However, it is not known if these options and advantages of diversification have a temperature threshold beyond which they are less effective.

Reduced grassland conversion is not likely to be affected as a response option *per se* since it is directed at conserving natural grassland areas, but these areas may face increased pressures for conversion if farmers experience crop failures under climate change and need to extensify holdings to make up for losses. Lobell et al. (2013) have estimated the impacts of investment decisions to adapt to the effects of climate change on crop yields to 2050 and find that cropland will expand over 23% more land area (over 3 Mkm^2), mostly in Latin America and Sub-Saharan Africa.

Integrated water management to improve water availability and reliability of water for agricultural production is likely to become more challenging in future scenarios of water declines, which are likely to be regionally uneven (section 2.5, 6.4.4).

Forest response options: The availability of improved forest management as a response option can be impacted by climate-induced changes, including increased diseases, pests and fires (Section 4.5.1.2; Dale et al. 2001; Logan et al. 2003). These impacts will affect reforestation and afforestation response options as well. Locatelli et al. (2015d) note that climate changes will influence seedling establishment, tree growth and mortality, and the presence of invasive species and/or pests; these can be buffered with modified silvicultural practices including species selection (Pawson et al. 2013). Climate changes can also alter the sink capacity for vegetation carbon sequestration, reducing the potential for REDD, reforestation and afforestation (Bonan 2008b; Mahli et al. 2002).

Soil management: Climate changes can alter the sink capacity for soil carbon sequestration, reducing the potential for increased soil organic carbon as an option. Projected climate changes can reduce soil resilience to extreme weather, pests and biological invasion, environmental pollutants and other pressures, making reduced soil erosion and reduced soil compaction as response options harder to achieve (Smith et al. 2015). Climate change will likely increase demand for irrigation in dryland areas, which can increase risks of salinisation, diminishing the effectiveness of this response (Smith et al. 2015). Biochar additions to soil may be affected by future climatic changes, such as rising soil temperatures, but little is known given that most research on the subject is from laboratory and not *in situ* field experiments, and there are wide estimates of the stability and residence times of biochar from this literature (Gurwick et al. 2013).

Other ecosystem management: Fire management is likely to become more challenging in a changing climate; some studies suggest an 50% increase in fire occurrence by end of the century in circumboreal forests (Flannigan et al. 2009). Landslide risks are related to climate through total rainfall, rainfall intensity, air temperature and the general weather system (Gariano and Guzzetti 2016a); thus reduced landslides and natural hazards as a response option will be made more difficult by increasing storms and seasonality of rainfall events projected for many areas of the world. Reduced pollution is likely less affected by climate change and can continue to be an option despite increasing temperatures.

Conversely, some invasive species may thrive under climate change, such as moving to new areas or being less susceptible to control protocols (Hellmann et al. 2008). Conversion of coastal wetlands will be more difficult to halt if loss of productive land elsewhere encourages development on these lands, but coastal wetlands will likely adapt to increased CO_2 and higher sea levels through sediment accretion, which will also enhance their capacity to act as carbon sinks (Duarte et al. 2013). While subarctic peatlands are at risk due to warming, these are not the main peatlands that are at risk form agricultural conversion (Tarnocai 2006); these peatlands, such as those in the tropics, may be more vulnerable in hotter scenarios to water table alterations and fire risk (Gorham 1991). Biodiversity conservation, such as through protected areas or corridors, may be threatened by increased land expansion under agriculture in climate change scenarios, including the newly available land in northern climates that may become agriculturally suited (Gimona et al. 2012), lessening the effectiveness of this response option.

CDR: The efficacy of enhanced weathering is not likely to be affected by future climate changes. On the other hand, climate change will affect the productivity of bioenergy crops (Cronin et al. 2018), influencing the mitigation potential of bioenergy and BECCS (Calvin et al. 2013a; Kyle et al. 2014). There is uncertainty in the sign and magnitude of the effect of climate change on bioenergy crop yields. As a result, there is uncertainty in whether climate change will increase or decrease the potential of bioenergy and BECCS.

Demand management of value chains: For most response options in demand side management, the tools are generally not made more difficult by future climate changes. For example, dietary change is not likely to be affected by climate change, and in fact, the opposite is more likely; that diets will shift in response to climate change impacts as reflected in high prices for some staple grains and meats, the productivity of which may be reduced (Tigchelaar et al. 2018). However, there is some indication that fruit and vegetable production will also be reduced in future scenarios, making healthier diets potentially harder to achieve in some regions (Springmann et al. 2016). Reduced post-harvest losses and reduced food waste may become an even more important option if water or heat stresses under climate change reduce overall harvests. Material substitution does have risks related to the availability of products if there are declines in the growth of forest and other biomass in certain future scenarios over time, although some evidence indicates that biomass may increase in the short-term with limited warming (Boisvenue and Running 2006).

Supply management of value chains: Sustainable sourcing relies on being able to produce consumer goods sustainably (palm oil, timber, cocoa, etc), and these may be at risk; for example, areas suitable for oil palm production are estimated to decrease by 75% by 2100 (Paterson et al. 2017). Improved management of supply chains is likely to increase in importance as a tool to manage food security, given that climate change threatens to lead to more production shocks in the future (Baldos and Hertel 2015). For enhanced urban food systems, climate stresses like heat island effects or increased water scarcity in urban areas may reduce the viability of food production in certain urban systems (da Silva et al. 2012). Improved food processing and retailing and improved energy use in agriculture are not likely to be impacted by climate change.

Risk management options: Most risk management response options are not affected by climate impacts *per se*, although the increased risks that people may face will increase the need for funding and support to deploy these options. For example, disaster risk management will likely increase in importance in helping people adapt to longer-term climate changes (Begum et al. 2014); it is also likely to cost more as increased impacts of climate change, such as intensification or frequency of storm events may increase. Management of urban sprawl may also be challenged by increased migration driven by climate change, as people displaced by climate change may move to unregulated urban areas (Adamo 2010). Livelihood diversification can assist in adapting to climate changes and is not likely to be constrained as a response option, as climate-sensitive livelihoods may be replaced by others less so. Use of local seeds as an effective response options may depend on the specific types of seeds and crops used, as some may not be good choices under increased heat and water stress (Gross et al. 2017). Risk sharing instruments are unlikely to be affected by climate change, with the exception of index and crop insurance, which may become unaffordable if too many climate shocks result in insurance claims decreasing the ability of the industry to provide this tool (Mills 2005).

Cross-Chapter Box 8: Ecosystem services and Nature's Contributions to People, and their relation to the land-climate system

Pamela McElwee (The United States of America), Jagdish Krishnaswamy (India), Lindsay Stringer (United Kingdom)

This Cross-Chapter Box describes the concepts of *ecosystem services (ES)* and *nature's contributions to people (NCP)*, and their importance to climate-land interactions. ES have become a useful concept to describe the benefits that humans obtain from ecosystems and have strong relevance to sustainable land management (SLM) decisions and their outcomes, while NCP is a new approach championed by the Intergovernmental Panel on Biodiversity and Ecosystem Services (IPBES) (explained below). It is timely that this SRCCL report includes attention to ES/NCP, as the previous Special Report on Land-Use, Land-Use Change and Forestry (LULUCF) did not make use of these concepts and focused mostly on carbon fluxes in land-climate interactions (IPCC 2000). The broader mandate of SRCCL is to address not just climate but land degradation, desertification and food security issues, all of which are closely linked to the provisioning of various ES/NCP, and the Decision and Outline for SRCCL explicitly requests an examination of how desertification and degradation "impacts on ecosystem services (e.g. water, soil and soil carbon and biodiversity that underpins them)". Attention to ES/NCP is particularly important in discussing co-benefits, trade-offs and adverse side effects of potential climate change mitigation, land management, or food security response options, as many actions may have positive impacts on climate mitigation or food production but may also come with a decline in ES provisioning, or adversely impact biodiversity {see 6.4.3}. This box considers the importance of the ES/NCP concepts, how definitions have changed over time, continuing debates over operationalisation and use of these ideas, and finally concludes with how ES/NCP are treated in various chapters in this report.

While the first uses of the term "ecosystem services" appeared in the 1980s (Lele et al. 2013; Mooney and Ehrlich 1997), the roots of interest in ES extends back to the late 1960s and the extinction crisis, with concern that species decline might cause loss of valuable benefits to humankind (King 1966; Helliwell 1969; Westman 1977). While concern over extinction was explicitly linked to biodiversity loss, later ideas beyond biodiversity have animated interest in ES, including the multi-functional nature of ecosystems. A seminal paper by Costanza et al. (1997) attempted to put an economic value on the stocks of global ES and natural capital on which humanity relied. Attention to ES expanded rapidly after the Millennium Ecosystem Assessment (Millenium Ecosystem Assessment (MA) 2005), and the linkages between ES and economic valuation of these functions were addressed by the Economics of Ecosystems and Biodiversity study (TEEB 2009). The ES approach has increasingly been used in global and national environmental assessments, including the United Kingdom National Ecosystem Assessment (Watson et al. 2011), and recent and ongoing regional and global assessments organised by the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) (Díaz et al. 2015). IPBES has recently completed an assessment on land degradation and restoration that addresses a range of ES issues of relevance to the SRCCL report (IPBES 2018).

The MA defined ES as "the benefits that ecosystems provide to people," and identified four broad groupings of ES: *provisioning services* such as food, water, or timber; *regulating services* that have impacts on climate, diseases or water quality, among others; *cultural services* that provide recreational, aesthetic, and spiritual benefits; and *supporting services* such as soil formation, photosynthesis, and nutrient cycling (Millenium Ecosystem Assessment (MA) 2005). The MA emphasised that people are components of ecosystems engaged in dynamic interactions, and particularly assessed how changes in ES might impact human well-being, such as access to basic materials for living (shelter, clothing, energy); health (clean air and water); social relations (including community cohesion); security (freedom from natural disasters); and freedom of choice (the opportunity to achieve) (Millenium Ecosystem Assessment (MA) 2005). Upon publication of the MA, incorporation of ES into land use change assessments increased dramatically, including studies on how to maximise provisioning of ES alongside human well-being (Carpenter et al. 2009); how intensive food production to feed growing populations required trading off a number of important ES (Foley et al. 2005); and how including ES in GCMs indicated increasing vulnerability to ES change or loss in future climate scenarios (Schröter et al. 2005).

Starting in 2015, IPBES has introduced a new related concept to ES, that of *nature's contributions to people (NCP)*, which are defined as "all the contributions, both positive and negative, of living nature (i.e., diversity of organisms, ecosystems and their associated ecological and evolutionary processes) to the quality of life of people" (Díaz et al. 2018). NCP are divided into regulating NCP, non-material NCP, and material NCP, a different approach than used by the MA (see figure 1). However, IPBES has stressed

NCP are a particular *way to think* of ES, rather than a replacement for ES. Rather, the concept of NCP is proposed to be broader umbrella to engage a wider range of scholarship, particularly from the social sciences and humanities, and a wider range of values, from intrinsic to instrumental to relational, particularly those held by indigenous and other peoples (Redford and Adams 2009; Schröter et al. 2014; Pascual et al. 2017; Díaz et al. 2018). The differences between the MA and IPBES approaches can be seen in Table 1.

Table 1. Comparison of MA and IPBES categories and types of ES and NCP

MA category	**MA: Ecosystem Services**	**IPBES category**	**IPBES: Nature's Contributions to People**
Supporting services	Soil formation		
	Nutrient cycling		
	Primary production		
Regulating services		**Regulating Contributions**	Habitat creation and maintenance
	Pollination		Pollination and dispersal of seeds and other propagules
	Air quality regulation		Regulation of air quality
	Climate regulation		Regulation of climate
	Water regulation		Regulation of ocean acidification
	See above		Regulation of freshwater quantity, flow and timing
	Water purification and waste treatment		Regulation of freshwater and coastal water quality
	Erosion regulation		Formation, protection and decontamination of soils and sediments
	Natural hazard regulation		Regulation of hazards and extreme events
	Pest regulation and disease regulation		Regulation of organisms detrimental to humans
Provisioning Services	Fresh water	**Material Contributions**	Energy
	Food		Food and feed
	Fibre		Materials and assistance

	Medicinal and biochemical and genetic		Medicinal, biochemical and genetic resources
Cultural Services	Aesthetic values	**Nonmaterial Contributions**	Learning and inspiration
	Recreation and ecotourism		Physical and psychological experiences
	Spiritual and religious values		Supporting identities
			Maintenance of options

Sources: Millenium Ecosystem Assessment (MA) 2005; Díaz et al. 2018

While there are many similarities between ES and NCP as seen above, the IPBES decision to use the NCP concept has been controversial, with some people arguing that an additional term is superfluous, that it incorrectly associates ES with economic valuation, and that the NCP concept is not useful for policy uptake (Braat 2018; Peterson et al. 2018). Others have argued that the MA approach is outdated, did not explicitly address biodiversity, and confused different concepts, like economic goods, ecosystem functions, and general benefits (Boyd and Banzhaf 2007). Moreover, for both ES and NCP approaches, it has been difficult to make complex ecological processes and functions amenable to assessments that can be used and compared across wider landscapes, different policy actors, and multiple stakeholders (de Groot et al. 2002; Naeem et al. 2015; Seppelt et al. 2011). There remain competing categorisation schemes for ES, as well as competing metrics on how most ES might be measured (Wallace 2007; Potschin and Haines-Young 2011; Danley and Widmark 2016; Nahlik et al. 2012). The implications of these discussions for this SRCCL report is that there remain many areas of uncertainty with regard to much ES/NCP measurement and valuation, which will have ramifications for choosing response options and policies.

This report addresses ES/NCP in multiple ways. Individual chapters have used the term ES in most cases, especially since the preponderance of existing literature uses the ES terminology. For example, Chapter 2 discusses CO_2 fluxes, nutrients, and water budgets as important ES deriving from land-climate interactions. Chapters 3 and 4 discuss issues such as biomass production, soil erosion, biodiversity loss, and other ES affected by land use change. Chapter 5 discusses both ES and NCP issues surrounding food system provisioning and trade-offs.

In chapter 6, the concept of NCP is used. For example, in chapter 6 Tables 6.70 to 6.72, possible response options to respond to climate change, to address land degradation or desertification, and to ensure food security are cross-referenced against the 18 NCP identified by Díaz et al. (2018) to see where there are co-benefits and adverse side-effects. For instance, while BECCS may deliver on climate mitigation, it results in a number of adverse side-effects that are significant with regard to water provisioning, food and feed availability, and loss of supporting identities if BECCS competes against local land uses of cultural importance. Chapter 7 has an explicit section 7.2.2.2 that covers risks due to loss of biodiversity and ES and Table 7.1 that includes policy responses to various land-climate-society hazards, some of which are likely to enhance risk of loss of biodiversity and ES. A case-study on the impact of renewable energy on biodiversity and ES is also included. Chapter 7 also notes that because there is no SDG covering freshwater biodiversity and aquatic ecosystems; this policy gap may have adverse consequences for the future of rivers and associated ES.

6.4.3 Impacts of integrated response options on Nature's Contributions to People and the UN Sustainable Development Goals

In addition to evaluating the importance of our response options for climate mitigation, adaptation, land degradation, desertification and food security, it is also necessary to pay attention to other co-benefits and trade-offs that may be associated with these responses. How the different options impact progress toward the SDG can be a useful shorthand for looking at the social impacts of these response options. Similarly, looking at how these response options increase or decrease the supply of ecosystem services/NCP (see Cross-Chapter Box 8 on Ecosystem Services in this chapter) can be a useful shorthand for a more comprehensive environmental impact beyond climate and land. Such evaluations are important as response option may lead to unexpected trade-offs with social goals (or potential co-benefits) and impacts on important environmental indicators like water or biodiversity. Similarly, there may be important synergies and co-benefits associated with some response options that may increase their cost-effectiveness or attractiveness. As we note in section 6.4.4, many of these synergies are not automatic, and are dependent on well-implemented and coordinated activities in appropriate environmental contexts (6.4.4.1), often requiring institutional and enabling conditions for success and participation of multiple stakeholders (6.4.4.3).

In the following sections and tables, we evaluate each response option against 17 SDG and 18 NCP. Some of the SDG categories appear similar to each other, such as SDG 13 on "climate action" and an NCP titled "climate regulation". However, SDG 13 includes targets for both mitigation and adaptation, so options were weighed by whether they were useful for one or both. On the other hand, the NCP "regulation of climate" does not include an adaptation component, and refers to specifically to "positive or negative effects on emissions of greenhouse gases and positive or negative effects on biophysical feedbacks from vegetation cover to atmosphere, such as those involving albedo, surface roughness, long-wave radiation, evapotranspiration (including moisture-recycling) and cloud formation or direct and indirect processes involving biogenic volatile organic compounds (BVOC), and regulation of aerosols and aerosol precursors by terrestrial plants and phytoplankton" (Díaz et al. 2018).

In all tables, colours represent the direction of impact: positive (blue) or negative (brown), and the scale of the impact (dark colours for large impact and/or strong evidence to light colours for small impact and/or less certain evidence). Supplementary tables show the values and references used to define the colour coding used in all tables. In cases where there is no evidence of an interaction or at least no literature on such interactions, the cell is left blank. In cases where there are both positive and negative interactions and the literature is uncertain about the overall impact, a note appears in the box. In all cases, many of these interactions are contextual, or the literature only refers to certain co-benefits in specific regions or ecosystems, so readers are urged to consult the supplementary tables for the specific caveats that may apply.

6.4.3.1 Impacts of integrated response options on Nature's Contributions to People

Tables 6.70–6.72 summarise the impacts of the response options on NCP supply. Examples of synergies between response options and NCP include positive impacts on habitat maintenance (NCP 1) from activities like invasive species management and agricultural diversification. For the evaluation process, we considered that NCP are about ecosystems, therefore options which may have overall positive effects, but which are *not* ecosystem-based are not included; for example, improved food transport and distribution could reduce ground-level ozone and thus improve air quality, but this is not an ecosystem-based NCP. Similarly, energy efficiency measures would increase energy availability, but the 'energy' NCP refers specifically to biomass-based fuel provisioning. This necessarily means that the land management options have more direct NCP effects than the value chain or governance options, which are less ecosystem-focused.

In evaluating NCP, we have also tried to avoid 'indirect' effects – that is a response option might increase household income which then could be invested in habitat-saving actions, or dietary change would lead to conservation of natural areas, which would then led to increased water quality. Similarly, material substitution would increase wood demand, which in turn might lead to deforestation which might have water regulation effects. These can all be considered *indirect* impacts on NCP, which were not evaluated[7]. Instead, the assessment focuses as much as possible on *direct* effects only: for example, local seeds policies preserve local landraces, which *directly* contribute to 'maintenance of genetic options' for the future. Therefore, this NCP table is a conservative estimation of NCP effects; there are likely many more secondary effects, but they are too difficult to assess, or the literature is not yet complete or conclusive.

Further, many NCP trade-off with one another (Rodriguez et al 2006), so supply of one might lead to less availability of another – for example, use of ecosystems to produce bioenergy will likely lead to decreases in water availability if mono-cropped high intensity plantations are used (Gasparaos et al 2011).

Overall, several response options stand out as having co-benefits across 10 or more NCP with no adverse impacts: improved cropland management, agroforestry, forest management and forest restoration, increased soil organic content, fire management, restoration and avoided conversion of coastal wetlands, and use of local seeds. Other response options may have strengths in some NCP but require trade-offs with others. For example, reforestation and afforestation bring many positive benefits for climate and water quality but may trade-off with food production (Table 6.70). Several response options, including increased food productivity, bioenergy and BECCS, and some risk sharing instruments like crop insurance, have significant negative consequences across multiple NCP.

[7] FOOTNOTE: The exception is NCP 6, regulation of ocean acidification, which is by itself an indirect impact. Any option that sequesters CO_2 would lower the atmospheric CO_2 concentration, which then indirectly increases the seawater pH. Therefore, any action that directly increases the amount of sequestered carbon is noted in this column, but not any action that avoids land use change and therefore indirectly avoids CO_2 emissions.

Table 6.70 Impacts on Nature's Contributions to People of integrated response options based on land management

Integrated response options based on land management	Habitat creation and maintenance	Pollination and dispersal of seeds and other propagules	Regulation of air quality	Regulation of climate	Regulation of ocean acidification	Regulation of freshwater quantity, flow and timing	Regulation of freshwater and coastal water quality	Formation, protection and decontamination of soils and sediments	Regulation of hazards and extreme events	Regulation of organisms detrimental to humans	Energy	Food and feed	Materials and assistance	Medicinal, biochemical and genetic resources	Learning and inspiration	Physical and psychological experiences	Supporting identities	Maintenance of options
Increased food productivity																		
Improved cropland management																		
Improved grazing land management

6.4.3.2 Impacts of integrated response options on the UN Sustainable Development Goals

Tables 6.73–6.75 summarise the impact of the integrated response options on the UN SDG. Some of the synergies between response options and SDG in the literature include positive poverty reduction impacts (SDG 1) from activities like improved water management or improved management of supply chains, or positive gender impacts (SDG 5) from livelihood diversification or use of local seeds. Because many land management options only produce indirect or unclear effects on SDG, we did not include these where there was no literature. Therefore, the value chain and governance options appear to offer more direct benefits for SDG.

However, it is noted that some SDG are internally difficult to assess because they contain many targets, not all of which could be evaluated (e.g., SDG 17 is about partnerships, but has targets ranging from foreign aid to debt restructuring to technology transfer to trade openness). Additionally, it is noted that some SDG contradict one another – for example, SDG 9 to increase industrialisation and infrastructure and SDG 15 to improve life on land. More industrialisation is likely to lead to increased resource demands with negative effects on habitats. Therefore, a positive association on one SDG measure might be directly correlated with a negative measure on another, and the table needs to be read with caution for that reason. The specific caveats on each of these interactions can be found in the supplementary material tables in the Chapter 6 appendix.

Overall, several response options have co-benefits across 10 or more SDG with no adverse side effects on any SDG: increased food production, improved grazing land management, agroforestry, integrated water management, reduced post-harvest losses, sustainable sourcing, livelihood diversification and disaster risk management. Other response options may have strengths in some SDG but require trade-offs with others. For example, use of local seeds bring many positive benefits for poverty and hunger reduction, but may reduce international trade (SDG 17). Other response options like enhanced urban food systems, management of urban sprawl, or management of supply chains are generally positive for many SDG but may trade-off with one, like clean water (SDG 6) or decent work (SDG 8), as they may increase water use or slow economic growth. Several response options, including avoidance of grassland conversion, reduced deforestation and degradation, reforestation and afforestation, biochar, restoration and avoided conversion of peatlands and coastlands, have trade-offs across multiple SDG, primarily as they prioritise land health over food production and poverty reduction. Several response options such as bioenergy and BECCS and some risk sharing instruments, such as crop insurance, trade-off over multiple SDG with potentially significant adverse consequences.

Overall, across both categories of both SDG and NCP, 17 of 40 options deliver co-benefits or no adverse side-effects for the full range of NCP and SDG. This include most agriculture- and soil-based land management options, many ecosystem-based land management options, improved forest management, reduced post-harvest losses, sustainable sourcing, improved energy use in food systems, and livelihood diversification. Only three options (afforestation, bioenergy and BECCS and some types of risk sharing instruments, such as crop insurance) have potentially adverse side-effects for five or more NCP or SDG.

6.4.4 Opportunities for implementation of Integrated Response Options

6.4.4.1 Where can the response options be applied?

As shown in Section 6.1.3, a large part of the land area is exposed to overlapping land challenges, especially in villages, croplands and rangelands. The deployment of land management responses may vary with local exposure to land challenges. For instance, with croplands exposed to a combination of land degradation, food insecurity and climate change adaptation challenges, maximising the co-benefits of land management responses would require selecting responses having only co-benefits for these 3 overlapping challenges, as well as for climate change mitigation which is a global challenge. Based on these criteria, Figure 6.6 shows the potential deployment area of land management responses across land use types (or anthromes).

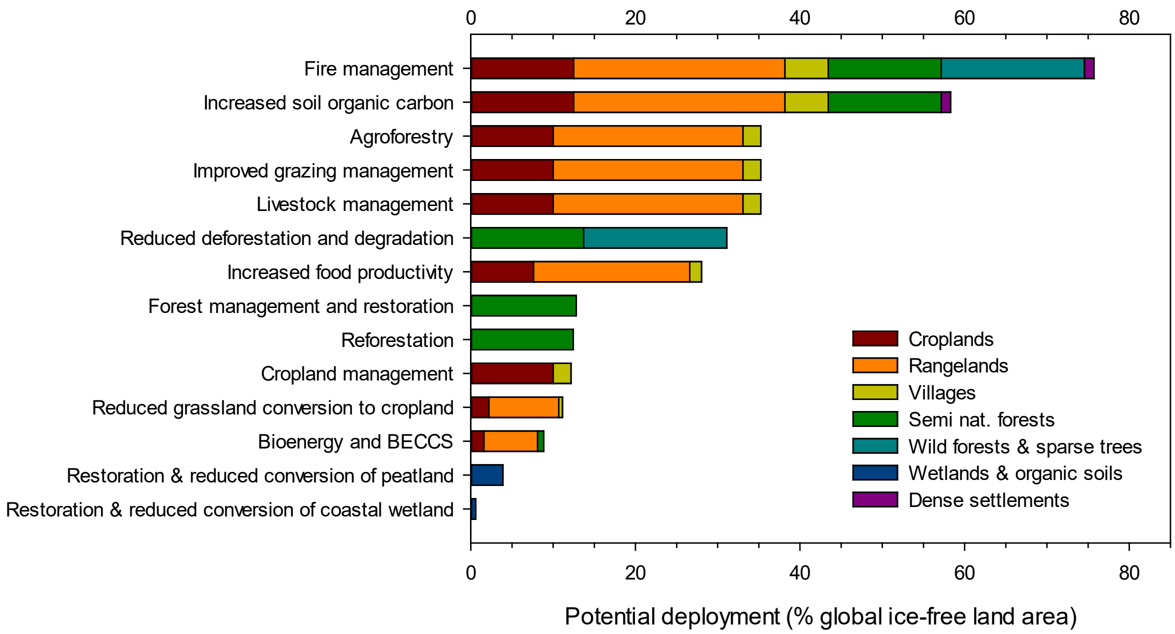

Figure 6.6 Potential deployment area of land management responses (see Table 6.1) across land use types (or anthromes, see section 6.3), when selecting responses having only co-benefits for local challenges and for climate change mitigation and no large adverse side-effect on global food security. See Figure 6.2 for the criteria used to map challenges (desertification, land degradation, climate change adaptation, chronic undernourishment, biodiversity, groundwater stress and water quality) considered. No response option was identified for barren lands.

Land management responses having co-benefits across the range of challenges, including climate change mitigation, could be deployed between one (coastal wetlands, peatlands, forest management and restoration, reforestation) and 5 (increased soil organic carbon) or 6 (fire management) land use types (Figure 6.6). Fire management and increased soil organic carbon have a large potential since they could be deployed with mostly co-benefits and few adverse effects over 76 and 58% of the ice-free land area. In contrast, other responses have a limited area-based potential due to biophysical constraints (e.g., limited extent of organic soils and of coastal wetlands for conservation and restoration responses), or due to the occurrence of adverse effects. Despite strong co-benefits for climate change mitigation, the deployment of bioenergy and BECCS would have co-benefits on only 9% of the ice-free land area (Figure 6.6), given adverse effects of this response option for food security, land degradation, climate change adaptation and desertification (see Tables 6.62-6.69).

Without including the global climate change mitigation challenge, there are up to 5 overlapping challenges on lands which are not barren (Fig. 6.7A, calculated from the overlay of individual challenges shown in Fig. 6.2) and up to 9 land management response options having only co-benefits for these challenges and for climate change mitigation (Fig. 6.7B). Across countries, the mean number of land management response options with mostly co-benefits declines ($p<0.001$, Spearman rank order correlation) with the mean number of land challenges. Hence, the higher the number of land challenges per country, the fewer the land management response options having only co-benefits for the challenges encountered.

Enabling conditions (see Section 6.1.2.2) for the implementation of land management responses partly depend upon human development (economics, health and education) as estimated by a country scale composite index, the Human Development index (HDI, United Nations Development Program, 2018) (Figure 6.7C). Across countries, HDI is negatively correlated ($p<0.001$, Spearman rank order correlation) with the mean number of land challenges. Therefore, on a global average, the higher the number of local challenges faced, the fewer the land management responses having only co-benefits and the lower the human development (Figure 6.7) that could favour the implementation of these responses.

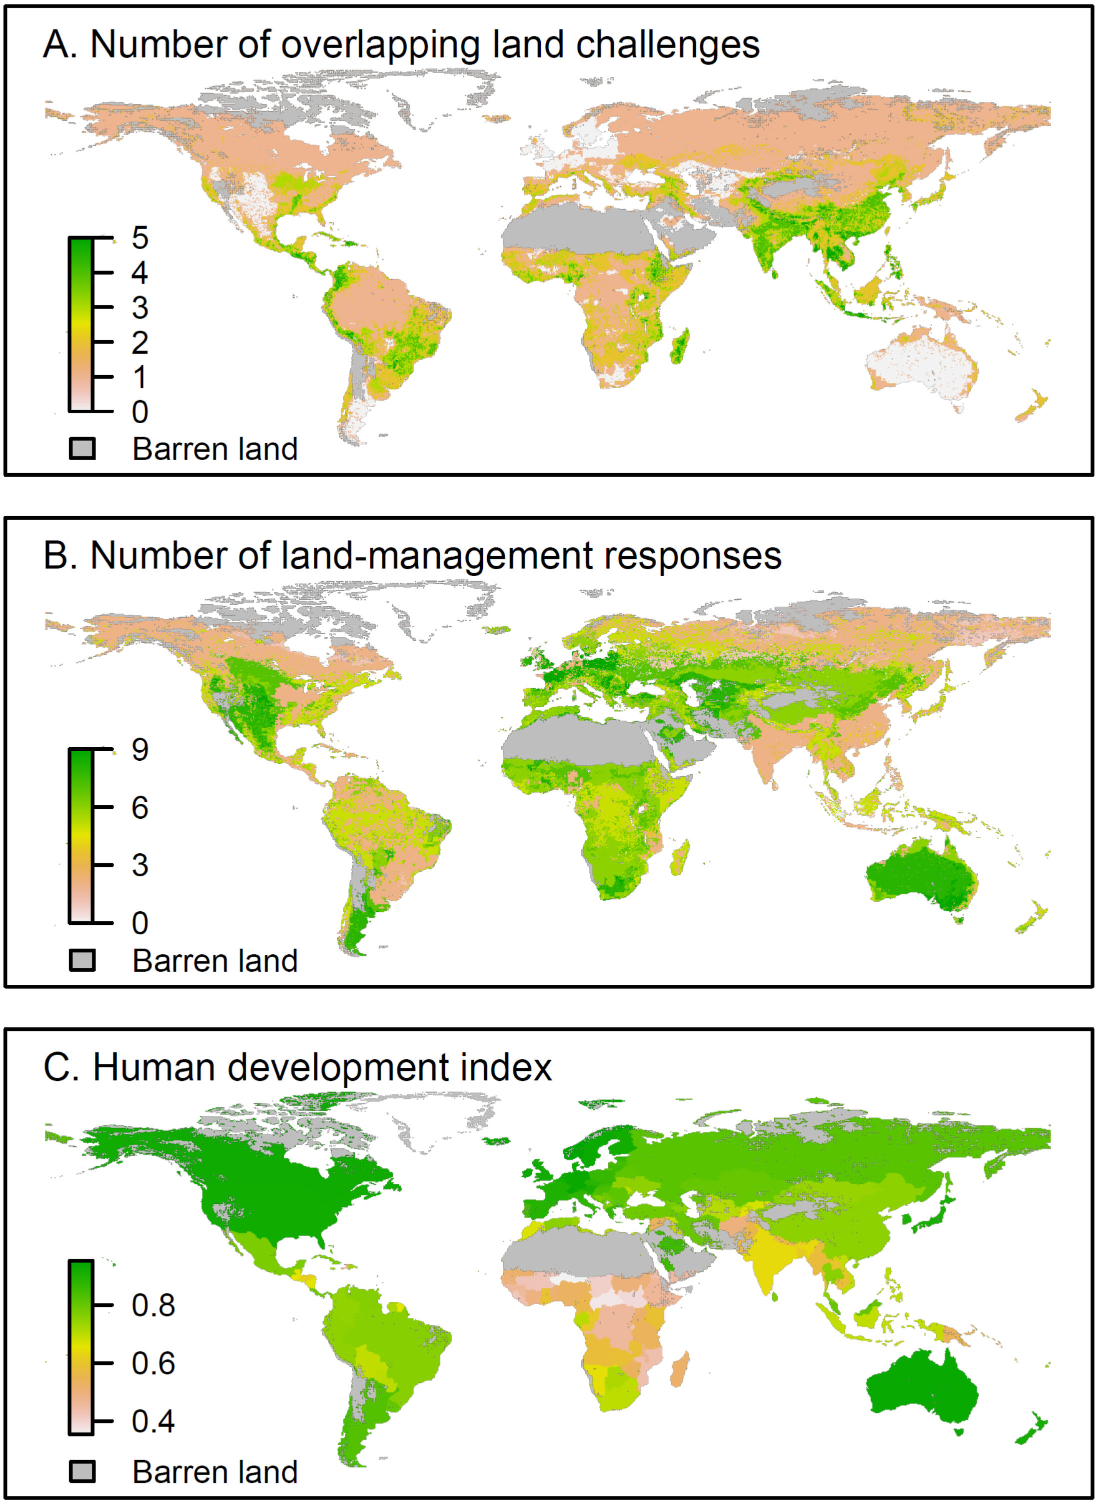

Figure 6.7 Global distributions of (A) number of overlapping land challenges (desertification, land degradation, climate change adaptation, chronic undernourishment, biodiversity, groundwater stress and water quality, see Fig. 6.2); (B) number of land management responses providing medium to large co-benefits and no adverse side-effects (see Fig. 6.6) across challenges; (C) Human Development Index (HDI) by country. The Human Development Index (United Nations Development Programme, 2018) is a country based composite statistical index measuring average achievement in three basic dimensions of human development

a long and healthy life (estimated from life expectancy at birth), knowledge (estimated from years of schooling) and a decent standard of living (estimated from gross national income per capita)

6.4.4.2 Interlinkages and response options in future scenarios

This section assesses more than eighty articles quantifying the effect of various response options in the future, covering a variety of response options and land-based challenges. These studies cover spatial scales ranging from global (Popp et al. 2017; Fujimori et al. 2018a) to regional (Calvin et al. 2016a; Frank et al. 2015) to country-level (Gao and Bryan 2017; Pedercini et al. 2018). This section focuses on models that can quantify interlinkages between response options, including agricultural economic models, land system models, and integrated assessment models. The IAM and non-IAM literature, however, is also categorised separately to elucidate what is and is not included in global mitigation scenarios, like those included in the SR15. Results from bottom-up studies and models (e.g., Griscom et al. 2017a) are assessed in Section 6.2-6.3.

Response options in future scenarios:

More than half of the 40 land-based response options discussed in this chapter are represented in global IAMs models used to develop and analyse future scenarios, either implicitly or explicitly (Table 6.76). For example, all IAMs include improved cropland management, either explicitly through technologies that improve N use efficiency (Humpenöder et al. 2018a) or implicitly through marginal abatement cost curves that link reductions in N_2O emissions from crop production to carbon prices (most other models).

However, the literature discussing the effect of these response options on land-based challenges is more limited (Table 6.76). Fifty-seven studies (forty-three IAM studies) articulate the effect of response options on mitigation, with most including bioenergy and BECCS or a combination of reduced deforestation, reforestation, and afforestation. Thirty-seven studies (twenty-one IAM studies) discuss the implications of response options on food security, usually using food price as a metric. While a small number of non-IAM studies examine the effects of response options on desertification (three studies) and land degradation (five studies), no IAM studies were identified. However, some studies quantify these challenges indirectly using IAMs either via climate outputs from the RCPs (Huang et al. 2016) or by linking IAMs to other land and ecosystem models (Brink et al. 2018; UNCCD 2017).

For many of the scenarios in the literature, land-based response options are included as part of a suite of mitigation options (Popp et al. 2017; van Vuuren et al. 2015a). As a result, it is difficult to isolate the effect of an individual option on land-related challenges. A few studies focus on specific response options (Calvin et al. 2014a; Popp et al. 2014b; Kreidenweis et al. 2016b; Humpenöder et al. 2018a), quantifying the effect of including an individual option on a variety of sustainability targets.

Table 6.76 Number of IAM and non-IAM Studies Including Specific Response Options (rows) and Quantifying Particular Land Challenges (columns). The third column shows how many IAM models include the individual response option; red indicates all models include the option, orange indicates more than half of all models, yellow indicates less than half, and white indicates no models. The remaining columns show challenges related to climate change (C), mitigation (M), adaptation (A), desertification (D), land degradation (L), food security (F), and biodiversity/ecosystem services/sustainable development (B). The colour indicates the number of total studies, with 0 (white), 1-5 (green), 6-10 (light blue), 11-15 (dark blue), and 16 or more (purple). Additionally, counts of total (left value) and IAM-only (right value) studies are included. Some IAMs include agricultural economic models which can also be run separately; these models are not counted as IAM literature when used on their own. Studies using a combination of IAMs and non-IAMs are included in the total only. A complete list of studies is included in the supplementary material.

[a] Only IAMs that are used in the papers assessed are included in this column.
[b] There are many indicators for land degradation (see Chapter 4). In this table, studies are categorised as quantifying land degradation if they explicitly discuss land degradation.
[c] Studies are categorised is quantifying food security if they report food prices or the population at risk of hunger.

Interactions and Interlinkages between Response Options:

The effect of response options on desertification, land degradation, food security, biodiversity, and other sustainable development goals depends strongly on which options are included and the extent to which they are deployed. For example, sections 2.6, 6.3.6, and the Cross-Chapter Box 7 on Bioenergy note that bioenergy and BECCS has a large mitigation potential but could potentially have adverse side effects for land degradation, food security, and other sustainable development goals. Global modelling studies demonstrate that these effects are dependent on scale. Increased use of bioenergy can result in increased mitigation (Figure 6.8, Panel A) and reduced climate change, but can also lead to increased energy cropland expansion (Figure 6.8, Panel B), and increased competition for land resulting in increased food prices (Figure 6.8, Panel C). However, the exact relationship between bioenergy deployment and each sustainability target depends a number of other factors, including the feedstock used, the underlying socioeconomic scenario, assumptions about technology and resource base, the inclusion of other response options, and the specific model used (Calvin et al. 2014a; Clarke and Jiang 2014b; Popp et al. 2014b, 2017; Kriegler et al. 2014).

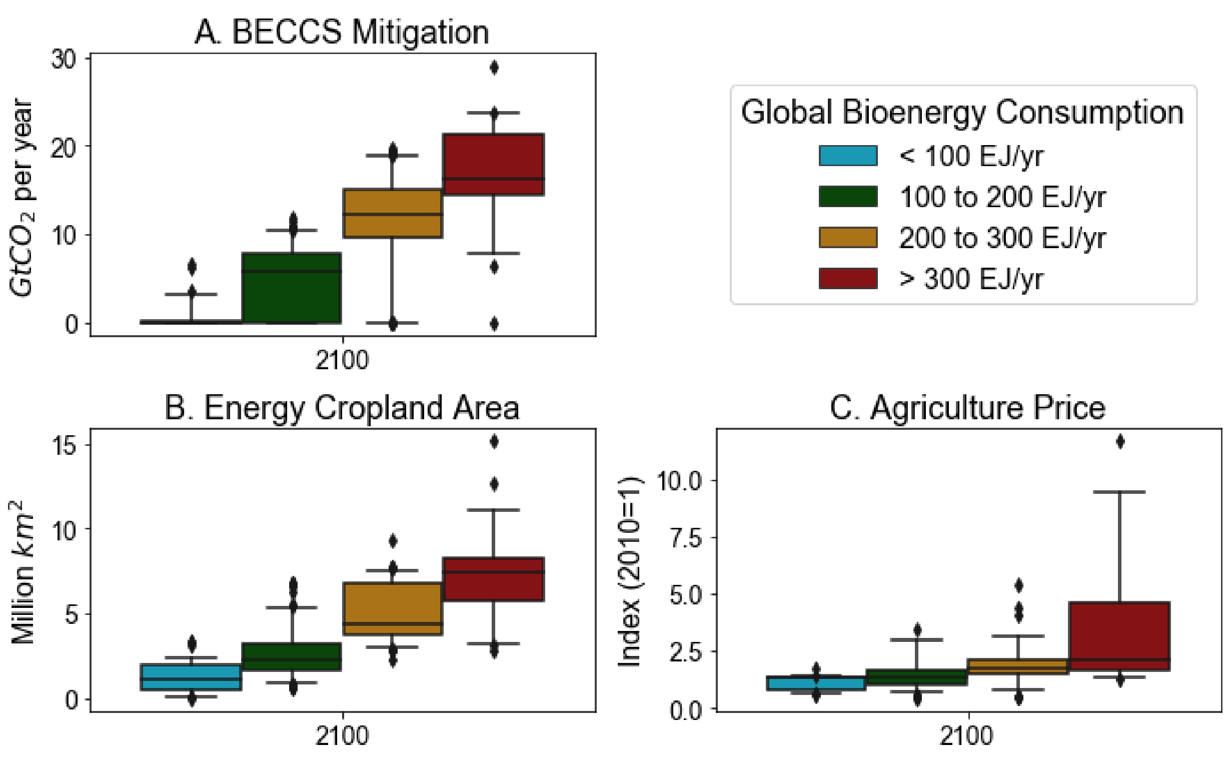

Figure 6.8 Correlation between Bioenergy Use and Other Indicators. Panel A shows global CO_2 sequestration by BECCS in 2100. Panel B shows global energy cropland area in 2100. Panel C shows agricultural prices in 2100 indexed to 2010. Data are binned based on the amount of bioenergy used globally in 2100. All scenario data that include both bioenergy consumption and the variable of interest are included in the figure; the resulting number of scenarios varies per panel with 352 in panel A, 262 in panel B, and 172 in panel C. The

boxes represent the interquartile range (i.e., the middle 50% of all scenarios), the line in the middle of the box represents the median, and the whiskers represent the 5 to 95% range of scenarios. Data is from an update of the IAMC Scenario Explorer developed for the SR15 (Huppmann et al. 2018; Rogelj et al. 2018b).

The previous sections have examined the effects of individual land-response options on multiple challenges. A number of studies using global modelling and analyses have examined interlinkages and interaction effects among land response options by incrementally adding or isolating the effects of individual options. Most of these studies focus on interactions with bioenergy and BECCS (Table 6.77). Adding response options that require land (e.g., reforestation, afforestation, reduced deforestation, avoided grassland conversion, or biodiversity conservation), results in increased food prices (Calvin et al. 2014a; Humpenöder et al. 2014a; Obersteiner et al. 2016a; Reilly et al. 2012a) and potentially increased temperature through biophysical climate effects (Jones et al. 2013). However, this combination can result in reduced water consumption (Hejazi et al. 2014c), reduced cropland expansion (Calvin et al. 2014a; Humpenöder et al. 2018a), increased forest cover (Calvin et al. 2014a; Humpenöder et al. 2018a; Wise et al. 2009a) and reduced biodiversity loss (Pereira et al. 2010), compared to scenarios with bioenergy and BECCS alone. While these options increase total mitigation, they reduce mitigation from bioenergy and BECCS as they compete for the same land (Wu et al. 2019; Baker et al. 2019a; Calvin et al. 2014a; Humpenöder et al. 2014a).

The inclusion of land-sparing options (e.g., dietary change, increased food productivity, reduced food waste, management of supply chains) in addition to bioenergy and BECCS results in reduced food prices, reduced agricultural land expansion, reduced deforestation, reduced mitigation costs, reduced water use, and reduced biodiversity loss (Bertram et al. 2018; Wu et al. 2019; Obersteiner et al. 2016a; Stehfest et al. 2009; van Vuuren et al. 2018a). These options can increase bioenergy potential, resulting in increased mitigation than from bioenergy and BECCS alone (Wu et al. 2019; Stehfest et al. 2009; Favero and Massetti 2014).

Other combinations of land response options create synergies, alleviating land pressures. The inclusion of increased food productivity and dietary change can increase mitigation, reduce cropland use, reduce water consumption, reduce fertiliser application, and reduce biodiversity loss (Springmann et al. 2018c; Obersteiner et al. 2016a). Similarly, improved livestock management combined with increased food productivity can reduce agricultural land expansion (Weindl et al. 2017). Reducing disturbances (e.g., fire management) in combination with afforestation can increase the terrestrial carbon sink, resulting in increased mitigation potential and reduced mitigation cost (Le Page et al. 2013a).

Studies including multiple land response options often find that the combined mitigation potential is not equal to the sum of individual mitigation potential as these options often share the same land. For example, including both afforestation and bioenergy and BECCS results in a cumulative reduction in GHG emissions of 1200 $GtCO_2$ between 2005 and 2100, which is much lower than the sum of the contributions of bioenergy (800 $GtCO_2$) and afforestation (900 $GtCO_2$) individually (Humpenöder et al. 2014a). More specifically, Baker et al. (2019a) find that woody bioenergy and afforestation are complementary in the near-term, but become substitutes in the long-term, as they begin to compete for the same land. Similarly, the combined effect of increased food productivity, dietary change, and reduced waste on GHG emissions is less than the sum of the individual effects (Springmann et al. 2018c).

Table 6.77 Interlinkages between bioenergy and BECCS and other response options. Table indicates the combined effects of multiple land-response options on climate change (C), mitigation (M), adaptation (A), desertification (D), land degradation (L), food security (F), and biodiversity/ecosystem services/sustainable development (O). Each cell indicates the implications of adding the option specified in the row in addition to bioenergy and BECCS. Blue colours indicate positive interactions (e.g., including the option in the second column increases mitigation, reduces cropland area, or reduces food prices relative to bioenergy and BECCS alone). Red colours indicate negative interactions; yellow indicates mixed interactions (some positive, some negative). Note that only response option combinations found in the assessed literature are included in the interest of space.

Increased food productivity; dietary change								

[a] Includes changes in biophysical effects on climate (e.g., albedo)
[b] Either through reduced emissions, increased mitigation, reduced mitigation cost, or increased bioenergy potential. For increased mitigation, a positive indicator in this column only indicates that total mitigation increases and not that the total is greater than the sum of the individual options.
[c] Uses changes in cropland or forest as an indicator (reduced cropland expansion or reduced deforestation are considered positive)
[d] Includes changes in water use or scarcity, fertiliser use, or biodiversity

Land-related response options can also interact with response options in other sectors. For example, limiting deployment of a mitigation response option will either result in increased climate change or additional mitigation in other sectors. A number of studies have examined limiting bioenergy and BECCS. Some such studies show increased emissions (Reilly et al. 2012a). Other studies meet the same climate goal, but reduce emissions elsewhere *via* reduced energy demand (Grubler et al. 2018; van Vuuren et al. 2018a), increased fossil CCS, nuclear energy, energy efficiency and/or renewable energy (van Vuuren et al. 2018a; Rose et al. 2014b; Calvin et al. 2014a; van Vuuren et al. 2017b), dietary change (van Vuuren et al. 2018a), reduced non-CO_2 emissions (van Vuuren et al. 2018a), or lower population (van Vuuren et al. 2018a). The co-benefits and adverse side-effects of non-land mitigation options are discussed in SR15, Chapter 5. Limitations on bioenergy and BECCS can result in increases in the cost of mitigation (Kriegler et al. 2014; Edmonds et al. 2013a). Studies have also examined limiting CDR, including reforestation, afforestation, and bioenergy and BECCS (Kriegler et al. 2018a,b). These studies find that limiting CDR can increase mitigation costs, increase food prices, and even preclude limiting warming to less than 1.5ºC above pre-industrial levels (Kriegler et al. 2018a,b; Muratori et al. 2016).

In some cases, the land challenges themselves may interact with land-response options. For example, climate change could affect the production of bioenergy and BECCS. A few studies examine these effects, quantifying differences in bioenergy production (Calvin et al. 2013a; Kyle et al. 2014) or carbon price (Calvin et al. 2013a) as a result of climate change. Kyle et al. (2014) finds increase in bioenergy production due to increases in bioenergy yields, while Calvin et al. (2013a) finds declines in bioenergy production and increases in carbon price due to the negative effects of climate on crop yield.

Gaps in the Literature:

Not all of the response options discussed in this chapter are included in the assessed literature, and many response options are excluded from the IAM models. The included options (e.g. bioenergy and BECCS; reforestation) are some of the largest in terms of mitigation potential (see Section 6.3). However, some of the options excluded also have large mitigation potential. For example, biochar, agroforestry, restoration/avoided conversion of coastal wetlands, and restoration/avoided conversion of peatland all have mitigation potential of ~1 $GtCO_2$ yr^{-1} (Griscom et al. 2017). Additionally, quantifications of and response options targeting land degradation and desertification are largely excluded from the modelled studies, with a few notable exceptions (Wolff et al. 2018; Gao and Bryan 2017; Brink et al. 2018; UNCCD 2017). Finally, while a large number of papers have examined interactions between bioenergy and BECCS and other response options, the literature examining other combinations of response options is more limited.

6.4.4.3 Resolving challenges in response option implementation

The 40 response options assessed in this chapter face a variety of barriers to implementation that require action across multiple actors to overcome (section 6.4.1). Studies have noted that while adoption of response options by individuals may depend on individual assets and motivation, larger structural and institutional factors are almost always equally important if not more so (Adimassu et al. 2016; Djenontin et al. 2018), though harder to capture in research variables (Schwilch et al. 2014). These institutional and governance factors can create an enabling environment for SLM practices, or challenges to their adoption (Adimassu et al. 2013). Governance factors include the institutions that manage rules and policies, the social norms and collective actions of participants (including civil society actors and the private sector), and the interactions between them (Ostrom 1990; Huntjens et al. 2012; Davies 2016). Many of Ostrom's design principles for successful governance can be applied to response options for SLM; these principles are: (1) clearly defined boundaries; (2) understanding of both benefits and costs; (3) collective choice arrangements; (4) monitoring; (5) graduated sanctions; (6) conflict-resolution mechanisms; (7) recognition of rights; and (8) nested (multi-scale) approaches. Unfortunately, studies of many natural resources and land management policy systems in developing countries in particular often show the opposite: a lack of flexibility, strong hierarchical tendencies, and a lack of local participation in institutional frameworks (Ampaire et al. 2017). Analysis of government effectiveness (GE)– defined as quality of public services, policy formulation and implementation, civil service and the degree of its independence from political pressures as well as credibility of the government's commitment to its policies (Kaufman et al. 2010) – has been shown to play a key role in land management. GE mediates land user actions on land management and investment, and government policies and laws can help land users adopt sustainable land management practices (Nkonya et al. 2016) (Figure 6.9).

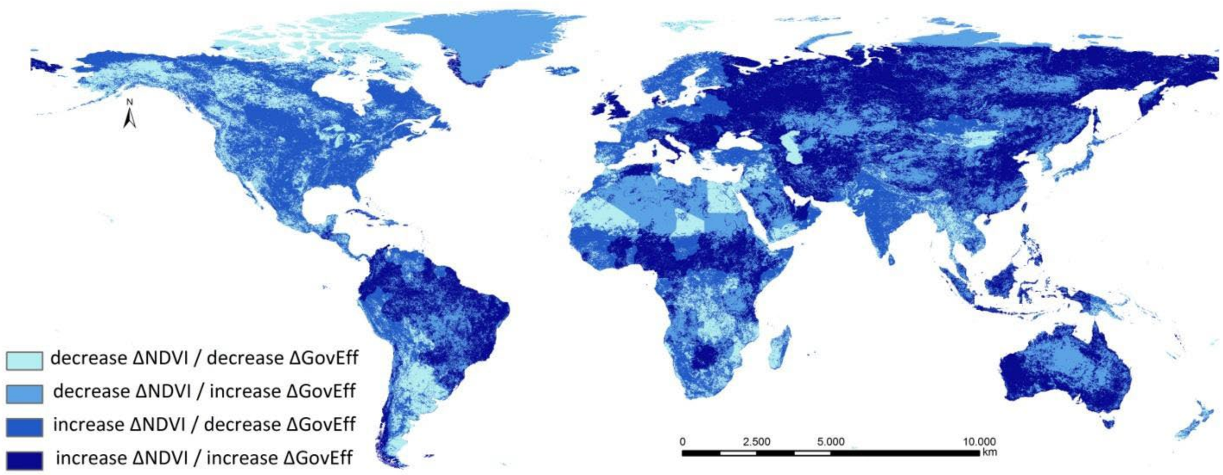

Figure 6.9 Relationship between changes in government effectiveness and changes in land management

Notes: ΔNDVI = Change in Normalized Difference Vegetation Index (baseline year 2001, Endline year 2010). Source of NDVI data: MODIS ΔGovEff = Change in Government effectiveness (baseline year 2001, Endline year 2010). Source of Government effectiveness: World Bank. Source: Nkonya et al 2016.

It is simply not a matter of putting the 'right' institutions or policies in place, however, as governance can be undermined by inattention to power dynamics (Fabinyi et al. 2014). Power shapes how actors gain access and control over resources, and negotiate, transform and adopt certain response options or not. These variable dynamics of power between different levels and stakeholders have an impact on the ability to implement different response options. The inability of many national governments to address social exclusion in general will have an effect on the implementation of many response options. Further, response options themselves can become avenues for actors to exert power claims over others

(Nightingale 2017). For example, there have been many concerns that reduced deforestation and degradation projects run the risk of reversing trends towards decentralisation in forest management and create new power disparities between the state and local actors (Phelps et al. 2010). Below we assess how two important factors, the involvement of stakeholders and the coordination of action across scales, will help in moving from response options to policy implementation, a theme chapter 7 takes up in further detail.

Involvement of stakeholders

There are a wide range of stakeholders that are necessary for successful land, agricultural and environmental policy, and implementing response options requires that a range of actors, including businesses, consumers, land managers, indigenous and local communities, scientists, and policymakers work together for success. Diverse stakeholders have a particularly important role to play in defining problems, assessing knowledge and proposing solutions (Phillipson et al. 2012; Stokes et al. 2006). Lack of connection between science knowledge and on-the-ground practice has hampered adoption of many response options in the past; simply presenting 'scientifically' derived response options is not enough (Marques et al. 2016). For example, the importance of recognising and incorporating local knowledge (LK) and indigenous knowledge (IK) is increasingly emphasised in successful policy implementation (see Cross-Chapter Box 13 on Indigenous Knowledge, Chapter 7), as local practices of water management, soil fertility management, improved grazing, restoration and sustainable management of forests are often well-aligned with response options assessed by scientists (Marques et al. 2016).

Stakeholder engagement is an important approach for successful environmental and climate policy and planning. Tools such as stakeholder mapping, in which affected and interested parties are identified and described in terms of their interrelationships and current or future objectives and aspirations, and scenario-based stakeholder engagement, which combines stakeholder analysis with climate scenarios, are increasingly being applied to facilitate better planning outcomes (Tompkins et al. 2008; Pomeroy & Douvere 2008; Star et al. 2016). Facilitated dialogues early in design processes have shown good success in bringing multiple and sometimes conflicting stakeholders to the table to discuss synergies and trade-offs around policy implementation (Gopnik et al 2012). Knowledge exchange, social learning, and other concepts are also increasingly being incorporated into understandings of how to facilitate sustainable land management (Djenontin et al. 2018), as evidence suggests that negotiating the complexity of SESs requires flexible learning arrangements in particular for multiple stakeholders (Gerlak and Heikkila 2011; Armitage et al. 2018; Heikkila and Gerlak 2018). Social learning has been defined as "a change in understanding and skills that becomes situated in groups of actors/communities of practice through social interactions," (Albert et al. 2012), and social learning is often linked with attempts to increase levels of participation in decision making, from consultation to more serious community control (Collins and Ison 2009; McCrum et al. 2009). Learning also facilitates responses to emerging problems and helps actors in SESs grapple with complexity. One outcome of learning can be adaptive risk management (ARM), in which "one takes action based on available information, monitors what happens, learns from the experience and adjusts future actions based on what has been learnt" (Bidwell et al. 2013). Suggestions to facilitate social learning, ARM, and decision-making include extending science-policy networks and using local bridging organisations, such as extension services, for knowledge co-production (Bidwell et al. 2013; Böcher and Krott 2014; Howarth and Monasterolo 2017) see further discussion in Chapter 7, section 7.5 on Decision-making for Climate and Land).

Insuring that women are included as key stakeholders in response option implementation is also important, as gender norms and roles affect vulnerability and access to resources, and gender inequality limits the possible range of responses for adoption by women (Lambrou and Piana 2006). For example, environmental change may increase women's workload as their access to natural resources may decline, or they may have to take up low-wage labour if agriculture becomes unsuitable in their local areas under climate change (Nelson et al. 2002). Every response option considered in this chapter potentially has a gender dimension to it that needs to be taken into consideration (Tables 6.73–6.75 note how response options intersect with SDG 5 Gender Equity); for example, to address food security through sustainable intensification will clearly have to address women farmers in Africa (Kondylis et al. 2016; Garcia and Wanner 2017) (For further information, see Cross-Chapter Box 11: Gender, in Chapter 7).

Challenges of coordination

Coordinated action to implement the response options will be required across a range of actors, including business, consumers, land managers, indigenous and local communities and policymakers to create enabling conditions. Conjoining response options to maximise social, climatic and environmental benefits will require framings of such actions as strong pathways to sustainable development (Ayers and Dodman 2010). As the chapter has pointed out, there are many potentials for synergies, especially among several response options that might be applied together and in coordination with one another (such as dietary change and improved land management measures). This coordination will help ensure that synergies are met and trade-offs minimised, but this will require deliberate coordination across multiple scales, actors and sectors. For example, there are a variety of response options available at different scales that could form portfolios of measures applied by different stakeholders from farm to international scales. Agricultural diversification and use of local seeds by smallholders can be particularly useful poverty reduction and biodiversity conservation measures, but are only successful when higher scales, such as national and international markets and supply-chains, also value these goods in trade regimes, and consumers see the benefits of purchasing these goods. However, the land and food sectors face particular challenges of institutional fragmentation, and often suffer from a lack of engagement between stakeholders at different scales (Biermann et al. 2009; Deininger et al 2014) (see section 7.6.2, Chapter 7).

Many of the response options listed in this chapter could be potentially implemented as 'community-based' actions, including community-based reforestation, community-based insurance, or community-based disaster risk management. Grounding response options in community approaches aims to identify, assist and implement activities "that strengthen the capacity of local people to adapt to living in a riskier and less predictable climate" (Ayers and Forsyth 2009). Research that shows that people willingly come together to provide mutual aid and protection against risk, to manage natural resources, and to work cooperatively to find solutions to environmental provisioning problems. Some activities that fall under this type of collective action can include the creation of institutions or rules; working cooperatively to manage a resource by restricting some activities and encouraging others; sharing information to improve public goods; or mobilising resources, such as capital, to fix a collective problem (Ostrom 2000; Poteete and Ostrom 2004); or engagement in participatory land use planning (Bourgoin 2012; Evers and Hofmeister 2011). These participatory processes "are likely to lead to more beneficial environmental outcomes through better informed, sustainable decisions, and win-win solutions regarding economic and conservation objectives" (Vente et al. 2016), and evaluations of community-based response options have been generally positive (Karim and Thiel 2017a; Tompkins & Adger 2004).

Agrawal (2001) has identified more than 30 different indicators that have been important in understanding who undertakes collective action for the environment, including the size of the group undertaking action; the type and distribution of the benefits from the action; the heterogeneity of the group; the dependence of the group on these benefits; the presence of leadership; presence of social capital and trust; and autonomy and independence to make and enforce rules. Alternatively, when households expect the government to undertake response actions, they have less incentive to join in collective action, as the state role has 'crowded out' local cooperation (Adger 2009). High levels of social trust and capital can increase willingness of farmers to engage in response options, such as improved soil management or carbon forestry (Stringer et al. 2012; Lee 2017), and social capital helps with connectivity across levels of SESs (Brondizio et al. 2009). (Dietz et al. 2013) lay out important policy directions for more successful facilitation of collective action across scales and stakeholders. These include: providing information; dealing with conflict; inducing rule compliance; providing physical, technical or institutional infrastructure; and being prepared for change. The adoption of participatory protocols and structured processes to select response options together with stakeholders will likely lead to greater success in coordination and participation (Bautista et al. 2017; Franks 2010; Schwilch et al. 2012a).

However, wider adoption of community-based approaches is potentially hampered by several factors: the fact that most are small scale (Forsyth 2013; Ensor et al. 2014) and it is often unclear how to assess criteria of success (Forsyth 2013). Others also caution that community-based approaches often are not able to adequately address the key drivers of vulnerability such as inequality and uneven power relations (Nagoda and Nightingale 2017).

Moving from response options to policies

Chapter 7 discusses in further depth the risks and challenges involved in formulating policy responses that meet the demands for sustainable land management and development outcomes, such as food security, community adaptation and poverty alleviation. Chapter 7 in Table 7.1 maps how specific response options might be turned into policies; for example, to implement a response option aimed at agricultural diversification, a range of policies from elimination of agricultural subsidies (which might favour single crops) to environmental farm programs and agro-environmental payments (to encourage alternative crops). Oftentimes, any particular response option might have a variety of potential policy pathways that might address different scales or stakeholders or take on different aspects of coordination and integration (section 7.6.1). Given the unique challenges of decision-making under uncertainty in future climate scenarios, Chapter 7 particularly discusses the need for flexible, iterative, and adaptive processes to turn response options into policy frameworks.

Cross-Chapter Box 9: Illustrative Climate and Land Pathways

Katherine Calvin (The United States of America), Edouard Davin (France/Switzerland), Margot Hurlbert (Canada), Jagdish Krishnaswamy (India), Alexander Popp (Germany), Prajal Pradhan (Nepal/Germany)

Future development of socioeconomic factors and policies influence the evolution of the land-climate system, among others in terms of the land used for agriculture and forestry. Climate mitigation policies can also have a major impact on land use, especially in scenarios consistent with the climate targets of the

Paris Agreement. This includes the use of bio-energy or Carbon Dioxide Removal (CDR), such as bioenergy with carbon dioxide capture and storage (BECCS) and afforestation. Land-based mitigation options have implications for GHG fluxes, desertification, land degradation, food insecurity, ecosystem services and other aspects of sustainable development.

Illustrative Futures

The three illustrative futures are based on the Shared Socioeconomic Pathways (SSPs; (O'Neill et al. 2014c; Riahi et al. 2017b; Popp et al. 2017; Rogelj et al. 2018b); Cross-Chapter Box 1 in Chapter 1). SSP1 is a scenario with a broad focus on sustainability including a focus on human development, technological development, nature conservation, globalised economy, economic convergence and early international cooperation including moderate levels of trade. The scenario assumes a low population growth, relatively high agricultural yields and a move towards less-meat intensive diets (van Vuuren et al. 2017b). Dietary change and reductions in food waste reduce agricultural demands and well-managed land systems enable reforestation and/or afforestation. SSP2 is a scenario in which societal as well as technological development follows historical patterns (Fricko et al. 2017). Land-based CDR is achieved through bioenergy and BECCS, and to a lesser degree by afforestation and reforestation. SSP3 is a scenario with limited technological progress and land-use regulation. Agricultural demands are high due to resource-intensive consumption and a regionalised world leads to reduced flows for agricultural goods. In SSP3, forest mitigation activities and abatement of agricultural GHG emissions are limited due to major implementation barriers such as low institutional capacities in developing countries and delayed as a consequence of low international cooperation (Fujimori et al. 2017a). Emissions reductions are achieved primarily through the energy sector, including the use of bioenergy and BECCS.

Policies in the Illustrative Futures

SSPs are complemented by a set of shared policy assumptions (Kriegler et al. 2014), indicating the types of policies that may be implemented in each future world. IAMs represent the effect of these policies on the economy, energy system, land use and climate with the caveat that they are assumed to be effective or in some cases the policy goals (e.g., dietary change) are imposed rather than explicitly modelled. In the real world, there are various barriers that can make policy implementation more difficult (see 7.4.9). These barriers will be generally higher in SSP3 than SSP1.

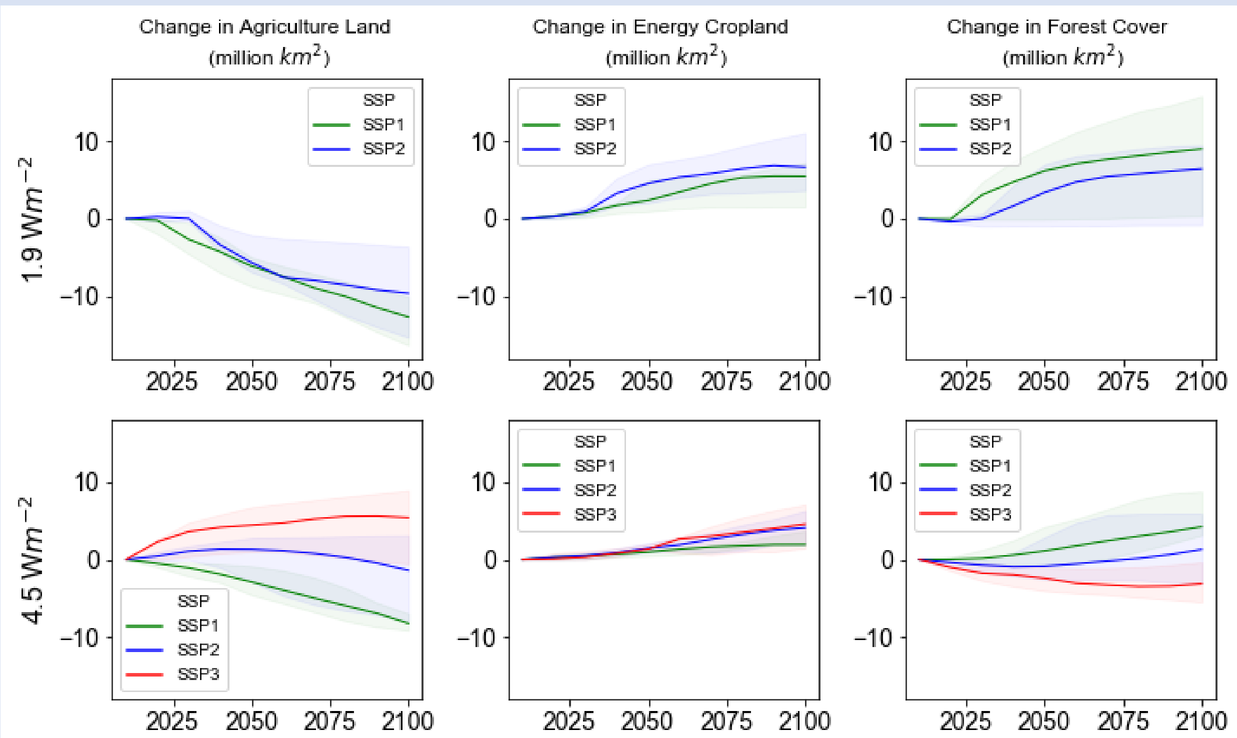
SSP1: A number of policies could support this SSP1 future including: effective carbon pricing, emission trading schemes (including net CO_2 emissions from agriculture), carbon taxes, regulations limiting GHG emissions and air pollution, forest conservation (mix of land-sharing and land sparing) through participation, incentives for ecosystem services and secure tenure, and protecting the environment, microfinance, crop and livelihood insurance, agriculture extension services, agricultural production subsidies, low export tax and import tariff rates on agricultural goods, dietary awareness campaigns, regulations to reduce and taxes on food waste, improved shelf life, sugar/fat taxes, and instruments supporting sustainable land management including payment for ecosystem services, land use zoning, REDD+, standards and certification for sustainable biomass production practices, legal reforms on land ownership and access, legal aid, legal education, including reframing these policies as entitlements for women and small agricultural producers (rather than sustainability) (O'Neill et al. 2017; van Vuuren et al. 2017b) (see 7.4).

SSP2: The same policies that support the SSP1 could support the SSP2 but may be less effective and only moderately successful. Policies may be challenged by adaptation limits (7.4.9), inconsistency in formal and informal institutions in decision making (7.5.1) or result in maladaptation (7.4.7). Moderately successful sustainable land management policies result in some land competition. Land degradation neutrality is moderately successful. Successful policies include those supporting bioenergy and BECCS (Rao et al. 2017; Riahi et al. 2017b; Fricko et al. 2017) (see 7.4.6).

SSP3: Policies that exist in SSP1 may or may not exist in SSP3, and are ineffective (O'Neill et al. 2014c). There are challenges to implementing these policies, as in SSP2. In addition, ineffective sustainable land management policies result in competition for land between agriculture and mitigation. Land degradation neutrality is not achieved (Riahi et al. 2017b). Successful policies include those supporting bioenergy and BECCS (see 7.4.6) (Kriegler et al. 2017; Fujimori et al. 2017a; Rao et al. 2017). Demand side food policies are absent and supply side policies predominate. There is no success in advancing land ownership and access policies for agricultural producer livelihood (7.6.5).

Land use and land cover change

Agricultural area in SSP1 declines as a result of the low population growth, agricultural intensification, low meat consumption, and low food waste. In contrast, SSP3 has high population and strongly declining rates of crop yield growth over time, resulting in increased agricultural land area. The SSP2 falls somewhere in between, with its modest growth in all factors. In the climate policy scenarios consistent with the Paris Agreement, bioenergy/BECCS and reforestation/afforestation play an important role in SSP1 and SSP2. The use of these options, and the impact on land, is larger in scenarios that limit radiative forcing in 2100 to 1.9 Wm^{-2} than in the 4.5 Wm^{-2} scenarios. In SSP3, the expansion of land for agricultural production implies that the use of land-related mitigation options is very limited, and the scenario is characterised by continued deforestation.



Cross-Chapter Box 9 Figure 1: Changes in agricultural land (left), energy cropland (middle) and forest cover (right) under three different SSPs (colours) and two different warming levels (rows). Agricultural land includes both pasture and non-energy cropland. Colours indicate SSPs, with SSP1 shown in green, SSP2 in blue, and SSP3 in red. Shaded area show the range across all IAMs; lines show the median across all models. Models are only included in a figure if they provided results for all SSPs in that panel. There is no SSP3 in the

top row, as 1.9 Wm^{-2} is infeasible in this world. Data is from an update of the IAMC Scenario Explorer developed for the SR15 (Huppmann et al. 2018; Rogelj et al. 2018a).

Implications for mitigation and other land challenges

The combination of baseline emissions development, technology options, and policy support makes it is much easier to reach the climate targets in the SSP1 scenario than in the SSP3 scenario. As a result, carbon prices are much higher in SSP3 than in SSP1. In fact, the 1.9 Wm^{-2} target was found to be infeasible in the SSP3 world (Cross-Chapter Box 9 Table 1). Energy system CO_2 emissions reductions are greater in the SSP3 than in the SSP1 to compensate for the higher land-based CO_2 emissions.

Accounting for mitigation and socioeconomics alone, food prices (an indicator of food insecurity) are higher in SSP3 than in the SSP1 and higher in the 1.9 Wm^{-2} than in the 4.5 Wm^{-2} (Cross-Chapter Box 9 Table 1). Forest cover is higher in the SSP1 than the SSP3 and higher in the 1.9 Wm^{-2} than in the 4.5 Wm^{-2}. Water withdrawals and water scarcity are in general higher in the SSP3 than the SSP1 (Hanasaki et al. 2013a; Graham et al. 2018b) and higher in scenarios with more bioenergy (Hejazi et al. 2014c); however, these indicators have not been quantified for the specific SSP-RCP combinations discussed here.

Climate change, results in higher impacts and risks in the 4.5 Wm^{-2} world than in the 1.9 Wm^{-2} world for a given SSP and these risks are exacerbated in SSP3 compared to SSP1 and SSP2 due to population's higher exposure and vulnerability. For example, the risk of fire is higher in warmer worlds; in the 4.5 Wm^{-2} world, the population living in fire prone regions is higher in the SSP3 (646 million) than in the SSP2 (560 million) (Knorr et al. 2016). Global exposure to multi-sector risk quadruples between the 1.5ºC[10] and 3ºC and is a factor of six higher in the SSP3-3ºC than in the SSP1-1.5ºC (Byers et al. 2018). Future risks resulting from desertification, land degradation and food insecurity are lower in the SSP1 compared to SSP3 at the same level of warming. For example, the transition moderate to high risk of food insecurity occurs between 1.3 and 1.7ºC for the SSP3, but not until 2.5 to 3.5ºC in the SSP1 (Section 7.2).

Table 1: Quantitative indicators for the illustrative pathways. Each cell shows the mean, minimum, and maximum value across IAM models for each indicator and each pathway in 2050 and 2100. All IAMs that provided results for a particular pathway are included here. Note that these indicators exclude the implications of climate change. Data is from an update of the IAMC Scenario Explorer developed for the SR15 (Huppmann et al. 2018; Rogelj et al. 2018b).

[a] The SSP2-19 is infeasible in two models. One of these models sets the maximum carbon price in the SSP1-19; the carbon price range is smaller for the SSP2-19 as this model is excluded there. Carbon prices are higher in the SSP2-19 than the SSP1-19 for every model that provided both simulations.

[a] Food demand estimates include waste.

[b] Animal product demand includes meat and dairy.

Summary

Future pathways for climate and land use include portfolios of response and policy options. Depending on the response options included, policy portfolios implemented, and other underlying socioeconomic drivers, these pathways result in different land-use consequences and their contribution to climate change mitigation. Agricultural area declines by more than 5 Mkm^2 in one SSP but increases by as much as 5 Mkm^2 in another. The amount of energy cropland ranges from nearly zero to 11 Mkm^2, depending on the SSP and the warming target. Forest area declines in the SSP3 but increases substantially in the SSP1. Subsequently, these pathways have different implications for risks related to desertification, land degradation, food insecurity, and terrestrial greenhouse gas fluxes, as well as ecosystem services, biodiversity, and other aspects of sustainable development.

6.4.5 Potential Consequences of Delayed Action

Delayed action, both in terms of overall GHG mitigation across both land and energy sectors, as well as delayed action in implementing the specific response options outlined in this chapter, will exacerbate the existing land challenges due to the continued impacts of climate change and socioeconomic and other pressures; can decrease the potential of response options and increase the costs of deployment; and will deprive communities of immediate co-benefits, among other pressures. The major consequences of delayed action are outlined below:

Delayed action exposes vulnerable people to continued and increasing climate impacts: Slower or delayed action in implementing response options exacerbates existing inequalities and impacts and will increase the number of people vulnerable to climate change, due to population increases and increasing climate impacts (SR15; AR 5). Future climate change will lead to exacerbation of the existing land challenges, increased pressure on agricultural livelihoods, potential for rapid land degradation, and millions more people exposed to food insecurity (Chapters 3, 4, 5; Schmidhuber & Tubiello 2007). Delay can also bring political risks and significant social impacts, including risks to human settlements (particularly in coastal areas), large-scale migration, and conflict (Barnett & Adger 2007; Hsaing et al. 2013). Early action reducing vulnerability and exposure can create an opportunity for a virtual circle of benefits: increased resilient livelihoods, reduced degradation of land, and improved food security (Bohle et al 1994).

Delayed action increases requirements for adaptation: Failure to mitigate climate change will increase requirements for adaptation. For example, it is likely that by 2100 with no mitigation or adaptation, 31–69 million people world-wide could be exposed to flooding (Rasmussen et al., 2018; SR15; Chapter 3); such outcomes could be prevented with investments in both mitigation and adaptation now. Some specific response options (e.g., reduced deforestation and degradation, reduced peatland and wetland conversion) prevent further detrimental effects to the land surface; delaying these options could lead to increased deforestation, conversion, or degradation, serving as increased sources of GHGs and having concomitant negative impacts on biodiversity and ecosystem services (section 6.2). Response options that aim at land restoration and rehabilitation can serve as adaptation mechanisms for communities facing climatic stresses like precipitation variability and changes in land quality, as well as providing benefits in terms of mitigation.

Delayed action increases response costs and reduces economic growth: Early action on reducing emissions through mitigation is estimated to result in both smaller temperature increases as well as lower mitigation costs than delayed action (Sanderson et al. 2016; Luderer et al. 2013; Fujimori et al., 2016; Rose et al., 2017; van Soest et al., 2017; Luderer et al., 2018). The cost of inaction to address mitigation, adaptation, and sustainable land use exceeds the cost of immediate action in most countries, depending on how damage functions and social cost of carbon are calculated (Dell et al. 2023; Moore & Diaz 2015). Costs of acting now would be one to two orders of magnitude lower than economic damages from delayed action, including both damage to assets from climate impacts, as well potentially reduced economic growth, particularly in developing countries (Moore and Diaz 2015; Luderer et al. 2013; 2016). Increased health costs and costs of energy (e.g. to run air-conditioners to combat increased heat waves) in the US by the end of the century alone are estimated to range from 10-58% of US GDP in 2010 (Deschênes and Greenstone 2011).

Delay also increases the costs of both mitigation and adaptation actions at later dates. In models of climate-economic interactions, deferral of emissions reductions now requires trade-offs leading to higher costs of several orders of magnitude and risks of higher temperatures in the longer term (Luderer et al 2013). Further, costs of action are likely to increase over time due to the increased severity of challenges in future scenarios.

Conversely, timely responses in implementing response options brings economic benefits. Carbon pricing is one component of economic responses to encourage adoption of response options (Jakob et al. 2016), but carbon pricing alone can induce higher risk in comparison to other scenarios and pathways that include additional targeted sustainability measures, such as promotion of less material- and energy-intensive lifestyles and healthier diets as noted in our response options (Bertram et al. 2018). While short term costs of deployment of actions may increase, better attainment of a broad set of sustainability targets can be achieved through these combined measures (Bertram et al. 2018).

There are also investments now that can lead to immediate savings in terms of avoided damages; for example, for each dollar spent on DMR, countries accrue avoided disaster-related economic losses of

USD4 or more (Mechler 2016). While they can require upfront investment, the economic benefits of actions to ensure sustainable land management, such as increased soil organic carbon, can more than double the economic value of rangelands and improve crop yields (Chapter 4; section 6.2).

Delayed action reduces future policy space and decreases efficacy of some response options: The potential for some response options decreases as climate change increases; for example, climate alters the sink capacity for soil and vegetation carbon sequestration, reducing the potential for increased soil organic carbon, afforestation, and reforestation (6.4.2). Additionally, climate change affects the productivity of bioenergy crops, influencing the potential mitigation of bioenergy and BECCS (Section 6.4.4).

For response options in the supply chain, demand side management, and risk management, while the consequences of delayed action are apparent in terms of continued GHG emissions from drivers, the tools for response options are not made more difficult by delay and could be deployed at any time. Additionally, given increasing pressures on land as a consequence of delay, some policy response options may become more cost effective while others become costlier. For example, over time, land-based mitigation measures like forest and ecosystem protection are likely to increase land scarcity leading to higher food prices, while demand side measures, like reduced impact diets and reducing waste, are less likely to raise food prices in economic models (Stevanović et al. 2017).

For risk management, some response options provide timely and rapidly-deployable solutions for preventing further problems, such as disaster risk management and risk sharing instruments. For example, early warning systems serve multiple roles in protecting lives and property and helping people adapt to longer-term climate changes and can be used immediately.

Delaying action can also result in problems of irreversibility of biophysical impacts and tipping points: Early action provides a potential way to avoid irreversibility - such as degradation of ecosystems that cannot be restored to their original baseline - and tipping points, whereby ecological or climate systems abruptly shift to a new state. Ecosystems, such as peatlands, are particularly vulnerable to irreversibility because of the difficulties of rewetting to original states (Section 6.2), and dryland grazing systems are vulnerable to tipping points when ground cover falls below 50%, after which productivity falls, infiltration declines, and erosion increases (Chapters 3 and 4). Further, tipping points can be especially challenging for human populations to adapt to, given lack of prior experience with such system shifts (Kates et al. 2012; Nuttall 2012).

Policy responses require lead time for implementation; delay makes this worse: For all the response options, particularly those that need to be deployed through policy implementation, there are unavoidable lags in this cycle. 'Policy lags', by which implementation is delayed by the slowness of the policy implementation cycle, are significant across many land-based, response options (Brown et al. 2019). Further, the behavioural change necessary to achieve some demand-side and risk management response options often takes a long time and delay only lengthens this process (Stern 1992; Steg & Vlek 2009). For example, actively promoting the need for healthier and more sustainable diets through individual dietary decisions is an important underpinning and enabling step for future changes, but is likely to be a slow-moving process, and delay in beginning will only exacerbate this.

Delay can lead to lock-in: Delay in implementation can cause 'lock-in' as decisions made today can constrain future development and pathways. For example, decisions made now on where to build infrastructure, make investments and deploy technologies, will have longer-term (decades-long) ramifications due to inertia of capital stocks (van Soest et al. 2017). In tandem, the vulnerability of the poor is likely to be exacerbated by climate change creating a vicious circle of "lock in" whereby an increasing share of the dwindling carbon budget may be needed to assist with improved energy use for the poorest (Lamb and Rao 2015).

Delay can increase the need for widespread deployment of land-based mitigation (afforestation, BECCS) (IPCC 2018; Streffler et al. 2018): Further delays in mitigation could result in an increased need for CDR options later; for example, delayed mitigation requires a 10% increase in cumulative CDR over the century (IPCC 2018).Similarly, strengthening near-term mitigation effort can reduce the CDR requirements in 2100 by a factor of 2-8 (Strefler et al., 2018). Conversely, scenarios with limited CDR require earlier emissions reductions (van Vuuren et al. 2017b) and may make more stringent mitigation scenarios, like the 1.5C, infeasible (Kriegler et al. 2018a,b).

Frequently Asked Questions

FAQ 6.1: What types of land-based options can help mitigate and adapt to climate change?

Land-based options that help mitigate climate change are various and differ greatly in their mitigation potential. The options with the moderate to large mitigation potential, and no adverse side-effects, include options that decrease pressure on land (e.g. by reducing the land needed for food production) and those that help to maintain or increase carbon stores both aboveground (e.g. forest measures, agroforestry, fire management) and belowground (e.g. increased soil organic matter or reduced losses, cropland and grazing land management, urban land management, reduced deforestation and forest degradation). These options also have co-benefits for adaptation by improving health, increasing yields, flood attenuation and reducing urban heat island effects. Another group of practices aim at reducing greenhouse emission sources, such as livestock management or nitrogen fertilisation management. Land-based options delivering climate change adaptation may be structural (e.g. irrigation and drainage systems, flood and landslide control), technological (e.g. new adapted crop varieties, changing planting zones and dates, using climate forecasts), or socio-economic and institutional (e.g. regulation of land use, associativity between farmers). Some adaptation options (e.g. new planting zones, irrigation) may have adverse-side effects for biodiversity and water. Adaptation options may be planned, such as those implemented at regional, national or municipal level (top-down approaches), or autonomous, such as many technological decisions taken by farmers and local inhabitants. In any case, their effectiveness depends greatly on the achievement of resilience against extreme events (e.g. floods, droughts, heat waves, etc.).

FAQ 6.2: Which land-based mitigation measures could affect desertification, land degradation or food security?

Some options for mitigating climate change are based on increasing carbon stores both above and below ground, so mitigation is usually related to increases in soil organic matter content and increased land cover by perennial vegetation. There is a direct relationship, with very few or no adverse side-effects for prevention or reversal of desertification and land degradation and the achievement of food security. This is so because both desertification and land degradation are closely associated with soil organic matter losses and the presence of bare ground surfaces. Food security depends on the achievement of healthy crops and high and stable yields over time, which is difficult to achieve in poor soils that are low in organic matter.

FAQ 6.3: What is the role of bioenergy in climate change mitigation and what are its challenges?

Plants absorb carbon as they grow. If plant-based material (biomass) is used for energy, the carbon it absorbed from the atmosphere is released back. Traditional use of bioenergy for cooking and heating is still widespread throughout the world. Modern conversion to electricity, heat, gas and liquid fuels can reduce the need to burn fossil fuels and this can reduce greenhouse gas emissions, helping to mitigate climate change. However, the total amount of emissions avoided depends on the type of biomass, where it is grown, how it is converted to energy, and what type of energy source it displaces. Some types of bioenergy require dedicated land (e.g., canola for biodiesel, perennial grasses, short rotation woody crops), while others can be co-produced or use agricultural or industrial residues (e.g., residues from sugar and starch crops for ethanol, manure for biogas). Depending on where, how, and the amount of bioenergy crops that are grown, the use of dedicated land for bioenergy could compete with food crops or other mitigation options. It could also result in land degradation, deforestation or biodiversity loss. In some circumstances, however, bioenergy can be beneficial for land, for example by increasing soil organic carbon. The use of co-products and residues for bioenergy limits the competition for land with food but could result in land degradation if carbon and nutrient-rich material is removed that would otherwise be left on the land. On the other hand, the by-products of some bioenergy conversion processes can be returned to the land as a fertiliser and may have other co-benefits (e.g. reducing pollution associated with manure slurry).

Supplementary Material for Chapter 6: Interlinkages between Desertification, Land Degradation, Food Security and GHG fluxes: synergies, trade-offs and Integrated Response Options

Supplementary Information for Section 6.4.1

Section 6.4.1 includes tables of feasibility dimensions for each of the 40 response options. This section includes the supporting material for those classifications.

Table SM6.1 Feasibility of land management response options in agriculture, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Increased food productivity				Limited ability to define and measure indicators of sustainable intensification (Barnes and Thomson 2014b)	better access to credit, services, inputs and markets (Schut et al. 2016)	educational (e.g., educational needs of women; Pretty and Bharucha 2014, and cultural / behavioural (Martin et al. 2015)	since increasing food productivity can be limited by climatic and environmental factors (Olesen et al. 2002)
Improved cropland management			USD74 to USD226 ha^{-1}	e.g., need for further development of nitrification inhibitors (Singh and Verma 2007b)	can be institutional in some regions (e.g., poor sustainability frameworks, Madlener et al. 2006)	educational (e.g., lack of knowledge; Reichardt et al. 2009b)and cultural / behavioural (e.g., promotion of cover crops needs to account for farmers' needs; Roesch-McNally et al. 2017)	e.g., land access (Bryan et al. 2009b; Bustamante et al. 2014c)

Improved grazing land management			< USD1 kg of meat^{-1} (Rolfe et al., 2010)	e.g., need for further development of nitrification inhibitors (Singh and Verma 2007b)	can be institutional in some regions (e.g., need for extension services; Ndoro et al., 2014)	educational (e.g., poor knowledge of best animal husbandry practices among farmers; Ndoro et al., 2014), and cultural / behavioural (e.g. strong cultural importance of livestock and traditional practices in some communities (Herrero et al. 2016)	e.g., unless degraded, grazing lands are already closer to saturation than croplands; Smith et al. 2015
Improved livestock management			USD120 to USD621 ha^{-1} (Barnhart et al., 2000)	e.g., many dietary additives are still at low technology readiness level; Beauchemin et al., 2008	can be institutional in some regions (e.g., need for extension services; Ndoro et al., 2014),	educational (e.g., poor knowledge of best animal husbandry practices among farmers; Ndoro et al., 2014), and cultural / behavioural (e.g., strong cultural importance of livestock in some communities (Herrero et al. 2016)	e.g., climate suitability of different cattle breeds in a changing climate (Thornton et al. 2009b; Rojas-Downing et al. 2017b)
Agroforestry			< USD5 tCO_2e^{-1} (Torres et al. 2010) Note that lack of reliable financial support	There are likely to be relatively few technological barriers (Smith et al. 2007).	institutional in some regions (e.g., seed availability; (Lillesø et al. 2011)	educational (e.g., poor knowledge of how best to integrate trees into agro-ecosystems, (Meijer et al. 2015b); lack of	susceptibility to pests (Sileshi et al. 2008)

			(Hernandez-Morcillo et al. 2018) could be a barrier.			information, (Hernandez-Morcillo et al. 2018) and cultural / behavioural (e.g., farmers perceptions, Meijer et al. 2015b)	
Agricultural diversification			Minimal (Wimmer et al. 2016) Diversification results in cost-saving and risk reduction, thus expected cost is minimal. Note that not always economically viable (Barnes et al. 2015)	technological, biophysical, educational, and cultural barriers may emerge that limit the adoption of more diverse farming systems by farmers (Barnett and Palutikof 2015; Ahmed and Stepp 2016a); Roesch-McNally et al. 2016)		technological, biophysical, educational, and cultural barriers may emerge that limit the adoption of more diverse farming systems by farmers (Barnett and Palutikof 2015; Ahmed and Stepp 2016a); Roesch-McNally et al. 2016)	technological, biophysical, educational, and cultural barriers may emerge that limit the adoption of more diverse farming systems by farmers (Barnett and Palutikof 2015; Ahmed and Stepp 2016a); Roesch-McNally et al. 2016)
Reduced grassland conversion to cropland			Minimal (Garibaldi et al. 2017) With increased demand for livestock products, it is expected that livestock has higher returns than crops. Note that avoiding conversion is low cost, but there	Since the response option involves not cultivating a current grassland, there are likely to be few biophysical or technological barriers	There could be institutional barriers in some regions (e.g., poor governance to prevent conversion)	educational (e.g., poor knowledge of the impacts of ploughing grasslands, and cultural / behavioural (e.g., strong cultural importance of crop production in some communities	Since the response option involves not cultivating a current grassland, there are likely to be few biophysical or technological barriers

			may be significant opportunity costs associated with foregone production of crops.				
Integrated water management			Minimal (Lubell et al. 2011) Integrated water management expected to reduce production costs and increase economic efficiency				

Table SM6.2 Feasibility of land management response options in forests, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Improved forest management			USD70 to USD160 ha^{-1} (Singer 2016)		e.g., better access to credit and markets, etc.	educational (e.g., limited knowledge of the most appropriate techniques)	Forest management affects the climate also through biophysical effects and the emissions of biogenic volatile organic compounds (BVOCs), which are both influenced by species composition.
Reduced deforestation and			USD500 to USD2600 ha^{-1}		e.g., land tenure, economic	educational (e.g., little information	e.g., susceptibility to climate and

degradation			Agricultural expansion is the major driver of deforestation in developing countries. Cost of reducing of deforestation is based on opportunity cost of not growing the most common crop in developing countries (Maize) for six years to reach tree maturity, with yield of 8 t ha^{-1} (high); 5 tons ha^{-1} (medium) & 1.5 t ha^{-1} & price of USD329 t^{-1}. Also, reduced deforestation practices have relatively moderate costs, but they requires transaction and administration costs (Overmars et al. ; Kindermann et al. 2008).		disincentives and transaction costs (Kindermann et al. 2008)	available in some regions) and cultural (different realities, e.g., small holder versus industrial production)	other unpredicted events (Ellison et al. 2017a)
Reforestation and forest restoration			USD10 to USD100 $tCO2e^{-1}$ (McLaren 2012b)			educational (e.g., low genetic diversity of planted forests)	e.g. availability of native species seedlings for planting

						and cultural (e.g., care of forest cultures)	
Afforestation			USD10 to USD100 $tCO2e^{-1}$ (McLaren 2012b)		e.g., policy makers commitment (Idris Medugu et al. 2010b)		

Table SM6.3 Feasibility of land management response options for soils, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Increased soil organic carbon content			USD50 to USD170 ha^{-1} (FAO 2014) Based on smallholder farming - which accounts for 72% farms in the world; India farmers (medium farmers) and largescale farmers in the US (FAO 2014). The cost indicated is only for manure application and ignores other costs done under business as usual (BAU). Assumes application of 10 t ha^{-1} of organic	e.g., difficult to measure and verify; (Smith 2006)	Can be institutional in some regions (e.g., lack of institutional capacity; Bustamante et al. 2014c)	educational (e.g., poor knowledge of best practices among farmers; (Reichardt et al. 2009b) though cultural / behavioural barriers are likely to be small compared to other barriers (Smith et al. 2007; Wollenberg et al. 2016b)	e.g., soil type; (Baveye et al. 2018b)

			manure after every three years and minimum tillage.				
Reduced soil erosion			USD50 to USD240 ha^{-1} (Morokong et al. 2019) Based on prevention of soil erosion using terraces using rocks. Costs reported is only for avoided loss of carbon sequestration.	Limited technology choices and technical support (Haregeweyn et al. 2015)	For instance, in Ethiopia farmers have shown an increased understanding of the soil erosion problem, but soil conservation programs face a host of barriers related to limited access to capital, limited benefits, land tenure insecurity (Haregeweyn et al. 2015)	Poor community participation (Haregeweyn et al. 2015)	
Reduced soil salinisation			USD50 to USD250 ha^{-1} (ICARDA 2012) For NENA region, salinity control recommended practice is deep ploughing, done once every 4 to 5 years to breakdown the hardpan subsoil. Deep ploughing costs USD200 ha^{-1} for the four-year cycle or USD50 ha^{-1} for each cropping season.	e.g., lack of appropriate irrigation technology; (Machado and Serralheiro 2017b; CGIAR 2016; Bhattacharyya et al. 2015)	Lack of alternative irrigation infrastructure; (Evans and Sadler 2008; CGIAR 2016)	educational (poor knowledge of the causes and salinisation and how to address it; (Greene et al. 2016; Dagar et al. 2016b), and cultural / behavioural (persistence of traditional practices; (Greene et al. 2016; Dagar et al. 2016b)	e.g., lack of alternative water sources; (Bhattacharyya et al. 2015; Dagar et al. 2016b)

Reduced soil compaction			Negative cost (McLaren 2012b)	Both compaction process and remediation technologies are well-known (Antille et al. 2016b) but technological barriers exist (e.g., few decision support systems for implementation of precision management of traffic compaction)		educational (knowledge gaps; Antille et al. 2016b)	Some soils are prone to compaction (Antille et al. 2016b)
Biochar addition to soil			USD100 to USD800 $tCO2e^{-1}$ (McLaren 2012b) A small amount of biochar potential could be available at negative cost, and some at low cost, depending on markets for the biochar as a soil amendment (Shackley et al. 2011b; Meyer et al. 2011; Dickinson et al. 2014)	e.g., feedstock and pyrolysis temperature have large impacts on biochar properties	Can be institutional in some regions (e.g., lack of quality standards; Guo et al. 2016)	educational (e.g., low awareness among end users; Guo et al. 2016) and cultural / behavioural (Guo et al. 2016)	e.g., land available for biomass production (Woolf et al. 2010)

Table SM6.4 Feasibility of land management response options in any/other ecosystems, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Fire management			USD0.2 to USD6.5 billion per country per year (USA, Australia, Canada)	Technologies for fire management exist, but the cost of its implementation is relatively moderate, since it requires constant maintenance (North et al. 2015a) and can be excessive for some local communities.	e.g., lack of social or political acceptance (Freeman et al. 2017b)	educational (e.g., poor knowledge of best practices, liability issues, casualty risks and little tolerance for management errors; North et al. 2015a)	e.g., susceptibility to climate and other unpredicted events (Hurteau et al. 2014) or steep or remote areas to its application (North et al. 2015a)
Reduced landslides and natural hazards				The implementation of practices for management of landslides and natural hazards is based on engineering works and more resilient cropping systems (Noble et al. 2014; Gill and Malamud 2017b), which are is often limited by their high costs, as well as biophysical, technological and educational barriers.	In the tropics, the most cited barriers for implementing landslide risk reduction measures are scientific and political in nature, and the ratio of implemented versus recommended landslide risk reduction measures is low for most landslide risk reduction components (Maes et al. 2017b).	The implementation of practices for management of landslides and natural hazards is based on engineering works and more resilient cropping systems (Noble et al. 2014; Gill and Malamud 2017b), which are often limited by their high costs, as well as biophysical, technological and educational barriers.	The implementation of practices for management of landslides and natural hazards is based on engineering works and more resilient cropping systems (Noble et al. 2014; Gill and Malamud 2017b), which are is often limited by their high costs, as well as biophysical, technological and educational barriers.
Reduced pollution including			USD2 to USD13 per household	e.g., lack of technology to	e.g., poor regulation and		Since air pollution is transboundary,

acidification			(Houtven et al. 2017)	inject fertilisers below ground to prevent ammonia emissions; Shah et al., 2018	enforcement of environmental regulations; Yamineva and Romppanen, 2017		sources are often far distant from the site of impact; Begum et al., 2011
Management of invasive species / encroachment			USD500 to USD6632 per ha (Jardine et al. 2017) High cost is for California invasive alien species control; low cost from control in Massachusetts	In the case of natural enemies can be technological (Dresner et al. 2015)	Where agricultural extension and advice services are poorly developed	Education can be a barrier, where populations are unaware of the damage caused by the invasive species. Cultural / behavioural barriers are likely to be small.	Restoration programmes can take a long time (Dresner et al. 2015)
Restoration and reduced conversion of coastal wetlands			Costs for coastal wetland restoration projects vary, but they can be cost-effective at scale (Erwin 2009)		Can be institutional in some regions (e.g., poor governance of wetland use in some regions; (Lotze et al. 2006)	educational (e.g., lack of knowledge of impact of wetland conversion), though technological and cultural / behavioural barriers are likely to be small compared to other barriers.	e.g., loss of large predators, herbivores, spawning and nursery habitat; (Lotze et al. 2006)
Restoration and reduced conversion of peatlands			USD4 to USD20 $tCO2e^{-1}$ (McLaren 2012b)		An be institutional in some regions (e.g., lack of inputs; Bonn et al. 2014)	educational (e.g., lack of skilled labour; Bonn et al. 2014), though technological and cultural / behavioural barriers are likely to be small	e.g., site inaccessibility; Bonn et al. 2014)

						compared to other barriers.	
Biodiversity conservation			USD10 to USD50 $tCO2e^{-1}$ (Minx et al. 2018)				

Table SM6.5 Feasibility of land management response options specifically for CDR, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Enhanced weathering of minerals			USD10 to USD40 $tCO2e^{-1}$ (McLaren 2012b) The main cost (and large energy input) is in the mining and comminution of the minerals (Renforth et al. 2012) with higher total costs compared to other low cost land management options (Smith et al. 2016a).	High energy costs of comminution; Smith et al. 2016a	In some regions (e.g., lack of infrastructure for this new technology; Taylor et al. 2016c)	Educational (e.g., lack of knowledge of how to use these new materials in agriculture). Cultural barriers could occur in some regions, for example, due to minerals lying under undisturbed natural areas where mining might generate public acceptance issues (e.g., Renforth et al. 2012)	e.g., limited and inaccessible mineral formations (Renforth et al. 2012)
Bioenergy and BECCS		BECCS "is one of the NET options that is less vulnerable to reversal" (Fuss et al. 2018)	USD50 to USD250 $tCO2e^{-1}$ (McLaren 2012b)	While there are a few small BECCS demonstration facilities, BECCS has not been implemented at	Institutional barriers include governance issues (Gough 2016)	Cultural barriers include social acceptance (Sanchez and Kammen 2016b) with CCS facing	Competition for land and water

				scale (Kemper 2015b)		concerns of safety and environmental issues and bioenergy facing additional scrutiny because of competition for land and water.	

Table SM6.6 Feasibility of demand management response options, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Dietary change				Inadequate storage options for e.g. fresh fruit and vegetables	Barriers might also be institutional in some regions (e.g., poorly developed dietary health advice, Wardle et al. 2000b)	cultural / behavioural (e.g., diets are deeply culturally embedded and behaviour change is extremely difficult to effect, even when health benefits are well known; Macdiarmid et al., 2016); educational (e.g., poor knowledge of what constitutes a healthy diet; Wardle et al. 2000b)	poor accessibility of healthy foods such and fruit and vegetables (e.g., Hearn et al. 1998b; Lock et al. 2005)
Reduced post-harvest losses				Lack of low-cost storage and preservation technologies	Barriers are largely institutional, since solutions may require	There are few biophysical, educational or cultural barriers, since preventing	There are few biophysical, educational or cultural barriers, since preventing

					dismantling and redesigning current food value chains	food loss is a priority in many developing countries.	food loss is a priority in many developing countries.
Reduced food waste (consumer or retailer)				Barriers in developing countries include reliability of transportation networks, market reliability, education, technology, capacity, and infrastructure (Kummu et al. 2012).	Specific barriers to reducing consumption waste in industrialised countries include inconvenience, lack of financial incentives, lack of public awareness, low cost of food, quality standards and regulations, consumer's ability to buy food products at any time, generalised oversupply in the distribution, and low prioritisation, among others (Kummu et al.); (Graham-Rowe et al. 2014); Diaz-Ruiz et al., 2018). Barriers in developing countries include reliability of transportation networks, market reliability, education, technology, capacity, and	Specific barriers to reducing consumption waste in industrialised countries include inconvenience, lack of financial incentives, lack of public awareness, and low prioritisation (Kummu et al.); (Graham-Rowe et al. 2014). Barriers in developing countries include reliability of transportation networks, market reliability, education, technology, capacity, and infrastructure (Kummu et al.)	

					infrastructure (Kummu et al.)		
Material substitution			Negligible (McLaren 2012b)	Improved treatments to prevent against fire and moisture needed (Ramage et al. 2017b)	Construction companies hesitant to take risks associated with wooden buildings and insurance companies rate wooden buildings as higher risk (Gustavson et al., 2006)	People perceive adverse effects of wood products on forests and increased risk of fire (Gustavson et al. 2006)	

Table SM6.7 Feasibility of supply management response options, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Sustainable sourcing	Reversibility could be an issue and while there are low cost options, the implementations can be expensive.	Reversibility could be an issue and while there are low cost options, the implementations can be expensive.			There are institutional barriers in some contexts (e.g., in low income African, Asian and Latin American countries where challenges associated with food insecurity and climate change vulnerability are more acute) (Ingram et al.	No obvious biophysical or cultural barriers	No obvious biophysical or cultural barriers

					2016a)		
Management of supply chains					political will within trade regimes, economic laissez-faire policies that discourage interventions in markets, and the difficulties of coordination across economic sectors (Poulton et al. 2006; Cohen et al. 2009; Gilbert 2012b)		
Enhanced urban food systems				There are likely to be few biophysical, technological or cultural / behavioural barriers to implementing improved urban food systems, though institutional and education barriers could play a role.	There are likely to be few biophysical, technological or cultural / behavioural barriers to implementing improved urban food systems, though institutional and education barriers could play a role.	There are likely to be few biophysical, technological or cultural / behavioural barriers to implementing improved urban food systems, though institutional and education barriers could play a role.	There are likely to be few biophysical, technological or cultural / behavioural barriers to implementing improved urban food systems, though institutional and education barriers could play a role.
Improved food processing and retailing			The implementation of strategies to improve the efficiency and sustainability of retail and agri-food industries can be expensive	Adoption of specific sustainability instruments and eco-innovation practices	Successful implementation is dependent on organisational capacity, the agility and flexibility of business strategies, the	No obvious cultural/behavioural barriers, but educational barriers exist	No obvious biophysical and cultural/behavioural barriers

					strengthening of public-private policies and effectiveness of supply-chain governance.		
Improved energy use in food systems				e.g., low levels of farm mechanisation	e.g., energy efficiency in agriculture depends strongly on the technology level (Vlontzos et al. 2014)	educational (e.g., poor knowledge of alternative energy sources), and behavioural / cultural (e.g., high levels of repetitive labour, making farming unattractive to the youth, and disproportionally affecting women; (Baudron et al. 2015b)	

Table SM6.8 Feasibility of risk management response options, considering cost, technological, institutional, socio-cultural and environmental and geophysical barriers and saturation and reversibility

Response option	Saturation	Reversibility	Cost	Technological	Institutional	Socio-cultural	Environmental and geophysical
Management of urban sprawl			USD0.5 to USD3 trillion yr^{-1} globally (New Climate Economy 2018) Global cost of prevention of urban sprawl done		Barriers to policies against urban sprawl include institutional barriers to integrated land use planning and the costs to national		

			by: densification; provision of sustainable and affordable housing; and investment in shared, electric, and low-carbon transport.		governments of restricting or buying back development rights (Tan et al. 2009)		
Livelihood diversification			Barriers to diversification include the fact that poorer households and female headed households may lack assets to invest in new income streams or have a lack of education about new income sources (Berman et al. 2012b; Ahmed and Stepp 2016a; Ngigi et al. 2017)			Barriers to diversification include the fact that poorer households and female headed households may lack assets to invest in new income streams or have a lack of education about new income sources (Berman et al. 2012b; Ahmed and Stepp 2016a; Ngigi et al. 2017)	
Use of local seeds						Barriers to seed sovereignty include concerns about equitability in access to seed networks and the difficulty of sustaining such projects when development donors leave (Reisman 2017b),	

						and disputes over the intellectual property rights associated with seeds (Timmermann and Robaey 2016)	
Disaster risk management			Barriers to EWS include cost; an early warning system for the 80 most climate vulnerable countries in the world is estimated to cost USD 2 billion over five years to develop (Hallegatte 2012).		Institutional and governance barriers such as coordination and synchronisation among levels also effect some EWS (Birkmann et al. 2015b).		
Risk sharing instruments			USD10 to USD90 ha^{-1} (Schnitkey 2017) Insurance cost depends on value of crop. We use maize as an example in US (high) and Sub-Saharan Africa (low).				

1 # Supplementary Information for Section 6.4.3

2 Section 6.4.3 includes tables regarding interactions for each of the 40 response options with Nature's Contributions to People (NCP) and Sustainable
3 Development Goals (SDG). This section includes the supporting material for those classifications.

4 **Table SM6.9 Impacts on Nature's Contributions to People of integrated response options based on land management**

Integrated response options based on land management		**Habitat creation and maintenance**	**Pollination and dispersal of seeds and other propagules**	**Regulation of air quality**	**Regulation of climate**	**Regulation of ocean acidification**	**Regulation of freshwater quantity, flow and timing**	**Regulation of freshwater and coastal water quality**	**Formation, protection and decontamination of soils and sediments**	**Regulation of hazards and extreme events**	**Regulation of organisms detrimental to humans**	**Energy**	**Food and feed**	**Materials and assistance**	**Medicinal, biochemical and genetic resources**	**Learning and inspiration**	**Physical and psychological experiences**	**Supporting identities**	**Maintenance of options**
	Increased food productivity	Higher productivity spares land (e.g. Balmford et al. 2018) especially if intensification is done sustainably.	Likely may reduce native pollinators if reliant on increased chemical inputs (Potts et al. 2010) but not if through sustainable intensification.	N/A	N/A	Increased food productivity might be achieved through increased pesticide or fertiliser use, which causes runoff and dead zones in oceans (Beusen et al. 2016).	Food productivity increases could impact water quality if increases in chemicals used, but evidence is mixed on sustainable intensification (Rockström et al. 2009; Mueller et al. 2012).	Food productivity increases could impact water flow due to demand for irrigation (Rockström et al. 2009; Mueller et al. 2012).	Intensification through additional input of nitrogen fertiliser can result in negative impacts on climate, soil, water and air pollution (Tilman et al. 2002).	N/A	Increasing food production through agro-chemicals may increase pest resistance over time (Tilman et al. 2002).	N/A	Sustainable intensification has potential to close yield gaps (Tilman et al. 2011).	N/A	N/A	N/A	N/A	N/A	N/A
	Improved cropland management	Improved cropland management can contribute to diverse agroecosystems (Tscharntke et al. 2005) and promotes soil biodiversity (Oehl et al. 2017)	Better crop management can contribute to maintaining native pollinators (Gardiner et al. 2009).	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Cropland conversion has major impacts on water quantity (Scanlon et al. 2007). Cropland management practices such as conservation tillage improve downstream water quality (Fawcett et al. 1994).	Cropland conversion leads to poorer water quality due to runoff (Scanlon et al. 2007).	Improved cropland management has positive impacts on soils (see main text) (Kern et al. 2003).	N/A	Some forms of improved cropland management can decrease pathogens and pests (Tscharntke et al. 2016).	N.A	Conservation agriculture contributes to food productivity and reduces food insecurity (Rosegrant and Cline 2003 ; Dar & Gowda 2011; Godfrey & Garnett 2014)	N/A	N/A	N/A	N/A	Many cropping systems have cultural components (Tenberg et al 2012).	N/A
Agriculture	**Improved grazing land management**	Can contribute to improved habitat (Pons et al. 2003; Plantureux et al 2005).	N/A	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Likely will improve water quality (Hibbert 1983).	Likely will improve water flow (Hibbert 1983)..	Improved grassland management increases soil carbon and quality (Conant et al. 2001).	N/A	N/A	N/A	Improved grassland management could contribute to food security (O'Mara 2012)	Grassland management can provide other materials (e.g. biofuel materials)	N/A	N/A	N/A	Many pastoralists have close cultural connections to livestock (Ainslie 2013)	N/A

														(Prochnow et al. 2009)					
	Improved livestock management	Can contribute to improved habitat if more efficient animals used, leading to less feed required (Strassburg et al. 2014)	N/A	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	N/A	Improved industrial livestock production can reduce water contamination (e.g. reduced effluents) (Hooda et al 2000). Improved livestock management can contribute to better water quality such as through manure management (Herrero & Thornton 2013)	N/A	N/A	N/A	N/A	Improved livestock management can contribute to reduced food insecurity among smallholder pastoralists (van't Hooft et al. 2012).	Livestock production also produces materials for use (leather, etc) (Hesse 2006)	N/A	N/A	N/A	Many pastoralists have close cultural connections to livestock (Ainslie 2013)	N/A
	Agro-forestry	Agroforestry mimics natural diversity and can improve habitat (Jose 2009).	Even intensive agroforestry can be beneficial for pollinators (Klein et al 2002).	Trees in the landscape can remove air pollutants (Sutton et al., 2007)	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Planting trees on farms can increase soil water infiltration capacity (Ilstedt et al. 2007). Agroforestry can be used to increase ecosystem services benefits, such as water quantity and quality (Jose 2009)	N/A	Likely to improve soil (Rao et al. 1997)	Agroforestry can reduce vulnerability to hazards like wind and drought (Thorlakson & Neufeldt 2012).	Landscape diversity generally improves opportunities for biological pest control (Gardiner et al. 2009); reduces pests/pathogens on smallholder farms (Vignola et al., 2015)	Agroforestry can be used to produce biomass for energy (Mbow et al., 2014).	Agroforestry contributes to food productivity and reduces food insecurity (Mbow et al. 2014).	Produces timber, firewood and animal fodder (Mbow et al., 2014)	Can provide medicinal and other resources (Rao et al., 2004).	N/A	N/A	Many cropping systems have cultural components (Rao et al., 2014)	Can contribute to maintaining diversity through native plantings (Rao et al., 2014).
	Agricultural diversification	Crop diversification improves resilience through enhanced diversity to mimic more natural systems and provide in-field habitat for natural pest defences (Lin 2011)	Diversification can enhance pollinator diversity (Altieri & Letrouneau 1982; Sardinas & Kremen 2015)	N/A	N/A	N.A	N/A	N/A	Diversification can introduce some crops that may have positive soil qualities (eg nitrogen fixation) and crop rotation with multiple crops can improve soil carbon (McDaniel et al. 2014).	N/A	Diverse agroecosystems tend to have less detrimental impacts from pests (Gardiner et al 2009; Altieri & Letourneau 1982)	N/A	Diversification is associated with increased access to income and additional food sources for the farming household (Pretty et al. 2003; Ebert 2014)	Diversification could provide additional materials and farm benefits (Van Huylenbroeck et al. 007)	Some agricultural diversification can produce medicinal plants (Chauhan 2010).	N/A	N/A	Many cropping systems have cultural components (Rao et al., 2014)	Can contribute to maintaining diversity through native plantings (Sardiñas et al. 2015)

	Avoidance of conversion of grassland to cropland	Can preserve natural habitat (Peeters, 2009)	N/A	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Will likely improve water quality (inferred from improved soil quality in Saziozzi et al., 2001)	Will likely improve water flow (inferred from improved soil quality in Saziozzi et al., 2001)	Will improve soil quality (Saziozzi et al., 2001)	N/A	Diverse agroecosystems tend to have less detrimental impacts from pests (Gardiner et al 2009; Altieri & Letourneau 1982)	N/A	Reducing cropland conversion can reduce food production (West et al. 2010).	N/A	N/A	N/A	N/A	N/A	Retaining natural ecosystems can preserve genetic diversity (Ekins et al., 2003).
	Integrated water management	Ecosystem health and services can be enhanced by improving water management (Boelee E and E 2011). Securing ecosystem (Lloyd et al. 2013), integrated ecosystem-based management into water resources planning and management, linking ecosystem services and water security (Nicole Bernex 2016), improving correlation between amount of water resources and supply ecosystem services, combining water resources management and supply of ecosystem services (Liu et al. 2016).	Some integrated water management strategies generate synergies between multiple ecosystem services, such as pollination, yield and farm profitability (Hipólito et. al, 2018).	IWM practices exert strong influence on ecosystem structure and function, with potentially large implications for regulating air quality (Xia et al., 2017; Hardiman et al, 2019).	IWM supports favourable forests conditions thereby influencing the storage and flow of water in watersheds (Eisenbies et al. 2007) which are important for regulating microclimates (Pierzynski et al., 2017).	N/A	Improving regulations for water sharing, trading and pricing (ADB 2016), water smart appliance, water smart landscapes (Dawadi and Ahmad 2013), common and unconventional water sources in use (Rengasamy 2006) will increase water quantity.	Improving regulation to prevent aquifer and surface water depletion, controlling over water extraction, improvement of water management and management of landslides and natural hazards. Watering shifting sand dunes (sprinkler), water resources conservation (Nejad 2013; Pereira 2002a), enhancing rainwater management, reducing recharge and increasing water use in discharge areas (DERM 2011).	IWM provide co-benefits such as healthier soils, more resilient and productive ecosystems (Grey and Sadoff 2007; Liu et al. 2017; Scott et al. 2011)	Change in water availability through improving co-managing floods and groundwater depletion at the river basin such as Managed Aquifer Recharge (MAR), Underground Taming of Floods for Irrigation (UTFI), restore over-allocated or brackish aquifers, groundwater dependent ecosystems protection, reducing evaporation losses are significantly contributed to response climate change and reduced impacts of extreme weather event in desertification areas (Dillon and Arshad 2016b).		IWM can support the production of biomass for energy and firewood (Mbow et al., 2014).	Increasing demand for food, fiber and feed will put great strains on land, water, energy and other resources (WBCSD, 2014). Water conservation and balance in the use of natural resources enforcement (based water resources, water conservation measures, water allocations) (Ward et al. 2008) are good options to response climate change and nature's prevention.	IWM supports favourable forests conditions thereby providing wood and fodder and other materials (Locatelli et al. 2015a). However, conservation restrictions on the storage and flow of water in watersheds (Eisenbies et al. 2007) can restrict the access to resources (e.g. firewood).					

Forests	**Forest management and forest restoration**	Forest landscape restoration specifically aims to regain ecological integrity and enhance human well-being in deforested or degraded forest landscape (Maginnis and Jackson 2007; Stanturf et al. 2014). For example, facilitating tree species mixture means storing at least as much carbon as monocultures while enhancing biodiversity (Hulvey et al. 2013). Selective logging techniques are “middle way” between deforestation and total protection, allowing to retain substantial levels of biodiversity, carbon, and timber stocks (Putz et al. 2012),	Likely contributes to native pollinators (Kremen et al. 2007)	Trees remove air pollution by the interception of particulate matter on plant surfaces and the absorption of gaseous pollutants through the leaf stomata. Computer simulations with local environmental data reveal that trees and forests in the conterminous United States removed 17.4 million tonnes (t) of air pollution in 2010 (range: 9.0–23.2 million t), with human health effects valued at 6.8 billion U.S. dollars (range: USD1.5–13.0 billion) (Novak et al., 2014)	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Forest cover can stabilise intense run-off during storms and flood events (Locatelli et al. 2015a) .Mangroves can protect coastal zones from extreme events (hurricanes) or sea level rise. However, forests also can have adverse side-effects for reduction of water yield and water availability for human consumption (Bryan and Crossman 2013).	Forests tend to maintain water quality by reducing runoff and trapping sediments and nutrients (Idris Medugu et al. 2010a; Salvati et al. 2014). Precipitation filtered through forested catchments delivers purified ground and surface water (co-benefits) (Calder 2005; Ellison et al. 2017; Neary et al. 2009).	Forests counteract wind-driven degradation of soils, and contribute to soil erosion protection and soil fertility enhancement for agricultural resilience (Locatelli et al. 2015a).	Forest cover can stabilise land against catastrophic movements associated with wave action and intense run-off during storms and flood events (Locatelli et al. 2015a). Reducing harvesting rates and prolonging rotation periods may induce an increased vulnerability of stands to external disturbances and catastrophic events (Yousefpour et al. 2018). Forest management strategies may decrease stand-level structural complexity and may make forest ecosystems more susceptive to natural disasters like wind throws, fires, and diseases (Seidl et al. 2014).	Forests can contribute to weed and pest control and landscape diversity generally improves opportunities for biological pest control (Gardiner et al. 2009)	SFM may increase availability of biomass for energy (Kraxner et al 2003; Sikkema et al 2014)	The proximity of forest to cropland constitutes a threat to livelihoods in terms of crop raiding by wild animals and in constraints in availability of land for farming (Few et al. 2017),. The competition for land between afforestation/reforestation and agricultural production is a potentially large adverse side-effect (Boysen et al. 2017a,b; Kreidenweis et al. 2016; Smith et al. 2013). An increase in global forest area can lead to increases in food prices through increasing land competition (Calvin et al. 2014; Kreidenweis et al. 2016; Reilly et al. 2012; Smith et al. 2013; Wise et al. 2009).	Forests provide wood and fodder and other materials (Locatelli et al. 2015a). However, conservation restrictions to preserve ecosystem integrity can restrict the access to resources (e.g. firewood).	Can provide medicinal and other resources.	Natural ecosystems often inspire learning (Turtle et al., 2015)	Forest landscape restoration specifically aims to enhance human well-being (Maginnis and Jackson 2007; Stanturf et al. 2014). Afforestation/reforestation and avoided deforestation benefit biodiversity and species richness, and generally improve the cultural and recreational value of ecosystems (co-benefits) (Knoke et al. 2014).	Many forest landscapes have cultural ecosystems services components (Plieninger et al. 2015)	Retaining natural ecosystems can preserve genetic diversity (Ekins et al., 2003).

	Reduced deforestation and degradation	Reduced deforestation can enhance connectivity between forest areas and conserve biodiversity hotspots (Ellison et al. 2017; Locatelli et al. 2011,a 2015a)	Likely contributes to native pollinators (Kremen et al. 2007)	Trees can improve air pollution problems (Novak et al., 2014)	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Forests tend to maintain water quality by reducing runoff and trapping sediments and nutrients (Idris Medugu et al. 2010a; Salvati et al. 2014).	Due to evapotranspiration, trees recharge atmospheric moisture, contributing to rainfall locally and in distant location, and trees' microbial flora and biogenic volatile organic compounds can directly promote rainfall (Arneth et al. 2010). Trees enhance soil infiltration and, under suitable conditions, improve groundwater recharge (Calder 2005; Ellison et al. 2017; Neary et al. 2009).	Forests counteract wind-driven degradation of soils, and contribute to soil erosion protection and soil fertility enhancement for agricultural resilience (Locatelli et al. 2015a).	Forest cover can stabilise land against catastrophic movements associated with wave action and intense run-off during storms and flood events (Locatelli et al. 2015a)	Landscape diversity generally improves opportunities for biological pest control (Gardiner et al. 2009)	Reduced deforestation may increase availability of some wood for energy and industry	The proximity of forest to cropland constitutes a threat to livelihoods in terms of crop raiding by wild animals (Few et al. 2017),. The competition for land between afforestation/reforestation and agricultural production is a potentially large adverse side-effect (Boysen et al. 2017a,b; Kreidenweis et al. 2016; Smith et al. 2013) that can lead to increases in food prices (Calvin et al. 2014; Kreidenweis et al. 2016; Reilly et al. 2012; Smith et al. 2013; Wise et al. 2009).	Could increase availability of biomass (Griscom et al., 2017)	Reduced deforestation can protect forest medicinal plants (Arnold & Perez 2001)	Natural ecosystems often inspire learning (Turtle et al., 2015)	Forest ecosystems often support recreational opportunities (Liddle 1997)	Many forest landscapes have cultural ecosystems services components (Plieninger et al. 2015)	Retaining natural ecosystems can preserve genetic diversity (Ekins et al., 2003).
	Reforestation	Forest landscape restoration specifically aims to regain ecological integrity and enhance human well-being in deforested or degraded forest landscape (Maginnis and Jackson 2007; Stanturf et al. 2014). Adverse side-effects potentially associated to forests include establishment of non-native species, especially with the risks related to the spread of exotic fast growing tree species (Brundu and Richardson	Likely contributes to native pollinators if native forest species used (Kremen et al. 2007)	Trees can improve air pollution problems (Novak et al., 2014)	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Forests tend to maintain water quality by reducing runoff and trapping sediments and nutrients (Idris Medugu et al. 2010a; Salvati et al. 2014).	Particular activities associated with forest landscape restoration, such as mixed planting, assisted natural regeneration, and reducing impact of disturbances (e.g. prescribed burning) have positive implications for fresh water supply (Ciccarese et al. 2012; Suding et al. 2015).	Forests contribute to soil erosion protection and soil fertility enhancement (Locatelli et al. 2015a).	Forest cover can stabilise land against catastrophic movements associated with wave action and intense run-off during storms and flood events (Locatelli et al. 2015a) Some forest ecosystems can be susceptive to natural disasters like wind throws, fires, and diseases (Seidl et al. 2014).	N/A	Reforestation can increase availability of biomass for energy (Swisher 1994).	The proximity of forest to cropland constitutes a threat to livelihoods in terms of crop raiding by wild animals and in constraints in availability of land for farming (Few et al. 2017),. The competition for land between afforestation/reforestation and agricultural production is a potentially large adverse side-effect (Boysen et al. 2017a,b; Kreidenweis et al. 2016;	Forests provide wood and fodder and other materials (Locatelli et al. 2015a). However, conservation restrictions to preserve ecosystem integrity can restrict the access to resources (e.g. firewoo	Source of medicines (UNEP, 2016)	Natural ecosystems often inspire learning (Turtle et al., 2015)	Afforestation/reforestation can increase areas available for recreation and tourism opportunities (Knoke et al. 2014).	Many forest landscapes have cultural ecosystems services components (Plieninger et al. 2015)	

		2016; Ellison et al. 2017).											Smith et al. 2013). An increase in global forest area can lead to increases in food prices through increasing land competition (Calvin et al. 2014; Kreidenweis et al. 2016; Reilly et al. 2012; Smith et al. 2013; Wise et al. 2009).	d).					
	Afforestation	Forest landscape restoration specifically aims to regain ecological integrity and enhance human well-being in deforested or degraded forest landscape (Maginnis and Jackson 2007; Stanturf et al. 2014). In the case of afforestation, simply changing the use of land to planted forests is not sufficient to increase abundance of indigenous species, as they depend on type of vegetation, scale of the land transition, and time required for a population to establish (Barry et al. 2014).	N/a	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Depends on where reforesting and with what species (Scott et al. 2005). Trees enhance soil infiltration and, under suitable conditions, improve groundwater recharge (Calder 2005; Ellison et al. 2017; Neary et al. 2009).	Afforestation using some exotic species can upset the balance of evapotranspiration regimes, with negative impacts on water availability particularly in arid regions (Ellison et al. 2017; Locatelli et al. 2015a; Trabucco et al. 2008). Afforestation in arid and semiarid regions using species that have evapotranspiration rates exceeding the regional precipitation may aggravate the groundwater decline (Locatelli et al. 2015a; Lu et al. 2016). Changes in runoff affect water supply but can also contribute to changes in flood risks, and irrigation of forest plantations can increase water consumption (Sterling et al. 2013).	Afforestation and reforestation options are frequently used to counteract land degradation problems (Yirdaw et al. 2017). whereas when they are established on degraded lands they are instrumental to preserve natural forests (co-benefit) (Buongiorno and Zhu 2014). Afforestation runs the risk of decreasing soil nutrients, especially in intensively managed plantations; in one study, afforestation sites had lower soil P and N content (Berthrong et al 2009).	Some afforestation may make forest ecosystems more susceptive to natural disasters like wind throws, fires, and diseases (Seidl et al. 2014).	N/A	Afforestation may increase availability of biomass for energy use (Obersteiner et al 2006)	Future needs for food production are a constraint for large-scale afforestation plans (Locatelli et al. 2015a). Global food crop demand is expected by 50%–97% between 2005 and 2050 (Valin et al. 2014). Future carbon prices will facilitate deployment of afforestation projects at expenses of food availability (adverse side-effect), but more liberalised trade in agricultural commodities could buffer food price increases following afforestation in tropical regions (Kreidenweis et al. 2016).	Could increase availability of biomass (Griscom et al., 2017)	N/A	N/A	Green spaces support psychological wellbeing (Coldwell & Evans, 2018)	Afforestation/ reforestation can increase areas available for recreation and tourism opportunities (Knoke et al. 2014).	N/A

Other ecosystems	**Reduced pollution including acidification**	Air pollution like acid rain has major impacts on habitats like lakes (Schindler et al 1989)	Pollution interferes with scents, which impact pollinators ability to detect resources (McFredrick et al 2008)	Will improve air quality with public health benefits (Nemet et al. 2010)	See main text for mitigation potentials	N/A	N/A	Pollution increases acidity of surface water, with likely ecological effects (Larssen et al 1999)	Soil acidification due to air pollution in a serious problem in many countries (Zhou et al. 2013)	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A

	Management of invasive species / encroachment	Improved management of IAS can lead to improved habitat and ecosystems (Richardson & van Wilgen 2004).	Invasive species can disrupt native plant-pollinator relations (Ghazoul 2006)	N/A	N.A	N/A	Many invasives can reduce water flow (Richardson & Van Wilgen 2004).	Invasive species can reduce water quality (Burnett et al. 2007; Chamier et al. 2012)	Likely to improve soil as invasive species generally have negative effects (Ehrenfeld & Scott 2001).	N/A	Many IAS are harmful pests (Charles & Dukes 2008).	N/A	IAS can compete with crops and reduce crop yields by billions of dollars annually (Pejchar & Mooney 2009)	Many invasives are important suppliers of materials (Pejchar & Mooney 2009).	N/A	N/A	N/A	N/A	Reducing invasives can increase biological diversity of native organisms (Simberloff 2005)
	Restoration and avoided conversion of coastal wetlands	Will preserve natural habitat (Griscom et al., 2017)	Will promote natural pollinators (Seddon et al., 2016)	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	The creation or restoration of wetlands, tidal marshes, or mangroves provide water retention and protect coastal cities from storm surge flooding and shoreline erosion during storms. Wetlands store freshwater and enhance water quality (Bobbink et al 2006)	Wetlands store freshwater and enhance water quality (Bobbink et al 2006)	Will improve soil quality (Griscom et al., 2017)	The creation or restoration of wetlands, tidal marshes, or mangroves provide water retention and protect coastal cities from storm surge flooding and shoreline erosion during storms (Haddad et al., 2015; Gittman et al. 2014; Kaplan et al. 2009).	Landscape diversity generally improves opportunities for biological pest control (Gardiner et al. 2009)	N/A	Mixed evidence: can affect agriculture/fisheries production when competition for land occurs, or could increase food production when ecosystems are restored (Crooks et al 2011)	Could increase availability of biomass (Griscom et al., 2017)	Wetlands can be sources of medicines (UNEP, 2016)	Natural ecosystems often inspire learning (Turtle et al., 2015)	Natural environments support psychological wellbeing (Coldwell & Evans, 2018)	Natural environments support psychological wellbeing (Coldwell & Evans, 2018)	Retaining natural ecosystems can preserve genetic diversity (Ekins et al., 2003).
	Restoration and avoided conversion of peatlands	Will preserve natural habitat (Griscom et al., 2017)	Could promote natural pollinators (Seddon et al., 2016)	N/A	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Peatland restoration will improve water quality as they play important roles in water retention and drainage (Johnston 1991).	Peatland restoration will improve water quality as they play important roles in water retention and drainage (Johnston 1991).	Will improve soil quality (Griscom et al., 2017)	N/A	Landscape diversity generally improves opportunities for biological pest control (Gardiner et al. 2009)	Will reduce supply of any biomass or energy sourced from peatlands (Pin Koh 2007)	May reduce land available for smallholders in tropical peatlands (Jewitt et al 2014)	Will reduce supply of some materials sourced from peatlands (e.g palm oil, timber) (Murdiyarso et al. 2010)	Natural ecosystems are often source of medicines (UNEP, 2016)	Natural ecosystems often inspire learning (Turtle et al., 2015)	Natural environments support psychological wellbeing (Coldwell & Evans, 2018)	Natural environments support psychological wellbeing (Coldwell & Evans, 2018)	Retaining natural ecosystems can preserve genetic diversity (Ekins et al., 2003).

	Biodiversity conservation	Biodiversity conservation includes measures aiming to promote species richness and natural habitats, and to mantain them through protected areas (Cromsigt et al., 2018).	Reduced or absent populations of seed-dispersing animals result in poor to no dispersal,especially of large-seeded trees that depend on large animals such as elephants (Anzures-Dadda et al.2011; Brodie and Aslan2012; Beaune et al.2013; Brockerhoff et al. 2017). Animal pollination, which is fundamental to the reproduction and persistence of most flowering plants, is an important ecosystem service (Millennium Ecosystem Assessment 2005). As biodiversity contributes to various ecosystem processes, functions and services, the declining diversity and abundance of pollinators (mainly insects and birds) has raised concerns about the effects on both wild and crop plants (Potts et al. 2010).	Trees in the landscape ensured by protected areas can remove air pollutants (Sutton et al., 2007)	See main text for mitigation potentials		Many actions taken to increase biodiversity (eg protected areas) can also have incidental effects of improving water quantity (Egoh et al. 2009)	Many actions taken to increase biodiversity (eg protected areas) can also have incidental effects of improving water quality (Egoh et al. 2009)	Management of wild animals and protected habitats can influence soil conditions via changes in fire frequency (as grazers lower grass and vegetation densities as potential fuels) and nutrient cycling and transport (by adding nutrients to soils). Conserving and restoring megafauna in northern regions also prevents thawing of permafrost. Management of wild animals can influence land degradation processes by grazing, trampling and compacting soil surfaces, thereby altering surface temperatures and chemical reactions affecting sediment and carbon retention. (Cromsigt et al., 2018; Schmitz et al., 2018)	Management of wild animals can influence fire frequency as grazers lower grass and vegetation densities as potential fuels (Schmitz et al 2014).			Regulation of wild animals affects food for hunting and availability of potential feed for livestock (Cromsigt et al., 2018).		Source of medicines (UNEP, 2016)	Natural ecosystems often inspire learning (Turtle et al., 2015)	indigenous peoples commonly link forest landscapes and biodiversity to tribal identities, association with place, kinship ties, customs and protocols, stories, and songs (Gould et al. 2014; Lyver et al. 2017a, b).		Retaining natural ecosystems can preserve genetic diversity (Ekins et al., 2003).

Carbon dioxide removal	**Enhanced weathering of minerals**	N/A	N/A	N/A	See main text for mitigation potentials	Addition of basic minerals counteracts ocean acidification (Taylor et al., 2016)	N/A	May have negative effects on water quality (Atekwane et al. 2005)	Could improve soil quality (Rau & Caldiera 1999; Kantola et al 2017)	N/A	N/A	N/A	Can contribute to increase food production by replenishing plant available silicon, potassium and other plant nutrients (Beerling et al., 2018)	N/A	N/A	N/A	N/A	N/a	N/A
	Bioenergy and BECCS	Likely will reduce natural habitat with negative effects on biodiversity (Hof et al. 2018)	Would reduce natural pollinators due to decreased natural habitat if in competition (Keitt 2009).	The use of BECCS could reduce air pollution (SR15)	See main text for mitigation potentials	Mitigation potential (see main text) will reduce ocean acidification.	Will likely require water for plantations of fast growing trees and models show high risk of water scarcity if BECCS is deployed on widespread scale (Popp et al 2011; Smith et al. 2016; Hejazi et al., 2014) through both increases in water withdrawals (Hejazi et al., 2014; Bonsch et al., 2015) and changes in surface runoff (Cibin et al., 2015)	Bioenergy can affect freshwater quality via changes in nitrogen runoff from fertiliser application. However, the sign of the effect depends on what would have happened absent any bioenergy production, with some studies indicating improvements in water quality (Ng et al., 2010) and others showing declines (Sinha et al., 2019)	Will likely decrease soil quality if exotic fast growing trees used (Stoy et al. 2018)	N/A	N/A	BECCS and biofuels can contribute up to 300 EJ of primary energy by 2100 (Clarke et al., 2014).	BECCS will likely lead to significant trade-offs with food production (Smith et al 2016; Popp et al., 2017; Fujimori et al., in review)	N/A	N/A	N/A	BECCS would drive land use conversion and reduce opportunities for recreation/tourism.	BECCS would drive land use conversion and reduce culturally significant landscapes.	BECCS would drive land use conversion and reduce genetic diversity.

Table SM6.10 Impacts on Nature's Contributions to People of integrated response options based on value chain management

Integrated response options based on value chain management		**Habitat creation and maintenance**	**Pollination and dispersal of seeds and other propagules**	**Regulation of air quality**	**Regulation of climate**	**Regulation of ocean acidification**	**Regulation of freshwater quantity, flow and timing**	**Regulation of freshwater and coastal water quality**	**Formation, protection and decontamination of soils and sediments**	**Regulation of hazards and extreme events**	**Regulation of organisms detrimental to humans**	**Energy**	**Food and feed**	**Materials and assistance**	**Medicinal, biochemical and genetic resources**	**Learning and inspiration**	**Physical and psychological experiences**	**Supporting identities**	**Maintenance of options**
Demand management	**Dietary change**	Will lead to reduced expansion of ag lands, which can increase natural habitat (Tilman et al. 2001)	N/A	N/A	See main text on climate mitigation impacts	N/A	Will reduce water consumption if less water-intensive food/livestock needs to be produced (Tilman et al. 2001)	Reduced meat consumption will improve water quality (Stoll-Kleeman & O'Riordan 2015)	N/A	N/A	N/A	N/A	Will help increase global food supplies (Kastner et al. 2012)	N/A	N/A	N/A	N/A	N/A	N/A

	Reduced post-harvest losses	Will lead to reduced expansion of ag lands, which can increase natural habitat (Tilman et al. 2001)	N/A	N/A	See main text on climate mitigation impacts	N/A	Will reduce water consumption if less water-intensive food/livestock needs to be produced (Tilman et al. 2001)	N/A	N/A	N/A	Reducing postharvest losses will include measures to deal with pests, some of which could be biological (Wilson & Pusey 1985)	N/A	Will help increase global food supplies (Kastner et al. 2012)	N/A	N/A	N/A	N/A	N/A	N/A
	Reduced food waste (consumer or retailer)	Improved storage and distribution reduces food waste and the need for compensatory intensification of agricultural areas thereby creating co-benefits for reduced land degradation (Stathers et al. 2013).			See main text on climate mitigation impacts		Will reduce water consumption if less water-intensive food/livestock needs to be produced (Tilman et al. 2001)	Reduced food production will reduce N fertiliser use, improving water quality (Kibler et al. 2018)	N/A	N/A	N/A	N/A	Will help increase global food supplies (Kastner et al. 2012)	N/A	N/A	N/A	N/A	N/A	N/A
	Material substitution	Material substitution increases demand for wood, which can lead to loss of habitat (Sathre & Gustavsson 2006). Supply management	**Sustainable sourcing**	Forest certification and other sustainable sourcing schemes can reduce habitat fragmentation as compared to conventional supply chains (Brown et al. 2001; Rueda et al. 2015))	N/A	Forest certification improved air quality in Indonesia by 5% due to reduced incidence of fire (Miteva et al. 2015)	N/A	N/A	Forest certification has led to improved water flow due to decreased road construction for logging (Miteva et al. 2015)	Forest certificaiton has improved riparian waterways and reduced chemical inputs in some schemes (Rueda et al 2015)	N/A	N/A	N/A	Sustainable sourcing can supply energy like biomass (Sikkema et al. 2014)	Sustainable sourcing can supply food and other goods (G. Smith 2007)	Sustainable sourcing is increasingly important in timber imports (Irland 2008)	Sustainable sourcing can supply medicinals (Pierce & Laird 2003).	N/A	N/A	N/A	N/A
	Management of supply chains	N/A	N/A	Better management of supply chains may reduce energy use and air pollution in transport (Zhu et al.	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	Improved supply chains will help increase global food supplies (Hamprecht 2005).	Improved supply chains will help increase material supplies due to efficiency gains (Burritt & Schaltegger 2014).	N/A	N/A	N/A	N/A	N/A

				2018)															
	Enhanced urban food systems	Urban gardening can improve habitat and biodiversity in cities (Orsini et al. 2014; Lin et al. 2015)	Urban beekeeping has been important in keeping pollinators alive (Gunnarsson & Federsel 2014)	Urban agriculture can increase vegetation cover and improve air quality in urban areas (Cameron et al. 2012; Lin et al. 2015).	See main text on climate mitigation impacts	N/A	Water access often a constraint on urban agriculture and can increase demands (De Bon et al 2010; Badami & Ramankutty 2015).	Urban agriculture can exacerbate urban water pollution problems (pesticide runoff, etc) (Pothukuchi & Kaufmann 1999)	N/A	N/A	N/A	N/A	Local urban food production is often more accessible to local populations and can increase food security (Eigenbrod & Gruda 2015)	N/A	N/A	Urban agriculture can be used for teaching and learning (Travaline & Hunold 2010).	N/A	Urban agriculture can promote cultural identities (Baker 2004)	Urban food can contribute to preserving local genetic diversity
	Improved food processing and retail	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A
	Improved energy use in food systems	N/A	N/A	N/A	See main text on climate mitigation impacts	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A

Table SM6.11 Impacts on Nature's Contributions to People of integrated response options based on risk management

<u>Integrated response options based on risk management</u>	Habitat creation and maintenance	Pollination and dispersal of seeds and other propagules	Regulation of air quality	Regulation of climate	Regulation of ocean acidification	Regulation of freshwater quantity, flow and timing	Regulation of freshwater and coastal water quality	Formation, protection and decontamination of soils and sediments	Regulation of hazards and extreme events	Regulation of organisms detrimental to humans	Energy	Food and feed	Materials and assistance	Medicinal, biochemical and genetic resources	Learning and inspiration	Physical and psychological experiences	Supporting identities	Maintenance of options
Management of urban sprawl	Reducing urban sprawl can help preserve natural habitat in periurban areas (Pataki et al 2011)	Reducing urban sprawl will help reduce loss of natural pollinators from habitat conversion (Cane 2005)	Urban sprawl is a major contributor to air pollution (Frumkin 2002)	See main text on climate mitigation impacts		Managing urban sprawl can increase water availability (Pataki et al 2011)	Urban sprawl is associated with higher levels of water pollution due to loss of filtering vegetation and increasing impervious surfaces (Romero & Ordenes 2004; Tu et al 2007; Pataki et al 2011)	Likely to be beneficial for soils as soil sealing is major problem in urban areas (Scalenghe & Marsan 2009)	N/A	N/A		Urban sprawl often competes with land for food production and can reduce overall yields (Chen 2007, Barbero-Sierra et al., 2013)	N/A	N/A	N/A	N/A	N/A	N/A

	Livelihood diversification	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	Diversification is associated with increased access to income and additional food sources for the household (Pretty et al. 2003)	Diversification can increase access to materials (Smith et al. 2017)	N/A	N/A	N/A	N/A	N/A
	Use of local seeds	Use of commercial seeds can contribute to habitat loss (Upreti & Upreti 2002)	Use of open pollinated seeds is beneficial for pollinators and creates political will to conserve them (Helicke 2015)	N/A	N/A	N/A	Local seeds often have lower water demands, as well as less use of pesticides that can contaminate water (Adhikari 2014)	Likely to contribute to less pollution as local seeds are usually grown organically (Adhikari 2014)	Likely to contribute to better soils as local seeds are usually grown organically (Adhikari 2014)	N/A	Local seeds often need less pesticides thereby reducing pest resistance (Adhikari 2014)	N/A	Local seeds can lead to more diverse and healthy food in areas with strong food sovereignty networks (Coomes et al. 2015; Bisht et al. 2018). However local seeds often are less productive than improved varieties.		Many local seeds can have multiple functions, including medicinals (Hammer & Teklu 2008)	Passing on seed information is important cultural learning process (Coomes et al. 2015)		Seeds associated with specific cultural identities for many (Coomes et al. 2015)	Food sovereignty movements have promoted saving of genetic diversity of crops through on-farm maintenance (Isakson 2009)
	<u>Disaster risk management</u>	N/A	N/A	N/A	N/A	N/A	N/A	N/A	N/A	DRM helps people avoid extreme events and adapt to climate change (Mechler et al. 2014)	N/A	N/A	Famine early warning systems have been successful in Sahelian Africa to alert authorities to impending food shortages so that food acquisition and transportation from outside the region can begin, potentially helping millions of people (Genesio et al. 2011; Hillbruner and Moloney 2012)		N/A	N/A	N/A	N/A	N/A

	Risk sharing instruments	Commercial crop insurance often encourages habitat conversion; Wright and Wimberly (2013) found a 531,000 ha decline in grasslands in the Upper Midwest of the US 2006-2010 due to crop conversion driven by higher prices and access to insurance.	Crop insurance is likely to impact natural pollinators due to incentives for production (Horowitz & Lichtenberg 1993)	N/A	N/A	N/A	N/A	Likely to have negative effect as crop insurance encourages more pesticide use (Horowitz & Lichtenberg 1993).	One study found a 1% increase in farm receipts generated from subsidised farm programs (including crop insurance and others) increased soil erosion by 0.135 tons per acre (Goodwin and Smith 2003).	N/A	Crop insurance increasess nitrogen use and leads to treating more acreage with both herbicides and insecticides (Horowitz & Lichtenberg 1993)	N/A	Crop insurance has generally lead to (modest) expansions in cultivated land area and increased food production (Claassen et al. 2011; Goodwin et al. 2004)		Insurance encourages monocropping leading to loss of genetic diversity for future (Glauber 2004)	N/A	N/A	N/A	Insurance encourages monocropping leading to loss of genetic diversity for future (Glauber 2004)

Table SM6.12 Impacts on the UN SDG of integrated response options based on land management

Integrated response options based on land management		**GOAL 1: No Poverty**	**GOAL 2: Zero Hunger**	**GOAL 3: Good Health and Well-being**	**GOAL 4: Quality Education**	**GOAL 5: Gender Equality**	**GOAL 6: Clean Water and Sanitation**	**GOAL 7: Affordable and Clean Energy**	**GOAL 8: Decent Work and Economic Growth**	**GOAL 9: Industry, Innovation and Infrastructure**	**GOAL 10: Reduced Inequality**	**GOAL 11: Sustainable Cities and Communities**	**GOAL 12: Responsible Consumption and Production**	**GOAL 13: Climate Action**	**GOAL 14: Life Below Water**	**GOAL 15: Life on Land**	**GOAL 16: Peace and Justice Strong Institutions**	**GOAL 17: Partnerships to achieve the Goal**
Agriculture	**Increased food productivity**	Increasing farm yields for smallholders contributes to poverty reduction (Irz et al 2001; Pretty et al 2003)	Increasing farm yields for smallholders reduces food insecurity (Irz et al 2001; Pretty et al 2003).	Increased food productivity leads to better health status (Rosegrant & Cline 2003; Dar & Gowda 2011)	N/A	Increased productivity can benefit female farmers, who make up 50% of agricultural labor in sub-Saharan Africa (Ross et al 2015)	Food productivity increases could impact water quality if increases in chemicals used, but evidence is mixed on sustainable intensification (Rockstro ̈m et al 2009; Mueller et al 2012).	N/A	Increased agricultural production generally (Lal 2006) contributes to increased economic growth.	N/A	Increased agricultural production can contribute to reducing inequality among smallholders (Datt & Ravallion 1998).	Increased food production can increase urban food security (Ellis & Sumberg 1998).	N/A	See main text on climate mitigation and adaptation	Increased food productivity might be achieved through increased pesticide or fertiliser use, which causes runoff and dead zones in oceans (Beusen et al 2016)	See main text on desertification and degradation	N/A	Improved agricultural productivity generally correlates with increases in trade in agricultural goods (Fader et al. 2013)

	Improved cropland management	Improved cropland management increases yields for smallholders and contributes to poverty reduction (Irz et al 2001; Pretty et al 2003; Schneider & Gugerty 2011).	Conservation agriculture contributes to food productivity and reduces food insecurity (Rosegrant & Cline 2003; Dar & Gowda 2011; Godfray & Garnett 2014).Land consolidation has played an active role in China to in increase cultivated land area,promoting agricultural production scale, improving rural production conditions and living environment, alle-viating ecological risk and supporting for rural development (Zhou et al. 2019).	Conservation agriculture contributes to improved health through several pathways, including reduced fertiliser/pesticide use which cause health impacts (Erisman et al 2011) as well as improved food security.	N/A	N/A	Cropland management practices such as conservation tillage improve downstream and groundwater water quality (Fawcett et al 1994, Foster 2018). Good management practices can substantially decrease P losses from existing land use, to achieve ‘good’ water quality in catchment in New Zealand, United Kingdom and United States (	N/A	Increased agricultural production generally (Lal 2006) contributes to increased economic growth, mainly in smallholder agriculture (Abrahan and Pingali 2017).	N/A	Increased agricultural production can contribute to reducing inequality among smallholders (Datt & Ravallion 1998, Abrahan and Pingali 2017)).	N/A	Improved conservation agriculture contributes to sustainable production goals (Hobbs et al. 2008).	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	Improved agricultural productivity generally correlates with increases in trade in agricultural goods (Fader et al. 2013)
	Improved grazing land management	Increases yields for smallholders and contributes to poverty reduction (Boval & Dixon 2012)	Improved grassland management could contribute to food security (O'Mara 2012)	Improved livestock and grazing management could contribute to better health among smallholder pastoralists (van't Hooft et al. 2012) but pathways are not entirely clear.	N/A	N/A	Grassland management practices can improve downstream and groundwater water quality (Foster 2018).	N/A	Improved land management for livestock can increase economic productivity, especially in global South (Pender et al 2006)	N/A	Improved pastoral management strategies can contribute to reducing inequality but are context specific (Lesorogol 2003)	N/A	Improved grassland management contributes to sustainable production goals (O'Mara 2012).	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	Grazing land management requires collective action and therefore can increase social capital and build institutions (Mearns 1996)	N/A
	Improved livestock management	Improved livestock management (e.g. better breeding) can contribute to poverty reduction for smallholder pastoralists (van't Hooft	Improved livestock management can contribute to reduced food insecurity among smallholder pastoralists (van't Hooft et	N/A	N/A	N/A	Improved industrial livestock production can reduce water contamination (e.g. reduced effluents) (Hooda et al 2000).	N/A	Improved livestock management can increase economic productivity and employment opportunities in	N/A	N/A	N/A	Sustainable livestock management contributes to sustainable production goals	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	Improved livestock productivity would likely correlate with increases in trade (Herrero et al. 2009)

		et al. 2012)	al. 2012).				Improved livestock management can contribute to better water quality such as through manure management (Herrero & Thornton 2013)		global South (Mack 1990)				(de Wit et al 1995).					
	Agro-forestry	Agroforestry can be usefully used for poverty reduction (Leakey& Simons 1997).	Agroforestry contributes to food productivity and reduces food insecurity (Mbow et al. 2014).	Agroforestry positively contributes to food productivity and nutritious diets (Haddad 2000)	N/A	Increased use of agroforestry can benefit female farmers as it requires low overhead, but land tenure issues must be paid attention to (Kiptot & Franzel 2012).	Agroforestry can be used to increase ecosystem services benefits, such as water quantity and quality (Jose 2009)	Agroforestry could increase biomass for energy (Mbow et al. 2014)	Agroforestry and other forms of employment in forest management make major contributions to global GDP (Pimental et al 1997).	N/A	Agroforestry promotion can contribute to reducing inequality among smallholders (Leßmeister et al 2018).	N/A	Agroforestry contributes to sustainable production goals (Mbow et al 2014).	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Agricultural diversification	Agricultural diversification is associated with increased welfare and incomes and decreased levels of poverty in several country studies (Arslan et al. 2018; Asfaw et al. 2018; Weinberger & Lumpkin 2007).	Diversification is associated with increased access to income and additional food sources for the farming household (Pretty et al. 2003; Ebert 2014).Diversification can also reduce the risk of crop pathogens spreading across landscapes (Lin 2011).	More diversified agriculture leads to diversified diets which have better health outcomes (Block & Webb 2001; Ebert 2014; Kadiyala et al 2014) particularly for women and children (Pretty et al. 2003)	N/A	N/A	N/A	N/A	Agricultural diversification can lead to economic growth (Rahman 2009; Pingali & Rosegrant 1995). It allows farmers to choose a strategy that both increases resilience and provides economic benefits, including functional biodiversity at multiple spatial and/or temporal scales, through practices developed via	N/A	Increased agricultural diversification can contribute to reducing inequality among smallholders (Makate et al 2016), although there is mixed evidence of inequality also increasing in commercialised systems (Pingali & Rosegrant 1995; Weinberger & Lumpkin 2007)	N/A	N/A		N/A	See main text on desertification and degradation	N/A	N/A

									traditional and/or agroecological scientific knowledge (Lin 2011 ; Kremen et al. 2012).									
	Avoidance of conversion of grassland to cropland	May reduce land available for cropping or livestock for poorer farmers ; some grassland restoration programs in China have been detrimental to poor pastoralists (Foggin 2008)	Can affect food security when competition for land occurs (O'Mara 2012)	N/A	N/A	N/A	Retaining grasslands contributes to better water retention and improved quality (Scanlon et al 2007).	N/A	Reduced cropland expansion may decrease GDP (Lewandrowski et al 1999)	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Integrated water management	Green water harvesting contributes to alleviate poverty in Sub-Saharan Africa (Rockström and Falkenmark 2015), Improving water irrigation (Rengasamy 2006), improving rainfed agriculture (integrating soil and water management, rainfall infiltration and water harvesting, provides a large co-benefit to delivery of food security and poverty reduction (UNCTAD 2011)	Integrated, efficient, equitable and sustainable water resource management (as water for agroecosystem) plays importance for food production and benefits to people (Lloyd et al. 2013).	Water is a finite and irreplaceable resource that is fundamental to human well-being. It is only renewable if well managed. Integrated water management is vital option for reducing the global burden of disease and improving the health, welfare and productivity of populations. Today, more than 1.7 billion people live in river basins where depletion through use exceeds natural recharge, a trend that	N/A	Involving both women and men in integrated water resources initiatives can increase project effectiveness and efficiency (Green & Baden 1995)	Water resource management is intended to solve watershed problems on a sustainable basis, and these problems can be categorised into lack of water (quantity), deterioration in water quality, ecological effects, poor public participation, and low output economic value for investment in watershed-related activities (Lee et al. 2018). Integrated water management, increase	N/A	Water is at the core of sustainable development and is critical for socio-economic development, healthy ecosystems and for human survival itself. Integrated water management can play a key enabling role in strengthening the resilience of social, economic and environmental systems in the light of rapid and unpredictable changes	N/A	IWM can increase access of industry to water for economic growth (Rahman & Varis 2005)	Water is a limiting factor in urban growth and IWM can help improve access to urban water supplies (Bao &Fang 2012)	Poor sectoral coordination and institutional fragmentation have triggered an unsustainable use of resources and threatened the long-term sustainability of food, water, and energy security (Rassul 2016).	See main text on climate mitigation and adaptation	IWM on land is likely to improve water quality runoff into oceans (Agboola & Braimoh 2009)	See main text on desertification and degradation	Integrated water management, increase water-use efficiency across all sectors and ensure sustainable withdrawals and supply of freshwater to address water scarcity, and substantially reduce the number of people suffering from water scarcity (UN Water, 2015).	

				will see two-thirds of the world's population living in water-stressed countries by 2025 (UNWater 2015)			water-use efficiency across all sectors and ensure sustainable withdrawals and supply of freshwater to address water scarcity, and substantially reduce the number of people suffering from water scarcity (UNWater 2015).		(UN Water, 2015).									
Forestry	**Forest management and forest restoration**	May contribute to poverty reduction if conditions are right (Blomley & Ramadhani 2006; Donovan et al 2006), but conflicting data, as it may also favor large landowners who are less poor (Rametsteiner and Simula 2003).	Forest expansion can affect crop production when competition for land occurs (Angelsen 2010). An increase in global forest area can lead to increases in food prices through increasing land competition (Calvin et al. 2014b; Kreidenweis et al. 2016c; Reilly et al. 2012b; Smith et al. 2013a; Wise et al. 2009b)	N/A	N/A	Women face challenges in sustainable forest management (Mwangi et al 2011), but N/A how SFM affects gender equity.	Forests tend to maintain water quality by reducing runoff and trapping sediments and nutrients (Idris Medugu et al. 2010c; Salvati et al. 2014a). Due to evapotranspiration, trees recharge atmospheric moisture, contributing to rainfall locally and in distant location, and trees' microbial flora and biogenic volatile organic compounds can directly promote rainfall (Arneth et al. 2010). Trees enhance soil infiltration and, under	SFM may increase availability of biomass for energy (Kraxner et al. 2013; Sikkema et al. 2013)	Forest management often require employment for active replanting, etc. (Ros-Tonen et al 2008)	Forestry supplies wood for industrial use (Gustavsson & Sathre 2011)	N/A	Community forest management can contribute to stronger communities (Padgee et al 2006)	Improved forest management contributes to sustainable production goals, e.g. thru certification of timber (Rametsteiner and Simula 2003).	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	Sustainable forest management often requires collective action institutions (Ros-Tonen et al 2008).	Sustainable forest management can contribute to increases in demand for wood products (e.g. certification) (McDonald & Lane 2004)

							suitable conditions, improve groundwater recharge (Calder 2005; Ellison et al. 2017a; Neary et al. 2009b). Particular activities associated with forest landscape restoration, such as mixed planting, assisted natural regeneration, and reducing impact of disturbances (e.g. prescribed burning) have positive implications for fresh water supply (Ciccarese et al. 2012; Suding et al. 2015).											
	Reduced deforestation and degradation	May contribute to poverty reduction but conflicting data. Although poverty is a focus of many REDD+ projects (Arhin 2014), evidence is thin that poverty reduction has actually happened (Corbera et al. 2017; Porkorny et al 2013; Scheba 2018) and in some cases benefits have been captured by wealthier	Avoided deforestation can affect crop production when competition for land occurs (Angelsen 2010).	Reduced deforestation can enhance human well-being by microclimatic regulation for protecting people from heat stresses (Locatelli et al. 2015c) and generally improve the cultural and recreational value of ecosystems (Knoke et al. 2014).	N/A	Unclear how avoided deforestation might enhance gender equity, but REDD+ projects need to pay attention to gender issues to be successful (Westholm & Arora-Jonsson 2015)	Forests tend to maintain water quality by reducing runoff and trapping sediments and nutrients (Idris Medugu et al. 2010c; Salvati et al. 2014b). Due to evapotranspiration, trees recharge atmospheric moisture, contributing to rainfall locally and in distant location, and trees'	Avoiding deforestation can take biofuel land out of production as they both tend to compete for land (Dixon et al. 2016)	Reduced forest exploitation may decrease GDP and thus needs to be compensated for (e.g. REDD+) (Motel et al 2009)	N/A	REDD+ has been shown to have no impact on inequality (Shresta et al 2017) or to increase inequality in some project areas (Andersson et al 2018; Pelletier et al 2018)	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	Likely to contribute to decline in trade in forest products, but increases in partnerships between donors and countries with REDD+ (Motel et al 2009).

		participants					microbial flora and biogenic volatile organic compounds can directly promote rainfall (Arneth et al. 2010). Trees enhance soil infiltration and, under suitable conditions, improve groundwater recharge (Calder 2005; Ellison et al. 2017a; Neary et al. 2009b).											
	Reforestation	May contribute to poverty reduction but conflicting data (Tschakert 2007). Many projects for reforestation may have some small impacts on poor households, while others actually increased poverty due to land losses or lack of economic impacts (Jindal et al 2008).	Forest expansion can affect crop production when competition for land occurs (Angelsen 2010). An increase in global forest area can lead to increases in food prices through increasing land competition (Calvin et al. 2014b; Kreidenweis et al. 2016c; Reilly et al. 2012b; Smith et al. 2013a; Wise et al. 2009b)	Reforestation can enhance human well-being by microclimatic regulation for protecting people from heat stresses (Locatelli et al. 2015c) and generally improve the cultural and recreational value of ecosystems (Knoke et al. 2014). Trends of forest resources of nations are found to positively correlate with UNDP Human Development Index (Kauppi et al. 2018).	N/A	N/A	Particular activities associated with forest landscape restoration, such as mixed planting, assisted natural regeneration, and reducing impact of disturbances (e.g. prescribed burning) have positive implications for fresh water supply (Ciccarese et al. 2012; Suding et al. 2015).	Reforestation can increase availability of biomass for energy (Swischer 1994).	Reforestation often require employment for active replanting, etc. (Jindal et al 2008)	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Afforestation	Although some have argued that afforestation can be a tool for poverty	Future needs for food production are a constraint for large-scale afforestation	Afforestation can enhance human well-being by microclimat	N/A	N/A	Afforestation using some exotic species can upset the	Afforestation may increase availability of biomass for energy use (Obersteiner	Afforestation often requires employment for active	N/A	N/A	N/A	N/A	See main text on climate mitigation and	N/A	See main text on desertification and degradation	N/A	N/A

		reduction (Holden et al 2003), afforestation can compete with land available for cropping and poor farmers often do not benefit from afforestation projects (McElwee 2009)	plans (Locatelli et al. 2015c). Global food crop demand is expected by 50%-97% between 2005 and 2050 (Valin et al. 2014). Future carbon prices will facilitate deployment of afforestation projects at expenses of food availability (adverse side-effect), but more liberalised trade in agricultural commodities could buffer food price increases following afforestation in tropical regions (Kreidenweis et al. 2016c)	ic regulation for protecting people from heat stresses (Locatelli et al. 2015c) and generally improve the cultural and recreational value of ecosystems (Knoke et al. 2014). Trends of forest resources of nations are found to positively correlate with UNDP Human Development Index (Kauppi et al. 2018)			balance of evapotranspiration regimes, with negative impacts on water availability particularly in arid regions (Ellison et al. 2017a; Locatelli et al. 2015c; Trabucco et al. 2008). Afforestation in arid and semiarid regions using species that have evapotranspiration rates exceeding the regional precipitation may aggravate the groundwater decline (Locatelli et al. 2015a; Lu et al. 2016). Changes in runoff affect water supply but can also contribute to changes in flood risks, and irrigation of forest plantations can increase water consumption (Sterling et al. 2013)	et al 2006)	replanting, etc. (Mather & Murray 1987).					adaptation				
Soil management	**Increased soil organic carbon content**	Can increase yields for smallholders, which can contribute to poverty	Lal (2006b) notes that "Food-grain production in developing countries can	There is evidence that increasing soil organic carbon	N/A	Gender impacts use of soil organic matter practices	Soil organic matter is known to increase water	N/A	Increased agricultural production generally	N/A	Increased agricultural production can contribute	N/A	Improved conservation agriculture	See main text on climate mitigation and	Rivers transport dissolved organic matter to oceans	See main text on desertification and degradation	N/A	N/A

		reduction, but because adoption often depends on exogenous factors these need to be taken into consideration (Wollni et al 2010; Kassie et al 2013).	be increased by 24-39 (32+-11) million Mgy-1 through improving soil quality by increasing the SOC pool and reversing degradation processes".	could be effective in reducing the prevalence of disease-causing helminths (Lal 2016; Wall et al. 2015). Also indirectly contributes to food productivity which may have impact on diets.		(Quansah et al 2001) but N/A how the relationship works in reverse.	filtration and protects water quality (Lehmann & Kleber 2015)		(Lal 2006c) contributes to increased economic growth.		to reducing inequality among smallholders (Datt & Ravallion 1998).		contributes to sustainable production goals (Hobbs et al. 2008).	adaptation	(Hedges et al 1997), but unclear if improved SOM will decrease this and by how much.			
	Reduced soil erosion	Can increases yields for smallholders and contributes to poverty reduction (Ananda & Herath 2003)	Contributes to agricultural productivity and reduces food insecurity (Pimentel et al. 1995; Shiferaw & Holden 1999).	Contributes to food productivity and improves farmer health (Pimentel et al. 1995; Shiferaw & Holden 1999).	N/A	N/A	Various researchers showed a relationship between impact of soil erosion and degradation on water quality indicating the source of pollutant as anthropogenic and industrial activities. in China (Issaka & Asheraf 2017). Managing soil erosion improves water quality (Pimentel et al 1995)	N/A	N/A	N/A	N/A	Particulate matter pollution, a main consequence of wind erosion, imposes severe adverse impacts on materials, structures and climate which directly affect the sustainability of urban cities (Al-Thani et al. 2018)	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Reduced soil salinisation	Salinisation can impoverish farmers (Duraiappah 1998) therefore preventing or reversing can increases yields for smallholders and contributes to poverty reduction.	Reversing degradation contributes to food productivity and reduces food insecurity (Pimiental et al. 1995; Shiferaw & Holden 1999).	Salinisation is known to have human health impacts: wind-borne dust and respiratory health; altered ecology of mosquito-borne diseases; and mental health consequences (Jardine	N/A	N/A	Management of soil salinity improves water quality and quantity (Kotb et al. 2000; Zalidis et al 2002)	N/A	N/A	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A

				et al 2007)														
	Reduced soil compaction	Soil compaction and other forms of degradation can impoverish farmers (Scherr 2000); prevention of compaction thus contributes to poverty reduction.	Compactions reduces agricultural productivity and thus contributes to food insecurity (Nawaz et al 2013)	Soil compaction has human health consequences as it contributes to runoff of water and pollutants into surface and groundwaters (Soane and van Ouwerkerk 1994)	N/A	N/A	Management of soil compaction improves water quality and quantity (Soane and van Ouwerkerk 1994; Zalidis et al 2002)	N/A	N/A	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Biochar addition to soil	Land to produce biochar may reduce land available for smallholders, and it tends to be unaffordable for poor farmers; as of yet, few biochar projects have shown poverty reduction benefits (Leach et al 2012)	Could potentially affect crop production if competition for land occurs (Ennis et al 2012)	N/A	N/A	N/A	Biochar improves soil water filtration and retention (Spokas et al 2011)	N/A	N/A	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Fire management	N/A	N/A	Fire management reduces health risks from particulates (Bowman & Johnston 2005).	N/A	N/A	Fires affect water quality and flow due to erosion exposure (Townsend & Douglas 2000).	N/A	N/A	N/A	N/A	Wildfires can threaten property and human health in urban areas, with unique vulnerabilities (Gill & Stevens 2009; Winter & Fried 2010), therefore management will reduce risk to urban areas. 	including acidification			deposition reduces health risks, including respiratory illnesses and increased morbidity (Lübkert-Alcamo & Krzyzanowski 1995; Larssen et al 1999)			acidity of surface water, with likely ecological effects (Larssen et al 1999)			pollution can increase demand for new technologies (Popp 2006).		reduce exposure to health risks in urban areas (Bartone 1991)		text on climate mitigation and adaptation	can improve water quality running to oceans (Doney et al 2007).	desertification and degradation		
	Management of invasive species / encroachment	Invasive species removal policies have been beneficial to the poor (van Wilgen & Wannenburgh 2016)	IAS can compete with crops and reduce crop yields by billions of dollars annually (Pejchar & Mooney 2009)	IAS have strong negative effects on human well-being (Pejchar & Mooney 2009)	N/A	N/A	IAS like the golden apple snail/zebra mussel have damaged aquatic ecosystems (Pejchar & Mooney 2009)	N/A	IAS removal policies can increased employment due to need for labor (van Wilgen & Wannenburgh 2016)	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A
	Restoration and avoided conversion of coastal wetlands	Impacts on poverty are mixed (Kumar et al 2011). May reduce land available for cropping, and poor design can impoverish people (Ingram et al 2006; Mangora 2011). Can also decrease vulnerability to coastal storms, however (Jones et al. 2012; Feagin et al 2010)	Mixed evidence: can affect agriculture/fisheries production when competition for land occurs, or could increase food production when ecosystems are restored (Crooks et al 2011)	Wetlands contribute to local well-being (Crooks et al 2011), and restoration generally improve the cultural and recreational value of ecosystems (Knoke et al. 2014).	N/A	N/A	Wetlands store freshwater and enhance water quality (Bobbink et al 2006)	N/A	Restoration projects often require employment for active replanting, etc. (Crooks et al. 2011).	Protecting coastal wetlands may reduce infrastructure projects in coastal areas (e.g. sea dikes, etc.) (Jones et al. 2012)	N/A	N/A	N/A	See main text on climate mitigation and adaptation	Restoration of coastal wetlands can play a large role in providing habitat for marine fish species (Bobbink et al 2006; Hale et al 2009)	See main text on desertification and degradation	N/A	N/A
	Restoration and avoided conversion of peatlands	May reduce land available for smallholders in tropical peatlands (Jewitt et al 2014)	Can affect crop production when competition for land occurs, although much use of peatlands in tropics is for palm oil, not food (Sellamuttu et al 2011)	N/A	N/A	N/A	Peatland restoration will improve water quality as they play important roles in water retention and drainage (Johnston 1991).	Peatlands in tropics are often used for biofuels and palm oil, so may reduce the availability of these (Danielsen et al 2008).	Reduced peatland exploitation may decrease GDP in Southeast Asia (Koh et al 2011)	N/A	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A

	Biodiversity conservation	There is mixed evidence on the impacts of biodiversity conservation measures on poverty	Biodiversity, and its management, is crucial for improving sustainable and diversified diets (Global Panel on Agriculture and Food Systems for Nutrition 2016). Indirectly, the loss of pollinators (due to combined causes, including the loss of habitats and flowering species) would contribute to 1.42 million additional deaths per year from non-communicable and malnutrition-related diseases, and 27.0 million lost disability-adjusted life-years (DALYs) per year (Smith et al. 2015). However, at the same time, some options to preserve biodiversity, like protected areas, may potentially conflict with food production by local communities (Molotoks et al. 2017)	Biodiversity, and its management, is crucial for improving sustainable and diversified diets (Global Panel on Agriculture and Food Systems for Nutrition 2016).	N/A	N/A	33 out of 105 of the largest urban areas worldwide rely on biodiversity conservation measures such as protected areas for some, or all, of their drinking water (Secretariat of the Convention on Biological Diversity 2008)	Some biodiversity conservation measures might increase access to biomass supplies (Erb et al. 2012)							Biodiversity conservation measures like protected areas can increase ocean biodiversity (Selig et al 2014)	Indigenous peoples' roles in biodiversity conservation can increase institutions and conflict resolution (Garnett et al. 2018)	Indigenous peoples commonly link forest landscapes and biodiversity to tribal identities, association with place, kinship ties, customs and protocols, stories, and songs (Gould 2014; Lyver et al. 2017a, b).	
	Enhanced weathering of minerals	N/A	N/A	N/A	N/A	N/A	Mineral weathering can affect the chemical composition of soil and surface waters (Katz	N/A	N/A	Will require development of new technologies (Schuiling and Krijgsman	N/A	N/A	N/A	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	N/A

							1989)			2006)								
CDR	Bioenergy and BECCS	Bioenergy production could create jobs in agriculture, but could also compete for land with alternative uses. Therefore, bioenergy could have positive or negative effects on poverty rates among smallholders, among other social effects (IPCC 2018).	Biofuel plantations may lead to decreased food security through competition for land (Locatelli et al. 2015c). BECCS will likely lead to significant trade-offs with food production (Popp et al. 2011c; Smith et al. 2016b).	BECCS could have positive effects through improvements in air and water quality (IPCC 2018), but BECCS could have negative effects on health and wellbeing through impacts on food systems (Burns and Nicholson 2017). Additionally, there is a non-negligible risk of leakage of sequestered CO2 (IPCC 2018).	No direct interaction (IPCC 2018).	No direct interaction (IPCC 2018).	Will likely require water for plantations of fast growing trees and models show high risk of water scarcity if BECCS is deployed on widespread scale (IPCC 2018).	BECCS and biofuels can contribute up to 300 EJ of primary energy by 2100 (cross-chapter box 7 on bioenergy); bioenergy can provide clean, affordable energy (IPCC 2018).	Access to clean, affordable energy will help economic growth (IPCC 2018).	BECCS will require development of new technologies (Smith et al. 2016c).	No direct interaction (IPCC 2018).	No direct interaction (IPCC 2018).	Switching to bioenergy reduces depletion of natural resources (IPCC 2018).	See main text on climate mitigation and adaptation	Reductions in carbon emissions will reduce ocean acidification. See main text on climate mitigation.	See main text on desertification and degradation	No direct interaction (IPCC 2018).	No direct interaction (IPCC 2018).

Table SM6.13 Impacts on the UN SDG of integrated response options based on value chain interventions

<u>Integrated response options based on value chain management</u>		GOAL 1: No Poverty	GOAL 2: Zero Hunger	GOAL 3: Good Health and Well-being	GOAL 4: Quality Education	GOAL 5: Gender Equality	GOAL 6: Clean Water and Sanitation	GOAL 7: Affordable and Clean Energy	GOAL 8: Decent Work and Economic Growth	GOAL 9: Industry, Innovation and Infrastructure	GOAL 10: Reduced Inequality	GOAL 11: Sustainable Cities and Communities	GOAL 12: Responsible Consumption and Production	GOAL 13: Climate Action	GOAL 14: Life Below Water	GOAL 15: Life on Land	GOAL 16: Peace and Justice Strong Institutions	GOAL 17: Partnerships to achieve the Goal
Demand management	Dietary change	Reduced meat consumption can free up land for other activities to reduce poverty (Röös et al. 2017; Stoll-Kleemann and O'Riordan 2015). However, reduced demand for livestock will have negative effect on pastoralists and could suppress	High-meat diets in developed countries may limit improvement in food security in developing countries (Rosegrant et al. 1999); dietary change can contribute to	Overnutrition contributes to worse health outcomes, including diabetes and obesity (Tilman and Clark 2014a; McMichael et al. 2007). Dietary change away from meat consumption	No direct interaction (IPCC 2018)	No direct interaction (IPCC 2018)	Reduced meat consumption will reduce water consumption. (Muller et al. 2017b) found that lower impact agriculture could be practiced if dietary change and	Dietary shifts away from meat to fish/fruits/vegetables increases energy use in the US by over 30% (Tom et al. 2016)	Health costs of meat-heavy diets add to health care costs and reduce GDP (Popkin 2008)	N/A	There are currently large discrepancies in diets between developed and developing nations (Sans & Combris 2015). Dietary change will reduce food inequality by reducing meat overconsumption in Western countries and	Dietary change is most needed in urbanised, industrialised countries and can help contribute to demand for locally grown fruits and vegetables (Tom et al. 2016)	A dietary shift away from meat can contribute to sustainable consumption by reducing greenhouse gas emissions and reducing cropland and pasture requirements (Stehfest et al. 2009; Bajželj	See main text on climate mitigation and adaptation	Dietary change away from meat might put increased pressure on fish stocks (Vranken et al. 2014; Mathijs 2015). Overall reduced emissions	See main text on desertification and degradation	N/A	N/A

		demand for other inputs (grains) that would affect poor farmers (Garnett 2011; IPCC SR15)	food security goals (Godfray et al. 2010a; Bajželj et al. 2014)	has major health benefits, including reduced heart disease and mortality (Popkin 2008; Friel et al. 2008). Dietary change could contribute to 5.1 million avoided deaths per year (Springmann et al. 2016)			waste reduction were implemented, leading to lower GHG emissions, lower rates of deforestation, and decreases in use of fertiliser (nitrogen and phosphorus), pesticides, water and energy. However, Tom et al. (2016) found water footprints of fruit/veg dietary shift in the US to increase by 16%				free up some cereals for consumption in poorer diets (Rosegrant et al. 1999)		et al. 2014).		would decrease rate of ocean acidification (Doney et al. 2009)			
	Reduced post-harvest losses	Reducing food losses from storage and distribution operation can increase economic well-being without additional investment in production activities (Bradford et al. 2018; Temba et al. 2016)	Reducing food losses increases food availability, nutrition, and lower prices (Sheahan and Barrett 2017b; Abass et al. 2014; Affognon et al. 2015)	Improved storage enhances food quality and can reduce mycotoxin intake (Bradford et al. 2018; Temba et al. 2016; Stathers et al. 2013; Tirado et al. 2010) especially in humid climates (Bradford et al. 2018). The perishability and safety of fresh foods are highly susceptible to temperature increase (Bisbis et al. 2018; Ingram et al. 2016a).	Reduced losses can increase income that could be spent on education, but no data available	Postharvest losses do have a gender dimension (Kaminski and Christiaensen 2014), but unclear if reducing losses will contribute to gender equality (Rugumamu 2009)	Kummu et al. (2012a) reported that 24% of global freshwater use and 23% of global fertiliser use is attributed to food losses. Reduced post harvest losses can decrease need for additional agricultural production and irrigation.	Reduced losses would reduce energy demands in production; 2030 +-160 trillion BTU of energy were embedded in wasted food in 2007 in the US (Cuéllar and Webber 2010)	In East and Southern Africa, postharvest loss for six major cereals was USD1.6 billion or 15% of total production value; reducing losses would thus boost GDP substantially in developing countries with PHL (Hodges et al. 2011)	Reducing PHL can involve improving infrastructure for farmers and marketers (Parfitt et al. 2010)	Poorer households tend to experience more PHL, and thus reducing PHL can contribute to reducing inequality among farmers (Hodges et al. 2011).	N/A	Reducing PHL contributes to sustainable production goals (Parfitt et al. 2010)	See main text on climate mitigati on and adaptati on	N/A	See main text on desertification and degradation	N/A	Post harvest losses contribute to higher food prices and constraints on trade (Tefera 2012)
	Reduced food waste (consumer or retailer)	Food waste tends to rise as incomes rise (Parfitt et al. 2010; Liu et al. 2013), so it is not clear what the relationship to poverty is. Could be potentially beneficial as it would free up	People who are already food insecure tend not to waste food (Nahman et al. 2012). Reduced food waste would	Food waste can increase with healthier diets (Parizeau et al. 2015). Health and safety standards can restrict some approaches to reducing food	N/A	Reducing food waste within households often falls to women (Stefan et al. 2013) and can increase their labor workload	Kummu et al. (2012a) reported that 24% of global freshwater and 23% of global fertiliser is used in the production of	Reduced losses would reduce energy demands in production; 2030 +-160 trillion BTU of energy were embedded in wasted food in 2007 in the US (Cuéllar and Webber 2010). Food waste can be a	Waste generation has grown faster than GDP in recent years (Thogerson 1996). Households in the UK throw out USD745	Food waste could be an important source of needed chemicals for industrial development in resource constrained countries (Lin et	Wealthier households tend to waste more food (Parfitt et al. 2010), but unclear how reducing waste may contribute to reducing inequality.	There have been large increases in the throughput of materials such as the food-waste stream, import and solid-waste	Post-consumer food waste in industrialised countries (222 million ton) is almost as high as the total net food production in sub- Saharan Africa (230	See main text on climate mitigati on and adaptati on	Reducing food waste may be related to food packaging, which is a major source of ocean pollution,	See main text on desertification and degradation	N/A	Food waste can contribute to higher food prices and constraints on trade (Tefera 2012)

		money to spend on other activities (Dorward 2012). Redistribution of food surplus to the poor could also have impacts on poverty (Papargyropoulou et al. 2014)	increase the supply of food (FAO 2011; Smith 2013), but it is unclear if this would benefit those who are food insecure in developing countries (Hertel and Baldos 2016).	waste (Halloran et al. 2014). Changes in packaging to reduce waste might have negative health impacts (e.g. increased contamination) (Claudio 2012)		(Hebrok and Boks 2017). Women also generate more food waste and could be a site for intervention (Thyberg and Tonjes 2016)	food losses, so reduction in food waste could provide significant co-benefits for freshwater provision and on nutrient cycling (Kummu et al. 2012). Muller et al. (2017b) found that lower impact agriculture could be practiced if dietary change and waste reduction were implemented, leading to lower GHG emissions, lower rates of deforestation, and decreases in use of fertiliser (nitrogen and phosphorus), pesticides, water and energy.	sustainable source of biofuel (Uçkun Kiran et al. 2014)	of food and drink each year as food waste; South Africans throw out USD 7billion worth of food per year (Nahman and de Lange 2013). Reductions of postconsumer waste would increase household income (Hodges et al. 2011)	al. 2013)		accumulation in urban areas (Grimm et al. 2008). Reducing compostable food waste reduces need for landfills (Smit and Nasr 1992; Zaman and Lehmann 2011)	million ton). (FAO 2011), thereby reducing waste contributes to sustainable consumption.		but relationship is not known (Hornweg et al 2013)			
	Material substitution	N/A	Could increase demand for wood and compete with land for agriculture, but no evidence of this yet.	N/A	N/A	N/A	If water is used efficiently in production of wood, likely to be positive impact over cement production (Gustavsson and Sathre 2011)	Concrete frames require 60-80% more energy than wood (Börjesson and Gustavsson 2000). Material substitution can reduce embodied energy of buildings construction by up to 20% (Thormark 2006; Upton et al. 2008)	The relationship between material substitution and GDP growth is unclear (Moore et al. 1996)	Material substitution may reduce need for industrial production of cement etc. (Petersen and Solberg 2005)	N/A	Changing materials for urban construction can reduce cities' ecological footprint (Zaman and Lehmann 2013)	Material substitution is a form of sustainable production/consumption which replaces cement and other energy-intensive materials with wood (Fiksel 2006)	See main text on climate mitigation and adaptation	Overall reduced emissions would decrease rate of ocean acidification (Doney et al. 2009)	See main text on desertification and degradation	N/A	N/A
Supply management	**Sustainable sourcing**	Value adding has been promoted as a successful poverty reduction strategy in many countries (Lundy et al. 2002; Whitfield 2012; Swanson 2006). Volatility of food supply and food price spikes in 2007 increased the number of people	Poor farmers can benefit from value-adding and new markets (Bamman 2007) and may help to improve food security by increasing its economic performance	Value-chains can help increase the nutritional status of food reaching consumers (Fan et al. 2012)	Value-adding can increase income that could be spent on education, but no data available	Women are highly employed in value-added agriculture in many developing countries, but do not always gain substantive benefits (Dolan and Sorby 2003).	Value-added products might require additional water use (Guan and Hubacek 2007), but depends on context.	N/A	Value-adding and export diversification generates additional employment and expands GDP in developing countries in particular (Newfarmer et al. 2009)	Value adding can create incentives to improve infrastructure in processing (Delgado 2010). Expanding value chains can incorporate new sources of food producers into industrial systems of	Value-adding can be an important component of additional employment for poorer areas, and can contribute to reductions in overall inequality. However, data shows high-value agriculture	Value-adding can increase incentives to keep peri-urban agriculture, but faces threats from rising land prices in urban areas (Midmore and Jansen	Value-adding in agriculture (.e.g. fair trade, organic) can be an important source of sustainable consumption and production (de Haen and Réquillart 2014)	See main text on climate mitigation and adaptation	N/A	See main text on desertification and degradation	N/A	Value-adding has a strong relationship to expanding trade in developing countries in particular (Newfarmer et al. 2009)

		under the poverty line by between 100 million people (Ivanic and Martin 2008) to 450 million people (Brinkman et al. 2009), and caused welfare losses of 3% or more for poor households in many countries (Zezza et al. 2009).	and revenues to local farmers (Reidsma et al. 2010). However, much value-adding is captured upstream, not by poor producers (McMichael and Schneider 2011b). Food prices strongly affect food security (Lewis and Witham 2012; Regmi and Meade 2013; Fujimori et al. 2018a), and policies to decrease volatility will likely have strong impacts on food security (Timmer 2009; Torlesse et al. 2003b; Raleigh et al. 2015b).			Value-chains that target women could increase gender equity, but data is scare (Gengenbach et al. 2018)				distribution (Bloom and Hinrichs 2011)	is not always a pathway toward enhanced welfare (Dolan and Sorby 2003), and much value-adding is captured not by smallholders but higher up the chain (Neilson 2007)	2003)
